About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews.
Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view.
By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: **researchtopics@frontiersin.org**

MODULARITY IN MOTOR CONTROL: FROM MUSCLE SYNERGIES TO COGNITIVE ACTION REPRESENTATION

Topic Editors:
Andrea d'Avella, University of Messina and IRCCS Fondazione Santa Lucia, Italy

Tamar Flash, Weizmann Institute, Israel

Modules are like bricks in a construction game: they represent building blocks that capture key organizational principles underlying versatility and adaptability in motor control. The many articles contributing to this Research Topics address modularity at different levels and demonstrate the impressive breadth of research currently being undertaken on this topic.
Image by Yuri Ivanenko and Andrea d'Avella

Mastering a rich repertoire of motor behaviors, as humans and other animals do, is a surprising and still poorly understood outcome of evolution, development, and learning. Many degrees-of-freedom, non-linear dynamics, and sensory delays provide formidable challenges for controlling even simple actions. Modularity as a functional element, both structural and computational, of a control architecture might be the key organizational principle that the central nervous system employs for achieving versatility and adaptability in motor control. Recent investigations of muscle synergies, motor primitives, compositionality, basic action concepts, and related work in machine learning have contributed to advance, at different levels, our understanding of the modular architecture underlying rich motor behaviors.

However, the existence and nature of the modules in the control architecture is far from settled. For instance, regularity and low-dimensionality in the motor output are often taken as an indication of modularity but could they simply be a byproduct of optimization and task constraints? Moreover, what are the relationships between modules at different levels, such as muscle synergies, kinematic invariants, and basic action concepts?

One important reason for the new interest in understanding modularity in motor control from different viewpoints is the impressive development in cognitive robotics. In comparison to animals and humans, the motor skills of today's best robots are limited and inflexible. However, robot technology is maturing to the point at which it can start approximating a reasonable spectrum of isolated perceptual, cognitive, and motor capabilities. These advances allow researchers to explore how these motor, sensory and cognitive functions might be integrated into meaningful architectures and to test their functional limits. Such systems provide a new test bed to explore different concepts of modularity and to address the interaction between motor and cognitive processes experimentally.

Thus, the goal of this Research Topic is to review, compare, and debate theoretical and experimental investigations of the modular organization of the motor control system at different levels. By bringing together researchers seeking to understand the building blocks for coordinating many muscles, for planning endpoint and joint trajectories, and for representing motor and behavioral actions in memory we aim at promoting new interactions between often disconnected research areas and approaches and at providing a broad perspective on the idea of modularity in motor control. We welcome original research, methodological, theoretical, review, and perspective contributions from behavioral, system, and computational motor neuroscience research, cognitive psychology, and cognitive robotics.

Table of Contents

08 ***Editorial: Modularity in motor control: from muscle synergies to cognitive action representation***
Andrea d'Avella, Martin Giese, Yuri P. Ivanenko, Thomas Schack and Tamar Flash

Section 1: Reviews and perspectives

14 ***Evolutionary and developmental modules***
Francesco Lacquaniti, Yuri P. Ivanenko, Andrea d'Avella, Karl E. Zelik and Myrka Zago

20 ***The flexion synergy, mother of all synergies and father of new models of gait***
Jacques Duysens, Friedl De Groote and Ilse Jonkers

29 ***Distinct thalamo-cortical controls for shoulder, elbow, and wrist during locomotion***
Irina N. Beloozerova, Erik E. Stout and Mikhail G. Sirota

50 ***Neural bases of hand synergies***
Marco Santello, Gabriel Baud-Bovy and Henrik Jörntell

65 ***Control of reaching movements by muscle synergy combinations***
Andrea d'Avella and Francesco Lacquaniti

72 ***Muscle synergies in neuroscience and robotics: from input-space to task-space perspectives***
Cristiano Alessandro, Ioannis Delis, Francesco Nori, Stefano Panzeri and Bastien Berret

88 ***The neural origin of muscle synergies***
Emilio Bizzi and Vincent C. K. Cheung

94 ***Neuromotor recovery from stroke: computational models at central, functional, and muscle synergy level***
Maura Casadio, Irene Tamagnone, Susanna Summa and Vittorio Sanguineti

108 ***Plasticity and modular control of locomotor patterns in neurological disorders with motor deficits***
Y. P. Ivanenko, G. Cappellini, I. A. Solopova, A. A. Grishin, M. J. MacLellan, R. E. Poppele and F. Lacquaniti

Section 2: Muscle synergies

119 ***Are muscle synergies useful for neural control?***
Aymar de Rugy, Gerald E. Loeb and Timothy J. Carroll

132 ***The number and choice of muscles impact the results of muscle synergy analyses***
Katherine M. Steele, Matthew C. Tresch and Eric J. Perreault

141 ***Quantitative evaluation of muscle synergy models: a single-trial task decoding approach***
Ioannis Delis, Bastien Berret, Thierry Pozzo and Stefano Panzeri

162 ***A methodology for assessing the effect of correlations among muscle synergy activations on task-discriminating information***
Ioannis Delis, Bastien Berret, Thierry Pozzo and Stefano Panzeri

178 ***Investigating reduction of dimensionality during single-joint elbow movements: a case study on muscle synergies***
Enrico Chiovetto, Bastien Berret, Ioannis Delis, Stefano Panzeri and Thierry Pozzo

190 ***Effort minimization and synergistic muscle recruitment for three-dimensional force generation***
Daniele Borzelli, Denise J. Berger, Dinesh K. Pai and Andrea d'Avella

204 ***Dimensionality of joint torques and muscle patterns for reaching***
Marta Russo, Mattia D'Andola, Alessandro Portone, Francesco Lacquaniti and Andrea d'Avella

225 ***Robustness of muscle synergies during visuomotor adaptation***
Reinhard Gentner, Timothy Edmunds, Dinesh K. Pai and Andrea d'Avella

237 ***Physiological modules for generating discrete and rhythmic movements: action identification by a dynamic recurrent neural network***
Ana Bengoetxea, Françoise Leurs, Thomas Hoellinger, Ana M. Cebolla, Bernard Dan, Joseph McIntyre and Guy Cheron

257 ***Physiological modules for generating discrete and rhythmic movements: component analysis of EMG signals***
Ana Bengoetxea, Françoise Leurs, Thomas Hoellinger, Ana Maria Cebolla, Bernard Dan, Guy Cheron and Joseph McIntyre

273 ***Effective force control by muscle synergies***
Denise J. Berger and Andrea d'Avella

286 ***Common muscle synergies for balance and walking***
Stacie A. Chvatal and Lena H. Ting

300 ***Between-subject variability of muscle synergies during a complex motor skill***
Julien Frère and François Hug

313 ***Feedback of mechanical effectiveness induces adaptations in motor modules during cycling***
Cristiano De Marchis, Maurizio Schmid, Daniele Bibbo, Anna Margherita Castronovo, Tommaso D'Alessio and Silvia Conforto

325 ***Distinguishing synchronous and time-varying synergies using point process interval statistics: motor primitives in frog and rat***
Corey B. Hart and Simon F. Giszter

Section 3: Motor primitives at the kinematic level

339 ***Kinematic decomposition and classification of octopus arm movements***
Ido Zelman, Myriam Titon, Yoram Yekutieli, Shlomi Hanassy, Binyamin Hochner and Tamar Flash

354 ***Segmenting sign language into motor primitives with Bayesian binning***
Dominik Endres, Yaron Meirovitch, Tamar Flash and Martin A. Giese

367 ***Transitions between discrete and rhythmic primitives in a unimanual task***
Dagmar Sternad, Hamal Marino, Steven K. Charles, Marcos Duarte, Laura Dipietro and Neville Hogan

380 From ear to hand: the role of the auditory-motor loop in pointing to an auditory source
Eric O. Boyer, Bénédicte M. Babayan, Frédéric Bevilacqua, Markus Noisternig, Olivier Warusfel, Agnes Roby-Brami, Sylvain Hanneton and Isabelle Viaud-Delmon

389 Spatio-temporal analysis reveals active control of both task-relevant and task-irrelevant variables
Kornelius Rácz and Francisco J. Valero-Cuevas

406 Dynamic primitives in the control of locomotion
Neville Hogan and Dagmar Sternad

Section 4: Neural substrates

422 Synaptic and functional linkages between spinal premotor interneurons and hand-muscle activity during precision grip
Tomohiko Takei and Kazuhiko Seki

430 Compositionality in neural control: an interdisciplinary study of scribbling movements in primates
Moshe Abeles, Markus Diesmann, Tamar Flash, Theo Geisel, Michael Herrmann and Mina Teicher

458 Muscle synergies evoked by microstimulation are preferentially encoded during behavior
Simon A. Overduin, Andrea d'Avella, Jose M. Carmena and Emilio Bizzi

468 Motor cortical regulation of sparse synergies provides a framework for the flexible control of precision walking
Nedialko Krouchev and Trevor Drew

492 Increased motor cortex excitability during motor imagery in brain-computer interface trained subjects
Olesya A. Mokienko, Alexander V. Chervyakov, Sofia N. Kulikova, Pavel D. Bobrov, Liudmila A. Chernikova, Alexander A. Frolov and Mikhail A. Piradov

Section 5: Models

499 Learned parametrized dynamic movement primitives with shared synergies for controlling robotic and musculoskeletal systems
Elmar Rückert and Andrea d'Avella

517 A musculoskeletal model of human locomotion driven by a low dimensional set of impulsive excitation primitives
Massimo Sartori, Leonardo Gizzi, David G. Lloyd and Dario Farina

539 A computational analysis of motor synergies by dynamic response decomposition
Cristiano Alessandro, Juan Pablo Carbajal and Andrea d'Avella

559 Learned graphical models for probabilistic planning provide a new class of movement primitives
Elmar A. Rückert, Gerhard Neumann, Marc Toussaint and Wolfgang Maass

579 Model selection for the extraction of movement primitives
Dominik M. Endres, Enrico Chiovetto and Martin A. Giese

592 Do muscle synergies reduce the dimensionality of behavior?
Naveen Kuppuswamy and Christopher M. Harris

613 ***Synergetic motor control paradigm for optimizing energy efficiency of multijoint reaching via tacit learning***
Mitsuhiro Hayashibe and Shingo Shimoda

624 ***A hexapod walker using a heterarchical architecture for action selection***
Malte Schilling, Jan Paskarbeit, Thierry Hoinville, Arne Hüffmeier, Axel Schneider, Josef Schmitz1 and Holk Cruse

641 ***Biological oscillations for learning walking coordination: dynamic recurrent neural network functionally models physiological central pattern generator***
Thomas Hoellinger, Mathieu Petieau, Matthieu Duvinage, Thierry Castermans, Karthik Seetharaman, Ana-Maria Cebolla, Ana Bengoetxea, Yuri Ivanenko, Bernard Dan and Guy Cheron

656 ***Modular neuron-based body estimation: maintaining consistency over different limbs, modalities, and frames of reference***
Stephan Ehrenfeld, Oliver Herbort and Martin V. Butz

672 ***A modular theory of multisensory integration for motor control***
Michele Tagliabue and Joseph McIntyre

Section 6: Robotics

690 ***Learning modular policies for robotics***
Gerhard Neumann, Christian Daniel, Alexandros Paraschos, Andras Kupcsik and Jan Peters

703 ***MACOP modular architecture with control primitives***
Tim Waegeman, Michiel Hermans and Benjamin Schrauwen

716 ***A soft body as a reservoir: case studies in a dynamic model of octopus-inspired soft robotic arm***
Kohei Nakajima, Helmut Hauser, Rongjie Kang, Emanuele Guglielmino, Darwin G. Caldwell and Rolf Pfeifer

735 ***Kinematic primitives for walking and trotting gaits of a quadruped robot with compliant legs***
Alexander T. Spröwitz, Mostafa Ajallooeian, Alexandre Tuleu and Auke Jan Ijspeert

Section 7: Intermittent control

748 ***The minimum transition hypothesis for intermittent hierarchical motor control***
Amir Karniel

756 ***Spatiotemporal characteristics of muscle patterns for ball catching***

Keywords: modularity, motor control, muscle synergies, motor primitives, compositionality, action representation, robotics

Mastering a rich repertoire of motor behaviors, as humans and other animals do, is a surprising and still a poorly understood outcome of evolution, development, and learning. Many degrees-of-freedom, non-linear dynamics, and sensory delays provide formidable challenges for controlling even simple actions. Modularity as a functional element, both structural and computational, of a control architecture might be the key organizational principle that the central nervous system employs for achieving versatility and adaptability in motor control. Recent investigations of muscle synergies, motor primitives, compositionality, basic action concepts, and related work in machine learning have contributed, at different levels, to advance our understanding of the modular architecture underlying rich motor behaviors.

However, the existence and nature of the modules comprising the control architecture is far from settled. For instance, regularity and low-dimensionality of the motor output are often taken as an indication of modularity but they could simply be a byproduct of optimization and task constraints. Moreover, what are the relationships between modules at different levels, such as muscle synergies, kinematic invariants, and basic action concepts?

One important reason for the new interest in understanding modularity in motor control from different perspectives is the impressive development in cognitive robotics. In comparison to animals and humans, the motor skills of today's best robots are limited and inflexible. However, robot technology is maturing to the point at which it can start approximating a reasonable spectrum of different perceptual, cognitive, and motor capabilities. These advances allow researchers to explore how these motor, sensory, and cognitive functions might be integrated into meaningful architectures and to test their functional limits. Such systems provide a new test bed to explore different concepts of modularity and to experimentally investigate possible interactions between motor and cognitive processes.

Thus, the goal of this Research Topic is to review, compare, and debate theoretical and experimental studies of the modular organization of the motor control system at different levels. By bringing together researchers seeking to understand the building blocks of coordinating many muscles, planning endpoint and joint trajectories, and representing motor and behavioral actions in memory we aim at promoting new interactions between often disconnected research areas and approaches and providing a broad perspective on the notion of modularity in motor control.

Reviews and Perspectives

A number of review articles present and discuss available evidence, conceptual frameworks, and fundamental questions concerning modularity in motor control. These cover a range of issues such as the effective dimensionality, movement invariants, neural underpinnings, evolution, motor learning, and recovery of motor function.

Lacquaniti et al. (2013) provides a comprehensive review of evolutionary and developmental modules. These authors focus on modular control of locomotion to argue that the building blocks used to construct different locomotor behaviors are similar across several animal species, presumably related to ancestral neural networks of command. The authors present evidence that modular units of development are highly preserved and recombined during evolution.

In a thought-provoking review article, Duysens et al. (2013) argue that there is large overlap between the notions on modules and the older concepts of reflexes. They reason that facilitation of the flexor synergy at the end of the stance phase is linked to the activation of circuitry that is responsible for the generation of locomotor patterns (CPG, "central pattern generator"). More specifically, it is suggested that the responses in that period relate to the activation of a flexor burst generator. The latter structure forms the core of a new asymmetric model of the CPG. Beloozerova et al. (2013) review data on the differential controls for the shoulder, elbow, and wrist that are used by populations of neurons in the thalamo-cortical network. It is one of manifestations of a modular organization of control for locomotion. The authors hypothesize that this contributes to an effective control of a global limb parameter, the length of the stride, which results in a great reduction in variability of paw placement during accurate stepping.

Santello et al. (2013) propose a theoretical framework to reconcile important and still debated concepts such as the definitions of "fixed" vs. "flexible" synergies and mechanisms underlying the combination of synergies for hand control. d'Avella and Lacquaniti (2013) review recent results from the analysis of reaching muscle patterns supporting a control strategy consisted in the sequencing of time-varying muscle synergies. Alessandro et al. (2013b) review the works related to muscle synergies in neuroscience and control engineering and provide an overview of the methods that have been employed to test the validity of the control scheme. Specifically, the authors suggest that to assess the functional role of muscle synergies, synergy extraction methods should explicitly take into account task execution variables. Bizzi and Cheung (2013) address two critical questions: the explicit encoding of muscle synergies in the nervous system, and how muscle synergies simplify movement production and motor learning.

Another important field of research is the outcome of interventions in neurological disorders with motor deficits. Uncovering a common underlying neural framework for the modular control of movements and its dysfunction represents an interesting avenue for future work. Casadio et al. (2013) review the state of the art of computational models for neuromotor recovery from stroke through exercise, and their implications for treatment. The review specifically covers models of recovery at central, functional and muscle synergy level. Ivanenko et al. (2013) review various examples of adaptation of locomotor patterns in patients and discuss the findings in a general context of compensatory gait mechanisms, spatiotemporal architecture, and modularity of the locomotor program. Such investigations may have important implications related to the construction of gait rehabilitation technology. Further research needs to clarify whether plasticity in muscle patterns originates from sharing common modules or by creating new muscle synergies and whether the rehabilitation programs may benefit from revitalizing the modules underlying motor behaviors.

Muscle Synergies

Amongst the original research articles, a large group of contributions is dedicated to the modular organization of multi-muscle activity across different motor tasks. It has been hypothesized that the nervous system simplifies muscle control through modularity, using neural patterns to activate muscles in groups called synergies.

An important example of ongoing debate is the current discussion of the critical aspects and organization of muscle synergies. de Rugy et al. (2013) argue that the usefulness of muscle synergies as a control principle should be evaluated in terms of errors produced and, using data from a force-aiming task in two dimensions, illustrate through simulation how synergy decomposition inevitably introduces substantial task space errors. They also show that the number of synergies required to approximate the optimal muscle pattern for an arbitrary biomechanical system increases with task-space dimensionality, which indicates that the capacity of synergy decomposition to explain behavior depends critically on the scope of the original database. Steele et al. (2013) present evidence that the number and choice of muscles impact the results of muscle synergy analyses. Thus, researchers should be cautious in evaluating muscle synergies when EMG is measured from a small subset of muscles.

Delis et al. (2013a,b) stress the effectiveness of the decoding metric in systematically assessing muscle synergy decompositions in task space and the functional role of trial-to-trial correlations between synergy activations. The results of Chiovetto et al. (2013) support the notion that each EMG decomposition provides a set of well-interpretable muscle synergies, identifying reduction of dimensionality in different aspects of the movements. Borzelli et al. (2013) test whether the CNS generates forces by minimum effort recruitment of either individual muscles or muscle synergies during the generation of isometric forces at the hand. The minimum effort recruitment of synergies predicts the observed muscle patterns better than the minimum effort recruitment of individual muscles. Russo et al. (2014) compare the torques acting at four arm joints during fast reaching movements in different directions and show that muscle pattern dimensionalities are higher than torques dimensionalities. They argue that this is necessary to overcome the non-linearities of the musculoskeletal

system and to flexibly generate endpoint trajectories with simple kinematic features using a limited number of building blocks.

In the context of direction-specific recruitment of muscle synergies, Gentner et al. (2013) investigate adaptation to a visuomotor rotation of a virtual target displacement and show that the structure of muscle synergies is preserved, suggesting that changes in muscle patterns are obtained by rotating the directional tuning of the synergy recruitment. Bengoetxea et al. (2014a,b) employ a dynamic recurrent neural network (DRNN) and principal component analysis of EMG activity during discrete and rhythmic arm movements. The authors discuss consistent patterns of muscle groupings in the context of their functional organization for controlling orthogonal movement directions. Berger and d'Avella (2014) recorded EMG activity and isometric hand forces during a force-aiming task in a virtual environment. In contrast to de Rugy et al. (2013), they show that muscle synergies can be used to generate target forces in multiple directions with the same accuracy achieved using individual muscles. Strikingly, human subjects are able to perform the task immediately after switching from force-control to EMG-control and synergy-control, suggesting that muscle synergies provide an effective strategy for motor coordination.

Whether muscle synergies are shared across tasks or they are task-specific is another debated aspect of modularity. Chvatal and Ting (2013) compare muscle synergies during multidirectional support-surface perturbations during standing and walking, as well as unperturbed walking. They find both shared and task-specific muscle synergies, suggesting that differences in muscle synergies across conditions reflect differences in the biomechanical demands of the tasks and that muscle synergies may define a repertoire of biomechanical subtasks recruited according to task-level goals. Frere and Hug (2012) demonstrate that the muscle synergies are consistent across experienced gymnasts, even during a skilled motor task that requires learning. De Marchis et al. (2013) investigate muscle synergies during pedaling in humans. Additional modules are identified when visual feedback about mechanical effectiveness is available and the structure of the identified modules is found similar to that extracted in other studies of human walking, confirming the existence of shared and task specific muscle synergies. Finally, Hart and Giszter (2013) present a method that uses point process statistics to discriminate the forms of synergies in motor pattern data. According to this method, frog and rat EMG data are most consistent with synchronous synergy models, supporting separated control of rhythm and pattern of motor primitives.

Motor Primitives at the Kinematic Level

A number of contributions aim at understanding motor primitives at the kinematic level. Zelman et al. (2013) explore whether different octopus arm movements are built up of elementary kinematic units by decomposing surfaces, representing curvature, and torsion values of the paths of points along the arm, into a weighted combination of 2D Gaussian functions, considered as motion primitives at the kinematic level of octopus arm movements. Endres et al. (2013a) investigate the endpoint trajectories of human movements (sign language) that are characterized by the power laws linking velocity and curvature. The parameters of these power laws are exploited for the unsupervised segmentation of actions into movement primitives. Sternad et al. (2013) propose that control of sensorimotor behavior may utilize dynamic primitives. Their results clearly indicate a gradual transition between discrete and rhythmic arm movements, supporting the proposal that representation is based on primitives rather than on veridical internal models. Boyer et al. (2013) investigate interactions between the auditory and motor systems to uncover different modular neural processes involved in the multisensory and motor representations of targets in goal-directed movements and corresponding reference frames for each sensory modality. Racz and Valero-Cuevas (2013) suggest that the similar nature of control actions across time scales in both task-relevant and task-irrelevant spaces points to a level of modularity not previously recognized in motor tasks. Hogan and Sternad (2013) propose that the spectacular performance of a wide range of upper- and lower-limb behaviors arises from encoding motor commands in terms of three classes of dynamic primitives: submovements, oscillations, and mechanical impedances. They present some methods for addressing the challenges posed by the experimental identification of these dynamic primitives and consider the implications of this theoretical framework for locomotor rehabilitation.

Neural Substrates

Another exciting area explored in this Research Topic is potential neural substrates for modularity in motor control and action representation. Takei and Seki (2013) argue about synaptic and functional linkage between spinal interneurons and the organization of hand-muscle synergies. Abeles et al. (2013) discuss the compositional structure of hand movements by analyzing and modeling neural and behavioral data obtained from experiments where monkeys performed scribbling movements. A classification of the neural data employing a hidden Markov model shows a coincidence of the neural states with the behavioral categories of movement segmentations that are primarily parabolic in shape. Overduin et al. (2014) investigate whether muscle synergies evoked by intracortical microstimulation (ICMS) in rhesus macaques are similarly encoded by nearby motor cortical units during object reach, grasp, and carry movements. They find that the synergy most strongly evoked at an ICMS site matches the synergy most strongly encoded by proximal units more often than expected by chance. The results suggest a common neural substrate for microstimulation-evoked motor responses and for the generation of muscle patterns during natural behaviors. Krouchev and Drew (2013) describe a modular organization of the locomotor step cycle in the cat in which a number of sparse synergies are activated sequentially during unobstructed locomotion and during voluntary gait modifications. The authors argue that the changes in phase and magnitude of a finite number of muscle synergies could be produced by changes in the activity of neurons in the motor cortex. Mokienko et al. (2013)

study motor imagery of grasping movements and corresponding neural underpinnings in brain-computer interface trained human subjects.

Models

A number of modeling papers address different aspects of modularity. In a multi-directional reaching task simulated with a musculoskeletal model of the human arm, Ruckert and d'Avella (2013) propose a movement primitive representation that employs parametrized basis functions, which combines the benefits of muscle synergies and dynamic movement primitives, and show how movement primitives can be used to learn appropriate muscle excitation patterns and to generalize effectively to new reaching skills. Sartori et al. (2013) use a Gaussian-shaped impulsive excitation curves or primitives as input drive for large musculoskeletal models across different human locomotion tasks. Alessandro et al. (2013a) examine the feasibility of controlling non-linear dynamical systems by linear combinations of a small set of torque profiles or motor synergies and suggest that in order to realize an effective and low-dimensional controller, synergies should embed features of both the desired tasks and the system dynamics.

Significant progress has been made with respect to some fundamental questions concerning optimization of control architectures and motor learning. Rückert et al. (2012) propose a movement primitive representation based on probabilistic inference in learned graphical models with properties that comply with salient features of biological movement control. In simulations of a complex 4-link balancing task, they show that movement primitives facilitate learning and lead to better generalization. Endres et al. (2013b) address the issue of the selection of the parameters of movement primitive models or the model type and propose an approach based on a Laplace approximation to the posterior distribution of the parameters of a given blind source separation model. They validate the approach on simulated data and on human gait data, finding that an anechoic mixture model with a temporal smoothness constraint on the sources can best account for the data. Kuppuswamy and Harris (2014) investigate whether muscle synergies can reduce the state-space dimensionality while maintaining task control. Based on the observation that constraining the control input to a weighted combination of temporal muscle synergies also constrains the dynamic behavior of a system in a trajectory-specific manner, they show that smooth straight-line Cartesian trajectories with bell-shaped velocity profiles emerged as the optima for the reaching task and that trajectory and synergy specific dimensionality reduction results from muscle synergy control. Hayashibe and Shimoda (2014) aim at identifying a modular control architecture realizing adaptability and optimality without prior knowledge of system dynamics. They propose a novel motor control paradigm based on tacit learning with task space feedback. The proposed paradigm can optimize solutions for reaching with a three-joint, planar biomechanical model, acquiring motor synergy, and finding energy efficient solutions for different load conditions.

A few contributions further examine the usage of neural networks. Schilling et al. (2013) demonstrate a solution for the selection and sequencing of different (attractor) states required to control different behaviors of a hexapod walker as forward walking at different speeds, backward walking, as well as negotiation of tight curves. The proposed control architecture of a recurrent neural network is characterized by different types of modules being arranged in layers and columns, and can also be considered as a holistic system showing emergent properties which cannot be attributed to a specific module. Hoellinger et al. (2013) describe the use of a DRNN mimicking the natural oscillatory behavior of human locomotion for reproducing the planar covariation rule in both legs at different walking speeds. This emerging property in the artificial neural networks resonates with recent advances in neurophysiology of inhibitory neurons that are involved in central nervous system oscillatory activities. The main message of this study is that this type of DRNN may offer a useful model of physiological central pattern generators for the purpose of gaining insights in basic research and developing clinical applications.

Ehrenfeld et al. (2013) address the question of how the brain maintains a probabilistic body state estimate over time from a modeling perspective. The results showed that the neural estimates can detect and decrease the impact of false sensory information, can propagate conflicting information across modules, and can improve overall estimation accuracy due to additional module interactions. Finally, Tagliabue and Mcintyre (2014) review different formulations of concurrent models for sensory integration and propose a modular approach in which the overall behavior is built by computing multiple concurrent comparisons carried out simultaneously in a number of different reference frames.

Robotics

Findings in biological research concerning a modular control hierarchy, which combines movement/motor primitives into complex and natural movements, inspire engineers in the quest for adaptive and skillful control for robots. Neumann et al. (2014) present a unified approach for learning a modular control architecture, introducing new policy search algorithms that are based on information-theoretic principles and are able to learn to select, adapt, and sequence the building blocks to compose more complex behaviors. The authors summarize their experiments for learning modular control architectures in simulation and with real robots. Waegeman et al. (2013) propose a modular architecture with control primitives (MACOP) which uses a set of controllers, where each controller becomes specialized in a subregion of its joint and task-space. The authors evaluate MACOP on a numerical model of a robot arm by training it to generate desired trajectories and show how MACOP compensates for the dynamic effects caused by a fixed control rate and the inertia of the robot. Nakajima et al. (2013) explore the idea that control, which is conventionally thought to be handled by the brain or a controller, can partially be outsourced to the physical body and the interaction with the environment. By using a soft robotic arm inspired by the octopus they

show in a number of experiments how control is partially incorporated into the physical arm's dynamics and how the arm's dynamics can be exploited to approximate non-linear dynamical systems. Spröwitz et al. (2014) implement kinematic primitives for walking and trotting gaits of a quadruped robot and show that a very low complexity of modular, rhythmic, feed-forward motor control is sufficient for level-ground locomotion in combination with passive compliant legged hardware.

Intermittent Control

Evidence for intermittency in human motor control has been repeatedly observed in the neural control of movement literature and it has been discussed in this Research Topic in the context of the modular organization of the motor control system. Karniel (2013) focuses on an area in which intermittent control has not yet been thoroughly considered, with respect to the structure of muscle synergies. He presents the minimum transition hypothesis and its predictions with regard to the structure of muscle synergies. D'Andola et al. (2013) demonstrate that that the control of interceptive movements (catching a flying ball) relies on a combination of reactive and predictive processes through the intermittent recruitment of time-varying muscle synergies. van de Kamp et al. (2013) explore modular organization in whole body control architecture within the intermittent control paradigm with an intermittent interval of around 0.5 s. The authors suggest that parallel sensory input converges to a serial, single channel process involving planning, selection, and temporal inhibition of alternative responses prior to low dimensional motor output and may underlie the flexibility of human control. Such studies may have important implications with respect to the design of brain machine interfaces and human robot interaction.

Action Representation

The final theme we have identified in the contributions centers on the modular organization and interaction between motor and cognitive processes. Land et al. (2013) explore the links between cognitive and biomechanical levels of motor control in order to understand the extent to which the output at a kinematic level is governed by representations at a cognitive level of motor control. The authors apply a new spatio-temporal decomposition method for assessing memory structures underlying complex actions in order to investigate the overlap between the structure of motor representations in memory and their corresponding kinematic structures.

Taken together, this Research Topic demonstrates the impressive breadth of research currently being undertaken on modularity in motor control.

The identification of biological modules at the systems level often follows top-down decomposition of a task goal, or bottom-up decomposition of multidimensional data arrays into basic elements or patterns representing shared features. These approaches traditionally have been applied to mature, fully developed systems. Here we review some results from two other perspectives on modularity, namely the developmental and evolutionary perspective. There is growing evidence that modular units of development were highly preserved and recombined during evolution. We first consider a few examples of modules well identifiable from morphology. Next we consider the more difficult issue of identifying functional developmental modules. We dwell especially on modular control of locomotion to argue that the building blocks used to construct different locomotor behaviors are similar across several animal species, presumably related to ancestral neural networks of command. A recurrent theme from comparative studies is that the developmental addition of new premotor modules underlies the postnatal acquisition and refinement of several different motor behaviors in vertebrates.

Keywords: activation pattern, CPG, gene expression, interneurons, locomotion

INTRODUCTION

Modules are easily defined in human-engineered product design. The final product is split up into components (modules) that are designed, manufactured, and tested independently. The modules can be reused in different systems that perform different tasks. Modular industrial design tends to reduce manufacturing complexity and costs. Parsimony, reduction of complexity, and evolutionary costs presumably also underlie modular solutions in biological systems, but biological modules are not always easily identifiable. We will return later to the issue of cost factors possibly underlying the evolution of modules. Here we first address the issue of the identification of biological modules.

According to Fodor (1983), modular systems are decomposable in a set of independent processes. However, the degree of independence among the basic components is not fixed. According to Simon (1969), the interactions among components are negligible in comparison with those within components only in fully decomposable systems. Instead, nearly decomposable systems are those in which the interactions among components are weak but not negligible. Finally, un-decomposable systems are those in which the interactions among components are as strong as those within components.

A biological module could be defined on the basis of structural (morphological), functional, or developmental elements. A structural module is defined by a set of spatially defined, interconnected elements. A functional module is a discrete entity whose function is separable from that of other modules (Hartwell et al., 1999). A developmental module is a component of a developing organism (e.g., an embryo) that is semi-autonomous relative to pattern formation and differentiation, or relative to a signaling cascade (Schlosser and Wagner, 2004).

Spatially bounded structures (e.g., the ribosomes) are the most clearly defined modules at a subcellular level. At a functional level, the ensemble of cellular proteins (proteome) can be partitioned into a limited set of complexes, which differentially combine to support diverse functions (Ravasz et al., 2002; Gavin et al., 2006). The identification of biological modules at the systems level is even more challenging. Top-down decomposition may help recognizing a modular structure. A complex event (such as the goal of a motor task) can be detailed by decomposing it in several more basic informational events. If the system being analyzed is structured as a hierarchy, decomposition can be performed recursively (iteratively), each stage leading to finer and finer basic components (Palmer and Kimchi, 1986). Successive decompositions remove some of the complexity that is inherent in higher levels of description, but they raise the issue of when to stop. Ideally, one would like to stop when a stage of primitive informational events has been reached. One could take as primitive some computationally plausible set of operations that is sufficient to perform the task. This approach has been used in the study of vision, for instance (Palmer, 1999). Thus, the task of visual object identification is decomposed in the distinct operations involved in image-based, surface-based, object-based, and category-based processing.

Modules may also be identified using bottom-up decomposition, instead of top-down decomposition. Starting from a multidimensional array (e.g., electromyographic EMG activity), we aim at identifying basic components that represent some common features, which are shared by a number of the original data (for instance, the output variables in a motor task, Lacquaniti et al., 2012b; d'Avella and Lacquaniti, 2013). Here the basic components represent building blocks that are used to construct a given behavior; therefore, they can be considered as primitives in a

computational sense (Flash and Hochner, 2005; Bizzi et al., 2008; Giszter et al., 2010).

Top-down and bottom-up approaches can be merged together using hierarchical multiple layers of representation. For example, hand action representations have been modeled as involving a temporal postural synergy (one kind of motor module) only if the ancestors of the synergy in the tree-structured organization are themselves involved in the action representation (Tessitore et al., 2013). The advantage of combining the two approaches consists in the possibility of validating an *a priori* hypothesis about the structure of the task implied in top-down decomposition with the *post hoc* identification of basic components derived from bottom-up decomposition.

EVOLUTIONARY AND DEVELOPMENTAL PERSPECTIVES

The approaches described above have been applied primarily to mature, fully developed systems. A different perspective on modularity is provided by comparative developmental and evolutionary studies (e.g., Gilbert et al., 1996; Wagner and Altenberg, 1996; Winther, 2001; Schlosser and Wagner, 2004; Flash and Hochner, 2005; Cheung, 2007; Gerhart and Kirschner, 2007; Raff, 2007; Giszter et al., 2010). Evolutionary developmental biology (often referred to as Evo-Devo) aims at understanding how evolutionary trajectories (phylogeny) are constrained by developmental rules (ontogeny), and how developmental rules themselves evolve. Thus, processes evolve to produce new patterns of development, new gene regulation, new morphologies, and new behaviors (Raff, 2007).

There is now much evidence that modular units of development were highly preserved and recombined during evolution. It has been argued that biological modularity is the result of evolution and facilitates evolution (Schlosser and Wagner, 2004). Evolvability, that is, the capacity of a system for adaptive evolution, is positively affected by modularity when the developmental modules of an organism match the modularity of specific adaptive functions (Kirschner and Gerhart, 1998; Schlosser and Wagner, 2004).

There are several applications of the concept of modularity from an evolutionary developmental perspective. We first consider a few examples of anatomical modules, because these are relatively well identifiable and represent a model for the more difficult identification of modules in motor control. During development, anatomical modules form integrated series of relatively distinct, autonomous components that help partitioning different parts of the embryo, reducing the effects of any changes on the organism as a whole (Reno et al., 2008). The developmental modules have a genetically discrete organization, resulting in identifiable domains within the developing organism, and these modules undergo evolution (Raff, 2007). The most basic modular gene expression networks provide the crucial regulation of body-plan development at the phylum level of the animal kingdom (Raff, 2007).

A striking example of genetically controlled modularity has been demonstrated by Halder et al. (1995). They obtained ectopic eyes on the wings, legs, and antennae of *Drosophila* by misexpression of the cDNA "eyeless" gene. (The products of "eyeless" and twin of "eyeless" gene are homologs of the vertebrate Pax6.) The ectopic eyes consisted of complete eye structures and were responsive to light, indicating that "eyeless" is the control master for the genesis of the fly eye.

Studies of fossils of Placodermi (prehistoric fishes) showed separate evolution of jaws and teeth, through distinct developmental modules, topographically related but each independently genetically regulated (Smith and Johanson, 2003; Rücklin et al., 2012). Comparative embryological studies showed that the transcription factor Satb2 specifies a developmental module within the mandibular jaw (Fish et al., 2011). Satb2 is expressed in the mesenchyme of the jaw primordia that gives rise to distal elements of both the upper and lower jaws.

The development of the limbs and their evolutionary adaptation to locomotion and other functions provide another important example of modularity. Limb development begins in the embryological limb field, followed by the ectoderm bulging out as the limb bud. Certain homeobox (Hox) genes act as selector genes with spatially regulated expression patterns that specify differential growth in distinct modules. Hox genes are widely shared across the animal kingdom, from insects to reptiles and mammals. In general, these genes are linearly ordered in a sequence which maps into the spatial order and timing of development of different body regions. Duplication of Hox genes can produce new body segments, and this mechanism probably played an important role in the evolution of segmented animals. In particular HoxA and HoxD specify segment identity along the limb axis.

It is well known that tetrapod limbs have evolved from fish fins. Teleosts are ray-fin fishes that diverged from the lobe-fin ancestors of tetrapods more than 400 millions of years ago. The fin buds of the living zebrafish (a teleost) exhibit the early phases of Hoxd13 expression that are observed in tetrapod limb buds, despite the fact that the appendages of zebrafish have no skeletal homologs in tetrapods (Raff, 2007). Zebrafish shows walking-like movements of the pectoral fins during slow swimming (Thorsen et al., 2004). Late-phase HoxD expression pattern was present in primitive bony fish and was lost together during evolution with the posterior portion of the ancestral fin in teleosts. It was retained, however, in sarcopterygians like *Tiktaalik*, and co-opted into the tetrapod limb (Raff, 2007). *Tiktaalik* was an extinct fish (late Devonian) with limb-like fins that probably allowed it "walking" on land.

Hoxa and Hoxd gene expression patterns also demarcate boundaries of several developmental domains in the limbs of birds and mammals. Thus, the five HoxD genes expressed in distal limb buds regulate the formation of the five digits in living tetrapods. In particular, anthropoids (humans, apes, new world, and old word monkeys) exhibit differential adaptations in forearm and digital skeletal proportions to the specific locomotor modes. It has been argued that Hox-defined developmental modules may have served as evolutionary modules during hand evolution in anthropoids (Reno et al., 2008). On the basis of forearm and digital morphometric data in several anthropoid species and of correlations with the spatial patterns of Hoxd expression territories during bone growth, Reno et al. (2008) postulated the existence of at least two developmentally independent growth modules: (1) a posterior digit module which includes the distal radius, posterior digit metacarpals, and phalanges of the long digits, and (2) a distal thumb module. The growth of the posterior digit module is

possibly regulated by Hoxd11, and the thumb module by Hoxa13 and Hoxd13. Thus, the posterior digit elongation observed in ateline and colobine (a new world and old word monkey, respectively) could have been achieved through an up-regulation of Hoxd11 expression (Reno et al., 2008). An elongated thumb, on the other hand, may interfere with brachiation; thus, thumb reduction in atelines and colobines may have been an adaptation to brachiation, and may have resulted from the modulation of Hoxa13/Hoxd13 expression. The length of the radius and posterior digits in humans is short relative to that of other higher primates. Instead, humans have very long thumb phalanges. This pattern could be achieved by the combination of up-regulation of the targets of Hoxd13 and/or Hoxa13 expression, and down-regulation of Hoxd11 targets (Reno et al., 2008).

SPINAL CIRCUITS FOR THE CONTROL OF LOCOMOTION

The identification of functional modules in motor control is more difficult than that of anatomical modules, but similar principles of evolutionary conservation probably apply. In particular, there is growing evidence that the building blocks used to construct locomotion are similar across several animal species, presumably related to ancestral neural networks of command. In all vertebrates, spinal neuronal networks termed Central Pattern Generators (CPGs) generate the basic rhythms and patterns of motor neurons (MNs) activation for locomotion (Grillner, 2006). CPGs are controlled by descending supraspinal inputs (including locomotor command regions in the brainstem), as well as by sensory inputs. Comparative studies in vertebrates using genetic and electrophysiological tools have consistently shown that there are several common principles in the organization and regulation of CPGs (Goulding, 2009; Kiehn, 2011). In particular, the core premotor components of locomotor circuitry mainly derive from a set of embryonic interneurons which are remarkably conserved across different species (Goulding, 2009). Grillner (2011) suggested that the neural control system for locomotion can be traced back to the lamprey, a jawless fish-like vertebrate, which appeared about 560 million years ago, before any legged animal had evolved yet. Notice that not only the spinal CPG modules, but also some supraspinal centers which contribute importantly to locomotor control, such as the basal ganglia, have been conserved throughout vertebrate phylogeny starting with the lamprey (Grillner et al., 2013).

In addition to the segmentally organized MNs that innervate adjacent myotomes, there are a few basic classes of neurons in the vertebrate locomotor CPG with established homologies across different aquatic (lamprey, *Xenopus*, zebrafish) and terrestrial (mouse) species (Grillner, 2006; Goulding, 2009; Kiehn, 2011). (1) Glycinergic inhibitory commissural interneurons project to the opposite side of the spinal cord, and provide the mid-cycle inhibition underlying left-right alternation: the muscles on each side of the body must contract out of phase with those on the opposite side. These interneurons are termed inhibitory CINs in the lamprey and *Xenopus*, CoSA neurons in the zebrafish, and $V0_D$ neurons in the mouse. (2) Ipsilaterally projecting inhibitory interneurons provide inhibition to MNs and to commissural interneurons, and can regulate the speed of locomotion. They are termed L-interneurons in the lamprey, CiA neurons in the zebrafish, and V1 neurons in the mouse. The V1 class includes Renshaw cells and Ia-inhibitory interneurons. (3) Glutamatergic excitatory interneurons project to the other CPG cell types. A number of these interneurons provide rhythmic drive to MNs and other CPG neurons. They are termed EIN in the lamprey, CiD neurons in the zebrafish, and V2a neurons in the mouse.

The close correspondence of several classes of spinal CPG neurons across aquatic and terrestrial vertebrates suggests that the corresponding neuronal modules may have been evolutionarily conserved between the swimming and walking CPG. This close phylogenetic relationship is especially evident in the embryonic spinal cord (Goulding, 2009; Kiehn, 2011). Nevertheless, the full neural circuitry required for legged-locomotion is more complex than that required for swimming, presumably in relation to the different biomechanics of these modes of locomotion (Goulding, 2009). Swimming movements of aquatic vertebrates differ considerably from the limbed locomotion of terrestrial vertebrates. Whereas fishes mainly use side-to-side flexion of the torso to shift in water, most extant tetrapods mainly use their limbs for propulsion, with trunk movements playing a subsidiary role in the potentiation of limb movements. In addition, legged-locomotion on land places unique demands related to weight-loading, postural, and limb control on uneven terrains.

We still do not know how the swimming CPG has been modified during evolution to sustain legged-locomotion. The transition may have been gradual, since amphibians and reptiles show oscillatory movements of the axial body that are tightly coupled to limb movements. Limb movements may have resulted from a reconfiguration of the swimming CPG at limb metamers, or they may have resulted from the addition of specialized modules controlling limb flexor–extensor muscles (Goulding, 2009). Some animal species can sustain swimming and walking at different developmental stages; for instance, amphibia shift from one locomotor mode to the other one from larval to adult metamorphosis (Combes et al., 2004). Also, as noted above, the zebrafish exhibits walking-like movements of the pectoral fins during slow swimming (Thorsen et al., 2004), indicating that some neural substrates for a walking mode are already present in teleosts (Goulding, 2009).

While most spinal cord is involved in the control of swimming in aquatic species (with a rostro-caudally traveling wave, phase-shifted in adjacent axial myotomes), CPGs at cervical and lumbar-sacral levels control the forelimbs and hindlimbs, respectively, of walking mammals. In particular, the isolated lumbar and sacral spinal cord is able to generate quasi-normal walking at the hindlimbs. According to one view, the CPG network for each limb may include multiple inter-connected modules controlling the movement of each joint, with a coupling of CPG activity across limb joints. The ability to generate rhythmic motor output is not evenly distributed in the lumbo-sacral cord, but there is a rostro-caudal excitability gradient (Deliagina et al., 1983; Cazalets and Bertrand, 2000; Kiehn, 2006). Indeed, isolated rostral segments (L1–L3 in rodents, L3–L5 in cats, D7–D10 in turtles) exhibit a stronger rhythmic drive than isolated caudal segments (L4–L6, L6–S1, and S1–S2, respectively). The stronger rhythmic drive of the rostral cord (which contains hip MNs) suggests that these segments act as leading oscillators, entraining more caudal and less excitable oscillators (perhaps those controlling knee and ankle joints). Motor bursts propagate rostrally and caudally

from the lumbar region to farther segments (Falgairolle and Cazalets, 2007). In addition to autonomous signals generated within the spinal networks, sensory signals from joint, muscle, and skin receptors play a major role in shaping locomotion. In particular, sensory signals are involved in the onset and on-line adjustment of the locomotor rhythm, they can affect the amplitude and phase of the activity profiles in motor output, and their central effects are gated temporally with the result that reflexive contributions become appropriate to the specific phase of the step cycle (Pearson, 2000).

CONTROL MODULES FOR LOCOMOTION

Although the evidence reviewed above suggests the existence of modularly organized circuits in spinal CPGs, their exact functional structure remains unclear. Modularity might be organized at a segmental level, involving the control of single joints (in limbed-animals) or single axial metamers (in swimming animals). While this scheme appears compatible with the organization of swimming CPGs (as in the lamprey, Grillner, 2006), it appears unlikely in mammals. Thus, in both cats and humans, single joint movements are controlled by distinct spinal segments, because muscles involved in joint flexion and extension are innervated in several different segments even far apart. Alternatively, there could exist distinct flexor and extensor modules spanning multiple joints (or metamers), distinct from the commissural modules (including commissural interneurons) involved in left-right alternation. However, in both cats and humans, flexor and extensor muscles can be co-activated in a given phase of the gait cycle, and it is not evident whether this co-activation reflects shared or independent drives directed to flexors and extensors. Still another possibility is that there exist distinct rhythm-generation and pattern-generation modules (McCrea and Rybak, 2008). This reflects the idea of multilayered organization of CPGs. Neurons in the rhythm-generating module would be two or more synapses upstream from MNs and project to pattern-generating neurons; the latter project monosynaptically to MNs. The main evidence for separate control of rhythm and pattern is provided by the observation that CPGs can maintain the period and phase of locomotor oscillations both during spontaneous deletions of MNs activity and during sensory stimulation affecting MNs activity (McCrea and Rybak, 2008).

DEVELOPMENT OF LOCOMOTION

Further cues about control modules are provided by developmental studies of locomotor patterns (Lacquaniti et al., 2012a). It has recently been shown that the primitive stepping patterns exhibited by human babies are retained and tuned, while new patterns are added during development (Dominici et al., 2011). Stepping can be elicited in newborns supported under the arms in an upright, slightly tilted forward posture, after contacting ground with the feet soles. Reflex stepping has been reported also in premature infants at 30+ weeks post-conception (Allen and Capute, 1986) and anencephalic newborns (Peiper, 1961). This is consistent with a predominant role of spinal and brainstem mechanisms, at a time when cerebral connections to the spinal cord are still immature. The neural patterns of muscle control have been studied by factorization of EMG activity into the basic components (Dominici et al., 2011). In human newborns, two patterns were sinusoidally modulated over the step cycle: one pattern was timed around the body support phase of stance, while the other one was timed during swing. Toddlers (∼1-year-old) at their first independent steps showed the same two patterns of the newborn, and 2 new patterns timed at touch-down and lift-off, probably contributing the shear forces necessary to decelerate and accelerate the body, respectively. In preschoolers (2–4-years), all four patterns showed transitional shapes: the older the child, the closer the waveform to the adult.

The development of adult gait from infant stepping depends on a progressive integration of supraspinal, intraspinal, and sensory control (Yang et al., 1998). In particular, the lack of muscle patterns around foot contact in the neonate might depend on immature sensory and/or descending modulation of stepping. Without sensory modulation (as in fictive locomotion), the spinal circuitry of animals also generates sinusoidal-like patterns (Falgairolle and Cazalets, 2007), similar to those observed in the human neonate. The addition of basic patterns in the first months of life implies a functional reorganization of inter-neuronal connectivity, the appearance of additional functional layers in the CPGs, and/or more powerful descending and sensory influences on CPGs.

Locomotor-like oscillatory activity can be recorded from the lumbar and sacral ventral roots of the isolated spinal cord of neonatal rats, bathed with dopamine plus NMDA or serotonin (Falgairolle and Cazalets, 2007). Factorization of the electroneurograms associated with this fictive walking showed two patterns essentially identical to those of human newborns (Dominici et al., 2011). Factorization of the EMG of adult rats, cats, macaques, and guinea fowls showed four patterns, closely resembling those found in human toddlers (Dominici et al., 2011). However, with development, the motor patterns may become tuned to the specific biomechanical requirements of each animal species. Thus, brief, pulsatile activations timed at the apex of limb oscillations is specific of human adult locomotion, perhaps in relation to our unique erect bipedal locomotion on extended legs and a heel-contact well ahead of the body (Dominici et al., 2011).

Also the topographical maturation of intraspinal connections in human babies is reminiscent of the organization observed in other animals. In rodents, turtles, and cats, a rostro-caudal excitability gradient has been described in the lumbo-sacral CPGs (Kiehn, 2006). Also human newborns exhibit a higher activation of lumbar vs. sacral segments (Ivanenko et al., 2013). With human development, the lumbar and sacral loci of activation become more dissociated with shorter activation times (Ivanenko et al., 2013), but the upper lumbar CPG may represent a major pacemaker also in human adults (Gerasimenko et al., 2010), whereas the sacral CPG could play a subordinate role for adaptation to specific foot-support interactions (Selionov et al., 2009). Overall, these behavioral results are consistent with the genetic and electrophysiological studies reviewed above which demonstrate that, despite the existence of species-specific features, there are several common principles in the neural organization and regulation of CPGs.

CONCLUSION

The goal of identifying modules based on independence of function has been reached only in selected cases so far. In particular, experimental attempts to associate specific functions to individual

modules of locomotor control mainly involved simple correlations between the temporal changes in biomechanical parameters and the parallel changes in muscle activity (Lacquaniti et al., 2012b). Computer simulations have also been used to correlate biomechanics and muscle activity (Neptune et al., 2009). The evolutionary developmental perspective may provide an alternative and fruitful approach by considering how developmental units match specific adaptive functions in different organisms (Kirschner and Gerhart, 1998; Schlosser and Wagner, 2004).

Although the evolutionary developmental approach is still in its infancy in the field of motor control, some general principles have already emerged. For example, the developmental addition of new premotor modules appears to underlie the postnatal acquisition and refinement of several different motor behaviors in vertebrates. We reviewed how new control patterns are added to the primitive ones during the development of human stepping (Dominici et al., 2011). Similar principles have been uncovered in the development of song. Thus, juvenile zebra finches initially produce babbling-like sub-songs, and start generating more mature songs with recognizable phrases around the seventh week after hatching (Aronov et al., 2008). This transition follows the formation of synaptic connections between the song premotor nucleus HVC and the motor nucleus RA, suggesting that more mature songs depend on the developmental addition of the HVC module to the premotor pathway (Aronov et al., 2008). Another example is provided by the development of murine vibrissal circuitry (Takatoh et al., 2013). Mice start employing rhythmic sweeping of their vibrissae for exploration around 2 weeks after birth. At about the same time, new sets of bilateral excitatory inputs are added to vibrissa facial MNs from neurons in the lateral paragigantocellularis nucleus (Takatoh et al., 2013). Moreover, descending axons from the motor cortex directly innervate these premotor neurons.

In general, modules can be conserved in their basic structural *bauplan,* but can lead to divergent morphologies and functions. Like a child with the Meccano®or Lego®parts, Nature has constructed a multitude of different forms and behaviors starting from a basic set of components over millions of years of evolution. Different animal species have gross morpho-functional differences, but they often use surprisingly similar organizational modules. A striking example is provided by the comparison of reaching strategies used by man and octopus, an invertebrate. Despite the evolutionary gap and morphological differences, humans, and octopuses evolved similar strategies to reach for a target (Sumbre et al., 2006). Thus, arm extension in octopus is controlled by basic muscle synergies involving the activation of all arm muscles (Sumbre et al., 2006), similar to the synergy control of human reaching (d'Avella and Lacquaniti, 2013). Moreover, octopus arms generate a quasi-articulated structure based on three dynamic joints with a tight temporal co-variance of joint motions (Sumbre et al., 2006). This kinematic invariance is closely reminiscent of the joint motion co-variance of human reaching movements (Soechting and Lacquaniti, 1981).

To make a simplistic metaphor, the flexible use and combination of similar basic components resulting in widely different behaviors could be equated to the different expression of similar genes resulting in widely different phenotypes and behaviors in different animal species. Novel evolutionary characteristics might have emerged from changes in expression of basic control patterns phylogenetically conserved, rather than the expression of totally new patterns. Here, we argued that features that are conserved across species might be modules that are recombined during evolution for the emergence of new phenotypes. However, an alternative possibility that currently we cannot rule out for complex organizations at systemic level, such as the motor patterns, is that their conservation is explained just as a result of convergent evolution, that is, they result from similar environmental pressure (natural selection).

Recently there has been a growing interest in the modular organization of leg movements, in particular those related to locomotion. One of the basic modules involves the flexion of the leg during swing and it was shown that this module is already present in neonates (Dominici et al., 2011). In this paper, we question how these finding build upon the original work by Sherrington, who proposed that the flexor reflex is the basic building block of flexion during swing phase. Similarly, the relation between the flexor reflex and the withdrawal reflex modules of Schouenborg and Weng (1994) will be discussed. It will be argued that there is large overlap between these notions on modules and the older concepts of reflexes. In addition, it will be shown that there is a great flexibility in the expression of some of these modules during gait, thereby allowing for a phase-dependent modulation of the appropriate responses. In particular, the end of the stance phase is a period when the flexor synergy is facilitated. It is proposed that this is linked to the activation of circuitry that is responsible for the generation of locomotor patterns (CPG, "central pattern generator"). More specifically, it is suggested that the responses in that period relate to the activation of a flexor burst generator. The latter structure forms the core of a new asymmetric model of the CPG. This activation is controlled by afferent input (facilitation by a broad range of afferents, suppression by load afferent input). Meanwhile, many of these physiologic features have found their way in the control of very flexible walking bipedal robots.

Keywords: flexion reflex, local sign, reflex modules, synergy, central pattern generator, gait, forward model

INTRODUCTION

One of the first authors to point out the modular organization of the motor control system was Sherrington (1910a,b). Reading his work, it is clear that for him the flexor reflex was the mother of all modules and synergies (in the broad sense, not in the sense of the mathematical synergies defined recently). He proposed that the flexor reflex is a basic building block of the central nervous system and that "the flexion reflex is in reality the reflex stepping of the limb" (pp. 69 in Sherrington, 1910b). In his view, stepping was basically a series of flexion reflexes, with extension occurring merely as the "rebound" following the flexion. The extension during the stance phase of gait could be provided as some type of "extensor thrust," evoked by "the weight of the animal applied through the foot against the ground" (pp. 78 in Sherrington, 1910b). In the absence of support (air stepping), the rhythmic activity continues, which for Sherrington was an argument for stating that "the extensor thrust cannot therefore be an indispensable factor in the reflex step" (pp. 79 in Sherrington, 1910b). This idea of a basic asymmetry in the control of locomotion has since lost terrain, mostly because of the powerful impact of the (symmetrical) half-center model for the central pattern generation of locomotion (one half of this center inducing activity in flexors, the other in extensors). The latter model was described by Brown (1914) and is known as the "half-center" model. The first ideas in that direction were actually presented by Sherrington himself on the basis of work by Brown (1911, 1912). They are based on experiments showing that cats with a transected spinal cord and with cut dorsal roots still showed rhythmic alternating contractions in ankle flexors and extensors. However, Sherrington did not necessarily propose a symmetrical organization. Instead, he and Brown proposed originally that gait was the result of a balance "between equal and opposite states of excitation" in flexors and extensors, while being well-aware that the origin of these states could be quite different. The latter notion seems to have been lost in later years.

In addition, in many cases the discussion on the credits for the original ideas about a central basis for locomotion has been simplified considerably in many accounts (as explained elegantly in a review by Stuart and Hultborn, 2008). Both Sherrington (1910a) and Philippson (1905) have indeed emphasized the idea that during gait one phase induced automatically the next one (reflex chain) but this does not mean that these authors excluded a central origin for the rhythmic activity (for details see also Clarac, 2008). In particular, Philippson believed that the spinal control was due to a combination of central and reflex mechanisms (Clarac, 2008). Hence it is a gross simplification to see this part of the history as a "victory" of Brown over his competitors (Sherrington and Philippson). Brown should be credited for

having provided compelling evidence for the central spinal origin of locomotor activity, while Sherrington and Philippson should be remembered for their important insights on the importance of afferent input for the control of gait.

The "half-center" model has helped us greatly in appreciating the spinal origin of the central pattern generator (CPG) for locomotion, but it may have led to the simplifying idea of symmetry within the CPG (Jankowska et al., 1967a,b; Lundberg, 1981; Lafreniere-Roula and McCrea, 2005). In that way it has deterred our thinking away from the notion of a basic asymmetry of the neural organization of locomotion.

Nevertheless, there have been attempts to remediate these shortcomings and to explain gait in terms of asymmetric models (for review see Guertin, 2009). For example, Pearson and Duysens (1976) introduced a swing generator model, based on work on cats and cockroaches (**Figure 1**).

This model again assigns the flexor synergy (defined as the synchronous activation of flexors) a central place ("swing generator"). In contrast, the activation of extensors is thought to rely more on feedback systems, notably for load receptors (Duysens and Pearson, 1980; Dietz and Duysens, 2000; Duysens et al., 2000; Pearson, 2004). For the flexor synergy, there is little doubt that there may be an involvement of part of the spinal CPG for locomotion, even for humans (Duysens and Van de Crommert, 1998). However, for the extensor synergy, the requirements are very different. The extensor synergy is called upon by the loading of the limb. Pressure on the foot sole can simulate this loading and results in an "extensor thrust" (Sherrington, 1906). Hence, it is basically a peripherally driven synergy, not a centrally triggered one. In terms of sensory feedback the organization of gait is basically asymmetrical since interaction with the environment is much more intense during the stance phase (Duysens, 2006). In contrast, for the swing phase, there is only the need for a trigger (in this case limb unloading and hip extension). Even Sherrington already recognized that the flexor synergy was greatly facilitated by hip extension (see pp. 81 in Sherrington, 1910b). For him, the extension phase followed automatically after the flexion phase, which was the only phase that needed to be centrally triggered. From earlier cat work, it is confirmed that this transition to the stance phase is indeed facilitated at the end of the flexor activity (Duysens, 1977).

Recent data have provided support for such asymmetric models. Thanks to the insights from recent use of genetic manipulations of CPG neurons, it is now widely accepted that the core premotor components of locomotor circuitry are common and derive from a set of embryonic interneurons that are remarkably conserved across different species (e.g., Goulding, 2009). In particular, it is of interest to consider the organization of "swimming" CPGs since they are the evolutionary basis for the "walking" CPGs. In this respect, it should be emphasized that these models of the swimming CPG are highly asymmetric. In the lamprey, for example, there are four functional classes of neurons in the swimming CPG. One of these four consists of excitatory glutamatergic neurons (EINs), projecting to all three other CPG neuron cell types. These cells provide rhythmic drive to other CPG neurons during swimming.

In mammalian systems the idea of an asymmetric CPG is also taken seriously (Brownstone and Wilson, 2008; Zhong et al., 2012). Some of the evidence relies on the observation that rhythmic bursts of activity (in muscles or nerves to leg muscles) sometimes are skipped during periods of real or fictive locomotion (this is termed "spontaneous deletions"). They often occur in reduced preparations of cats (Duysens, 1977, 2006) or rats (Zhong et al., 2012). Such deletions are hard to explain on the basis of a simple half-center model (McCrea and Rybak, 2007, 2008). One typical feature is that these deletions are highly asymmetric: flexor deletions are accompanied by sustained ipsilateral extensor activity, whereas rhythmic flexor bursting is not altered

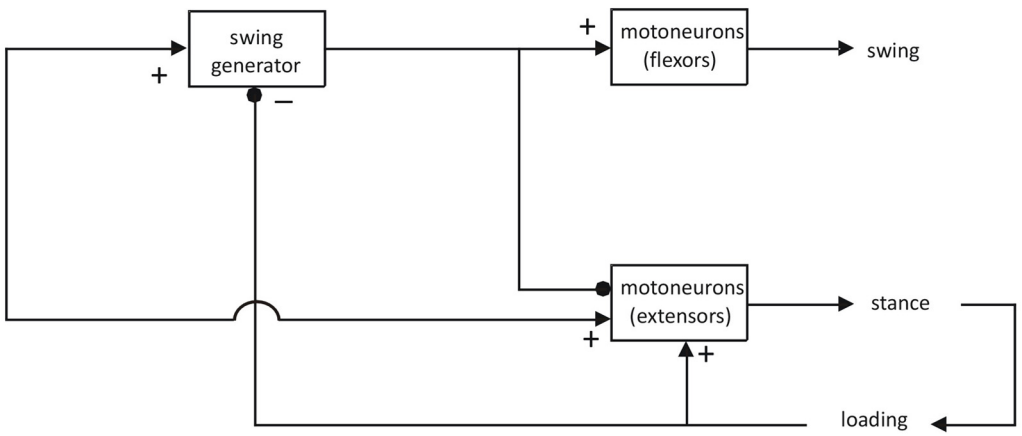

FIGURE 1 | Asymmetric model for the generation of locomotion. Adapted from Pearson and Duysens (1976). This model could underlie a number of locomotor behaviors, as long as they include a flexor and an extensor phase. In humans, the question has been raised whether one should not assume that there are separate spinal CPGs for different types of gait, such as for forward and backward gait (Jansen et al., 2012) or for walking and running (Sylos Labini et al., 2011). In general, these studies are more in favor of the idea that the same CPGs can be utilized for different locomotor behaviors but that different supraspinal descending systems facilitate the reconfiguration of the spinal CPGs. This is in line with recent work on animal species where it is possible to record from individual neurons within CPGs (see "Discussion" in the papers mentioned above).

during extensor deletions. Such results are best explained by a rhythm generator that provides direct input to a "swing" or "flexor burst" generator but not to the extensor part of the CPG (Rybak et al., 2006a,b; Zhong et al., 2012). Hence, it is basically similar to the model proposed originally by Pearson and Duysens (1976) except that the swing generator is split up in a rhythm generator and a flexor center.

Some earlier cat modeling work had pointed toward asymmetry as well. For example, the model proposed by Prochazka and Yakovenko (2007a) seems symmetrical at first sight but it already contains important elements of asymmetry. In particular it is argued that interneurons in the extensor timing element may receive less inputs generating persistent inward currents, therefore as a network "they are not only set to have longer half-cycle durations, but also to be more sensitive to synaptic commands." Interestingly, the model was only stable for extensor dominant phase-duration characteristics (where extension durations vary more than flexion durations; see also Prochazka and Yakovenko, 2007a,b). This pattern is seen in the normal cat. The inverse (flexor dominant) was, however, not observed in the model while it has been observed experimentally, but only in fictive locomotion (rhythmic output of the spinal cord in paralyzed cat preparations). This is an important point as the existence of both flexor- and extensor-dominated patterns has often been invoked to support the notion of a symmetrical CPG (McCrea and Rybak, 2008). However, one may wonder whether the flexor-dominated pattern is not simply an artifact of the preparation used, since the output observed is one from CPGs without interaction with afferent input. As pointed out above, the afferent input is crucial for the automated phase transitions. Experimental work on cats has clearly established that peripheral input from the paw (as occurs during touchdown) is very potent in terminating the flexor phase and initiating the extensor phase (Duysens, 1977). Hence, in the absence of such feedback it is not surprising to see flexor phases of abnormally long duration.

This feature was not always recognized and perhaps for this reason, the concept of an asymmetric model first met some resistance (McCrea and Rybak, 2007, 2008). However, due to more recent data (Brownstone and Wilson, 2008; Zhong et al., 2012), the idea of an asymmetric pattern generator has reemerged and it is therefore worthwhile to reexamine the presumed basis of the swing generator, namely the flexor synergy, its adaptations (for example to stimulation of different skin areas on the leg, a phenomenon referred to as "local sign" in physiology) and its integration in the process of locomotion.

THE TASK TO WITHDRAW AND THE CORRESPONDING FLEXOR SYNERGIES IN THE SPINAL CORD: A DEFENSE IN FAVOR OF THE "LOCAL SIGN"

For the flexor reflex, it is clear that the synergy (as described by Sherrington) corresponds very well to the task of withdrawal. This protective reflex is so important that it is present at birth and can be elicited with about any type of stimulus to the foot. In neonates, the flexion reflex responses to innocuous stimulation are already present (Andrews and Fitzgerald, 1999). How do these responses compare to the more recently described synergies (or "components")? In the adult, the flexor reflex cannot simply be related to just one component, although factor 5, as described by Ivanenko et al. (2004), or P3 as described by Dominici et al. (2011), are close candidates. For example, the factor 5 of Ivanenko et al. (2004) relies of strong activations of Sartorius and Tibialis Anterior during the middle of the swing phase.

In neonates, the gait is explained (up to 89%) by just two patterns, one of which peaks at about 75% of the step cycle, hence in the swing phase. This "swing" pattern persists in the adults and is seen in a wide variety of species. When one considers the large input of flexors to these basic patterns, it is tempting to relate these components to the flexor synergy as described by Sherrington (1910b). Furthermore, the appearance of these components in swing is nicely in line with the Sherrington proposal of a common neural basis for the flexor reflex and the flexion phase of stepping. Further experimental evidence for such common use of neural circuitry has been obtained in animal studies. For example, in the turtle, Berkowitz has described interneurons that are active in both types of activity (flexion phase and flexor reflex; Berkowitz, 2007, 2010). In addition, in the same species it was shown that often the same interneurons can be involved in various types of rhythmic behavior (swimming, scratching), thereby supporting the idea that basic synergies can be used in various behaviors (Berkowitz and Hao, 2011; see also Grillner, 1985).

During maturation in humans, the threshold for the reflex increases and biceps femoris responses dominate (Andrews and Fitzgerald, 1999). Furthermore, the pattern of the flexor reflexes changes. The recruitment of specific flexor muscles depends increasingly more on the area of skin stimulated ("local sign"), thereby allowing a more efficient withdrawal when stimuli are applied at various distinct locations on the limb. This has led several authors to propose the existence of a variety of reflex modules both in humans (Andersen et al., 1999, 2001; Sonnenborg et al., 2000, 2001) and in animals (Schouenborg and Weng, 1994; Tresch et al., 1999).

There is no doubt that these new experiments have provided a wealth of very precise data but still the question arises whether this has basically altered our way of thinking. The idea of a "local sign" goes back to the early days of reflex physiology. Creed and Sherrington (1926) stated (pp. 265): "The term flexion-reflex . . . denotes strictly speaking a group of reflexes, all more or less alike . . . yet from one afferent to another differing in detailed distribution of the motor units employed, while yet always conforming to the general type flexion-reflex." Especially this last point is important as it is proposed originally that there remains a basic synergy ("flexion-reflex") underlying all these different variations. The data of Creed and Sherrington (1926) showed that, despite variations in some of the distal flexors, the hip and knee flexors always participated in the various reflexes (see their table on pp. 260). More recent work supports this, both in the frog (Tresch et al., 1999) and in the rat (Schouenborg and Kalliomaki, 1990). However, this common element is often not emphasized and the impression may arise that the recently defined "modules" and "synergies" are independent entities. This certainly differs from the view of Creed and Sherrington (1926), who viewed the different versions of the flexor reflexes as expression or adaptations of one and the same basic flexor synergy. Hence the basic issue is whether the recently described reflex modules are also

mostly variations of a basic synergy (the flexion reflex) or whether they really constitute separate entities.

In our opinion, there is no convincing evidence for the latter, at least when one considers the literature on withdrawal reflexes. Local cutaneous reflexes do exist, but they differ from withdrawal reflexes. For example, the selective activation of extensor reflexes such as the gastrocnemii was observed when stimulating the skin that covered these muscles (Hagbarth, 1960). For withdrawal reflexes, in contrast, there is no data to show convincing evidence for neural pathways for separate types of flexor reflexes. They mainly show modifications of a basic flexor pattern. These modifications are likely to be due to changes in activity in spinal dorsal horn cells (Schouenborg et al., 1995). During development, the withdrawal reflexes are "fine-tuned" by the spontaneous movements of the individual but the resulting reflexes always have a component of hip and/or knee flexion (Holmberg and Schouenborg, 1996). Hence these studies provide a substantial contribution to our knowledge on the "local sign" but they do not show that there is a conceptual deviation from the notion of "local sign," as originally defined. In addition these studies underline the plasticity of reflexes. Synergies, as defined more recently in mathematical terms, do not fully overlap with these reflexes. Nevertheless, several authors have emphasized that these muscle synergies and modules may also be highly plastic and basically represent solutions for specific tasks at a given time (Latash, 1999; Ivanenko et al., 2013).

PATHOLOGY

The data provided by pathology further support the notion of variations in flexor reflexes rather than a set of separate modules. As one might expect, the adjustments and fine-tuning of the flexor reflex relates to input from descending pathways. Hence, when a lesion occurs in these pathways, one should see a reversal to the more primitive state. This is exactly what happens.

In spinal cord injury (SCI) there is a loss of "local sign" and a return to the simpler forms of flexor reflexes (Schmit et al., 2003; "an invariant flexion response pattern was produced regardless of stimulus location"). In addition, in these patients there is a link between a normal flexor reflex and the ability to recover gait (Dietz et al., 2009). After some 6–12 months, this ability deteriorates when the early flexor reflex (latency 60–120 ms) decreases over time. Again, this illustrates the importance of the flexor reflex circuitry for the generation of gait. In stroke, a similar return to a more primitive synergy occurs after the insult and this phenomenon is known as the Babinski sign (Babinski, 1922). Stimulation of the sole of the foot induces dorsiflexion of the big toe, by activating the extensor hallucis longus muscle, a flexor in the physiological sense. Babinski pointed out that this reflex was part of the flexion synergy of the lower limb and in fact clinicians, still as of today, are advised to watch for flexion of the whole limb as an obligatory concomitant of the reflex (Van Gijn, 1978; Kumar, 2003). The whole reflex is a return to the condition of the neonate, where indeed a dorsiflexion Babinski is normally present, usually in conjunction with a brisk flexion of the whole limb. Interestingly, in the neonate it is important not to stimulate too gently, because otherwise a grasp reflex occurs. This shows that actually what we know as the "normal plantar reaction" (plantar flexion of the toes) may actually be a superposition of two reflexes, with the grasp reflex dominating the flexor reflex. This makes sense in an evolutionary context since, for example, grasping tree branches might have been more important than a "blind" withdrawal defense toward any type of stimulus. In complete SCI subjects, the occurrence of the Babinski sign has been described as well, although it can be absent in some patients due to associated peripheral nerve damage (Petersen et al., 2010).

CAN THE REAL FLEXOR REFLEX PLEASE STAND UP!

One problem in this research field is the confusion on the flexor reflex terminology. In humans, most studies do not use pure nociceptive stimuli such as heat. Instead, electrical stimulation is used. However, it is impossible to activate nociceptive afferents in any nerve without coactivating large myelinated fibers. Therefore, in humans, the response to high intensity electrical stimuli typically has two components, an early (60–120 ms) and a late one (120–200 ms; Shahani and Young, 1971). The difficulty is to decide which afferents are responsible for a given component. If only high intensity stimuli are used, one is easily misled in thinking that the early response is a nociceptive one, while in fact it often can be elicited by low intensity stimuli as well. The problem is aggravated by differences in definition. Hugon (1973) defined the early response (RII) as having a latency of 40–60 ms and the late response (RIII) as having a latency of 85–120 ms (for review see Sandrini et al., 2005). Hence, RIII is really the equivalent of the "early" flexor reflex. In normal control subjects, walking on a treadmill, one can easily evoke RIII responses in a variety of muscles with stimuli that are just above perception threshold (Duysens et al., 1990). Nevertheless, some people label this component as "the flexor reflex" and in fact it was even claimed to be useful as an index of pain (Willer, 1977).

Part of the problem is that some of these reflexes are also task-dependent, needing stronger stimulation under unfavorable conditions. For example, the RIII component can be elicited very easily by stimulation of non-nociceptive low threshold afferents during gait while the same responses may be small or absent in subjects at rest (Duysens et al., 1993; Komiyama et al., 2000). During gait, the RIII responses are especially prominent in muscles such as biceps femoris and tibialis anterior both in intact cats (Duysens and Loeb, 1980) and in intact humans (Duysens et al., 1990; Yang and Stein, 1990; Zehr et al., 1997). When cutaneous stimuli are given at the ankle just prior to the onset of the swing phase, they elicit responses in these flexors, just as one would expect from Sherringtons' work (see Duysens et al., 2004). However, at end of swing the same stimuli elicit facilitatory responses in extensor muscles (Duysens et al., 1990) while providing suppression to flexor muscles (Duysens et al., 1990; Yang and Stein, 1990). This has been termed "reflex reversal" (in analogy with the use of this term in cat literature, Forssberg et al., 1975; Duysens and Pearson, 1976). In later work it was shown that such reversal of EMG responses resulted in a reversal of behavioral responses (flexion, extension) as well (Duysens et al., 1992; Zehr et al., 1997). Furthermore, the responses depended heavily on "local sign"

(Van Wezel et al., 1997; Zehr et al., 1997, 1998; Nakajima et al., 2006).

These examples show that synergies are extremely flexible and their expression depends highly on the task and the phase of the movement ("phase-dependent modulation"). A given stimulus does not always elicit the same responses in the same muscles. One way to interpret this type of results is by assuming that a given afferent input (or descending command) is translated in the spinal cord into responses that are appropriate for the state of the interneurons related to a given phase of the movement (Drew, 1991). This view differs from the contention that reflexes or synergies are fixed building blocks. Instead it opens the way to the idea that they are highly adaptable entities depending on the constraints of the environment and the state of the central nervous system ("time-varying muscle synergies," d'Avella et al., 2003; Ivanenko et al., 2006b).

An important unresolved issue concerns the pathways of the flexor reflexes or synergies. Since both components of the flexor reflex persist in patients with a complete spinal cord lesion, it is evident that the minimal responsible pathways could go through the spinal cord (Shahani and Young, 1971). In fact, in recent literature the first component is often simply labeled "spinal reflex" (Dietz et al., 2009; Bolliger et al., 2010; Dietz, 2010; Hubli et al., 2011, 2012). While this is entirely appropriate for SCI patients, it can be questioned whether this can also be used as a valid term when intact humans are tested since responses with similar latencies have been related to circuits either through brainstem (spinobulbospinal "SBS" reflexes, Shimamura et al., 1980) as well as through cortex (Christensen et al., 1999). Hence, the responses at a given latency can arise from very different sources.

ACTING AGAINST GRAVITY: EXTENSOR SYNERGIES IN THE SPINAL CORD

In the interaction with the environment, one of the most crucial forces to deal with is gravity. This even applies to the flexor reflex. Indeed, it is often overlooked that the flexor reflex involves not only the activation of flexor muscles but also the suppression of extensor activity. This could be particularly important for situations where the limb is loaded, for example during the stance phase of gait. In such cases it is crucial that a contact with a nociceptive stimulus (a sharp object) can induce a fast unloading of the limb (Santos and Liu, 2007). However, in most cases with normal ground surface, there is no need for unloading but instead there is a need to recruit additional extensor activity as soon as the limb is loaded (early stance). In the latter case, there is a need to suppress the flexor synergy. Work on cats has revealed that this is achieved through the activation of load receptors in the extensor muscles (Duysens and Pearson, 1980; Whelan, 1996; Duysens et al., 2000). Models, allowing reinforcing feedback from extensors during the stance phase of gait, have successfully simulated cat gait (Prochazka et al., 1997). In humans, the role of load feedback in shaping the extensor output during gait has been recognized as well (Dietz and Duysens, 2000). Under conditions of simulated reduced gravity, even minimal contact forces, and a very limited amount of loading during the stance phase, have profound effects since it completely restores normal limb trajectory (Ivanenko et al., 2002).

In recent work, the activation of various extensors in the stance phase is identified as a synergy, based on a mathematical decomposition of the EMG data (factors 1 and 2 in Ivanenko et al., 2004; see also Ivanenko et al., 2006a,b, 2007, 2008). Consistent with the idea of combinations of synergies to simplify motor control, the combination of these patterns with other synergies leads to the full process of walking, (d'Avella et al., 2003; Lacquaniti et al., 2012). During maturation there is a gradual transition from a two synergy state control of gait (flexor extensor, in neonates) to a four state synergies in toddlers (Dominici et al., 2011) This is consistent with the idea that additional tasks (such as equilibrium control) are achieved by the addition of extra synergies. In this context, it is of interest that the synergy approach has also been applied successfully in studies on balance and posture (Ting and Macpherson, 2005; Torres-Oviedo et al., 2006). For gait, these synergies are well-established (Ivanenko et al., 2005) and they have been shown to be robust in a wide variety of gait conditions (Ivanenko et al., 2004, 2006a,b, 2007). In fact, it is now possible to use these synergies to model human gait (see below) and in the future it is conceivable that these new notions enter the field of robotics, since there is increasing interest to incorporate physiological features in the design of walking robots (Klein and Lewis, 2012).

INTRODUCING SYNERGIES IN MODELS OF HUMAN GAIT

The question arises whether synergies can help to achieve a closer correspondence between calculated and experimentally measured muscle activity in models of human gait. Although it is recognized that muscle activity patterns underlying gait originate from a highly flexible modular system, this is largely ignored in simulation frameworks aiming to causally relate muscle action to gait kinematics and kinetics. Due to the redundancy of the musculoskeletal system, a single motion can be obtained by different muscle coordination strategies. Typically, a performance criterion is optimized to predict the muscle coordination strategy underlying a given motion. Static optimization algorithms minimize muscle activity while imposing that the corresponding muscle forces produce the net joint torques calculated using inverse dynamics (Anderson and Pandy, 2001). Although such optimization approaches predict some basic features seen in the muscles' EMG, other features are not well-predicted. Hence, in addition to biomechanical constraints, it is important to take the principles of neural control into account when estimating muscle activations (Ting et al., 2012). Recently, simulated gait motions based on modular activation patterns were successfully produced (Neptune et al., 2009; Allen and Neptune, 2012; Sartori et al., 2012). Neptune et al. (2009) use five muscle activation modules identified from EMG and assigned each muscle to one module. They then used an optimization approach to find the magnitude and timing of the activation patterns that minimized the tracking error in a forward simulation of gait. They found that the five modules framework they proposed can successfully simulate 2D walking but that it does

not provide all control needed for 3D walking. This additional control is important since it may underlie the transition from neonate to adult walking (Dominici et al., 2011; see above).

Alternatively, and in contrast to Neptune et al. (2009), an inverse approach can be used that allows each module to contribute to the activation pattern of all muscles, as described below. Ivanenko et al. (2006a) showed that during gait five Gaussian components $G_k(t)$ with a standard deviation of 6% of the gait cycle duration and appropriate timing account for 90% of the EMG variation. This representation was used to model muscle activation patterns underlying locomotion with each individual muscle activation pattern $a_m(t)$ described as a weighted sum of Gaussian components:

$$a_m(t) = \sum w_{mk} G_k(t),$$

with w_{mk} the weight of muscle m for component k. This description of muscle activation patterns with a static optimization approach allows calculating muscle activations underlying a previously measured gait motion. However, in this approach, the timing of the Gaussian components and the muscle-specific weights of these components were determined using an optimization procedure minimizing the sum of muscle activations squared while a penalty term was used to impose that the corresponding muscle forces produce the net joint torques. The resulting activation patterns were compared to the solution of a "classic" static optimization approach without any constraints on the activation pattern and the measured EMG patterns (**Figure 2**). The experimental protocol, data processing including inverse dynamics, and the static optimization approach are described in De Groote et al. (2012).

The optimized timing of the Gaussian components is 18, 42, 55, 69, and 100% of the gait cycle. The differences between the calculated timings and the timings proposed by Ivanenko et al. are 8, 3, 0, 6, and 5%, respectively. The key features of the EMG are well-predicted by the modules-based activations. Although the correspondence with the inverse dynamics joint torques is higher when the activation patterns are not constraint to a weighted sum of Gaussians, the modules-based activations better predict the measured EMG of biceps femoris, gastrocnemius, and tibialis anterior. For other muscles such as soleus, gluteus medius,

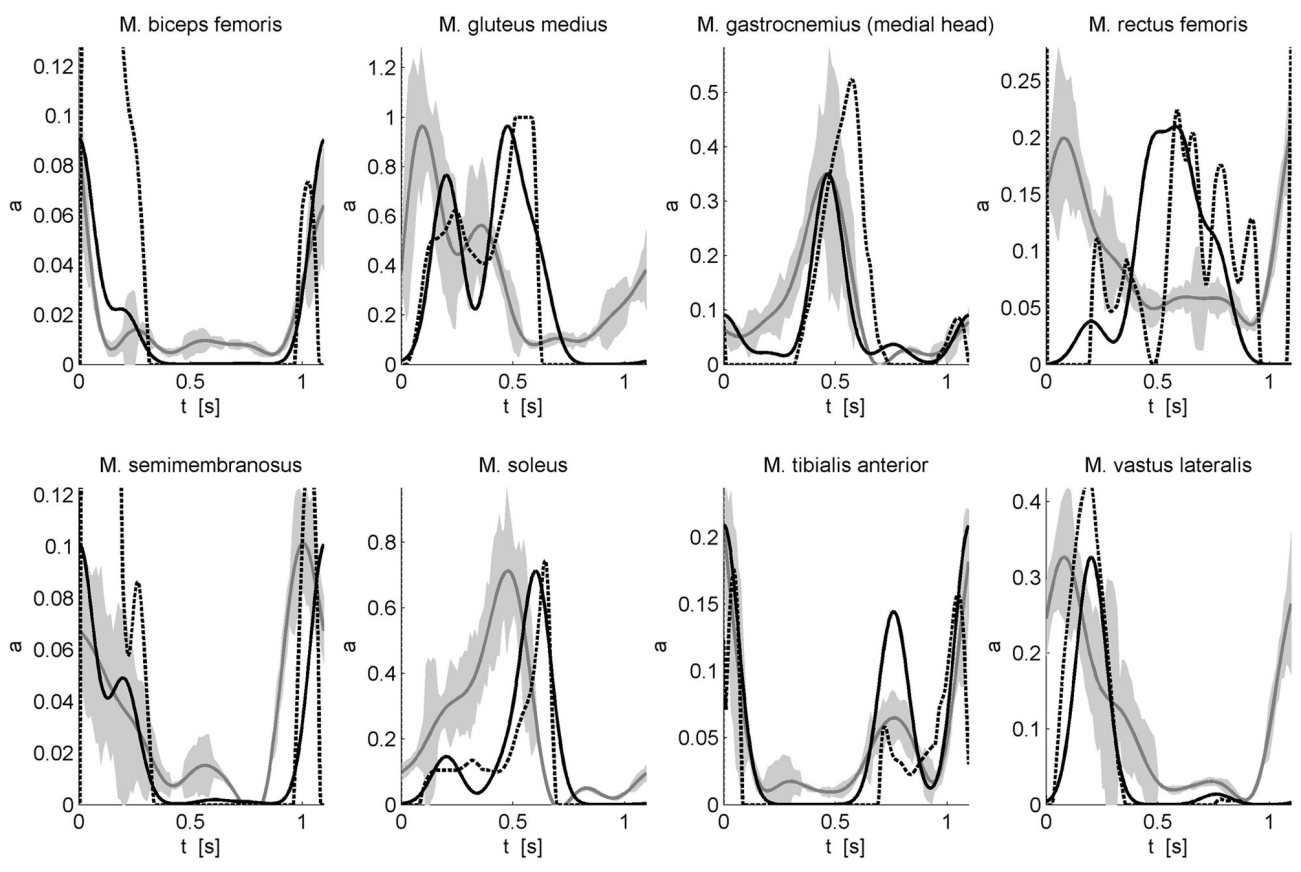

FIGURE 2 | Comparison of calculated activations and measured EMG for eight superficial muscles. Activations underlying an experimentally measured gait motion were calculated using static optimization without any constraints on the activation pattern (dashed black) and by modeling the activation patterns as a weighted sum of Gaussian modules (solid black). EMG was measured for eight superficial muscles using surface electrodes. The EMG (solid gray with standard deviation indicated by the gray band) is scaled to the maximal modules-based activation. For more details on the experimental protocol and data processing see De Groote et al. (2012).

semimembranosus, and vastus lateralis there are still differences in timing. Based on preliminary results we feel that this can be improved by adding positive force feedback to the simulation. Finally for M. rectus femoris (RF) the fit is poor. The weak correspondence between measured EMG and calculated activations for RF is seen in both activation patterns and may be related to the notorious problem of cross-talk for surface EMG for this muscle (Nene et al., 1999, 2004). In fact, it has been recognized that cross-talk can affect synergies as well, but only to the degree that weighting coefficient are altered (Ivanenko et al., 2004). Therefore, some authors have insisted on using fine wire EMG recordings (Ivanenko et al., 2004). Another reason for the difficulty of modeling RF is that this muscle presumably has activity which depends heavily on afferent input and reflexes. For example, in cats the activity in RF differed between fictive locomotion (i.e., in absence of reflexes) and normal forward level walking, indicating that afferent input helps shaping the activity profile of this muscle during locomotor activity (Markin et al., 2012).

CONCLUSIONS

It is clear that the synergy approach is very fruitful and that it can improve our understanding of human gait and its models, including new asymmetrical models of the CPG. Furthermore, it can be helpful in providing the basis of new neuro-computational approaches, as was shown here, as a proof of principle, for inverse dynamic calculation of muscle activations. Nevertheless, as concerns the popular notion of independent modules, a word of caution is in place since it is not fully appropriate to depict the modular organization as being a replacement of some of the older theories ("local sign"), such as those put forward by early physiologists (Creed and Sherrington, 1926).

Recent data from this laboratory on differential controls for the shoulder, elbow, and wrist exerted by the thalamo-cortical network during locomotion is presented, based on experiments involving chronically instrumented cats walking on a flat surface and along a horizontal ladder. The activity of the following three groups of neurons is characterized: (1) neurons of the motor cortex that project to the pyramidal tract (PTNs), (2) neurons of the ventrolateral thalamus (VL), many identified as projecting to the motor cortex (thalamo-cortical neurons, TCs), and (3) neurons of the reticular nucleus of thalamus (RE), which inhibit TCs. Neurons were grouped according to their receptive field into shoulder-, elbow-, and wrist/paw-related categories. During simple locomotion, shoulder-related PTNs were most active in the late stance and early swing, and on the ladder, often increased activity and stride-related modulation while reducing discharge duration. Elbow-related PTNs were most active during late swing/early stance and typically remained similar on the ladder. Wrist-related PTNs were most active during swing, and on the ladder often decreased activity and increased modulation while reducing discharge duration. In the VL, shoulder-related neurons were more active during the transition from swing-to-stance. Elbow-related cells tended to be more active during the transition from stance-to-swing and on the ladder often decreased their activity and increased modulation. Wrist-related neurons were more active throughout the stance phase. In the RE, shoulder-related cells had low discharge rates and depths of modulation and long periods of activity distributed evenly across the cycle. In sharp contrast, wrist/paw-related cells discharged synchronously during the end of stance and swing with short periods of high activity, high modulation, and frequent sleep-type bursting. We conclude that thalamo-cortical network processes information related to different segments of the forelimb differently and exerts distinct controls over the shoulder, elbow, and wrist during locomotion.

Keywords: cat, motor cortex, thalamus, PTN, ventro-lateral thalamus, reticular nucleus of thalamus, accuracy, walking

INTRODUCTION

Locomotion is one of the most essential and frequently used behaviors. The neural mechanisms that determine the timing and pattern of muscle activity and the coordination of limb movements during locomotion resides in the spinal cord (Shik and Orlovsky, 1976; Grillner and Zangger, 1979; Forssberg et al., 1980a,b). The spinal mechanisms can produce locomotor movements with different rhythms and intensities to adapt to different speeds, different inclines of the support surface, etc. The real environment, however, consists of irregular terrain full of obstacles. Navigating such environments requires land-living animals to control the transfer and placement of their feet accurately. The spinal mechanisms, however, lack information about objects in the outside world that are at a distance. The motor centers of the brain adapt locomotion to the peculiarities of the environment. The motor thalamo-cortical network plays a central role in this adaptation.

In this review we present our recent findings of differential activities of the shoulder, elbow, and wrist-related populations of neurons in the thalamo-cortical network during simple locomotion on flat surface and accurate target stepping along a complex terrain.

Results of a number of biomechanics studies suggest that different segments of the limb are controlled differently. Indeed, limb segments differ in mechanical characteristics, such as dimensions and weight, and differ in their role during movements. Whereas displacements of proximal segments greatly affect the kinematics and kinetics of more distal segments, the influence of a distal segment movement on the mechanical characteristics of proximal segments is much smaller. When Galloway and Koshland (2002) studied point-to-point whole arm movements in humans, they found that movement dynamics differed greatly between the joints. A number of other studies have reported similar data (reviewed in Dounskaia, 2005, 2010). For locomotion, it was shown that the hip angle is an important factor in determining the initiation of the stance-swing phase transition, while angles of distal joints have no effect (Grillner and Rossignol, 1978). In a recent study we found that when stepping has to be accurate

during walking along a horizontal ladder, movements in different joints adapt differently to the accuracy demands (Beloozerova et al., 2010). Based on biomechanical evidence, a "leading joint hypothesis" has been advanced proposing that the joints of a limb play roles in movement production according to their mechanical subordination in the joint linkage (Dounskaia, 2005).

Several lines of evidence suggest that the neuronal mechanisms underlying the differences in controls for different forelimb segments are also different. For example, it is well-known that lesions to the pyramidal tract in primates evoke devastating effects on the fine movements of the fingers and wrist, while the disturbances to movements in the proximal joints are much less severe (e.g., Lawrence and Kuypers, 1968). For a reach and prehension task, it was shown that postspike effects of motor cortex pyramidal tract projecting neurons (PTNs) are both more numerous and more prominent on distal muscles as compared to proximal ones (McKiernan et al., 1998). Furthermore, in a study of postnatal development of the forelimb representation in the motor cortex in the cat, Chakrabarty and Martin (2000) have found that the motor map develops in a proximal-to-distal sequence, with shoulder and elbow controls developing earlier than wrist and digit controls. Developmental differences in the controls for different forelimb joints have been reported in humans as well (e.g., Konczak and Dichgans, 1997). Differences were reported also at the single neuron level. While it has been found that nearly all neurons in the shoulder/elbow area of the motor cortex modulate their activity during reaching in accordance with the posture of the arm (Scott and Kalaska, 1997), the activity of only a fraction of neurons in the hand area is wrist posture-related (Kakei et al., 2003). However, the neuronal mechanisms underlying differences in controls for different limb segments have never been explicitly studied until recently. Here we present our data on the differential controls for the shoulder, elbow, and wrist that are used by populations of neurons in the thalamo-cortical network.

All our experiments were conducted in chronically instrumented cats walking on a flat surface and along a horizontal ladder (**Figure 1**). Neurons in the motor cortex (MC), all of which were identified as PTNs; neurons in the motor thalamus, most of which were identified as thalamo-cortical projection neurons (TCs) of the ventrolateral nucleus of the thalamus (VL); and inhibitory interneurons of the motor compartment of the reticular nucleus of the thalamus (RE) were recorded (**Figure 3**). Neurons recorded within each of the MC, VL, and RE were grouped according to the location of their receptive field into shoulder-, elbow, and wrist/paw-related subpopulations. The discharges of these subpopulations within each of the motor centers were compared across the step cycle of simple and ladder locomotion and between the centers. Significant differences were found both between the neuronal groups within each of the motor centers as well as between the centers.

Original data on biomechanics of ladder locomotion were published in Beloozerova et al. (2010); on the activity of the MC – in Stout and Beloozerova (2012); on the activity of the VL – in Marlinski et al. (2012a); and on the activity of the RE – in Marlinski et al. (2012b). Data on biomechanics and the activity of the MC, VL, and RE were all obtained in identical experiments although

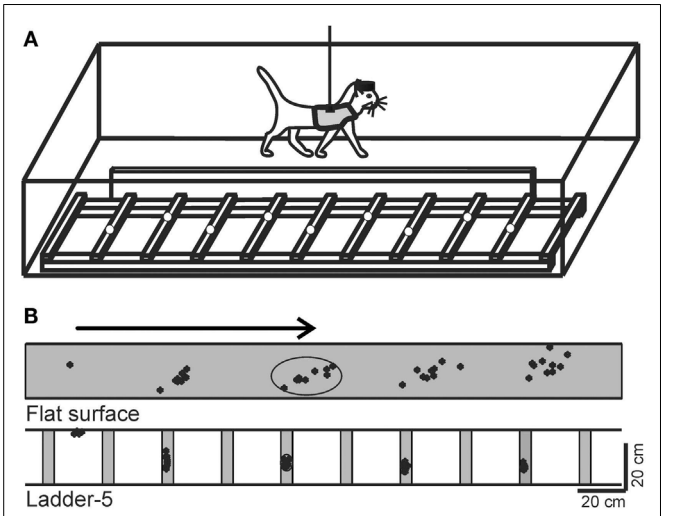

FIGURE 1 | Locomotion tasks. **(A)** Cats walked in an experimental box that was divided into two corridors. In one of the corridors, the floor was flat, while the other corridor contained a horizontal ladder. White circles on the crosspieces of the ladder schematically show placements of cat forelimb paws. This schematic drawing is not to scale. **(B)** A typical distribution of right forelimb paw prints recorded from one cat during 10 walking passages though each corridor: on a flat surface (simple locomotion) and along the ladder with crosspieces 5 cm wide (complex locomotion). View from above. The direction of the cat's progression is shown by the arrow on the top. For simple locomotion, paw prints are adjusted to start in the same position. During the ladder task, the first paw placement during ladder locomotion was between the crosspieces. Ellipses enclose approximate areas in which 95% of paw prints were found. (Adapted with modifications from Beloozerova et al., 2010).

conducted on different sets of cats. Methods of data collection and spike trains analysis have been described earlier (Beloozerova and Sirota, 1993a; Prilutsky et al., 2005; Beloozerova et al., 2010; Marlinski et al., 2012a,b; Stout and Beloozerova, 2012) and will be briefly outlined below when necessary. All experiments were conducted in accordance with NIH guidelines and with the approval of the Barrow Neurological Institute Animal Care and Use Committee.

LOCOMOTION TASKS

Two locomotion tasks were used: (1) simple locomotion on a flat surface, and (2) accurate stepping on the crosspieces of a horizontal ladder (**Figure 1A**). A box 2.5 m long and 0.6 m wide served as an experimental chamber. It had two corridors. In one of the corridors, the floor was flat, while the other corridor contained a horizontal ladder. The crosspieces of the horizontal ladder were flat and 5 cm wide, so that cats had full paw support on the crosspieces. Crosspieces were spaced 25 cm apart, that is, at half of the mean stride length observed in the chamber during locomotion on flat floor (Beloozerova and Sirota, 1993a; Beloozerova et al., 2010). Cats were continuously walking around the chamber, sequentially passing through both corridors, briefly stopping after each round in one of the corners for a food reward.

In our studies we have used a comparison between "non-accurate" locomotion on the flat surface and "accurate" stepping

on crosspieces of a horizontal ladder as a tool to reveal the portion of neuronal activity that represents control signals for accurate foot placement during locomotion. It has been demonstrated in several studies that simple locomotion does not require vision and can be successfully performed after the MC has been ablated or inactivated, while locomotion that requires accurate foot placement on complex surfaces, including on a horizontal ladder, depends on vision (Sherk and Fowler, 2001; Beloozerova and Sirota, 2003; Marigold and Patla, 2008), and on the activity of the MC and VL (Trendelenburg, 1911; Liddell and Phillips, 1944; Chambers and Liu, 1957; Beloozerova and Sirota, 1993a, 1998; Metz and Whishaw, 2002; Friel et al., 2007).

Our detailed examination of biomechanics (229 full-body biomechanical variables were tested) have shown only limited differences between the tasks, apart from paw placement. The variability of paw placement is dramatically smaller during ladder locomotion where, in the direction of progression, it is 5 mm, than during simple unconstrained walking, where it is 70 mm (**Figure 1B**; Beloozerova et al., 2010). In addition, on the ladder, angles at the distal metacarpophalangeal and metatarsophalangeal joints are slightly different, the wrist is more plantarflexed during swing and its plantar flexion moment during most of stance is lower than during simple locomotion (**Figure 2**). In contrast to distal joints, there is no significant difference in the values of the proximal joint angles or moments between simple and ladder locomotion (**Figure 2**). On the ladder cats tilt their neck and head more toward the ground, and the vertical position of the general center of mass and the centers of mass of the neck/head and trunk segments are lower by ∼1–2 cm during ladder as compared to simple locomotion. Out of 229 variables tested, however, there is little else different between simple and ladder locomotion. In particular, the horizontal and vertical displacements of limb segments do not differ significantly between the tasks during most of the step cycle, and the time histories of paw horizontal velocity are symmetric and smooth; there is no statistical difference in the paw velocities between simple and ladder locomotion.

THE THALAMO-CORTICAL NETWORK FOR LOCOMOTION

In this review we will summarize the activities of the three chief elements of the thalamo-cortical network for locomotion (**Figure 3**). We will first compare and contrast the activities of shoulder-, elbow, and wrist/paw-related neurons of the motor cortex (MC, red plate). All of these neurons were identified as PTNs (red arrow). We will then describe the activity of shoulder-, elbow, and wrist/paw-related neurons of the ventrolateral nucleus of thalamus, a part of the "motor thalamus" (VL, blue circle). The VL receives its major input from the interposed and lateral nuclei of cerebellum (purple arrow), and also receives input from the spinal cord (green arrow). The VL forms the main subcortical input to the MC. Most neurons whose activities are summarized here were identified as thalamo-cortical projection neurons (TCs, blue arrow). TCs synapse on both PTN and interneurons of the MC (Jones, 2007). Finally, we will consider shoulder-, elbow, and wrist/paw-related neurons of the motor compartment of the reticular nucleus of thalamus (RE, gray plate). The RE is a collection of inhibitory neurons that receive inputs from TCs as well as the cortico-thalamic neurons (CT) of the motor cortical layer VI (orange arrow). The RE projects back to the VL, inhibiting it. The RE neurons whose activities are described here received inputs from both the MC and VL. We will not discuss the activity of the CTs of cortical layer VI because, in the MC, they lack somatosensory receptive fields (Sirota et al., 2005), and thus cannot be grouped into shoulder-, elbow, and wrist/paw-related categories.

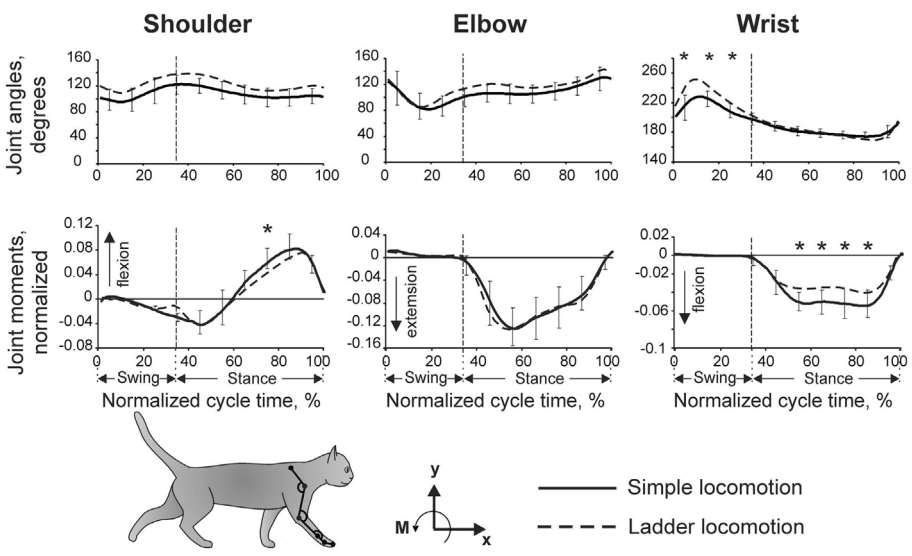

FIGURE 2 | Forelimb joint angles and moments during simple and ladder locomotion. Parameters were averaged across five cats. Vertical dashed lines separate the swing and stance phases of the stride. Standard deviations were similar across the two tasks and for clarity are shown only for simple locomotion. Symbol * indicates significant ($p < 0.05$, *post hoc t*-test) difference. The cat forelimb model is shown at the bottom. Orientation of each segment was determined as the angle between the negative direction of the vertical axis and the longitudinal segment axis directed from the distal end of the segment to the proximal one. (Adapted with modifications from Beloozerova et al., 2010).

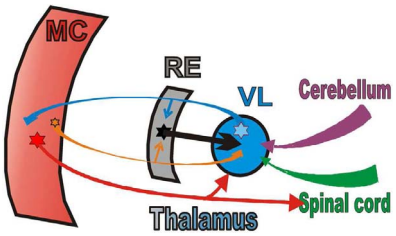

FIGURE 3 | The scheme of the thalamo-cortical network for locomotion. MC, motor cortex; RE, motor compartment of the reticular nucleus of thalamus; VL, ventrolateral nucleus of thalamus. Colored stars and arrows show neurons giving excitatory connections. Black star and arrow shows inhibitory neurons and connection.

In our studies, a "relation" of a neuron to control of the shoulder, elbow, or wrist/paw was inferred solely based on receptive field of the neuron. For PTNs, evidence exists that there is a substantial correspondence between a part of the limb, from which a PTN receives somatosensory information, and whose spinal networks it influences (Asanuma et al., 1968; Sakata and Miyamoto, 1968; Rosen and Asanuma, 1972; Murphy et al., 1975). In particular, it was shown that micro-stimulation in the forelimb region of the MC typically produces contraction in single muscles or in small groups of muscles in the area that composes the receptive field at the stimulation site (Asanuma et al., 1968; Sakata and Miyamoto, 1968; Rosen and Asanuma, 1972; Murphy et al., 1975; Armstrong and Drew, 1985a) and affects monosynaptic reflexes of only one or two muscles (Asanuma and Sakata, 1967). Even when series of pulses of 20 μA were used in locomoting subjects, micro-stimulation of a quarter of sites within forelimb motor cortex still affected only one or two muscles (Armstrong and Drew, 1985b). Experiments that used spike-triggered averaging of EMGs in primates showed that although many PTNs excite several motoneuron pools, including those related to muscles on two different segments of the limb or occasionally even across the entire forelimb, approximately half of PTNs influence motoneuron pools that only innervate muscles on one segment of the limb (Buys et al., 1986; McKiernan et al., 1998). For VL and RE neurons no analogous data exist primarily because they are quite remote from muscles. However, the grouping into shoulder-elbow, and wrist/paw-related categories was applied similarly through all elements of the thalamo-cortical network for locomotion. We acknowledge that, at present, it is unknown exactly how cells with different receptive fields in the VL, MC, and RE are connected with each other.

Somatosensory receptive field testing and classification was performed as follows. The receptive fields of neurons were examined in the animals sitting on a comfort pad with their head restrained. Stimulation was produced by palpation of muscle bellies, tendons, and by passive movements of joints. In this review, only neurons with the following somatosensory receptive fields are discussed. (1) The shoulder-related group included neurons responsive only to passive movements in the shoulder joint, and/or palpation of upper back, chest, or lower neck muscles. (2) The elbow-related group included neurons responsive only to passive movements in the elbow joint and/or palpation of upper arm muscles. (3) The wrist-related group included neurons responsive only to passive movements in the wrist joint, and/or palpation of distal arm muscles, and/or to stimulation of the palm or back of the paw. Neurons responsive to movements of toes or claws, those that had receptive field spanning more than one forelimb segment, and neurons without receptive fields were not included.

CHARACTERISTICS OF NEURONS INCLUDED IN THIS REVIEW

PTNs OF THE MC

The activity of 115 PTNs was recorded in eight cats. The vast majority of neurons were sampled from the region of the MC rostral to the cruciate sulcus. In **Figure 4A**, circles overlaying the cortex schematically show microelectrode entry points into the cortex for tracks in which PTNs with different receptive fields were recorded during locomotion. Receptive fields of all these PTNs were located on the contralateral forelimb and were excitatory. Forty-five PTNs were shoulder-related, 30 were elbow-related, and 40 PTNs were wrist-related. There was extensive spatial overlap between PTN groups.

In their somatosensory responses, most PTNs had some directional preference. Among shoulder-related PTNs, 33% were preferentially responsive to flexion, while 20% were preferentially responsive to extension. The other 43% were responsive to abduction or adduction of the joint, or to palpation of the muscles on the back or chest. Among elbow-receptive PTNs, 37% were preferentially receptive to flexion, and 60% were preferentially receptive to extension. Finally, among wrist-receptive PTNs, 42.5% were receptive to plantar (ventral) flexion of the wrist, while 32.5% were receptive to its dorsal flexion. The remaining 25% of the wrist-related PTNs were receptive to palpation of muscles on the forearm or paw.

To determine whether a MC neuron was projecting through the pyramidal tract, the test for collision of spikes was applied (Bishop et al., 1962; Fuller and Schlag, 1976). It is illustrated in **Figures 4B,C**. The latencies of antidromic responses of different PTNs to pyramidal tract stimulation varied in the range of 0.4–5.0 ms. Estimated conduction velocities were between 5 and 80 m/s. In shoulder-, elbow-, wrist-related, and non-responsive PTN groups, the proportions of fast and slow conducting neurons were similar.

VL NEURONS, INCLUDING TCs

The activity of 97 VL neurons, including 53 TCs, was recorded in three cats. Neurons were sampled starting at the most rostral aspect of the VL that borders the ventral anterior nucleus of the thalamus (VA) at the level of the caudal putamen (**Figures 5A,B**) and were found caudally up to the level of the rostral aspect of the lateral geniculate body (**Figure 5C**). In two of cats, retrograde tracers were injected in the area of recoding to determine afferent connections of the areas (WGA-HRP in cat 1, or red fluorescent beads in cat 2). In both cats, numerous labeled neurons were found in the lateral and interposed cerebellar nuclei on the contralateral side, and in cat 1, where recording included the VL-VA border zone, labeled neurons were also found in the lateral half of the ipsilateral entopeduncular nucleus. The receptive fields of all recorded VL neurons were on the contralateral forelimb and were excitatory.

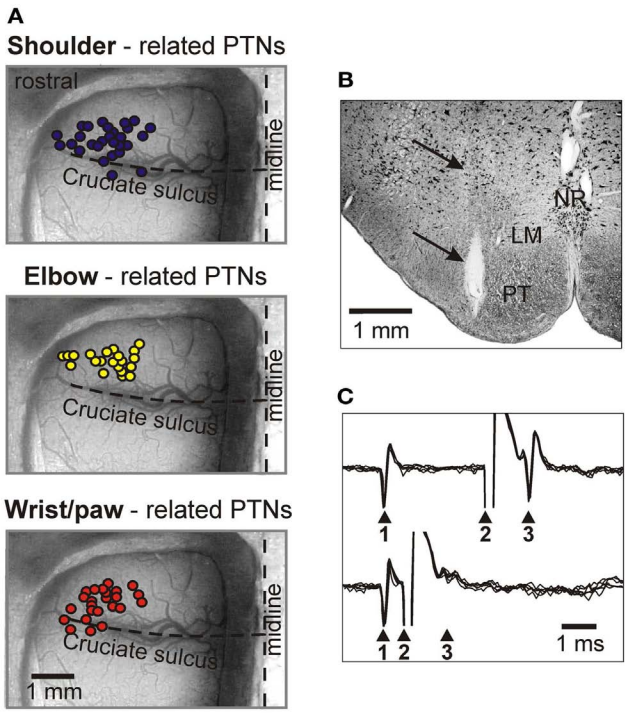

FIGURE 4 | Location of MC neurons and identification of PTNs. **(A)** Area of recording in the forelimb representation of the left motor cortex. Microelectrode entry points into the cortex are combined from eight cats and shown by circles on the photograph of the cortex of one cat. Tracks where PTNs with shoulder-related, elbow-related, and wrist-related receptive fields were recorded are shown by purple, yellow, and red circles, respectively. **(B)** Reference electrolytic lesion in the left pyramidal tract. Gliosis surrounding the electrode track and the reference lesion mark are indicated by arrows. Abbreviations: LM, lemniscus medialis; NR, nucleus raphes; PT, pyramidal tract. Frontal 50 μm thick section, cresyl violet stain. **(C)** A collision test determines whether a PTN response was antidromic. Top trace, the PTN spontaneously discharges (arrowhead 1), and the pyramidal tract is stimulated 3 ms later (arrowhead 2). The PTN responds with latency of 1 ms (arrowhead 3). Bottom trace, the PTN spontaneously discharges (arrowhead 1) and the pyramidal tract is stimulated 0.7 ms later (arrowhead 2). PTN does not respond (arrowhead 3) because in 0.7 ms its spontaneous spike was still en route to the site of stimulation in the pyramidal tract, and thus collision/nullification of spontaneous and evoked spikes occurred. (Adapted with modifications from Stout and Beloozerova, 2012).

Fifty-one cells, including 34 TCs, responded to passive movements of the shoulder joint and/or palpation of muscles on the back or neck. Slightly more than half of these cells showed a directional preference to shoulder movement, and responded better either to flexion or to extension and/or abduction of the joint. Thirty neurons, including 17 TCs, responded to movements in the elbow joint. Almost all of these neurons had a directional preference: half of them responded to flexion and another half to extension of elbow. Sixteen cells, including two TCs, had receptive fields on the paw or wrist. Typically, these neurons responded to pressure on the paw or to the wrist ventral flexion. In **Figure 5D**, shapes of different colors show estimated locations of all recorded neurons. According to the most often used atlases of the cat diencephalon (Reinoso-Suarez, 1961; Snider and Niemer, 1961; Berman and Jones, 1982), our recordings included the entire rostro-caudal and most of the dorso-ventral extents of the VL. In addition, based on an assessment of receptive fields of the neurons we also concluded that we have covered most of the medio-lateral extent of the forelimb representation in the VL. Neurons that responded to stimulation of different parts of the forelimb were distributed randomly in the VL: there were no clear clusters of shoulder-, elbow-, or wrist paw-related cells.

To determine whether a neuron was projecting to the MC, stimulating electrodes were placed in the layer VI of area 4γ of the distal forelimb representation (paw, MCd) and in the proximal forelimb representation (elbow, shoulder; MCp; **Figure 5E**), and the test for collision of spikes was applied (**Figure 5F**; Bishop et al., 1962; Fuller and Schlag, 1976). Thalamo-cortical projection cells (TCs) were distributed fairly evenly throughout the area of recording (**Figure 5D**). Most TC neurons responded either to stimulation of MCd or MCp, and only few responded to stimulation of both sites. Interestingly, the vast majority (72%) of neurons projecting to MCd had receptive fields on proximal parts of the forelimb, shoulder, or elbow, and only 9% had receptive fields on the wrist or paw. Neurons projecting to MCp had various receptive fields. Latencies of antidromic responses of different TCs varied in the range of 0.5–5.5 ms. Estimated conduction velocities ranged from 5 to 70 m/s.

RE NEURONS

Forty-six RE neurons with receptive fields on the contralateral forelimb were recorded from two cats. In **Figure 6** the recording sites, combined from both cats, are shown on frontal sections of the thalamus. Cells were collected from the rostro-lateral compartment of the RE at approximate coordinates A 11.75–12.5, L 5.5–7.0, and V 1.0–4.0. The RE was identified by neurons' characteristic bursts of spikes during sleep (**Figures 6E–H**). Within these bursts the discharge frequency first ramps up and then winds down (**Figure 6H**). The motor compartment of the RE was identified by orthodromic responses of the neurons to electrical stimulation of the MC and VL. The overwhelming majority of cells responded vigorously to both stimulations (**Figure 8I**). A single shock applied to the cortex or VL evoked a sequence of several spikes with interspike intervals of 2–6 ms. Latencies to the first spike were in a range of 1–8 ms, similar for both the cortex and VL. This short latency response was followed by a 120–150 ms period of silence, after which another barrage of high frequency discharge occurred.

In one of the cats, red fluorescent beads were injected into the rostro-lateral part of the explored RE area to reveal the areas of thalamus and cortex that projected to these neurons. In **Figure 6A**, an arrow points to the site of injection, and **Figures 6L–O** show locations of neurons retrogradely labeled in the VL. Labeled neurons extended rostro-caudally from A11 to A9, medio-laterally from 3.5 to 5.5, and vertically from 0.5 to 3.0; in addition, labeled neurons were found in a part of the somatosensory ventral posterolateral nucleus (VPL) adjacent to the VL.

Receptive fields of all RE neurons were excitatory. Nineteen cells (41%) were activated by passive movements of the shoulder and/or palpation of muscles on the upper back. Nearly all of these cells had directional preference to shoulder movement,

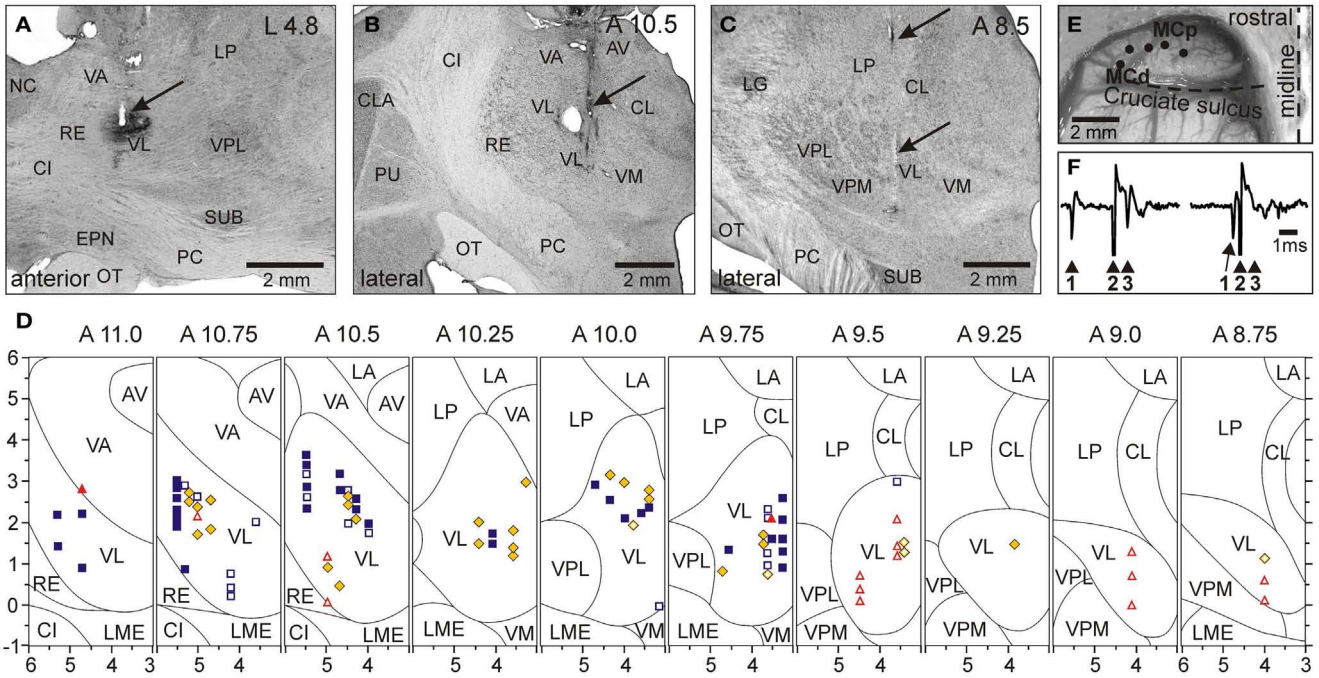

FIGURE 5 | Location of VL neurons and identification of TCs. **(A)** The recording site in cat A is shown on a photomicrograph of a parasagittal section of the thalamus. It was located in the rostral VL. The arrow points to the electrolytic lesion mark and the darkened area of tissue filled with WGA-HRP. The site is ∼2 mm caudally to the Nucleus caudatus (NC) of the basal ganglia. **(B)** The recording site in cat B is shown on a photomicrograph of a coronal section of the thalamus. It was positioned in the middle of the VL. The arrow points to the electrolytic lesion mark and darkened area where fluorescent beads were deposited. The caudal part of putamen (PU), a landmark for the anterior-posterior position of the section, is seen laterally. **(C)** The recording site in cat C is shown on a photomicrograph of a coronal section of the thalamus. It was positioned in the caudal VL. The arrows point to a track from a reference electrode. The most rostral aspect of the lateral geniculate body (LG), a landmark for the anterior-posterior position of the section, is visible laterally. **(A–C)** 50 μm thick sections, cresyl violet stain. **(D)** A photograph of the dorsal surface of the left frontal cortex of cat B. Entrance points of stimulation electrodes into the precruciate sulcus are schematically shown by black dots. Electrodes were placed in the paw (the motor cortex distal forelimb representation, MCd), the elbow and shoulder representations (the motor cortex proximal forelimb representation, MCp) as determined by multiunit recording and micro-stimulation procedures. Cru, cruciate sulcus; Pcd, post-cruciate dimple; mAns, medial ansate sulcus. **(E)** A collision test determined whether a neuron response was antidromic. Stimulation of the MC evoked a spike in the neuron with a latency of 0.8 ms. To determine whether this spike was elicited antidromically, on a next trial a spontaneous spike of the neuron was used to trigger MC stimulation with 0.4 ms delay. Stimulation delivered with a delay smaller than the time needed for a spontaneous spike to reach the site of stimulation (that is approximately equal to the latent time of an antidromic spike) was not followed by a response. This indicated a collision of ortho- and antidromically conducted spikes and confirmed the antidromic nature of the evoked spike. **(F)** A reconstruction of positions of individual neurons recorded during locomotion in cats A, B, and C. ■, Purple squares show neurons with somatosensory receptive fields on the shoulder: responding to passive movements in the shoulder joint and/or palpation of muscles on the back or neck; ♦, Yellow diamonds show cells that were activated by movements in the elbow; ▲, Red triangles represent neurons with receptive fields on the wrist or paw. Filled symbols represent neurons with axonal projections to the MC (thalamo-cortical neurons, TCs); open symbols represent neurons whose projections were not identified. Abbreviations: AV, nucleus anterio-ventralis thalami; CI, capsula interna; CL, nucleus centralis lateralis; CLA, claustrum; EPN, nucleus entopeduncularis; LA, nucleus lateralis anterior; LG, lateral geniculate nucleus; LME, lamina medullaris externa thalami; LP, nucleus lateralis posterior; NC, nucleus caudatus; OT, optic tract; PC, pedunculus cerebri; PU, putamen; RE, nucleus reticularis thalami; SUB, nucleus subthalamicus; VA, nucleus ventralis anterior; VL, nucleus ventralis lateralis; VM, nucleus medialis; VPL, nucleus ventralis postero-lateralis; VPM, nucleus ventralis postero-medialis (Adapted with modifications from Marlinski et al., 2012a).

and either responded better to flexion or adduction (13/19) or to extension or abduction of the joint (6/19). Eighteen neurons (39%) had receptive fields on the paw or wrist or responded to passive movements of the wrist, typically in only one direction. The number of neurons responding to passive movements of the elbow was relatively small (20%, 9/46); and all responses were to extension rather than flexion. In **Figures 6A–D** cells with different receptive fields are depicted with different shapes. There was coarse dorso-ventral topography: cells with receptive fields involving the shoulder were located dorsal to neurons whose receptive fields involved the wrist/paw.

EXAMPLES OF LOCOMOTION-RELATED ACTIVITY OF NEURONS ACROSS THE THREE MAIN ELEMENTS OF THE THALAMO-CORTICAL NETWORK FOR LOCOMOTION

Analysis of spike trains was performed as follows. The onset of swing phase was taken as the beginning of step cycle. The duration of each step cycle was divided into 20 equal bins, and a phase histogram of spike activity of the neuron in the cycle was generated. The coefficient of stride-related frequency modulation, the "depth" of modulation, dM, that characterizes fluctuation in probability of the spike occurrence, was calculated as $dM = (N\max - N\min)/N \times 100\%$, where $N\max$ and $N\min$ are

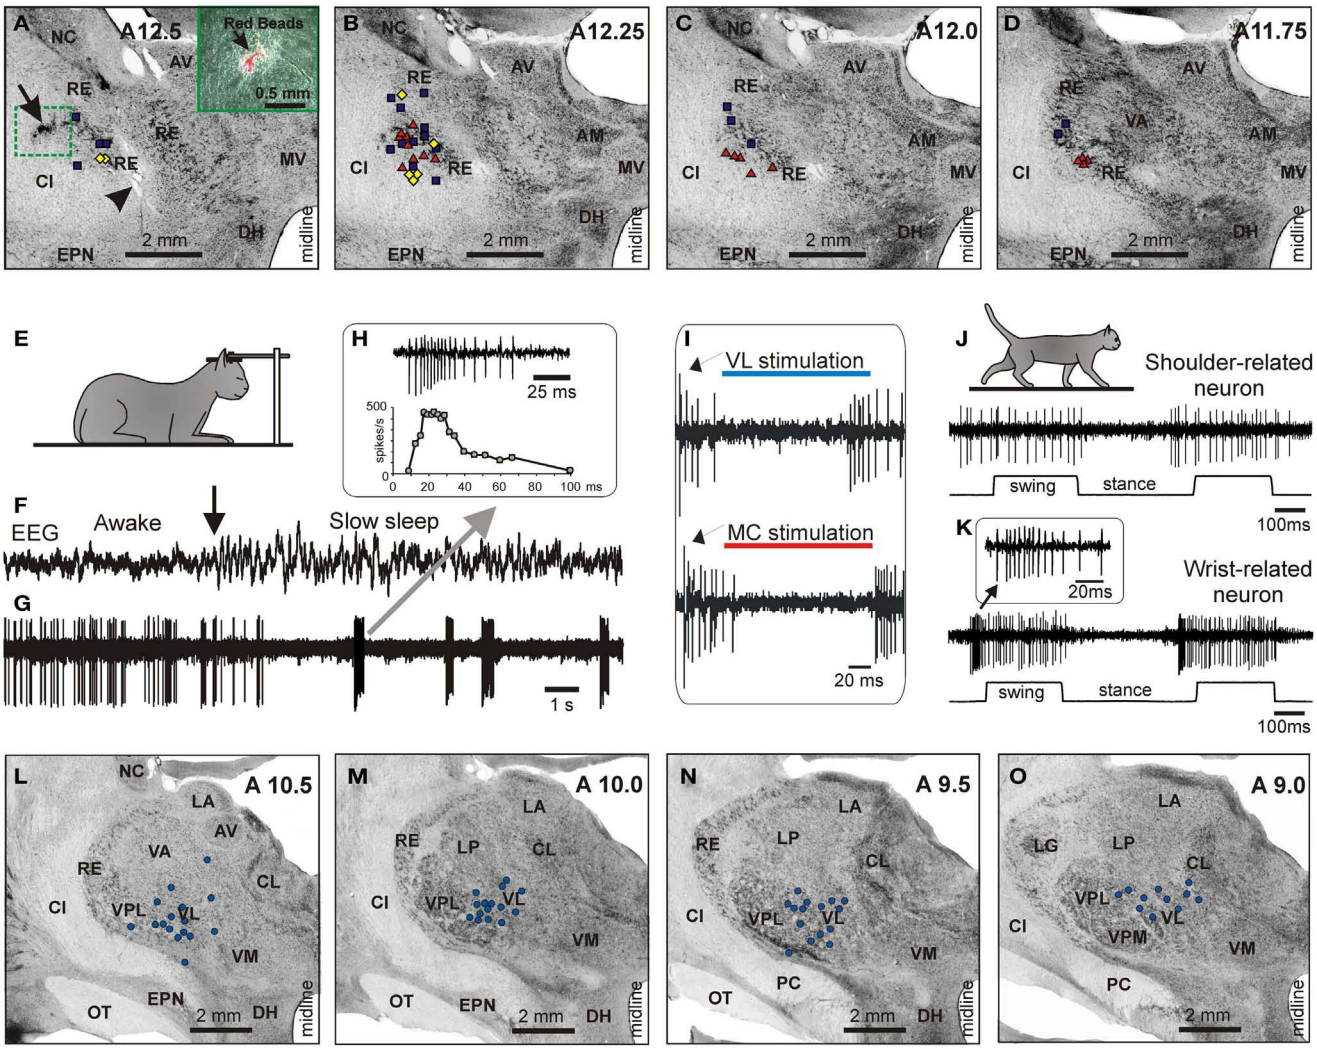

FIGURE 6 | Location and identification of RE neurons. **(A–D)** Location of RE neurons recorded during locomotion. Estimated locations of neurons are combined from two cats and are shown by various symbols on frontal sections of thalamus of one of them: ■, Purple squares show neurons with somatosensory receptive fields on the shoulder: responding to passive movements in the shoulder joint and/or palpation of muscles on the back or neck; ♦, Yellow diamonds show cells that were activated by movements in the elbow; ▲, Red triangles represent neurons with receptive fields on the wrist or paw. In **(A)**, an arrowhead is pointing to a reference electrolytic lesion and an arrow indicates the site of injection of red fluorescent beads. **(A)** close-up to the injection site is shown in the insert. Abbreviations: AM, nucleus anterio-medialis; AV, nucleus anterio-ventralis thalami; CI, capsula interna; DH, dorsal hypothalamus; EPN, nucleus entopeduncularis; MV, nucleus medio-ventralis; NC, nucleus caudatus; RE, nucleus reticularis thalami; VA, nucleus ventralis anterior. Frontal 50 μm thick sections, cresyl violet stain. **(E–H)** Identification of RE neurons by characteristic profile of their bursts during sleep. **(E)** Cat sleeping with its head restrained. **(F,G)** An example of activity of a RE neuron while cat is awake and asleep. At the beginning of the record desynchronized activity in EEG indicates that the cat was awake, and the neuron was discharging fairly regularly. The arrow points to the beginning of "spindle waves" in EEG, which are a sign of beginning of slow wave sleep. Shortly thereafter very high frequency irregular bursts separated by long periods of inactivity replaced the regular discharge of the neuron. **(H)** Close-up on a burst. The first interspike interval in this burst was longer than the second one, and the second interval was longer that the third. Several following interspike intervals were of an approximately similar duration, while the last ones were progressively longer. The lower trace shows change of discharge frequency within the burst. Such a burst with ramping up and then winding down firing rate identifies this neuron as belonging to the RE. **(I)** Identification of the motor compartment of the RE by responses of neurons to electrical stimulation of the VL (upper trace) and MC (lower trace). In response to either stimulation the cell generates a short latency burst followed by a period of silence and then by another burst. **(J)** Locomotion-related activity of a representative neuron with shoulder-related receptive field. The activity of this neuron is modulated to strides but does not contain any "sleep-type" busts. **(K)** Accelerating-decelerating frequency "sleep-type" bursting during locomotion in a wrist/paw-related neuron. A burst is shown in the insert at a fast time scale. Such bursts often appeared at the beginning of the locomotion-related activation of this neuron. **(L–O)** Thalamic projections to the area of recording in the RE. Neurons in the VL and VL/VPL border zone in one of the cats where red fluorescent beads were injected in the rostro-lateral part of the explored RE area, retrogradely labeled with red fluorescent beads. Neurons are shown on photomicrographs of frontal sections of the left thalamus ipsilateral to the injection site. Each circle represents one labeled neuron. Abbreviations: CL, nucleus centralis lateralis; LA, nucleus lateralis anterior; LG, lateral geniculate nucleus; LP, nucleus lateralis posterior; OT, optic tract; PC, pedunculus cerebri; VL, nucleus ventralis lateralis; VM, nucleus medialis; VPL, nucleus ventralis postero-lateralis; VPM, nucleus ventralis postero-medialis; other abbreviations are as in **Figure 5** (Adapted with modifications from Marlinski et al., 2012b).

the number of spikes in the maximal and the minimal histogram bin, and N is the total number of spikes in the histogram. Neurons with dM > 4% were judged to be stride-related based on an analysis of fluctuation in the activity of neurons in the resting animal (Marlinski et al., 2012a). In stride-related neurons, the portion of the cycle in which the activity level exceeded 25% of the difference between the maximal and minimal frequencies in the histogram was defined as a "period of elevated firing," or PEF. In neurons with a single PEF, the "preferred phase" of discharge was calculated using circular statistics (Batshelet, 1981; Drew and Doucet, 1991; Fischer, 1993; see also Beloozerova et al., 2003a; Sirota et al., 2005).

An example activity of a PTN during simple and ladder locomotion is shown in **Figures 7A–E**. At rest, this PTN was activated by passive adduction of the shoulder. The PTN was rather steadily active during standing. When locomotion began, its activity reduced overall but became modulated with respect to the stride: it was greater during stance phase of the stride and smaller during swing. Rasters in **Figures 7B,D** show that the activity of the PTN was very consistent across strides. The activity is summed in **Figures 7C,E** showing histograms of PTN firing rate across the step cycle during simple (**Figure 7C**) and ladder (**Figure 7E**) locomotion. The PEF is indicated by a black horizontal bar, and the preferred phase is shown by an open circle. Note that during ladder locomotion, the discharge of the neuron during the stance phase was much higher as compared to that during simple locomotion while remaining low during swing phase. Thus, the magnitude of frequency modulation, dM, was larger during ladder locomotion. In addition, the duration of the period of elevated firing, PEF, was shorter by 20% of the cycle.

An example activity of a TC neuron is shown in **Figures 7F–J**. At rest, this neuron was activated by palpation of muscles around the shoulder. During simple locomotion the neuron discharged throughout all phases of the stride, except for the middle of stance when it was practically silent (**Figures 7F–H**). This pattern of activity was very consistent across many strides (**Figure 7G**). The discharge within the PEF varied in intensity, however, forming three small sub-peaks; the maximum discharge rate was 80 spikes/s. During ladder locomotion, rather than discharging throughout most of the stride cycle, the neuron was active almost exclusively around the swing-stance transition (**Figures 7F,I,J**), but peaked near the same preferred phase as during simple locomotion. Its firing rate reached 118 spikes/s, significantly higher than during simple locomotion ($p < 0.05$, t-test), whereas the activity in the trough during stance remained low. Consequently, the magnitude of modulation was larger during ladder than simple locomotion. The duration of the PEF shortened by one half.

An example activity of a RE neuron is shown in **Figures 7K–O**. At rest, this neuron responded to passive flexion and extension of the shoulder. During locomotion, it was highly active during the end of swing and beginning of stance, and less active at the end of stance phase and beginning of swing. This pattern of activity was consistent across many strides (**Figure 7L**). The maximum discharge rate of the neuron was 102 spikes/s (**Figure 7M**). During ladder locomotion, discharge of the neuron during the first half of swing decreased, increasing during the second half of swing to 123 spikes/s. As a result, similarly to both PTN and VL neurons, the magnitude of modulation of the RE neuron's discharge was larger during ladder than simple locomotion and the PEF was shorter.

We want to note that for none of the MC, VL, or RE, is there a single "typical" neuron with respect to the activity during locomotion. Instead, each of the motor centers contains a variety of neurons that differ in the phases of their discharges during the stride, in the number of PEFs they produce per cycle, in the manner by which they respond to the accuracy demand imposed by the ladder, and other parameters. We did our best to describe these different cell types in our original research reports (Marlinski et al., 2012a,b; Stout and Beloozerova, 2012). In **Figure 7** we show neurons with shoulder-related receptive fields that belong to the most populous group of cells: those that discharge a single PEF per cycle and respond to accuracy demand on stepping by increasing the magnitude of their stride-related modulation and by shortening the PEF.

For populations of shoulder-, elbow-, and wrist/paw-related neurons, we will first overview their activities during simple unconstrained locomotion and then consider their discharges during accurate stepping along the horizontal ladder.

SIMPLE LOCOMOTION: SETTING DISTINCT FRAMES FOR THE SHOULDER, ELBOW, AND WRIST/PAW CONTROLS

PTN ACTIVITY

During simple locomotion, shoulder- and wrist-related PTNs were more active than elbow-related PTNs (18.9 ± 1.3 vs. 13.8 ± 1.7 spikes/s; t-test, $p < 0.05$). In 97% of all cells the discharge rate was modulated with respect to the stride: it was greater in one phase of the stride and smaller in another phase. Most PTNs (79%) had one PEF per stride, while 21% had two PEFs. The proportion of two-PEF cells was similar between groups of PTNs with different somatosensory receptive fields, and one- and two-PEF neurons will be considered jointly in this review. The depth of modulation was similar between PTN groups (10.2 ± 0.4%) as was the duration of the PEF (55–60% of the cycle). PEFs of individual PTNs of all groups were distributed across the step cycle. However, this distribution was different between groups (**Figure 8**, two left columns). Shoulder-related PTNs were more often active during the late stance and early swing (**Figures 8A1**,**3**), and their discharge rate was highest during the stance-to-swing transition, at 21.8 ± 2.0 spikes/s (here and below: mean ± SEM), while the firing rate during the opposite phase was 8.4 spikes/s lower ($p < 0.05$, t-test; **Figures 8A2**,**4**). Elbow-related PTNs were largely active in antiphrase with shoulder-related cells (**Figures 8B1**,**3**), discharging during the late swing and early stance at 17.4 ± 2.4 spikes/s, while giving only 10.6 ± 2.1 spikes/s during the opposite phase (**Figures 8B2**,**4**). In contrast to both of these groups, PEFs of wrist-related neurons were distributed fairly equally throughout the step cycle (**Figures 8C1**,**3**), and their population' average discharge rate only slightly fluctuated around 20 spikes/s (**Figures 8C2**,**4**).

VL NEURON ACTIVITY

During simple locomotion, the activity of shoulder-, elbow-, and wrist-related VL neurons was similar, and averaged at 23.8 ± 1.4 spikes/s, ∼5 spikes/s higher than the average activity of the most active PTN populations (t-test, $p = 0.01$). The activity of 85.5% of neurons, including 87% of TCs, was modulated in the

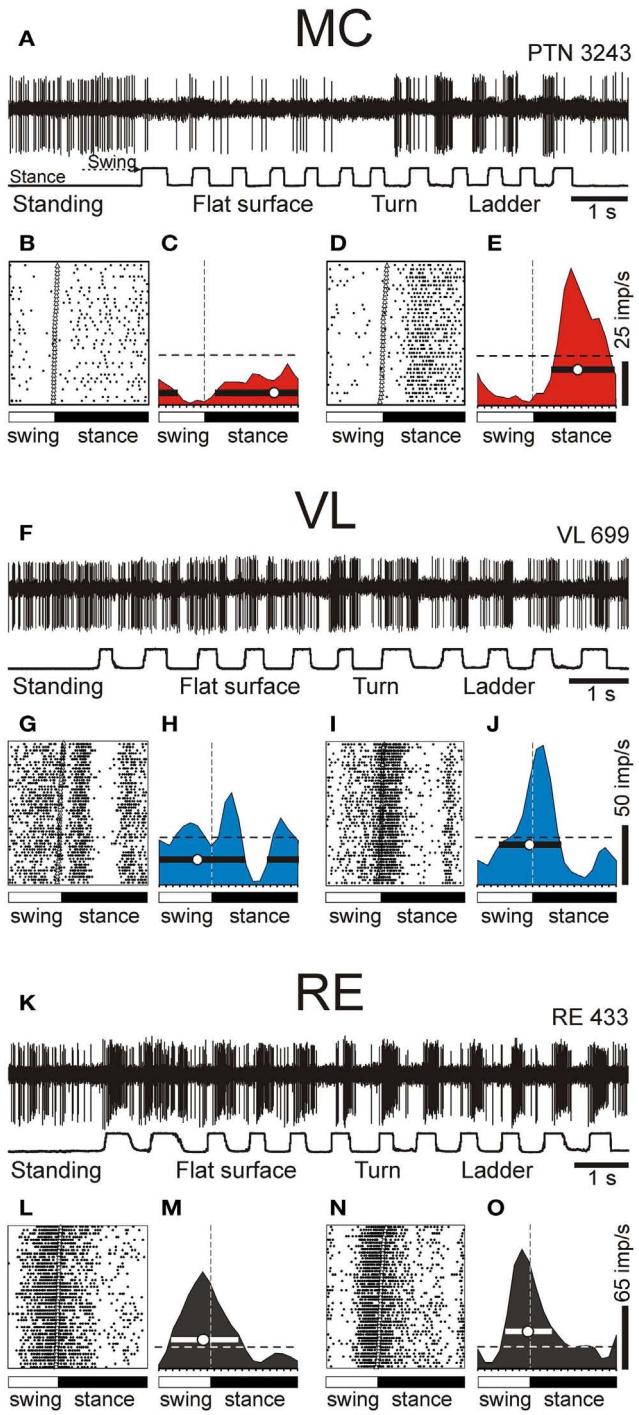

FIGURE 7 | Example activity of MC, VL, and RE cells during locomotion. **(A,F,K)** Activity of MC **(A)**, VL **(F)**, and RE **(K)** cells during standing, simple, and ladder locomotion. The bottom trace shows the stance and swing phases of the step cycle of the right forelimb that is contralateral to the recording site in the cortex and thalamus. **(B,C,G,H,L,M)** Activities of the same neurons during simple locomotion are presented as rasters of 37–47 step cycles **(B,G,L)** and as histograms **(C,H,M)**. In the rasters, the duration of step cycles is normalized to 100%, and the rasters are rank-ordered according to the duration of the swing phase. The beginning of the stance *(Continued)*

phase in each stride is indicated by an open triangle. In the histograms, the horizontal interrupted line shows the level of activity during standing. The horizontal black bar shows the period of elevated firing (PEF) and the circle indicates the preferred phase. **(D,E,I,J,N,O)** Activities of the same neurons during ladder locomotion are presented as rasters **(D,I,N)** and as histograms **(E,J,O)**. (Examples of the activity of MC, VL, and RE neurons are adapted with modifications from Beloozerova et al., 2010; Marlinski et al., 2012a,b, respectively).

rhythm of strides. Similarly to PTNs, two basic patterns of modulation were seen: one or two PEFs. The one PEF pattern was the most common one (67% of neurons, including 63% TCs). Two PEFs were observed in 31% of cells, including 35% TCs. The proportion of one- and two-PEF cells was similar between groups of VL neurons, and one- and two-PEF cells will be considered jointly below. In the shoulder-related group, the depth of modulation was higher at $9.3 \pm 0.6\%$ as compared to either elbow- or wrist/paw-related cells ($7.3 \pm 0.5\%$; $p = 0.02$, t-test), and the duration of the PEF was shorter ($58 \pm 3\%$ vs. $65 \pm 3\%$ of the cycle; $p = 0.04$, t-test). PEFs of individual cells of all groups were distributed across the step cycle. However, as with PTNs, this distribution was different between neuronal groups with different receptive fields (**Figure 8**, two middle columns).

PEFs of shoulder-related neurons were fairly evenly distributed across the step cycle (**Figures 8D1,3**); however, neurons with PEFs during end of swing/beginning of stance were more active than other cells (**Figure 8D2**), and the mean discharge rate of the shoulder-related population was higher during this period, at 27.7 ± 4.0 spikes/s, while the firing rate during mid-stance was 11.2 spikes/s less ($p = 0.04$, t-test; **Figure 8D4**). In contrast, cells of both elbow- and wrist/paw-related groups were most often active during the stance phase (**Figures 8E1,3**,F1,**3**). However, while elbow-related neurons attained their maximal population discharge rate at the end of the stance only and during the stance-to-swing transition (**Figure 8E4**), the mean discharge rate of the wrist/paw-related group was at its highest in the beginning of the stance phase (**Figure 8F4**). Strikingly, each of VL groups was active largely in anti-phase with their MC counterparts.

RE NEURON ACTIVITY

During simple locomotion, wrist-related RE neurons were more active then either shoulder- or elbow-related cells (31.4 ± 3.0 vs. 22.6 ± 3.1 spikes/s; $p < 0.05$, t-test). The discharge of 96% of all RE neurons was modulated with respect to the stride. Most neurons (74%) had one PEF per step cycle, and 26% had two. Between groups of cells with different somatosensory receptive fields, the proportions of neurons with one and two PEFs were similar. The activity of neurons with receptive fields on the wrist/paw were more modulated than that of either shoulder- or elbow-related groups (12.5 ± 1.1 vs. 8.0 ± 0.6 or $8.4 \pm 0.9\%$; $p < 0.01$, t-test), and their PEFs were shorter (54 vs. 66% of the step cycle; $p = 0.036$, t-test). As in the PTNs and VL neurons, there was a prominent difference between the phase positions of PEFs of RE cells with different receptive fields. PEFs of wrist/paw-related cells promptly terminated at the end of the swing phase and did not restart before the middle of the stance (**Figures 8I1,3**). In contrast, PEFs

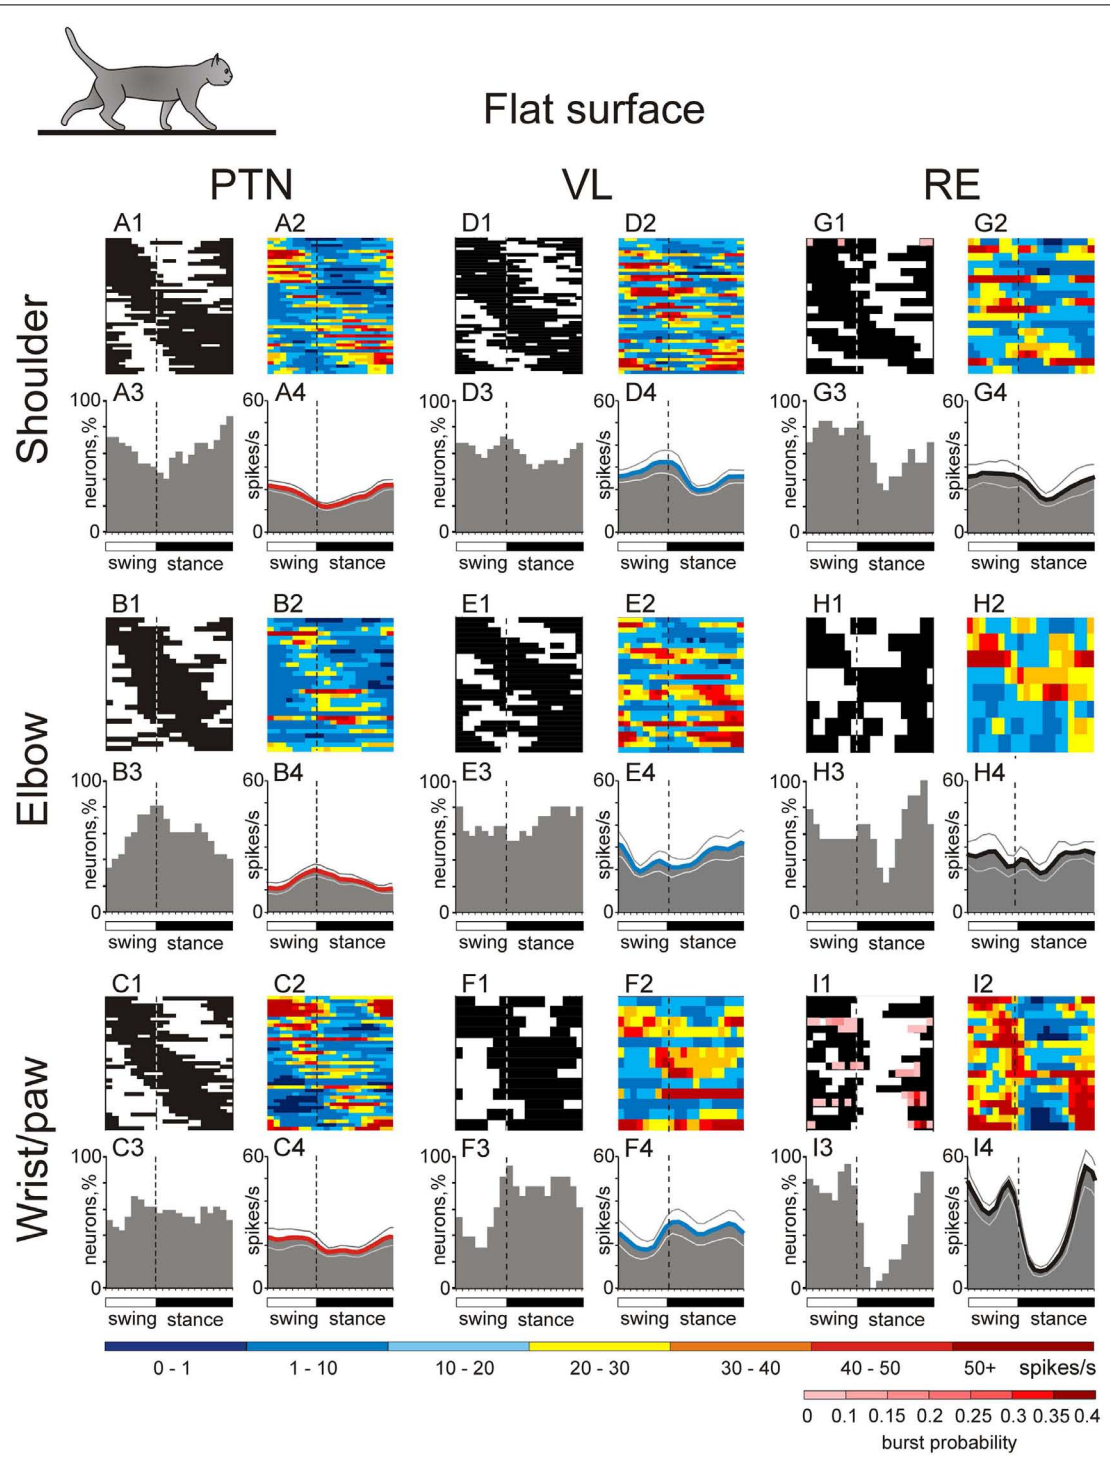

FIGURE 8 | Activities of the shoulder-, elbow-, and wrist/paw-related cells in the thalamo-cortical network during simple locomotion. **(A,D,G)** Activity of neurons responsive to movements in the shoulder joint, and/or palpation of back, chest, or neck muscles in the MC **(A)**, VL **(D)**, and RE **(G)**. **(A1,D1,G1)** Phase distribution of PEFs. **(A2,D2,G2)** Corresponding phase distribution of discharge frequencies. The average discharge frequency in each 1/20th portion of the cycle is color-coded according to the scale shown at the bottom. **(A3,D3,G3)** Proportion of active neurons (neurons in their PEFs) in different phases of the step cycle. **(A4,D4,G4)** The mean discharge rate. Thin lines show SEM. Vertical interrupted lines denote end of swing and beginning of stance phase. **(B,E,H)** Activity of neurons responsive to passive movement of the elbow joint in the MC **(B)**, VL **(E)**, and RE **(H)**. **(C,F,I)** Activity of neurons responsive to stimulation of the paw or movement in the wrist joint in the MC **(C)**, VL **(F)**, and RE **(I)**. (Data on the activity of PTNs, VL, and RE neurons are adapted with modifications from Stout and Beloozerova, 2012; Marlinski et al., 2012a,b, respectively).

of shoulder- and elbow-related neurons were distributed more evenly across the cycle (**Figures 8G1**,**3**,H1,**3**). Both the wrist/paw- and shoulder-related neurons attained their highest discharge rates during swing and lowest during stance, but the wrist/paw-related population was almost twice as active at the peak as compared to the shoulder-related one (42 and 24 spikes/s, respectively). Overall, RE elbow- and wrist/paw-related neurons were active more or less in anti-phase with their counterparts in the VL, while shoulder-related cells were mostly active in-phase.

In addition to differences in their discharge rates and phase preferences, wrist/paw-, and shoulder-related cells differed sharply in their inclination to produce sleep-type bursts of spikes during locomotion (**Figures 6J,K**). The activity of a shoulder-related neuron shown in **Figure 6J** was modulated with respect to the step cycle, but otherwise was rather regular. This firing behavior contrasted sharply with that of a wrist/paw-related neuron shown in **Figure 6K**. The activity of this neuron was also modulated in relation to the step cycle, however, after a period of silence during stance, it discharged dense bursts of spikes, in which the spike frequency first increased and then decreased. The insert in **Figure 6K** shows a burst at sufficient temporal resolution to illustrate that its structure during locomotion was similar to the signature RE-type bursts during sleep (**Figure 6H**). All but one shoulder-related cell had relatively regular firing behavior during locomotion, similar to that of the neuron shown in **Figure 6J**. In contrast, a significant portion of wrist/paw-related cells (39%, 7/18) discharged sleep-type bursts during walking, similar to those shown in **Figure 6K**.

GENESIS OF LOCOMOTION-RELATED ACTIVITY IN THE MC, VL, AND RE DURING SIMPLE LOCOMOTION

We have shown in all three key centers of the thalamo-cortical network for locomotion, MC, VL, and RE, that neurons responsive to stimulation of different forelimb joints are active differently during simple locomotion. While it might be tempting to suggest that these differences are due to differences in the neurons' somatosensory receptive field characteristics, at least for PTNs, somatosensory information seems not to play a leading role in determining their locomotion-related discharges. Indeed, PTNs with similar receptive fields often discharge during quite different phases of the locomotion cycle (Armstrong and Drew, 1984b). It has been shown that the locomotion-related responses of MC neurons are only slightly affected by changes in the vigor of movements during up- and downslope walking, weight bearing, or alterations in speed (Armstrong and Drew, 1984a; Beloozerova and Sirota, 1993b) – changes that most certainly cause significant changes to proprioceptive afferentation. With regard to cutaneous input, Armstrong and Drew (1984b) have demonstrated that in the MC, neurons with cutaneous receptive fields, including on the forefoot, still rhythmically discharge during locomotion with a similar phasing relative to the step cycle when their response to mechanical stimulation in the receptive field is temporarily reduced or abolished by local anesthesia of the skin. In our recent study we found that the great majority of PTNs with direction-specific receptive fields did not show any particular preference to discharge in-phase with stimulation of their receptive field during locomotion (Stout and Beloozerova, 2012). Similarly poor relationships between phasing of task-related discharges and directional specificity of PTN resting receptive fields were reported in previous studies from our and other laboratories (Armstrong and Drew, 1984b; Drew, 1993; Beloozerova et al., 2003b, 2005; Karayannidou et al., 2008).

For VL and RE neurons, the above experiments have not been conducted; however, one can argue that discharges of neurons in these thalamic nuclei during simple locomotion are likewise, at the very least, not entirely driven by stimulation of somatosensory receptive fields. In our studies we did not find any simple correlation between neuronal responses to somatosensory stimulation in the quiescent animal and preferred phases of VL neurons activity during locomotion (Marlinski et al., 2012a). In decerebrated cats, it was found that the cerebellum plays the pivotal role in driving locomotion-related discharges in the neurons of subcortical motor centers, including neurons of the red nucleus, vestibular nuclei, and the neurons of the reticular formation giving rise to the reticulo-spinal tract (Orlovsky, 1970, 1972a,b; reviewed in Arshavsky et al., 1986; Orlovsky et al., 1999). For these centers, the role of direct afferentation from the spinal cord for periodic modulation of activity during locomotion is minimal, because in the majority of their neurons, locomotion-related modulation disappears after removal of the cerebellum in the decerebrate preparation. It can be expected that the VL, as a subcortical motor nucleus receiving direct connections from the cerebellum, does not differ in this respect from the brainstem motor centers. It is important to stress that the locomotion-related output of the cerebellum during simple locomotion is almost exclusively formed on the basis of information that is obtained from the spinal locomotor CPG (rev. in Arshavsky et al., 1986 and Orlovsky et al., 1999). The VL receives this information. All deep cerebellar nuclei project to the area of VL that we explored (Rinvik and Grofová, 1974; Rispal-Padel and Grangetto, 1977; Angaut, 1979; Nakano et al., 1980; Ilinsky and Kultas-Ilinsky, 1984; Evrard and Craig, 2008; Marlinski et al., 2012a), and it was shown that all these nuclei house neurons whose activity is strongly step-related during locomotion, with characteristics that are very suitable for driving locomotion-related activity in the VL (Orlovsky, 1972c; Armstrong and Edgley, 1984, 1988; Beloozerova and Sirota, 1998; Nilaweera and Beloozerova, 2009).

Signals to the motor compartment of the RE come from collaterals of VL TCs and the collaterals of MC cortico-thalamic (CT) neurons of layer VI (**Figure 3**; rev. in Jones, 2007). A comparison of locomotion-related discharges in these two regiones (Sirota et al., 2005 for CTs; Marlinski et al., 2012a for TCs) shows that the activity of the RE is very similar to that of the VL and appears to be predominantly driven by it (see Marlinski et al., 2012b for a detailed discussion). Therefore, one can conclude that if during simple locomotion VL neurons are, at least to a significant extent, driven by the spinal locomotor CPG, so too are the neurons of the RE.

If the activity of MC, VL, and RE neurons is influenced by signals from the spinal locomotor CPG, then this influence is quite different for neurons associated with different joints of the forelimb (**Figure 8**), as we found that these cells tend to discharge differently during simple locomotion. Namely, for VL neurons that are the "entry" elements of the network (**Figure 3**), the

influence from the CPG onto shoulder- and wrist/paw-related groups is maximal during the swing-to-stance transition, and onto the elbow-related group during the opposite phase. For RE neurons, which form a feedback inhibition loop for the VL, the influence from the CPG, although arriving in a similar phase of the stride, greatly differs in magnitude between the wrist/paw-related group and the shoulder- and elbow-related groups. For PTNs, which are the output elements of the network, the influence from the CPG onto the shoulder-related group is maximal during the stance-to-swing-transition, during the opposite phase for the elbow-related group, and roughly even throughout the step cycle for the wrist-related group.

FUNCTION OF LOCOMOTION-RELATED ACTIVITY IN THE MC, VL, AND RE DURING SIMPLE LOCOMOTION

Many studies have demonstrated that the MC does not exert decisive control over simple locomotion. Analogous data was also reported for the VL (Fabre and Buser, 1979; Beloozerova and Sirota, 1993a). In our earlier publication we have suggested that the stride-related modulation of the activity that MC neurons exhibit during simple locomotion has an informational character, allowing these neurons, if a need arises, to influence the spinal locomotor mechanism for correction of movements without disturbing the overall stepping rhythm (Beloozerova and Sirota, 1993a). We have later extended this hypothesis to both the VL and RE (Marlinski et al., 2012b).

It is important to understand how setting of permissible "windows of influence" takes place. Locomotion-related modulation of PTNs appears to be primarily caused by the activity of the VL, the main subcortical input to the MC. The general importance of this input for MC activity is well-known (Massion, 1976; Fabre-Thorpe and Levesque, 1991; Shinoda et al., 1993; Horne and Butler, 1995; Steriade, 1995; Destexhe and Sejnowski, 2001); however, the contribution of the VL to the transmission of locomotion-related signals has been not researched before. We found that discharges of 92% of VL neurons are modulated in the rhythm of strides with cells expressing one- and two-PEF patterns in proportions that are close to those seen in PTNs (Armstrong and Drew, 1984a; Beloozerova and Sirota, 1993a; Drew, 1993; Stout and Beloozerova, 2012). Thus, TCs can contribute to the activity in the MC during locomotion. However, in the four major characteristics of locomotion-related activity: mean discharge frequency, depth of frequency modulation, duration of activity bursts, and their stride phase distribution, there are two notable differences in the activity of VL neurons as compared to PTNs. The average depth of modulation is lower in the VL: 7.3–9.3 $\pm$ 0.5% vs. 10.2 $\pm$ 0.4% ($p < 0.05$, t-test), and the discharge within the activity bursts is typically more variable (Marlinski et al., 2012a). That is, stride-related responses of VL neurons are less phase-specific as compared to those of PTNs. This agrees with previous findings of a weaker directional specificity of VL neurons discharges during arm and wrist movements as compared to that of neurons in the motor cortex (Strick, 1976; Kurata, 2005), as well as with the well-known fact that, in the visual system, the responses of neurons in the lateral geniculate nucleus are less specific to visual stimuli than those of cells in the visual cortex (e.g., Tsao and Livingstone, 2008). This means that even during simple locomotion, the MC integrates its own information processing into signals received from the VL and likely takes into account other, predominantly cortical, inputs.

In addition to general differences in VL and PTN activities during locomotion, each of the shoulder-, elbow-, and wrist-related VL groups discharges in anti-phase with their respective PTN counterpart much of the time (**Figures 8** and **11**). This can have several reasons. First, it is possible that TCs direct their main output to PTNs not with a similar, but rather a dissimilar receptive field. Using electrical stimulation of the MC we found that the vast majority (72%) of TCs projecting to distal forelimb representation in the MC had receptive fields on proximal parts of the forelimb. Correspondingly, shoulder-related TC neuron activity is roughly in-phase with that of wrist/paw-related PTNs (**Figures 8C4,D4**). Although we did not find any other statistically significant crossed projections, elbow-related TCs activity was in-phase with that of shoulder-related PTNs, and wrist-related TCs as a group were active roughly in-phase with elbow-related PTNs.

A second explanation for the generally antiphasic activity of VL and PTNs subpopulations with similar receptive fields is that, in analogy with the somatosensory cortex where TCs powerfully excite inhibitory interneurons (Swadlow, 2002), PTNs may receive their main input from TCs not directly but via an inhibitory cortical network. This is quite plausible because putative inhibitory interneurons with suitable locomotion-related properties have been seen in the MC (Beloozerova et al., 2003a,c; rabbit, cat; Murray and Keller, 2011, rat). GABAergic inhibitory interneurons are thought to be involved in regulating both spatial and temporal response properties of cortical neurons (Sillito, 1975; Hicks and Dykes, 1983; Dykes et al., 1984), and it was demonstrated that they importantly participate in motor-related responses of PTNs as reduction of cortical $GABA_A$ inhibition enhances PTN activity during voluntary movements (Matsumura et al., 1992) and postural corrections (Tamarova et al., 2007).

Finally, since among both VL and PTN subpopulations there are neurons that are active in any phase of the stride, it is possible that although gross populational activities of VL and PTNs are in anti-phase, individual TC neurons influence those PTNs with which they are active in-phase. This will imply that VL neurons active during different phases of the stride have different divergence/convergence ratios for different PTNs. For example, in the wrist/paw domain, the few TC neurons active during swing diverge and powerfully drive many PTNs, while the many TCs that are active during stance converge upon similar overall numbers of PTNs, but drive them less powerfully (**Figures 8C3,4,F3,4**). These possibilities of fine organization of TC to PTN projection can and should be tested experimentally.

The activity of the VL is shaped by operation of the inhibitory feedback through the RE (**Figure 3**). While a wealth of information is available on the properties of RE neurons in brain slices, in anesthetized animals, and during sleep (Steriade et al., 1990; McCormick and Bal, 1997; Funke and Eysel, 1998; McCormick and Contreras, 2001; Hartings et al., 2003; Lam and Sherman, 2005, 2007, 2011; Cotillon-Williams et al., 2008; Sillito and Jones, 2008), the involvement of the RE in the production of movements has not been researched until recently (Marlinski et al., 2012b). In our studies we found that the activity of 90% of RE neurons is step phase-related during locomotion. The fact that the activity of

the RE, at both the individual and population level, changes with the phase of the stride indicates that during different stride phases RE neurons exerts different influences upon the VL. The activity of all RE subpopulations is more intense during late stance and swing as compared to early stance (**Figures 8** and **11**). This means that their target VL neurons are most inhibited during late stance and swing, thus allowing only the strongest ascending signals to pass through and reach the MC during these periods. A blockade of thalamic transmission permits other inputs to the MC to gain a greater contribution to the formation of cortical output during late stance and throughout swing phase. In contrast, during the early stance phase, when the activity of RE neurons is the lowest and thus their target VL cells are disinhibited, more ascending information passes through thalamus to the MC allowing the thalamus to provide a larger contribution to the cortical output during this period.

RE neurons with receptive fields on different segments of the forelimb, likely related to control of different segments of the limb, act differently during locomotion. Wrist/paw-related neurons, which are located ventrally in the nucleus, greatly exceed both shoulder- and elbow-related cells in the magnitude of their population activity modulation (**Figures 8** and **11**). They also have the highest discharge rates and greatest depths of frequency modulation in discharges of individual neurons, and are prone to high frequency bursting. The shoulder-related cells, which are located dorsally in the nucleus, have the lowest discharge rates and depths of modulation and rarely if ever burst. Thus, the VL-to-MC signal transmission in the distal limb domain is the most heavily influenced by the RE and is least influenced in the proximal limb domain.

LADDER LOCOMOTION: EXERTING DIFFERENTIAL CONTROLS OVER SHOULDER, ELBOW, AND WRIST/PAW FOR ACHIEVEMENT OF ACCURATE STEPPING

The ladder adds accuracy requirements to the locomotion task. On the ladder, cats are forced to constrain their paw placement to the raised crosspieces. They step accurately on their tops, showing much less spatial variability in feet placement as compared to simple locomotion (Beloozerova et al., 2010; **Figure 1B**). It has been demonstrated that walking with accurate stepping requires visual control (Sherk and Fowler, 2001; Beloozerova and Sirota, 2003; Marigold and Patla, 2008) and the activity of the MC and VL to be successful (Trendelenburg, 1911; Liddell and Phillips, 1944; Chambers and Liu, 1957; Beloozerova and Sirota, 1988, 1993a, 1998; Metz and Whishaw, 2002; Friel et al., 2007). In our experiments, all neurons that were tested during walking on the flat surface were also tested during locomotion along the ladder.

PTN ACTIVITY

Upon transition from simple to ladder locomotion, 97% of PTNs changed at least one characteristic of their activity, and 76% changed two or more. During ladder locomotion, high proportions of PTNs in all somatosensory response groups, 27–42% depending on the group, increased their average discharge rate as compared to simple walking, on average by $99 \pm 74\%$. Overall, fewer cells decreased the activity. Wrist- and elbow-related groups differed sharply, however: wrist-related PTNs had a fair number of cells with diminishing activity (40%), while the elbow-related group had only few (15%). In result, the average discharge rate of elbow-related group increased and became similar to that of shoulder- and wrist/paw-related PTNs. The average rate for all PTNs was 19.3 ± 1.2 spikes/s.

The activity of all but three PTNs was stride-related during ladder locomotion. The average depth of modulation was $11.4 \pm 0.4\%$. The same two patterns of modulation were observed in proportions similar to those seen during simple locomotion. Half of shoulder- and wrist-related PTNs increased the depth of modulation, on average by $62 \pm 44\%$ (**Figure 9A**). To do this, wrist/paw-related PTNs most commonly decreased discharge rate during the inter-PEF interval, while shoulder-related neurons could either increase it within the PEF or decrease in-between the PEFs (**Figures 9B,C**). Decreases of modulation also occurred in these neurons, but only half as frequently. In contrast, a typical response of elbow-related PTNs to the ladder task was a decrease of modulation depth (**Figure 9A**), typically by a decrease in the firing rate during the PEF (**Figure 9D**). About one third of shoulder- and wrist-related PTNs decreased the duration of their PEF, on average by ∼40%, but typically kept the same number of PEFs. In contrast, the elbow-related neurons typically did not change the PEF's duration, but tended to change the number of PEFs by either increasing or decreasing it.

A number of PTNs, especially within the elbow-related group, changed their preferred phases of the activity by either discharging earlier or later in the cycle. However, the phasing preferences of the entire shoulder- and elbow-related subpopulations during ladder locomotion remained largely similar to those during simple locomotion (**Figures 8** and **10**). In shoulder-related PTNs the mean discharge rate during stance-to-swing transition slightly rose to 24.4 ± 2.9 spikes/s; however, the activity during the opposite phase also rose, reaching 16.1 ± 2.4 spikes/s. Elbow-related PTNs still had a tendency to discharge more intensively during the swing-to-stance transition (**Figures 8** and **10**). In stark contrast to those groups, wrist-related PTNs developed a strong phase preference. While during simple locomotion this group showed only a subtle tendency to discharge more intensively during swing, during ladder locomotion this preference became pronounced (**Figures 8** and **10**). The discharge during swing was now slightly higher and, in addition, the discharge rate during stance substantially decreased. So, the difference in the discharge rate between swing and stance of wrist-related PTNs was 14.6 spikes/s during ladder locomotion.

VL NEURON ACTIVITY

Upon transition from simple to ladder locomotion, 79% of VL neurons changed at least one characteristic of their activity. One third of cells changed the discharge rate by either increasing or decreasing it by $51 \pm 7\%$ on average. While the average discharge rate of shoulder-, elbow-, and wrist-related neurons remained similar to that during simple locomotion (23–25.5 spikes/s), the elbow-related VL group was different from both other groups in that it had significantly more neurons whose activity diminished upon transition from simple to ladder locomotion ($p = 0.01$, χ^2 test). This change in the activity of VL elbow-related neurons directly opposed that of elbow-related PTNs.

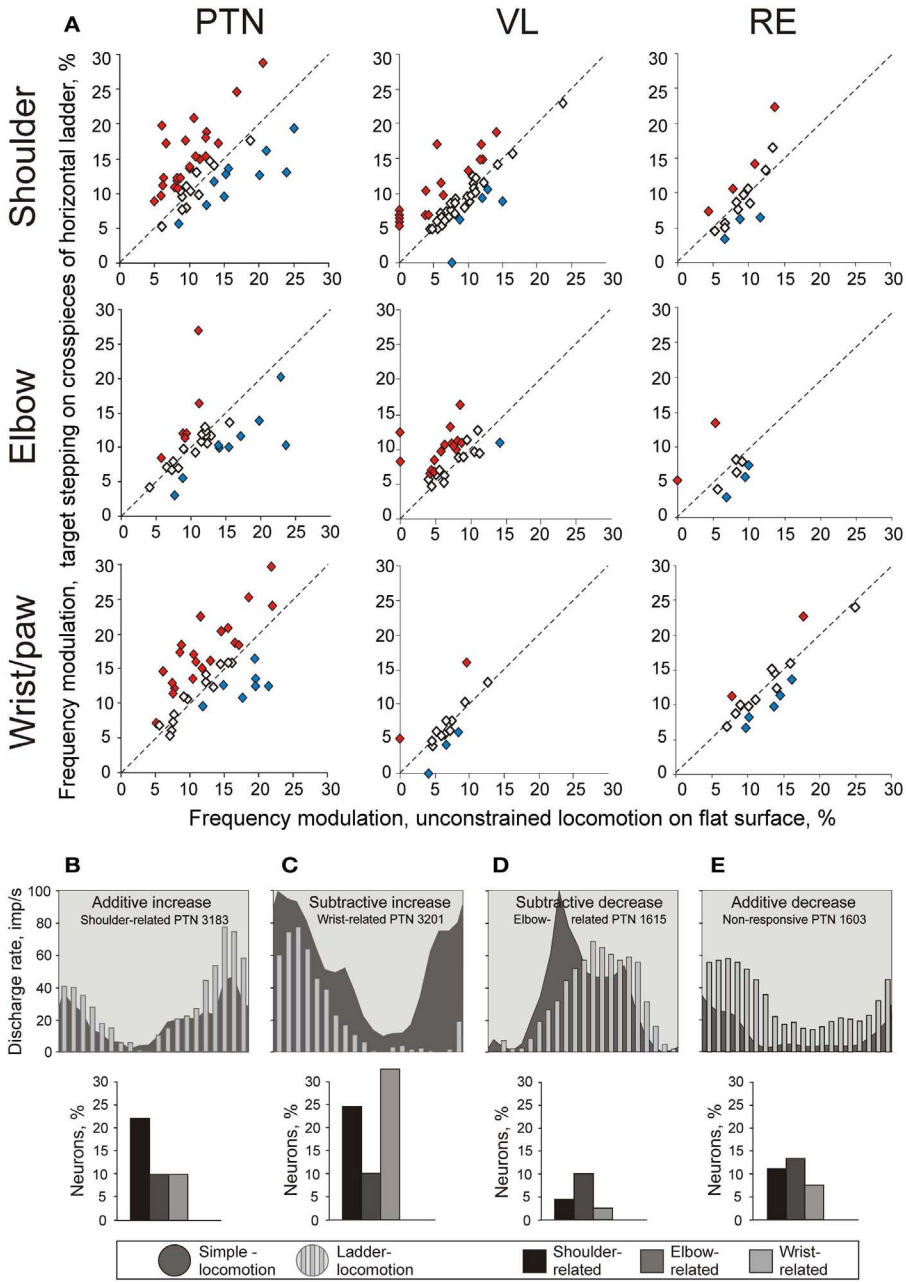

FIGURE 9 | Change in the depth of frequency modulation upon transition from simple to ladder locomotion. **(A)** Comparison of depth of modulation in the activity of individual MC, VL, and RE neurons. The abscissa and ordinate of each point show the values of the depth of modulation of a neuron during simple and ladder locomotion, respectively. Neurons whose depths of modulation were statistically significantly different during the two tasks are shown with filled diamonds, the other ones are shown with open diamonds. **(B–E)** Typical changes in the depth of modulation upon transition from simple to ladder locomotion in PTNs. The area histograms show the activity of typical PTNs during simple locomotion, and the bar histograms show activity of the same PTNs during ladder locomotion. Bar graphs beneath the histograms show the proportion of PTNs from each group exhibiting that type of modulation change. **(B):** Increase in the depth of modulation by additive mechanism. **(C)** Increase in the depth of modulation by subtractive mechanism. **(D)** Decrease in the depth of modulation by subtractive mechanism. **(E)** Decrease in the depth of modulation by additive mechanism. (Adapted with modifications from Stout and Beloozerova, 2012).

The activity of 92% of all VL neurons was step-related during ladder locomotion, with eight neurons becoming step cycle-modulated only during this complex task. The average depth of modulation was $9.1 \pm 0.4\%$. The same two patterns of discharge modulation as during simple locomotion were expressed: the one PEF (63% of neurons) and the two-PEF (34% of neurons) patterns. In the shoulder-related group, 32% of cells increased and 10% decreased the depth of modulation, but the average depth of

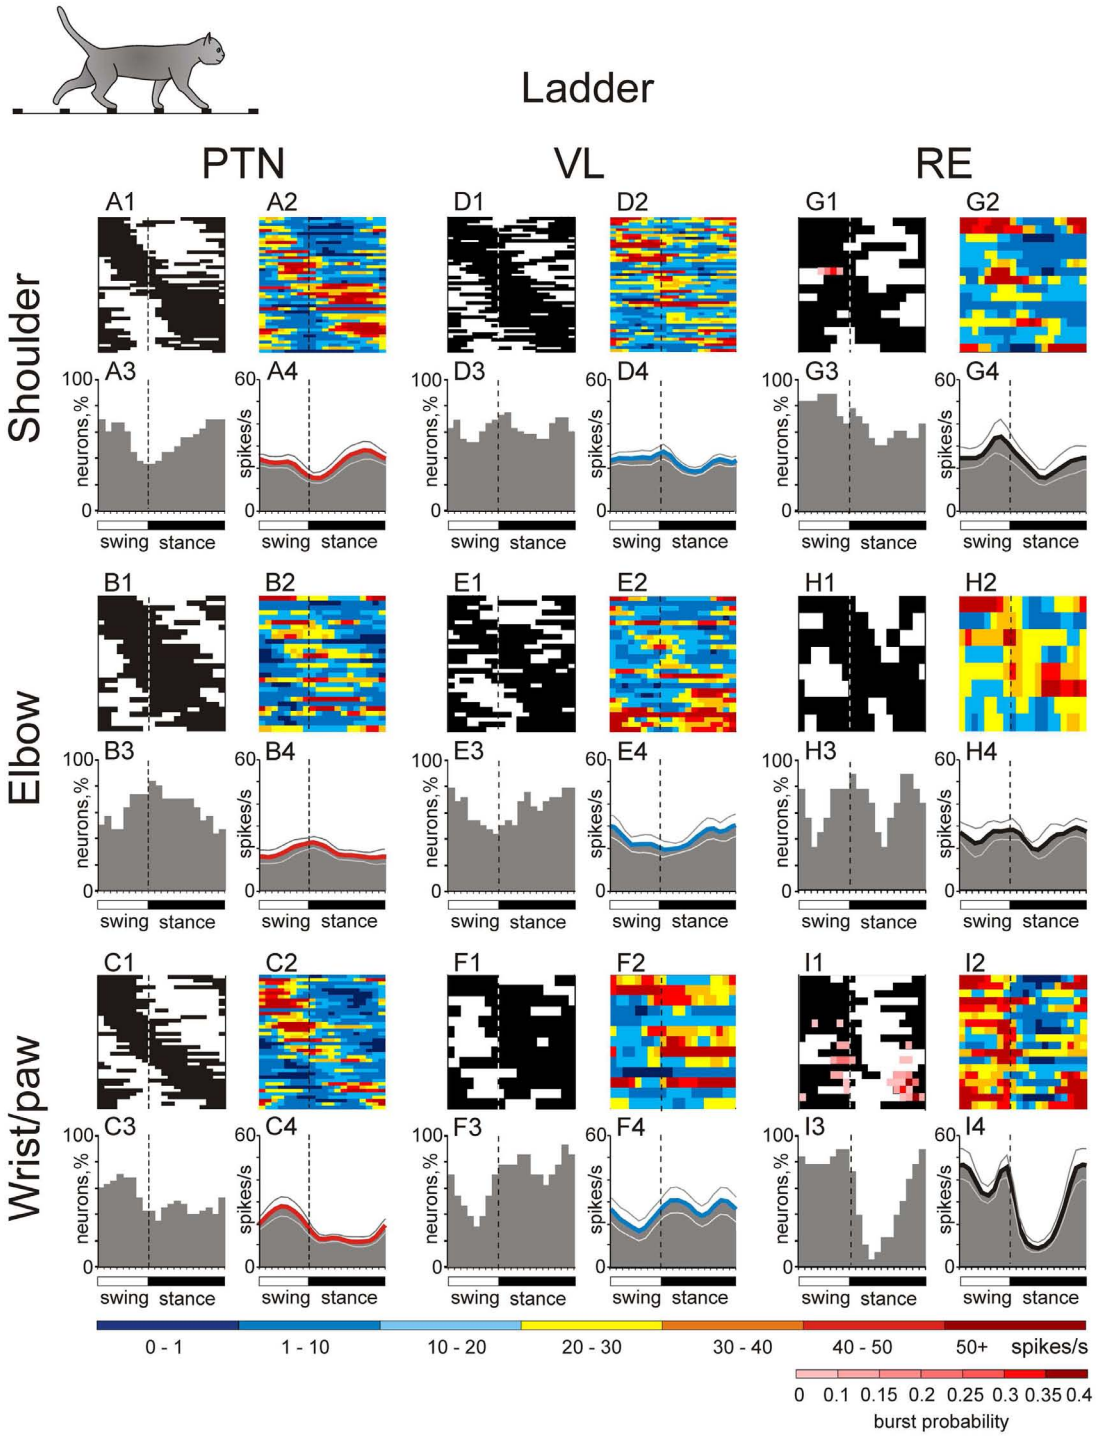

FIGURE 10 | Activities of the shoulder-, elbow-, and wrist/paw-related cells in the thalamo-cortical network during ladder locomotion. **(A,D,G)** Activity of neurons responsive to movements in the shoulder joint, and/or palpation of back, chest, or neck muscles in the MC **(A)**, VL **(D)**, and RE **(G)**. **(A1,D1,G1)** Phase distribution of PEFs. (Data on the activity of PTNs, VL, and RE neurons are adapted with modifications from Stout and Beloozerova, 2012; Marlinski et al., 2012a,b, respectively).

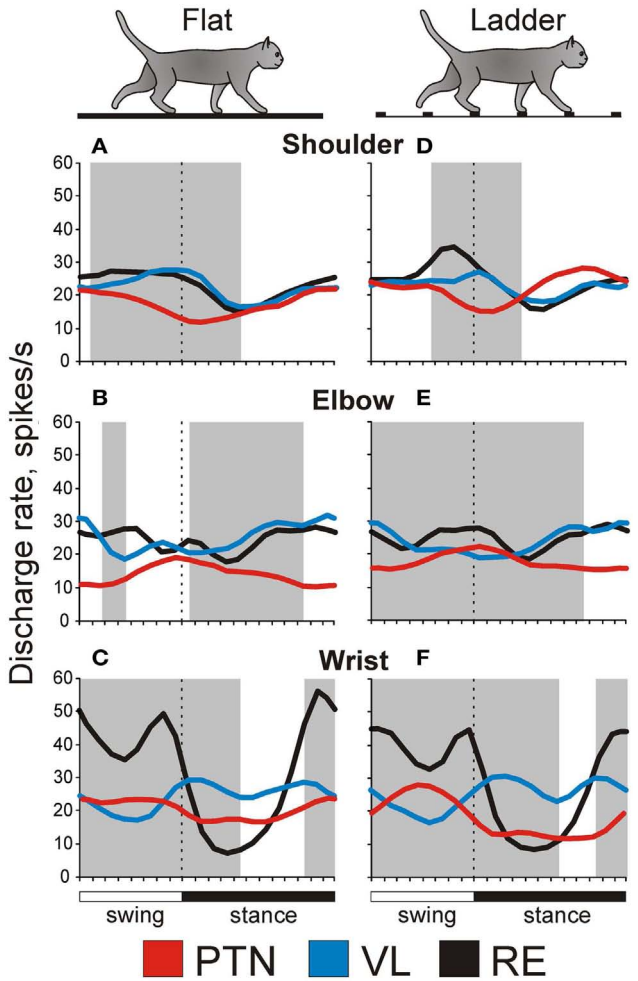

FIGURE 11 | Distinct thalamo-cortical controls for shoulder, elbow, and wrist during locomotion. Red lines show population activities of shoulder-, elbow-, and wrist/paw-related neurons of the MC, blue lines show those of the VL, and black lines represent the corresponding activities of inhibitory neurons of the RE. Shaded are periods of the step cycle when the activities of the MC and VL are in anti-phase. (Data on the activity of PTNs, VL, and RE neurons are adapted with modifications from Stout and Beloozerova, 2012; Marlinski et al., 2012a,b, respectively).

modulation for this subpopulation did not significantly change. In contrast, half of the elbow-related cells increased the depth of modulation, on average by 60 ± 7% (**Figure 9A**), and in result, the depth of modulation of the elbow-related group increased to 9.5 ± 0.6%. In the wrist-related group, only 15% of cells increased modulation and 15% decreased it, and the average modulation of wrist/paw-related cells remained low. The duration of the PEF was similar across the three VL neuronal groups, averaging 61 ± 1.5% of the cycle, however, in about one third of cells the number of PEFs per cycle changed. Elbow-related neurons differed from both other groups by almost always increasing the number of PEFs on the ladder from one to two, while shoulder- and wrist/paw-related cells more often decreased it from two to one. In approximately one quarter of neurons that were modulated with one PEF during both locomotion tasks, regardless of their receptive field, the preferred phase of the activity on the ladder was different from that during simple locomotion.

Ventrolateral thalamus neurons with receptive fields involving different joints tended to have their PEF in different phases of the step cycle (**Figure 10**, two middle columns). Despite changes in preferred phases of activity of individual neurons, populations' activity distributions were generally similar to those seen during simple locomotion. Shoulder-related neurons were more active during the transitions from swing-to-stance phase, and the mean discharge rate of the stride-related population was higher during this period, at 27.0 ± 3.3 spikes/s, while the firing rate during mid-stance was 10 spikes/s less (**Figure 10D4**). Elbow-related neurons tended to be more active in the opposite phase, reaching maximum in the activity at 30 ± 5.0 spikes/s during the late stance and early swing (**Figure 10E4**). Wrist-related neurons were more active throughout stance at 25–30 spikes/s while discharging 10–15 spikes/s less during mid swing (**Figure 10F4**).

RE NEURON ACTIVITY

Upon transition from simple to ladder locomotion, 75% of RE neurons changed at least one characteristic of their activity (**Figure 9A**). During ladder locomotion, wrist-related RE neurons still tended to be more active then either shoulder- or elbow-related cells (29 ± 3.4 vs. 24.5 ± 3.0 spikes/s). The discharge of 91% of all RE cells was modulated with respect to the stride, and as with the MC and VL neurons, the same two patterns of modulation were observed in proportions similar to those seen during simple locomotion.

There were substantial differences in the activity between neurons with different receptive fields (**Figure 10**). As with the VL populations, distributions were generally similar to those seen during simple locomotion. PEFs of shoulder-related cells were distributed rather evenly across the cycle (**Figures 10G1–4**), and their average discharge rate was relatively low (23 ± 3.3 spikes/s). They also had low average depth of modulation (8 ± 1%) and long PEFs (70 ± 3% of the cycle). In contrast, wrist/paw-related cells discharged most intensively during the swing and end of stance, generally sparing the first half of stance (**Figures 10I1–4**). They also tended to be more active (29 ± 3.4 spikes/s), were much more modulated (12.4 ± 1.2%), and exhibited shorter PEFs than neurons of any other group (55 ± 4.5% of the cycle). In addition, wrist/paw- and shoulder-related cells still differed dramatically in production of sleep-type spike bursts. The most frequently bursting wrist/paw-related cell generated a burst nearly every third stride, while shoulder- and elbow-related generated very few if any. Three wrist-related neurons had a significantly higher probability to discharge a sleep-like burst during ladder than simple locomotion ($p = 0.001$, t-test). The activity characteristics of elbow-related neurons were in-between of those of shoulder- and wrist/paw-related cells (**Figures 10H1–4**).

DISTINCT MC CONTROLS FOR SHOULDER, ELBOW, AND WRIST DURING COMPLEX LOCOMOTION

It is clear that the MC plays a critical role in the control of accurate stepping, as precise positioning of limbs is nearly impossible after destruction of the MC or even its short-lasting inactivation

(Trendelenburg, 1911; Liddell and Phillips, 1944; Chambers and Liu, 1957; Beloozerova and Sirota, 1988, 1993a; Metz and Whishaw, 2002; Friel et al., 2007). In cats walking on a treadmill belt, it was shown that the activity of many neurons in the MC changes periodically according to the step cycle, and significantly increases during unexpected perturbations and voluntary gait modifications (Armstrong and Drew, 1984a; Drew, 1993; Widajewicz et al., 1995; Drew et al., 1996). In our earlier work, we found that when paw positioning on the surface was restricted such that visually guided adaptation of gait was required to place the paws accurately, the activity of 60–70% of the neurons in the MC, depending on the task, changed dramatically as compared to walking on the flat surface, and the changes in neuronal activity increased as the requirements for accurate foot placement became increasingly demanding (Beloozerova and Sirota, 1993a). Later, we additionally found that, as accuracy demand on stepping progressively increases, many neurons in the MC progressively refine their discharge timing, producing activity more precisely in a specific and restricted phase of the stride (Beloozerova et al., 2010).

Several lines of evidence indicate that the differences in MC activity during simple and ladder locomotion reflect different modes of cortical descending control during these tasks, not a difference in the afferent signals. First, as discussed above, afferent signals appear to play little role in driving locomotion-related responses in MC neurons (Armstrong and Drew, 1984a,b; Beloozerova and Sirota, 1993a,b; Stout and Beloozerova, 2012). Second, in our recent study we have examined 229 full-body biomechanical variables of cats walking on the flat surface and along a horizontal ladder with flat rungs placed at a convenient for the cat distance (Beloozerova et al., 2010). We found that on such ladder, cats step on support surface with much less spatial variability (**Figure 1B**) but the overwhelming majority of other biomechanical variables do not differ between the tasks. This suggests that afferentation received by the MC during simple and ladder locomotion may be very similar. While it was shown that the level of fusimotor activity is often higher during difficult motor tasks, especially those that are novel, strenuous, or are associated with high degree of uncertainty (Prochazka et al., 1988; Hulliger et al., 1989), our ladder locomotion task was well practiced, entirely predictable, and, judging from levels of EMG activity (Beloozerova et al., 2010) not at all strenuous. Thus, it does not seem very likely that a difference in the proprioceptive afferentation between simple and ladder locomotion can be responsible for the entire volume and spectrum of discharge differences of MC, VL, and RE neurons during these two tasks. Nevertheless, in the majority of these neurons, discharge rate averages, peak values, depths of stride-related frequency modulation, and duration of PEFs are very different during ladder locomotion as compared to simple walking (**Figure 9**). We suggest that during ladder locomotion MC activity reflects processes that are involved in integration of visual information with ongoing locomotion and represents cortical commands that control stride length. These controls are different for different joints of the forelimb.

Shoulder-related PTNs often increase their discharge rate and depth of modulation while reducing discharge duration. They typically do not change their preferred phase, but as a group become more active at the end of stance (**Figures 10** and **11**). Such activity modifications are consistent with the hypothesis that during precise stepping shoulder-related PTNs have a significant role in planning of limb transfer, which is believed to occur before the end of stance phase (Laurent and Thomson, 1988; Hollands and Marple-Horvat, 1996), as well as in the initial phases of limb transfer when adjustment of the foot trajectory is still possible (Reynolds and Day, 2005; Marigold et al., 2006). In addition, during the second half of stance, accurate paw placement of the opposing limb is taking place, and precise posture maintenance from the supporting limb is important to maintain balance. This could be another reason for shoulder-related PTNs, specifically those related to shoulder extension, to increase their activity and modulation during stance.

Wrist-related PTNs, whose activity was fairly evenly distributed throughout the cycle during simple locomotion, as a group became strongly modulated, exhibiting a prominent activity peak during swing (**Figures 10** and **11**). In contrast to shoulder-related PTNs, individual wrist-related PTNs often decreased discharge rate while also increasing depth of modulation and reducing their discharge duration. Such activity modifications are consistent with the hypothesis that wrist-related PTNs, specifically those related to the wrist plantar (ventral) flexion, are involved in distal limb transfer during accurate target stepping by ensuring greater plantar flexion of the wrist during the swing phase during ladder locomotion (**Figure 2**). It is well-known that activation of the MC results in contraction of more flexor than extensor muscles, and this rule holds during locomotion (Armstrong and Drew, 1985a).

Although both shoulder- and wrist-related PTNs often increase modulation during ladder locomotion as compared to simple walking, they generally do so using different mechanisms (Stout and Beloozerova, 2012). Shoulder-related PTNs often achieve an increase in modulation by increasing their peak discharge rate. This is likely to result in a more intensive signal to the spinal network, often along with a more specific timing of the discharge. Wrist-related PTNs achieve increases in the modulation chiefly by decreasing the firing outside of PEF, thus increasing the salience of the signal without making it more intense. This modification could specifically improve the temporal precision of the controls for limb transfer during a accurate stepping task.

In contrast to shoulder and wrist-related PTNs, upon transition from simple to ladder locomotion, elbow-related PTNs do not often increase the depth of modulation or discharge duration, but often increase discharge rate and change preferred phase. Their group activity becomes evenly distributed throughout the cycle during complex locomotion (**Figures 10** and **11**). The change in the preferred phase and the number of PEFs might reflect incorporation of visual information about the location of crosspieces into the CPG activity-based locomotor pattern, serving to "tweak" the limb into place to secure accurate stepping. The generally elevated activity of the elbow-related group is likely to enhance efficacy of their influence during complex locomotion task.

An effective way for PTNs to differentially influence different segments of the forelimb during locomotion is to influence individually the respective locomotion pattern formation networks in the spinal cord (McCrea and Rybak, 2008) by modulating the amplitude and potentially the timing of their output. Indeed, Asante and Martin (2010) recently found that in the mouse spinal

projections from shoulder-, elbow-, and wrist-related areas in the MC primarily contact those spinal premotor circuits that connect to shoulder-, elbow-, and wrist-related motoneuron pools, respectively. Based on results of experiments with micro-stimulation in the MC, analogous mechanisms for control of limb segments have been previously suggested by Drew (1991) for the forelimb and by Bretzner and Drew (2005) for the hind limb of the cat.

SIGNALS FROM THE VL-TO-MC DURING ACCURATE STEPPING CONTAIN INTEGRATED VISUO-MOTOR INFORMATION FOR FOOT PLACEMENT, DIFFERENTIATED BY FORELIMB JOINT

How are motor cortical controls for shoulder, elbow, and wrist formed? The main subcortical input to the MC comes from the VL. The VL obtains locomotor CPG-generated information from the cerebellum, receives direct input from the spinal cord, and also receives visual information from the cerebellum and probably from the cortex. We found that during locomotion VL neurons discharge in a manner that is very suitable to contribute to the additional modulation of the activity in the MC that occurs during locomotion over complex terrain. Namely, the activity of VL neurons with one PEF is modulated more strongly on the ladder than during simple locomotion, the overwhelming majority of individual VL neurons change their discharges upon transition from simple to ladder locomotion, and the dominant change, similar to that in the MC, is an increase in the depth and temporal precision of the modulation.

What is the content of information conveyed by the VL to the motor cortex during ladder locomotion? Considering the rather similar limb motor patterns (Beloozerova et al., 2010) but dramatically different gaze behaviors (Rivers et al., 2009, 2010) in the two locomotion tasks, we suggest that at least a part of the differences in discharges of VL neurons during simple and ladder locomotion reflects differences in processing of visual information during these two tasks, as well as the changes in motor commands made on the basis of visual information. During locomotion in complex environments, visual information about the position of the stepping target is first processed through visual networks and then at some point is incorporated into the basic locomotion rhythm in order to guide the limb. From this point on it becomes integrated "visuo-motor" information that, in the afferent sense, is "(processed) visual information," while in the efferent sense it is a "limb control signal" reflecting preparation of the movement. It has been suggested that visual information about the environment is integrated with movement-related information in the cerebellum, and then funneled to the motor cortex via the VL for control of limb movements (Glickstein and Gibson, 1976; Stein and Glickstein, 1992; Glickstein, 2000). Our data indicate, however, that the VL is more than a simple relay for signals passing to the MC during ladder locomotion. Many of VL neurons discharge in different phases of the cycle during simple and ladder locomotion. This shows that information related to the complex environment changes the basic locomotion-related discharge pattern of VL neurons. In our original research report we have described five major modes of this integration (Marlinski et al., 2012a).

THE RE DIFFERENTIALLY GATES TC SIGNALS DEPENDING ON LOCOMOTION TASK

Two thirds of RE neurons change at least one aspect of their activity upon transition from simple to ladder locomotion. This indicates that participation of the RE in shaping of VL signals going to the MC depends on the task. The mean and peak activities in 33–37% of RE neurons during ladder locomotion are different from those during simple walking. This signifies differences in the intensity of regulation of the VL-to-MC transmission between two tasks. Differences in the depth of modulation in 40% of RE neurons mean differences in the salience of the RE to VL influence. Differences in the preferred phase, duration of PEFs and/or in the number of PEFs mean differences to the timing of RE influences on the thalamo-cortical signal transmission, and these are often seen in RE neurons between two tasks.

CONCLUSION

In this review, we have presented the results of a series of studies that examined the differences in the activities of shoulder-, elbow-, and wrist/paw-related neurons in the thalamo-cortical network for locomotion. Substantial differences were found both between the subpopulations of neurons with different receptive fields within each of the MC, VL, and RE, as well as between neurons with similar receptive fields residing in different motor centers. We conclude that the thalamo-cortical network for locomotion processes information related to different segments of the forelimb differently and exerts distinct controls over shoulder, elbow, and wrist. We hypothesize that this contributes to an effective control of a global limb parameter, the length of the stride, which results in a great reduction in variability of paw placement during accurate stepping. It is one of manifestations of a modular organization of control for locomotion. The efficacy and contribution of synaptic connections between neurons with similar and dissimilar receptive fields in different sites in the thalamus and cortex need to be determined, however, to further reveal the operation of thalamo-cortical neuronal network during locomotion.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Boris I. Prilutsky for a fruitful collaboration on the analysis of biomechanics of cat locomotion, for many insightful discussions, and a critical review of the manuscript. The research was supported by National Institute of Neurological Disorders and Stroke grants R01 NS-39340 and R01 NS-058659 to Irina N. Beloozerova.

† These authors have contributed equally to this work.

The human hand has so many degrees of freedom that it may seem impossible to control. A potential solution to this problem is "synergy control" which combines dimensionality reduction with great flexibility. With applicability to a wide range of tasks, this has become a very popular concept. In this review, we describe the evolution of the modern concept using studies of kinematic and force synergies in human hand control, neurophysiology of cortical and spinal neurons, and electromyographic (EMG) activity of hand muscles. We go beyond the often purely descriptive usage of synergy by reviewing the organization of the underlying neuronal circuitry in order to propose mechanistic explanations for various observed synergy phenomena. Finally, we propose a theoretical framework to reconcile important and still debated concepts such as the definitions of "fixed" vs. "flexible" synergies and mechanisms underlying the combination of synergies for hand control.

Keywords: degrees of freedom, premotor neurons, manipulation, motor cortex

INTRODUCTION

The structure of the hand, with its intricacy of bones, muscles, tendons, blood vessels, and nerves, is a marvel of evolution yet unsurpassed by any artificial hand. At the functional level, the hand is also a marvel of dexterity and versatility that combines a rich sensory endowment with strength: it holds the scalpel of the neurosurgeon, the pen of the scribe, the brush of the aquarellist as well as the hammer of the blacksmith or the sword of the warrior. One sign of the importance of the hand for humans is its remarkable evolution, with the development of the opposable thumb which underlies all skilled procedures of which the hand is capable (Napier, 1956, 1980) and, at the neuronal level, of the corticospinal tract, which allows the brain to control it in a much more direct way than in other species. The role that the hand plays in almost all our activities and its adaptability to a wide range of behavioral contexts, have led some to see the hand as a simple executant of the commands coming from the higher centers in the brain.

Whereas the motor apparatus of the hand offers a tremendous movement range and adaptability (or, in more technical terms, features a very high number of *degrees of freedom*, DoF), this feature also makes the human hand exceedingly difficult to control—as underscored by the challenges faced by robotics and neuroprosthetics in controlling the latest generation of anthropomorphic hands. The biomechanical and functional characteristics of the hand make it a remarkable model to investigate how the brain controls the many DoFs of the body, one of the fundamental problems of motor control (e.g., Bernstein, 1967; Turvey, 2007; Latash, 2008). As pointed out by many investigators, having a large number of DoFs allows one to perform a task in a wide variety of ways, which presents considerable advantages in terms of flexibility and adaptability. For example, one might grasp an object or distribute the forces holding the object differently depending on specific and possibly contingent events such as holding two cups at once, or grasping them using a broken finger. However, the flexibility afforded by the many DoFs of the hand, which allows it to be used in a wide variety of situations, comes also with the price that the central nervous system (CNS) must control a system that is in general vastly more complex than necessary to execute any particular task. This control problem becomes even more daunting if one considers the entire time course of an action. A simple count of the number of mechanical DoFs like the number of joints or muscles in the hand vastly underestimates the complexity of the problem that the motor system must solve since it amounts to counting the number of parameters necessary to specify the hand state at a precise moment in time. Most actions are dynamic and require a constant and mutual adjustment of all elements of the system. For example, reaching for an object requires transporting the hand while orienting and pre-shaping it, as well as making postural adjustments to keep the body's center of gravity within the base of support defined by the positions of the feet. The number of redundant DoFs increases almost without limits if we consider the temporal evolution of the system rather than a static snapshot of it.

The concepts of synergy and "synergy control" have attracted considerable interest in motor control neuroscience in recent years as a possible solution to this problem. According to Turvey (2007), a synergy is "a collection of relatively independent degrees of freedom that behave as a single functional unit – meaning

that the internal degrees of freedom take care of themselves, adjusting to their mutual fluctuations and to the fluctuations of the external force field, and do so in a way that preserves the function integrity of the collection" (p. 659). In other words, a synergy is a functional property of a multi-element system performing an action, whereby many elements of the system are or can be constrained to act as a unit through a few coordination patterns to execute a task. In principle, "synergy control" could combine dimensionality reduction with great flexibility.

The main goal of this review is to illustrate how various analyses of hand motor control point to the fact that the control problem of apparently complex manual tasks is solved by extensive dimensionality reduction and that the number of effective DoFs present in a task might actually be quite small. We will start out by describing the peripheral apparatus and the biomechanical characteristics of the hand that are more relevant to this review. We then review work on kinematic synergies, i.e., tasks involving actual hand movements, and proceed with force synergies, i.e., tasks involving different kinds of grasping and the force equilibrium maintained through the fingertips. In the last section we review evidence for synergy control embedded in the "infrastructure" of the nervous system, i.e., the neuronal circuitry involved in hand movement control. Finally, we conclude with open questions and directions for future research.

BIOMECHANICAL CONSTRAINTS

The hand is first and foremost a complex mechanical structure that includes 27 bones actuated by 18 intrinsic and 18 extrinsic muscles by means of a complex web of tendons. A first measure of the complexity of the hand is to consider the number of joints in the hand. A simple kinematic model of the hand typically consists of four DoFs for each finger, four or five DoFs for the thumb, plus one DoF at the radio-ulnar joint and two DoFs at the wrist, yielding a total of 23 or 24 DoFs. A more detailed kinematic model would include additional parameters to describe arching of the palm that occurs when the thumb tip approaches the tip of the ring or little fingers. A complete biomechanical model of the hand would also include the 36 muscles acting on the thumb and fingers and the complex web of tendons that actuate the hand, yielding total of at least 60 DoFs without even taking into account muscles acting on the wrist and radioulnar joints or additional DoFs associated with contact forces. Therefore, even for seemingly trivial motor tasks such pushing a key with a finger, a complete biomechanical account of the action would require a description of how the combined activation of many muscles contributes to generate desired motions and contact forces.

There are several reasons why knowledge of hand biomechanics is important for understanding the neural control of the hand. First, biomechanical constraints might limit the actions of the hand, therefore motor commands must adapt to these constraints to avoid engaging these actions, to find ways around the constraints, or to exploit them. For example, we cannot stick a finger in an S-shaped tube because of the impossibility to fold the two inter-phalangeal joints in different directions. Another constraint is that hand dimensions and digit lengths limit the size of an object that can be grasped with one hand. Secondly, biomechanical constraints can, in principle, reduce the number of independent DoFs. For example, extrinsic finger flexor and extensor muscles have tendons that span several joints of each finger (see **Figure 1**). Therefore, assuming a perfectly focal activation of a single muscle compartment (e.g., the index finger compartment of *m. flexor digitorum profundus*), contraction of that muscle would cause flexion at several joints. This partly accounts for the difficulty encountered when trying to move only the distal phalange of a finger without also moving the more proximal joints. It should also be noted that the biomechanical architecture constraining coupled actions at multiple joints *within* a digit also characterizes coupled actions *across* digits. Specifically, interconnections between tendons of hand muscles and long tendons spanning all finger joints limit the extent to which focal activation of hand muscles innervating a finger can isolate torque generation at one joint or at a given finger from torque generation in adjacent fingers [see Schieber and Santello (2004), for review of peripheral constraints on hand function]. Third, what might appear like simple movement, e.g., flexion of one finger around one joint, might require the coordinated action of several hand muscles (Reilly and Schieber, 2003; Schieber and Santello, 2004). Fourth, and most importantly, biomechanics is crucial to understanding the mechanical functions of a muscle and how motor commands adapt to task conditions. For example, finger posture has been shown to significantly affect the mapping between muscle activation and isometric joint torque production (Kamper et al., 2006).

This brief description of the hand anatomy should make clear that the brain does not directly control the movement of the individual muscles or joints of the hand. Therefore, the biomechanical structure of the hand defines a complex mapping between the motor commands and the observable motions or contact forces at the digits.

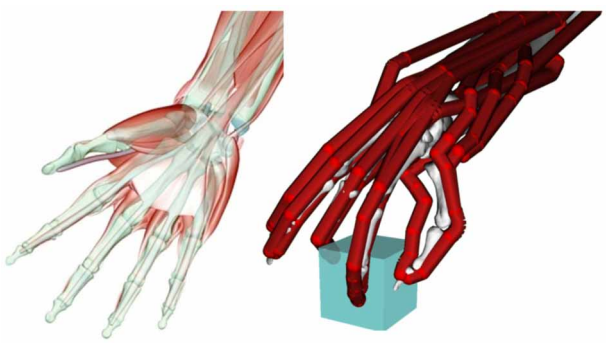

FIGURE 1 | Left: muscular and skeletal architecture of the hand. Note the multi-joint tendons of the extrinsic finger flexor muscle (m. flexor digitorum profundus). **Right**: simplified model of a hand grasping an object with three fingertips (tripod grasp). The bones are only vaguely visible in the background, whereas the tendons are indicated in red. Only a subset of the tendons/muscle acting on each finger is included in this model (Holzbaur et al., 2005).

KINEMATIC SYNERGIES

In the past 20 years, hand kinematics has been studied in a variety of tasks. Despite significant differences in the requirements of these tasks, all of these studies share a main observation: simultaneous motion of multiple digits occurs in a consistent fashion, even when the task may require a fairly high degree of movement individuation such as grasping a small object or typing.

COVARIATION OF FINGER MOVEMENTS

The word "synergy" has been used in several contexts when describing thumb and finger movements, often referring to qualitative observations of movement patterns that are characterized by simultaneous motion of the fingers in the early stages of development (palmar grasp reflex) and for the purpose of classifying hand movements (Elliott and Connolly, 1984) or grasp postures along a functional gradient (Napier, 1956, 1980; Cutkosky, 1989). The first attempts at quantifying the kinematics of hand synergies focused on the spatial and temporal coordination of digit movements in serial tasks requiring isolated motion of one digit, i.e., typing (Fish and Soechting, 1992; Flanders and Soechting, 1992; Angelaki and Soechting, 1993; Gordon et al., 1994; Gordon and Soechting, 1995; Soechting and Flanders, 1997), and later extended to movement sequences involving motion of one or more digits [in piano playing and finger spelling (Engel et al., 1997; Jerde et al., 2003a,b)]. These studies found that when subjects typed a single letter with a finger ("focal movement"), motion that was not necessary to complete the task ("corollary motion") also occurred at other fingers in a subject-dependent but stereotypical fashion. These studies also reported that the degree of correlation of movement across pairs of digits—stronger for adjacent than non-adjacent digits and higher when neither of a pair of fingers is used to strike the key—was not obligatory, hence not uniquely due to biomechanical constraints (Fish and Soechting, 1992; Angelaki and Soechting, 1993; Soechting and Flanders, 1997). These early observations led to the suggestion that "... synergistic finger motions would simplify the problem of controlling the large number of DoFs inherent in motion of all of the fingers of the hand ..." (Fish and Soechting, 1992). A subsequent typing study further revealed that only a few principal components (PCs) could characterize motion of a subset (17) of all kinematic DoFs of the hand, thus implying "... a reduction in the number of dofs independently controlled by the nervous system" (Soechting and Flanders, 1997) stemming from musculoskeletal and neural constraints. The consistency with which these constraints operate significantly facilitates hand shape recognition in finger spelling due to "leakage" of information across finger joint angles (Jerde et al., 2003a). Similarly to what was found for typing movements, however, covariations in finger joint excursions exhibit some degree of task-dependency as indicated by the sensitivity of hand shape to the preceding or following letter (Jerde et al., 2003b). A recent application of PC analysis has been introduced to study sensorimotor transformations by quantifying humans' ability to perceive and reproduce hand postures with the contralateral hand as a function of grasping force and forearm orientation relative to gravity (Pesyna et al., 2011).

DIMENSIONALITY REDUCTION IN THE ANALYSIS OF FINGER MOVEMENTS DURING REACH-TO-GRASP

Research on synergy control has been devoted to developing analytical techniques to reveal if and how a reduction in the dimensionality of the hand control space is attained. In this section we discuss the reduction in dimensionality of hand kinematics defined as joint angles observed during grasping and reach-to-grasp movements.

The concept of synergies, often quantified and defined through dimensionality reduction techniques [principal components analysis, PCA; singular value decomposition, SVD; nonnegative matrix factorization, for review see Tresch et al. (2006)], has also been invoked when describing systematic covariations of joint angular excursions of hand postures used for grasping. The first description of hand postural synergies for grasping movements (Santello et al., 1998) was based on grasping a large number of imagined objects with different sizes and shapes. This design was motivated by the fact that hand shape at contact with an object results from central planning as well as the mechanical interaction of the hand with the object. By asking subjects to shape the hand to imagined objects, one could examine the central planning of hand posture as a function of object shape. Subsequent work on grasping real objects (Santello et al., 2002) confirmed the main observations made on hand posture used for grasping imagined objects by revealing, as expected, a larger number of PCs when physical contact was allowed.

Similar to the results of PCA of typing movements (Soechting and Flanders, 1997), the main finding of the study by Santello et al. (1998) was that a few linear combinations of the 15 DoFs that were measured could account for most of the variance in the original set of hand postures. The lower order components (PC1-3) described more "basic" patterns of finger motion, e.g., hand opening/closing caused by motion at all metacarpal-phalangeal or proximal-interphalangeal joints. Interestingly, however, hand shapes reconstructed by adding higher order PCs (up to the fifth or sixth) provided additional information about the object. These observations led to the suggestion that the control of hand posture might be implemented by a combination of postural synergies ranging from those responsible for the general shape of the hand (lower PCs) to those responsible for subtler kinematic adjustments (Santello et al., 1998). A similar framework was also proposed when interpreting the results of an earlier study on matching haptically or visually perceived object size (Santello and Soechting, 1997). As noted by the authors, PCs do not need have any physical significance, and therefore they cannot be used to infer the relative contribution of peripheral constraints vs. central commands in generating coupled motion of the digits. However, transcranial magnetic stimulation (TMS) of primary motor cortex can elicit synergistic finger movement patterns similar to those found when the same subjects grasped imagined objects (Gentner and Classen, 2006), suggesting a modular organization of cortical representations of hand muscles. Nevertheless—and as noted above for finger movement patterns in typing—covariation patterns of finger motion are not obligatory. This implies that hand synergies revealed by the above studies are not a mere byproduct of anatomical factors such as multi-tendoned and multi-joint muscles, and therefore that the

CNS retains the ability of partially overriding, in a task-dependent fashion, anatomical constraints. Specifically, finer modulation of neuromuscular activity might be required to overcome peripheral coupling when the task requires independent finger actions (Santello et al., 1998) or to exploit it when multi-digit actions require all digits to act as a unit (Schieber and Santello, 2004). These considerations also explain why manipulations characterized by different requirements in the spatio-temporal coordination of the digits can elicit different number and patterns of PCs (Todorov and Ghahramani, 2004). Similarly, task-dependencies in finger joint angle covariations have also been reported when comparing whole-hand grasping of one object vs. individuated finger movements (Braido and Zhang, 2004). However, the relatively large number of PCs associated with haptic exploratory procedures can be used to reconstruct grasp postures, indicating some commonalities of digit movement coordination patterns across these tasks (Thakur et al., 2008).

Hand kinematics and coordination patterns of multi-digit motion, although not always quantified or defined as synergies in a lower dimensional space, have also been examined in terms of the temporal evolution of hand shape during reach-to-grasp as a function of object geometry (Santello and Soechting, 1998), sudden changes of either object shape (Ansuini et al., 2008), gravitational conditions (Micera et al., 2002), task in healthy subjects (Mason et al., 2001; Ansuini et al., 2006, 2008) and neurologically impaired individuals (Schettino et al., 2004, 2006, 2009; Ansuini et al., 2010), and sensory feedback in humans (Santello et al., 2002; Schettino et al., 2003; Winges et al., 2003) and non-human primates (Mason et al., 2004; Theverapperuma et al., 2006). These studies have characterized tendencies in task and/or sensory modality-specific kinematic coordination patterns. For example, it has been shown that online visual feedback of the hand and/or object are not necessary for whole-hand shaping to object geometry (Santello et al., 2002; Mason et al., 2004) but it might nevertheless be used to modulate finger motion in the late portion of the reach (Schettino et al., 2003). Another important observation is that the temporal evolution of hand posture to object shape in monkeys occurs through a stereotypical temporal coordination of finger motion superimposed on a movement amplitude scaling (Theverapperuma et al., 2006). More recently, dimensionality reduction in hand control has been described during bimanual grasping (Vinjamuri et al., 2008) and while learning cursor control through finger movements (Vinjamuri et al., 2009). These authors have also used PCA and SVD analyses to characterize digit joint velocities of grasping movements performed at natural (Vinjamuri et al., 2007) and fast speed (Vinjamuri et al., 2010a,b).

In summary, all these studies of hand kinematics point to the same, main conclusion: the dimensionality of the kinematic space of a large repertoire of hand behaviors is significantly smaller than that defined by the number of the hand's mechanical DoFs.

FORCE SYNERGIES

Grasping can be defined as holding an object stationary within the hand[1]. Precision grasps predominantly involve the fingertips while power grasps usually involve contact with more extended parts of the hand such as the palm. Grasp planning requires that one selects a grasp (e.g., whether to use a precision or power grasp) as well as the position of the contact points on the object for a particular grasp. In precision grasps, the position of the fingertips on the object plays an important role in determining the net force/torque that can be produced. It should be noted that some choices might be incompatible with the task constraints. For example, it might be impossible to use a pinch grasp to lift a very slippery object. Alternatively, multiple grasps may be compatible with task demands. Finally, some choices might lead to desirable properties of the grasp. For example, force closure ensures that it is possible to produce an arbitrary net force and/or torque while form closure ensures a stable grasp in the absence of friction forces (Bicchi et al., 2011).

Once a contact is established, a precise control of the contact forces with the object and/or net force is necessary in order to be able to perform any skilled manipulation. For example, when holding an object immobile in the air, the net force must balance exactly the gravitational force. Similarly, the use of most tools requires a precise control of interaction forces. While a complete mechanical analysis of the finger forces during this phase is outside the scope of this review (see **Inset 1**), task and frictional constraints do not, in general, fully specify the contact forces. In other words, from a control point of view, there is usually an infinite number of ways of setting the contact forces that are compatible with all constraints (Murray et al., 1994; Li et al., 1998; Zatsiorsky et al., 2003a).

The extent to which the CNS can control finger forces independently has been studied in multi-finger pressing tasks where one must produce force by pressing on a surface with one or more fingers. In these studies, a sensor measured the force produced by each finger while subjects were instructed to produce certain levels of force. A common observation is that all fingers produced forces even when the participant was instructed to apply a force with only one finger (Li et al., 1998; Reilly and Hammond, 2000, 2004; Zatsiorsky et al., 2000). This phenomenon, called *enslaving*, is in agreement with the observation that it is difficult to move one finger without moving the others [Kilbreath and Gandevia, 1994; Hager-Ross and Schieber, 2000; Lang and Schieber, 2003; Kim et al., 2008; see above *Kinematic Synergies* section].

In tasks involving grasping, lifting, and holding an object against gravity with five digits, the variations of the contact forces while holding an object have also been analyzed to understand the spatial and temporal coordination of multi-digit forces. For example, Santello and Soechting (2000) described consistent in-phase relations between pairs of digit normal forces. These coordination patterns, also found regardless of hand dominance or object property predictability (Rearick and Santello, 2002), could theoretically be dismissed as a by-product of biomechanical factors constraining the temporal relations among digit forces. However, a subsequent study revealed these patterns to be task-dependent as they disappear when the same forces are applied to the object resting on a table as opposed to being held against gravity (Rearick et al., 2003). These findings suggest an active, neural component compensating for temporal fluctuations in multi-digit forces to satisfy the above-described constraints of mechanical equilibrium.

[1] In-hand manipulation of objects are not reviewed here as they have not been studied to the same extent.

Inset 1 | Task constraints and degrees of freedom in the control of contact forces.

Force synergies reflect coordination patterns at the level of the contact forces. This inset gives an overview of the contact forces involved in precision grasps in order to clarify the parameters that need to be controlled and the task constraints that act at this level. Contacts in precision grasps involve small areas of the hand such as the fingertips and can be modeled as a force applied at a point on the object together with a moment along the normal of the contact surface [the so-called *soft finger model*, (Murray et al., 1994)]. According to this model, four parameters are needed to describe each contact. More complex models accounting for the geometry and/or compliance of the finger pads have been developed in robotics but are outside the scope of this article as they are rarely used to analyze human grasps.

When grasping and manipulating an object, *task constraints* define the net force and moment. For example, when holding an object immobile in the air, the net force must oppose the gravitational force and the net moment must be 0. To satisfy these constraints, the contact forces must satisfy *equilibrium equations* that relate the finger forces to the net force and moment. In addition, each contact force must also satisfy a *frictional constraint* which specifies that the normal force (i.e., the force component perpendicular to the contact surface) must be larger than the tangential force (i.e., the force component parallel to the contact surface) divided by the coefficient of friction of the contact surface to avoid a slip of the finger. Geometrically, this constraint states that the contact force must be in the so-called friction cone, the aperture of which depends on coefficient of friction of the surface (see **Figure 2**). Often, this constraint implies that one must squeeze the object with more force to increase the normal forces when the load (i.e., the tangential force) increases.

In the analysis of contact forces, the complexity of the control task is often defined in terms of the number of redundant DoFs, i.e., the number of DoFs that are not constrained by the task. In general, the number of redundant DoFs increases with the number of digits involved in the grasp. For example, in precision grasps where the structure of the hand allows control of the direction and magnitude of the force at each fingertip independently, there are at least 3 redundant DoFs in a tripod grasp (left panel of **Figure 2**) and 9 redundant DoFs in a five-digit grasp. This high degree of redundancy raises the question of how the brain selects one solution among all possible ones (Bernstein, 1967).

Counting the number of degrees of freedom is not without difficulties however (see also Introduction). In the analysis of force synergies, the number of DoFs of the grasp is often defined as the total number of parameters needed to specify the contact forces. However, this definition assumes that all parameters can be controlled independently, which is not always the case. For example, when a finger makes two contacts with an object, it is impossible to control the direction and magnitude of the two contact forces independently. Similarly, when holding a pen, the structure of the hand does not afford control of the contact force between the pen and the palm independent from the contact force between the fingertips and the pen (see right panel of **Figure 2**). In these cases, a more complex analysis of the structure of the hand is necessary to identify the effective number of DoFs.

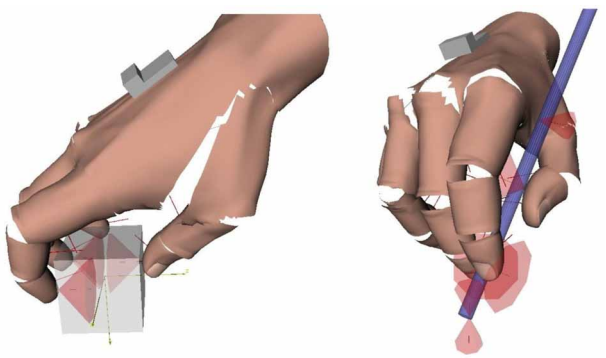

FIGURE 2 | Contacts in precision grasps. Left: example of multi-digit (tripod) grasp invovling only contacts with the fingertips. Contacts are represented by their friction cones. **Right**: hand-object contacts in the pen grasp. The friction cones at the extremity of the pen represent the contact with the table. The computation of the contacts and graphical rendering was done with Grasp-It, an open-source software dedicated to the analysis of grasps (Miller and Allen, 2004).

A striking observation in force production and grasping tasks is the high amount of inter-trial variability present in these tasks. For example, in multi-finger force production tasks where the total force is constrained, the normal forces produced by each finger vary much more than the total force (Latash et al., 2001). In these tasks, fingers clearly act synergistically to produce a stable performance.

HIERARCHICAL CONTROL OF CONTACT FORCES

To explain force synergies observed in grasping, a general idea is that contact forces are controlled hierarchically. In other words, higher-level constraints might impose coordination patterns between the contact forces.

Latash and collaborators have proposed that the variables controlled by the CNS are not the individual finger forces but the *force modes*, i.e., force patterns distributed across fingers reflecting the enslaving phenomenon in force or grasping tasks (Danion et al., 2003). Their analysis focused on the normal component of the contact forces and they assumed the existence of five force modes, one per finger. The instruction of pressing against a surface with only one finger would presumably activate one mode that primarily controls the instructed finger. Different force patterns required in other tasks would be obtained by activating simultaneously two or more force modes. Follow-up studies extended this idea to various grasping tasks (Zatsiorsky et al., 2003b). Conceptually, the force modes correspond to a re-parameterization of the finger force parameters but it is not clear whether they actually reduce the number of parameters that the CNS needs to control. Moreover, a comparison between the results obtained from the same individuals in pressing and grasping tasks showed that force modes could be both task-specific (Olafsdottir et al., 2005) and subject-dependent (Gao et al., 2003). This flexibility, however, raises the question of whether controlling an alternative set of variables (the force modes) to control contact forces is actually simpler than controlling contact forces directly. Therefore, one might as well look for multi-digit synergies not at the level

of force modes, but at the level of the components of the contact forces themselves [(Latash, 2008), p. 207].

The analysis of the variability in motor tasks by the same group of researchers led them to formulate the *uncontrolled manifold (UCM) hypothesis,* which they have used to discover and quantify synergies (Scholz and Schoner, 1999; Scholz et al., 2003; Kang et al., 2004). The hierarchical nature of the UCM hypothesis is reflected in the distinction between *elemental* and *performance* variables. Elemental variables are loosely defined as related to the parts of the system (e.g., components of the contact forces) while performance variables are related to the task (e.g., production of a given total force across multiple digits). This classification is central to establishing another distinction between the so-called bad variance (VB), i.e., variability of the elemental variables that would lead to a loss of precision in the task, and good variance (VG), i.e., variability of elemental variables that would compensate each other and thus not affect the performance. A large ratio VG/VB would be the sign of a strong synergy while a smaller ratio would correspond to a weak synergy.

Another proposal to explain the observed coupling between finger forces is the *virtual finger (VF) hypothesis*. This hypothesis proposes that the brain controls the position and force of one or more VFs at a higher level of the control hierarchy (Iberall et al., 1986; Baud-Bovy and Soechting, 2001; Shim et al., 2003; Zatsiorsky et al., 2003b; Smith and Soechting, 2005). At a lower level, the forces produced by the physical fingers would be coordinated to match the constraints induced by the VF(s). Unlike the force mode hypothesis, the VF hypothesis does not determine a fixed pattern of covariation between the contact forces because the constraints induced by the VF(s) still leave redundant DoFs in the grasp. For example, the VF hypothesis in the tripod grasp can account for the coupling between contact forces of the index and middle fingers, but does not fully specify their directions, which might be optimized to increase the stability of the grasp as a function of object shape (Baud-Bovy and Soechting, 2001).

One issue with hierarchical control schemes is that higher-level constraints do not in general specify all parameters at the lower level, which raises the question of how remaining parameters are selected (see **inset 1**). One partial answer is that these parameters might be selected so as to maximize the stability and efficiency of the grasp. More generally, the core idea of optimal control is that behavior reflects the optimum of some cost function (Todorov and Jordan, 2002; Todorov, 2004). In the context of grasping, this general framework has been used to explain both how a set of contact positions (Friedman and Flash, 2007; Lukos et al., 2007, 2008; Ciocarlie et al., 2009; Fu et al., 2010, 2011; Craje et al., 2011; Gilster et al., 2012) and contact forces (Hershkovitz et al., 1997; Chalfoun et al., 2004; Pataky et al., 2004; Baud-Bovy et al., 2005; Niu et al., 2009; Terekhov et al., 2010) are selected. However, a problem with this framework is that it does not explain how the optimal solution might be actually computed in a biologically plausible manner.

Another possibility might be that the CNS does not control all parameters of the grasp (e.g., contact forces, finger positions, net force, and torque). Actually, this might be excessively difficult to do because it would require the CNS to have an inverse model of the complex biomechanical structure of the hand in order to activate the muscles to obtain a very specific level of force at each contact point to satisfy the equilibrium equations. Instead, the CNS might rely on the compliance of the fingers to balance the contact and external forces. In this case, the coordination patterns observed between the contact forces could reflect both the passive properties of the hand-holding-an-object system and the active contribution of the CNS (Ostry and Feldman, 2003; Winges et al., 2007; Gabiccini et al., 2011). Recent work has been conducted to re-interpret multi-digit synergies in the framework of the equilibrium point hypothesis (Pilon et al., 2007; Latash et al., 2010).

MUSCLE SYNERGIES

The hypothesis that movements are generated by combining a small group of muscles has been extensively studied since the early observations of Sherrington (1910) on the wide range of reflex-mediated movement patterns in the cat. These combinations are generally referred to as "muscle synergies" [for recent reviews, see Ting and McKay (2007), Tresch and Jarc (2009)]. Whereas the number of muscles acting around one or more joints is finite, the number of muscle synergies can theoretically be very large when considering modulation of the timing at which muscles can be activated relative to each other and/or the number of motor units that can be recruited in a given muscle. The timing of muscle and motor unit activation is best measured by direct recordings of their activity through electromyographic (EMG) recordings.

EMG AND THE STUDY OF MUSCLE SYNERGIES IN THE HAND

EMG has been extensively used as a tool to study the spatial and temporal coordination of multiple muscles. The characteristics of the EMG signals recorded from active muscles, e.g., its magnitude, frequency content, and/or timing, all reflect the net output of the interactions of neural inputs to the spinal alpha-motorneurons (alpha-MNs). Therefore, EMG signals recorded from muscle fibers innervated by the motor nuclei of hand muscles have been studied to determine the organization and plasticity of the neural drive responsible for coordinating multiple hand muscles during individual finger movements or multi-digit movements, e.g., grasping and manipulation.

The divergence of inputs to motor units of hand muscles has been quantified by measuring temporal and/or frequency correlations in EMG signals (motor-unit synchrony and coherence, respectively) at the single unit level or as multi-unit interference EMG [for review see Santello (in press)], as well as by measuring correlations in the magnitude of EMG signals across muscles acting on one (e.g., Valero-Cuevas et al., 1998; Valero-Cuevas, 2000), or two digits during force production (Maier and Hepp-Reymond, 1995), and three digits during object hold (Danna-Dos Santos et al., 2010; Poston et al., 2010). The existence of these correlations is interpreted as denoting common inputs to hand motor nuclei, and therefore could be considered as a manifestation of "building blocks" of muscle synergies. Correlations in EMG amplitude of hand muscles, quantified through PC analysis, have also been described for whole-hand grasping (Weiss and Flanders, 2004) as well as for tasks that do not involve contact forces, e.g., finger spelling (Weiss and Flanders, 2004; Klein Breteler et al., 2007). In non-human primate models, covariation

in EMG amplitude of hand muscles has been described when reaching to grasp objects with different shapes (Brochier et al., 2004). A recent study provided further evidence for muscle synergies in a non-human primate model by revealing the existence of a small number of EMG synergies that could capture the variance of EMG activity patterns elicited by grasping objects of variable shapes and sizes (Overduin et al., 2008). A follow-up study further revealed that similar postures could be elicited by electrical microstimulation to motor cortical areas (Overduin et al., 2012).

Human studies using analyses of EMGs from all muscles inserting on the index finger during force production in different directions revealed that the variance-per-dimension (one for each of the 7 muscles) was smaller in the task-relevant subspace than in the task-irrelevant subspace (Valero-Cuevas et al., 2009). This finding supports the "principle of minimum intervention" or optimal sensorimotor control (Todorov and Jordan, 2002; Todorov, 2004), hence compatible with the earlier framework of synergies proposed by Bernstein (1967) (see also above-discussed uncontrolled manifold hypothesis). However, the non-negligible variance in all seven dimensions was also interpreted as evidence against the framework of muscle activation as resulting from the combination of a small set of synergies. A recent study further revealed that EMG amplitude of intrinsic muscles is modulated in tandem with that of extrinsic muscles when holding an object at different wrist angles, even though wrist posture changes the length and moment arm of extrinsic muscles only (Johnston et al., 2010a). The mechanisms underlying these covariations and the cost function(s) being minimized through these coordination patterns remain to be understood. Nevertheless, these findings indicate that the CNS consistently exploits a small set of solutions (motor commands) among many equally valid ones. The question of the extent to which the above-described covariation patterns of EMG amplitudes can be flexibly modulated to task conditions or, conversely, reflect relatively rigid neural constraints, is addressed in the Discussion.

INTERPRETATION OF SYNERGIES IN EMG RECORDINGS

When examining the activity of concurrently active motor units, the nature of these common inputs can be further distinguished depending on the lags between action potentials, near-synchronous discharges being indicative of shared inputs from branched axons of single last-order neurons (short-term synchrony) and longer lags denoting synchrony of separate presynaptic inputs to the alpha-MNs (Kirkwood, 1979). Inferences about the mechanisms responsible for coherence between spike trains of motor units (EMG-EMG coherence) can be made based on the range of frequencies across which significant correlations occurs [i.e., periodic or non-periodic inputs; (Halliday and Rosenberg, 2000; Taylor and Enoka, 2004)], coherence strength (e.g., Johnston et al., 2005, 2010b; Winges et al., 2006), as well as by quantifying the relation between motor-unit synchrony and coherence (e.g., Semmler et al., 2003; Johnston et al., 2005) [for review, see Grosse et al. (2002)]. Motor-unit synchrony has been reported to occur both within and across muscle compartments of finger flexor muscles (i.e., Hockensmith et al., 2005; Winges et al., 2008) and extensor muscles (Keen and Fuglevand, 2004). Furthermore, in static grasp tasks involving multi-digit force coordination, e.g., object hold, it has been found that common neural input is heterogeneously distributed across hand muscles. Specifically, extrinsic hand muscles (e.g., long flexors of the fingers) tend to receive stronger common input than intrinsic hand muscles (Winges and Santello, 2004; Johnston et al., 2005; Danna-Dos Santos et al., 2010; Poston et al., 2010).

It should be noted that alpha-MNs are very large neurons, receiving thousands of synaptic inputs on their dendritic tree. Individual synaptic inputs generally have an amplitude of 0.1 mV or less (Asanuma et al., 1979), meaning that the effect of inputs from a single afferent neuron is normally negligible. It follows that synergistic muscle activation requires that the corresponding alpha-MNs share direct inputs from corticospinal tract neurons as well as indirect inputs through a relatively large number of spinal premotor neurons and that these inputs are activated in a concerted fashion (**Figure 3**). Due to the huge number of synaptic inputs to alpha-MNs and the stochastic properties of the spike firing in alpha-MNs (Moritz et al., 2005), it is difficult to establish the exact mechanisms underlying the moderate strength of synchrony across motor units of different hand muscles, or the difference in the extent of across-motor unit synchrony between long finger flexors and intrinsic muscles such as first dorsal interosseus and first palmar interosseus (Winges et al., 2008). Specifically, EMG recordings can only capture the *net* effect of excitatory and inhibitory inputs, while precluding a clear distinction between these two types of inputs. However, interestingly, synchronized discharge in alpha-MNs, at frequencies which are not present in the excitatory input signal to these neurons, may be generated for example by Renshaw inhibitory interneurons (Williams and Baker, 2009) or possibly other types of spinal inhibitory interneurons driven by Ia afferents (Jankowska, 1992).

NEURAL SYNERGIES

In the previous sections, we have presented numerous behavioral and physiological observations indicating that the CNS operates in terms of synergy control with respect to the coordination of multi-digit movements and forces. Do the properties of the underlying neuronal circuitry support this notion? Whereas it is indisputable that activation of a given hand muscle generates torque across more than one joint through multi-joint tendons and passive linkages, it is less well-appreciated that in terms of neural control, activation of hand muscle synergies essentially seems to be an inevitable consequence of the known neural connectivity patterns. As we will present below, given that the "infrastructure" of the neuronal connectivity defines the lower bound of what can be achieved in terms of individuated muscle control, it is very difficult to see how the brain could possibly control the hand on a muscle-per-muscle basis.

ARRANGEMENT OF HAND MOTOR NUCLEI IN THE SPINAL CORD vs. NEURONAL CONNECTIVITY

An important indicator of the nature of the neural control of the hand is the anatomical distribution of the motor nuclei innervating hand muscles. In a system in which there is a point-to-point innervation of single muscles, one would expect that the motor nuclei of individual muscles would lie separated in the nervous tissue, similar to the oculomotor nuclei in the brain stem.

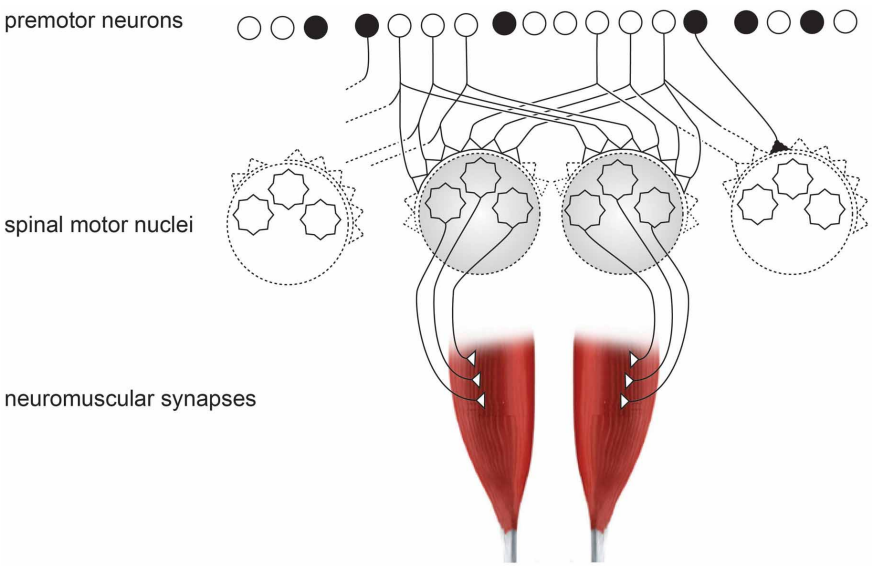

FIGURE 3 | Schematic organization of neural inputs from premotor neurons to spinal motor nuclei of two hand muscles. Black neuron represents the inhibitory interneurons, which exist in high numbers.

Conversely, in a system in which multiple muscles as a rule are controlled as synergies, the motor nuclei would be expected to lie closely spaced, perhaps even partly overlapping. A relatively complete study of the distribution of hand muscle motor nuclei exists only for the cat (Fritz et al., 1986a,b) but the general findings seem applicable also to the monkey (Jenny and Inukai, 1983). These studies clearly show that the motor nuclei of individual hand muscles are extremely narrow in the transverse plane (i.e., in the cross-section plane of the spinal cord where the motor nuclei are only 2–4 alpha-MNs across) and that the alpha-MNs of different hand muscles are densely packed with the dendrites of the neurons partly extending into the adjacent nuclei containing the alpha-MNs of other muscles. In the longitudinal plane, these motor nuclei form extremely elongated structures, with a substantial overlap in the rostrocaudal extent of the different motor nuclei (Fritz et al., 1986a,b). Considering the wide distribution of the termination territories of single premotor axons (corticospinal and spinal interneurons) in both cat and monkey (Shinoda et al., 1979, 1981; Jankowska, 1992) in the transverse plane, the anatomical structure of the neuronal network seems to be a construct that would promote synergy control.

DIVERGENT CONNECTIVITY IN MOTOR PATHWAYS SUPPORTS SYNERGY CONTROL

In addition to having a divergent innervation to target numerous alpha-MN pools (Shinoda et al., 1981), the majority of the corticospinal terminations in primates are made inside the population of spinal premotor interneurons in laminae VI–VIII (Bortoff and Strick, 1993), where they may be expected to primarily target spinal interneurons. Furthermore, the spinal interneurons of both cat and monkey branch in their innervation of the alpha-MN pools (Jankowska, 1992; Perlmutter et al., 1998; Takei and Seki, 2008, 2010) and hence may add an additional divergence factor on top of the divergent corticospinal terminations (Cheney et al., 1985). Although direct corticomotoneuronal connections have been the focus in the literature of hand muscle control, it is clear that indirect effects, presumably by way of the spinal interneurons, dominate the muscle activation from a single motor cortex cell (Schieber and Rivlis, 2007). In primates, although monosynaptic corticomotoneuronal effects are evident in alpha-MN, indirect effects mediated via the spinal interneurons can be more powerful (Isa et al., 2006, 2007; Alstermark et al., 2007, 2011). Furthermore, the neurons contacting individual hand muscles have a wide distribution across the motor cortex, which heavily overlaps the distributions of neurons controlling other hand muscles (Rathelot and Strick, 2006).

SPINAL PREMOTOR MACHINERY—EMBEDDED MOTOR FUNCTIONS AND SYNERGY CONTROL

Much of the literature on neural control of hand movements typically takes its origin in the motor cortex. However, the field of motor cortex research, which has focused on finding correlations between motor cortex neuron discharge and physical parameters of the movement controlled, has failed to reach a consensus of what the functions of the individual neurons are. A possible caveat, which may explain why no consistent pictures have emerged, is that perhaps the neural code in motor cortex does not code for any physical parameter directly, but may rather be a compound code to be deciphered by the downstream neurons in the target region of the spinal cord.

Even for the simplest hand movements, neurons distributed over a large part of the motor cortex are activated (see for example, Schieber and Hibbard, 1993; Georgopoulos et al., 2007) and a single neuron is typically found to be engaged in a wide variety of movement types (Schieber and Hibbard, 1993; Poliakov and Schieber, 1998, 1999; Schieber and Rivlis, 2007). One interpretation of these findings is that in order to generate a movement, the motor cortex needs to control a large proportion of the spinal

interneuron pool, which determines the excitability level of most or all of the alpha-MNs innervating the muscles within the arm and hand. Since spinal premotor neurons are strongly driven by peripheral feedback from Ia muscle afferents, Ib tendon organ afferents, and skin sensor afferents (Jankowska, 1992), they cannot be left uncontrolled during any movement or any phase of the movement since the outcome in terms of alpha-MN activation may be unpredictable. By allowing high excitability in *some* interneurons, these types of sensory feedback can instead be utilized by the CNS to become an integral part of the motor command, since the feedback during a given type of movement will become quite predictable as a specific movement pattern is established.

Interestingly, spinal premotor neurons, in addition to innervating alpha-MN nuclei, as a rule have a recurrent axon collateral that either go all the way up to the lateral reticular nucleus for transmission to the cerebellum as mossy fibers (Clendenin et al., 1974a,b; Alstermark et al., 1981; Ekerot, 1990) [including spinal neurons below the C3–C4 segments (Ekerot, 1990)], or to a local projection neuron that issues ascending axons that directly issue mossy fibers to the cerebellum (Oscarsson, 1973; Mrowczynski et al., 2001). This gives the cerebellum direct information about the involvement of the spinal premotor pool. Since it is likely that these premotor neurons are involved in the selection of local motor programs (Grillner, 2003) and thereby synergies, the cerebellum will also be informed about the synergies employed. Whether the implication is that the cerebellum has a role in the learning of muscle synergies is an interesting issue for future studies.

Detailed functional analysis indicates that the spinal cord is to be regarded as a full motor system in its own right (Raphael et al., 2010; Arber, 2012) and its circuitry can play a pivotal role in hand dexterity (Kinoshita et al., 2012). By using the spinal interneuron system, descending motor commands can act on a complex neuronal machinery that comes with a number of features that can facilitate motor control of the complex structure of the extremities. In line with this view, spinal interneurons are activated in advance of onset of movement and alpha-MN activation (Maier et al., 1998; Perlmutter et al., 1998; Prut and Fetz, 1999; Fetz et al., 2002), which can be interpreted as a step to set up the dynamics of this circuitry in advance of the start of the movement. By using the dynamics of the subcortical circuitry the motor cortex could be relieved of solving control issues at a high level of detail. An essential part of this semi-automatic control system is the peripheral feedback from the various sensors of the muscles, joints, and skin. However, although the spinal cord neuronal circuitry has been extensively studied (Jankowska, 1992; Kitazawa et al., 1993; Hultborn, 2001), the complexity of this network has so far prevented us from obtaining a detailed picture of its complete structure in terms of connectivity and function. This remains an important outstanding question for future research on brain synergy control.

DISCUSSION

The many DoFs of the hand combined with its dexterity and versatility would suggest that the hand must be exceedingly complex to control. On the other hand, as seen in the previous sections, the analysis of the movement of the hand and contact forces has revealed that the DoFs of the hand are typically correlated at every level of description. It should be noted that it is often possible to reduce the observed behavior to the combination of a few basic patterns (see Kinematic and Force Synergies sections). Similarly, the analysis of muscular activities has shown evidence of a common drive between motor units of different muscles. Altogether, these observations indicate that synergy control is a pervasive element of hand function.

However, it should be noted that, in the literature, synergies have been defined in ways that reflect the level at which analysis is performed, even though all definitions point to a reduction in the dimensionality of the control space. Specifically, at the *kinematic level* synergies have been defined as covariation patterns among digit joints during reach-to-grasp and manipulation tasks. At the *kinetic level*, synergies denote coordination patterns among digit forces that are thought to minimize given cost functions. At the *neural level*, synergies consist of common divergent inputs to multiple neurons.

In this section, we propose a control scheme where the spinal circuitry would play a central role in explaining the observed coordination patterns. This proposed scheme could also explain a long-standing question in biology about whether synergies are flexible or fixed. Even during simple hand movements, cortical activation involves large parts of hand motor areas in the primary motor cortex, which via divergent direct and indirect connections would result in excitatory drive to a large proportion, most likely all, of the alpha-MNs innervating all the muscles of the lower arm. However, for any given alpha-MN, the output activity depends on the balance of excitatory and inhibitory inputs from the premotor neurons. As a consequence, inhibitory spinal premotor neurons, the only element providing synaptic inhibition to alpha-MNs, may play a key role in the actual selection of the muscles that will *not* be activated.

Overall, the pool of premotor neurons seems to include all the necessary circuitry to function as a dynamical system endowed with one or, possibly, several stable states corresponding to specific patterns of muscle activation or synergies. **Figure 4** provides a schematic representation of this theoretical framework, where the descending motor commands would control the dynamics of the system by controlling the shape of its potential function. We do not argue that the dynamics of the pool of premotor neurons can always be adequately represented by a potential function but this example is used here because it is sufficient to describe the concept of synergies as we conceive it. According to this view, a synergy corresponds to a pattern of muscle activation (**Figure 4A**). The number of premotor neurons and motor nuclei involved in a synergy might vary (**Figure 4B**). For example, the coordination of contact forces between five digits might require that a larger number of motor nuclei are coordinated together. This view is also compatible with the concept of motor primitives, which could correspond to a set of synergies that are simultaneously activated to control the hand. In this case, separate sub-pools of premotor neurons would form distinct dynamical systems that could each determine a specific muscle activation pattern or motor primitive (**Figure 4C**). The convergent input of these pools of excitatory and inhibitory premotor neurons

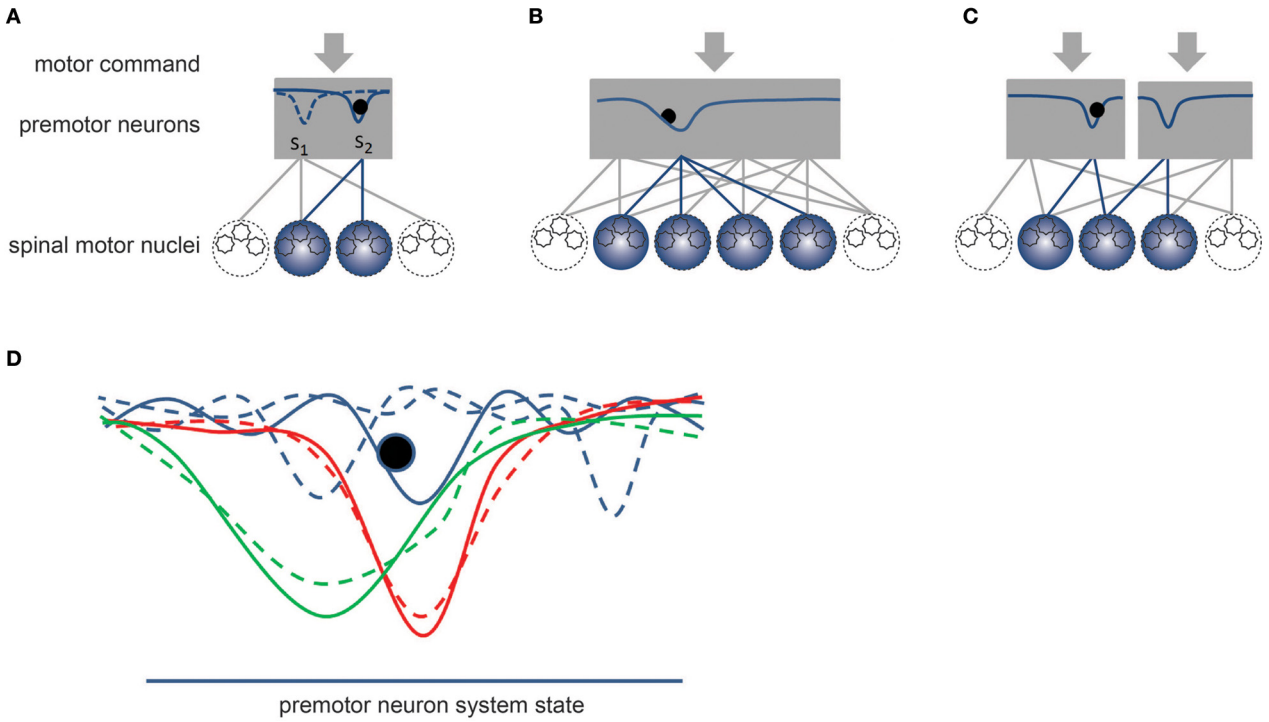

FIGURE 4 | Schematic representation of synergies. The gray rectangles represent the dynamic system formed by pools of premotor neurons. By definition, a synergy would correspond to a stable state of the dynamical system. **(A)** The solid curve within the rectangle represents the potential field of the system, which is controlled by the descending motor commands. The dashed curve corresponds to another potential field that might be established by a different set of motor commands. Once a synergy is enabled, the current state (black sphere) of the system converges toward the stable state of the system, which establishes a specific coordination pattern or synergy between the alpha-MNs belonging to different motor nuclei. **(B)** Example of a synergy involving a larger number of spinal motor nuclei. **(C)** Example of compartmentalization of premotor neuronal pool allowing for the simultaneous activation of several synergies. The divergent connections from premotor to alpha-MNs combine together the contributions of these pools. **(D)** Effect of learning. Blue curves represent a set of unstable strategies. A slight variation in the motor commands could easily change the dynamic of the system (see dashed curves). The red and green curves represent two stable synergies, in which the impact on the system dynamics of small variations of the motor commands is smaller (dashed curves). A narrow valley (red curve) would correspond to a fixed synergy while a wider valley (green curve) would correspond to a more flexible synergy.

would summate in the alpha-MNs of the different muscles, hence determining the pattern of muscle activation (see also **Figure 3**). This scheme might allow the CNS to control hand muscle activation by combining together various activation patterns (see the above-discussed force mode hypothesis and kinematic synergies).

According to this view, the degree to which a specific synergy (under a given task condition) is stable (or the degree to which it will appear fixed) may reflect the degree to which this synergy is learned in the circuitry. In absence of well-defined synergies, the dynamic of the system formed by the pool of premotor neurons would correspond to a relatively flat potential function with multiple local minima. Sensory feedback or noise could disruptively affect the state of premotor neurons and spinal motor nuclei, which would have to be precisely controlled from higher centers. Another possibility in novel situations with no pre-learned movement patterns is that subjects may resort to using and combining pre-existing synergies. In this case, poorly learned tasks may therefore be associated with a larger degree of variability in the synergy selection, but this would not necessarily imply that the processing at the premotor neuron level itself is in an unstable state.

In contrast, stable synergies would correspond to deeper valleys of the potential field (see **Figure 4D**). By definition, these deeper and possibly wider valleys make it less likely that the system will exit from this stable state. Interestingly, it might be possible to relate the degree of flexibility of a synergy to the width of the valley: a narrow valley would correspond to fixed synergy while a wider valley might correspond to a more flexible synergy. A narrow valley would result in a more rigid coordination pattern, less susceptible to disruptions or noise, thereby appearing fixed. In contrast, the state of the system and, therefore, the coordination pattern of a flexible synergy might fluctuate as a result of sensory feedback. In particular, a wide valley synergy might accommodate in a flexible manner perturbations or unexpected events such as grasping a bigger than expected object or an object slip during manipulation.

If the spinal interneuron pool is involved in the synergy formation mechanism, the types and patterns of sensory feedback may strongly influence the synergy. Spinal premotor neurons in many cases receive monosynaptic feedback from peripheral sensors and hence provide a very fast pathway for sensory feedback to affect the selection of activated alpha-MNs with short temporal delays.

The strong drive provided by sensory feedback cannot be ignored by the higher centers that control the dynamic of the spinal circuitry underlying the formation of synergies. It is conceivable that the higher centers might set up the dynamic of this system in such a manner as to switch the motor output or the coordination pattern when some external event happens. For example, such mechanisms could be used to control the various phases of a lift in an automated manner (Johansson and Flanagan, 2009).

According to the ideas presented in this discussion, the direct corticomotoneuronal connections provided by some of the layer V neurons (i.e., the monosynaptic connections from the motor cortex to the alpha-MNs) would have almost no part in the formation of hand synergies because these connections do not influence directly the circuitry formed by the spinal premotor neurons. They also lack the inhibitory component which is necessary to prevent their widely divergent excitatory connections from resulting in the inadvertent activation of all hand muscles. This view, however, does not negate that these well-documented connections play an important role in the control of the hand. This role might include, for example, a direct control of the hand movement when hand synergies are absent or not activated. These connections could also allow the cortex to control or modulate the effect of hand synergies by applying a bias to specific finger muscles when necessary. However, due to the divergence also of the direct corticomotoneuronal connections, this role, too, may be exerted in a synergistic fashion (Shinoda et al., 1979, 1981; Fetz and Cheney, 1980; Cheney and Fetz, 1985; Cheney et al., 1985; Buys et al., 1986; Lemon and Mantel, 1989; Bennett and Lemon, 1994; McKiernan et al., 1998; Rathelot and Strick, 2006, 2009). How cortical and spinal circuits interact in selecting and shaping hand synergies remains a major question in motor neuroscience. Nevertheless, the proposed framework capitalizes on recent developments in our understanding of the spinal machinery suggesting that the spinal circuits could explain many experimental observations about synergies as revealed by studies of hand kinematics, kinetics, and EMG. Note that our framework incorporates the notion of variable time shifts of individual synergies that is central to the notion of "time-varying" synergies [for review see Bizzi et al. (2008)]. Specifically, in our proposal, shifts in the temporal relation among synergies would result from time-varying interactions between cortical inputs to pre-motor neurons and afferent signals from the periphery.

If one accepts this view of synergy control, a number of interesting consequences unfold.

First, for a synergy which is often used, the premotor circuitry could adapt in a way that allows a fairly wide range of spatiotemporal patterns in the motor commands and still produce the same synergy. Compatible with this notion is the effect that cortical microstimulation in various places in the motor cortex of the monkey, which would be expected to evoke a large variety of spatiotemporal patterns in the corticospinal tract, evokes just a handful of synergies (Overduin et al., 2012). In other words, in the framework that we propose the brain might not have to control the state of the premotor and motoneurons with the same precision as it would in absence of synergies. The synergies, as already postulated by Bernstein, would greatly simplify performance of a given task by the CNS while minimizing the effects of noise from higher centers on motor output.

Secondly, with respect to the long-standing question about the degree of flexibility of synergies, the flexibility of the synergy would be related to the shape of the potential field of the dynamical system, which suggests that a whole range of possibilities exists between a deep valley (a fixed synergy) and a flat potential which would correspond to the absence of any synergy. This scheme also allows for the possibility that synergies could be fixed along some directions and flexible along other ones (for example, see the unconstrained manifold hypothesis).

Admittedly, this view is still more of a framework than a detailed model. Nonetheless, it clarifies the respective roles that the spinal circuitry, motor commands, sensory feedback, and learning could play in the formation of synergies. This theoretical framework remains to be thoroughly tested in experiments. In particular, numerous proposed circuitry mechanisms in brain synergy control remain almost completely unexplored. Altogether, these considerations point to the need for designing complementary behavioral, neurophysiological, and modeling studies to more conclusively demonstrate the interplay among the above factors underlying the modulation of synergies.

Controlling the movement of the arm to achieve a goal, such as reaching for an object, is challenging because it requires coordinating many muscles acting on many joints. The central nervous system (CNS) might simplify the control of reaching by directly mapping initial states and goals into muscle activations through the combination of muscle synergies, coordinated recruitment of groups of muscles with specific activation profiles. Here we review recent results from the analysis of reaching muscle patterns supporting such a control strategy. Muscle patterns for point-to-point movements can be reconstructed by the combination of a small number of time-varying muscle synergies, modulated in amplitude and timing according to movement directions and speeds. Moreover, the modulation and superposition of the synergies identified from point-to-point movements captures the muscle patterns underlying multi-phasic movements, such as reaching through a via-point or to a target whose location changes after movement initiation. Thus, the sequencing of time-varying muscle synergies might implement an intermittent controller which would allow the construction of complex movements from simple building blocks.

Keywords: muscle synergies, reaching movements, human, motor control, intermittency, EMG

INTRODUCTION

We perform reaching movements frequently and effortlessly, for example when eating food or using a tool. Reaching is a prototypical goal directed behavior and, as such, has been investigated extensively in human and non-human primates. Kinematic and kinetic analyses of reaching have revealed invariant features suggesting that the central nervous system (CNS) relies on simple rules for movement planning and execution. For point-to-point movements, hand paths are often roughly straight and tangential velocity is "bell-shaped" (Morasso, 1981). Moreover, paths do not change much with speed (Soechting and Lacquaniti, 1981) or load (Lacquaniti et al., 1982; Atkeson and Hollerbach, 1985). Tangential velocity profiles have the same shape when normalized for speed and distance. Moreover, shoulder and elbow motions can be quasi-linearly related to each other (Soechting and Lacquaniti, 1981; Lacquaniti et al., 1986), as are the corresponding dynamic muscle torques, i.e., the net muscle torque minus the torque required to counteract gravity (Gottlieb et al., 1997).

In contrast, the analysis of the electromyographic (EMG) activity recorded from many muscles acting on the shoulder and elbow joints has revealed complex dependencies of the shape and timing of the EMG waveforms on the movement direction and speed. For reaching in vertical planes, the EMG waveforms are constructed by combining components related to both dynamic and gravitational torques (Flanders, 1991). The waveform components responsible for the dynamic torques (phasic activations) have an intensity and timing that change with the movement direction in a complex manner: each muscle has a distinct spatial and temporal pattern, with a recruitment intensity which is maximal in multiple directions and a recruitment timing that changes gradually across directions (Flanders et al., 1994, 1996). Thus, there is an apparent discrepancy between the kinematic/kinetic regularities of reaching movements and the variability/complexity of the muscle patterns underlying their control.

The control of reaching movements requires a sensorimotor transformation of visual and proprioceptive information about the target and the initial state of the arm into the coordinated activation of many muscles acting on several joints. Because the dynamic relationships between muscle activation and joint torques and between joint torques and joint motions are complex and non-linear, the control of reaching would seem as a challenging task for the CNS (Bernstein, 1967). In robotics, if the geometrical and inertial characteristics of the arm are known or can be estimated precisely, inverse kinematics and inverse dynamics can be used to compute joint angle trajectories and joint torque commands necessary to follow a desired end-effector trajectory. Moreover, if fast sensing and actuation is available, a desired joint angle trajectory can be executed using feedback control. However, it is unlikely that the CNS performs inverse dynamics computations explicitly. Moreover, the CNS has to cope with substantial sensorimotor delays which often make feedback control insufficient. One possibility that has gained increasing support in recent years is that the CNS simplifies the control of goal directed movements by implementing

a direct mapping from the initial state of the arm and the goal into appropriate muscle activity patterns through the combination of a few muscle synergies, that is, coordinated recruitments of groups of muscles (Bizzi et al., 2002, 2008; Tresch et al., 2002; Giszter et al., 2007; Ting and McKay, 2007; d'Avella and Pai, 2010; Lacquaniti et al., 2012). Thus, muscle synergies are thought to be stable and reproducible modules organized by the CNS to take the role of "basis functions." Support for a modular control architecture has been provided in frogs (Tresch et al., 1999; Saltiel et al., 2001; d'Avella et al., 2003; Hart and Giszter, 2004, 2010; Cheung et al., 2005; d'Avella and Bizzi, 2005), cats (Ting and Macpherson, 2005; Torres-Oviedo et al., 2006), monkeys (Overduin et al., 2008, 2012), and humans (Krishnamoorthy et al., 2003; Ivanenko et al., 2004, 2005; d'Avella et al., 2006, 2008, 2011; Torres-Oviedo and Ting, 2007) by identifying a small number of muscle synergies whose combinations explain a large fraction of the variation in the muscle patterns.

Here we first review two notions of muscle synergies commonly used to model the modular organization of muscle patterns, that is, the time-invariant and time-varying muscle synergies. We then review recent results from the analysis of muscle patterns recorded during reaching movements in humans indicating that modulation and superposition of time-varying muscle synergies is a key mechanism for the control of reaching. Time-varying muscle synergies capture spatiotemporal features in the reaching muscle patterns and provide a parsimonious description of the changes of the muscle patterns across conditions, allowing to reconcile the apparent discrepancy between kinematic and kinetic regularities and muscle pattern complexity. Moreover, the superposition and sequencing of time-varying muscle synergies may underlie the intermittent control of complex, multiphasic arm movements.

MUSCLE SYNERGIES

Muscle synergies are building blocks that can be used to control a task in different conditions by selecting a small number of parameters. Synergies are building blocks because they capture a set of features in the muscle patterns that can be reused across movement conditions. In the spatial domain, i.e., across muscles, a muscle synergy captures a specific relationship in the strength of activation of a group of muscles. In the temporal domain, a synergy may capture time-invariant or time-varying relationship among muscles. Considering D muscles, a *time-invariant* synergy can be expressed as a D-dimensional vector $\mathbf{w}$ of weighting coefficients specifying the relative activation level of the muscles (**Figure 1A**). Then, a set of N synergies, $[\mathbf{w}_i]_{i=1,\ldots,N}$, can be linearly combined to generate distinct muscle patterns (**Figure 1B**):

$$\mathbf{m}(t) = \sum_{i=1}^{N} c_i(t)\,\mathbf{w}_i \qquad (1)$$

where $\mathbf{m}(t)$ is a D-dimensional vector that specifies the activation of each muscle at time t and $c_i(t)$ is the time-varying combination coefficient for the i-th synergy. Across movement conditions, either the synergies $\mathbf{w}_i$ or the activation coefficients $c_i(t)$, also referred to as temporal components (Ivanenko et al., 2004), may be invariant. A *time-varying synergy*, in contrast, is comprised by a collection of muscle waveforms that can be expressed as a time-varying vector $\mathbf{w}(t)$ (**Figure 1C**). In this case, the time dependence of the muscle activations is captured by the temporal structure of the synergies and by their onset times (t_i) and Equation 1 can be written as (**Figure 1D**) (d'Avella et al., 2003):

$$\mathbf{m}(t) = \sum_{i=1}^{N} c_i\,\mathbf{w}_i(t - t_i) \qquad (2)$$

The combination of time-varying synergies can be seen as a special case of anechoic mixture model (Omlor and Giese, 2011). Thus, time-varying synergies provide a parsimonious representation of the motor output because, once the synergies are given, a few scalar amplitude and onset coefficients are sufficient to specify the entire spatiotemporal structure of the muscle pattern. In contrast, with time-invariant synergies the full time-series of combination coefficients must be specified. When both types of synergies are extracted from the same data, the spatial organization of the time-varying synergies, given by the synergy waveforms averaged across time, closely matches the time-invariant synergies (d'Avella and Bizzi, 2005). However, a larger number of time-invariant synergies is required to capture invariant asynchronous activations across muscles (d'Avella et al., 2006).

SYNERGIES FOR FAST REACHING MOVEMENTS

The analysis of the muscle patterns for fast reaching movements in 3D revealed that the complex dependence of the muscle activation waveforms on movement direction results from the combination of 4/5 time-varying synergies (d'Avella et al., 2006). Muscle synergies were identified from the phasic muscle activation waveforms recorded from up to 19 shoulder and arm muscles during fast point-to-point movements between a central location and eight peripheral targets in both a frontal and a sagittal plane. Phasic waveforms are the components of the EMG signal related to accelerating and decelerating the arm and were computed by subtracting the tonic components responsible for balancing gravitational forces and maintaining postural stability. For each subject, an iterative optimization algorithm was used to extract sets of synergies with an increasing number of elements which minimized the average muscle pattern reconstruction error across multiple directions (d'Avella and Tresch, 2002; d'Avella et al., 2003). The number of synergies was determined, as a compromise between model parsimony and reconstruction accuracy, observing the relationship between the amount of data variation explained by the model (R^2) and the number of synergies. The optimal number of synergies was selected as the number at which the R^2 curve had a change in slope, suggesting that additional synergies only captured small residual amounts of variation attributable to noise.

Five synergies extracted in one subject (**Figure 2A**) illustrate the typical basic features. Each synergy recruits a specific subset of muscles with a similar biomechanical action (e.g., elbow flexors in the first synergy, elbow extensors in the second synergy) but each synergy involves muscles involving multiple joints (e.g., brachioradialis and trapezius superior in the first synergy), and the same muscle is often recruited by multiple synergies (e.g., medial

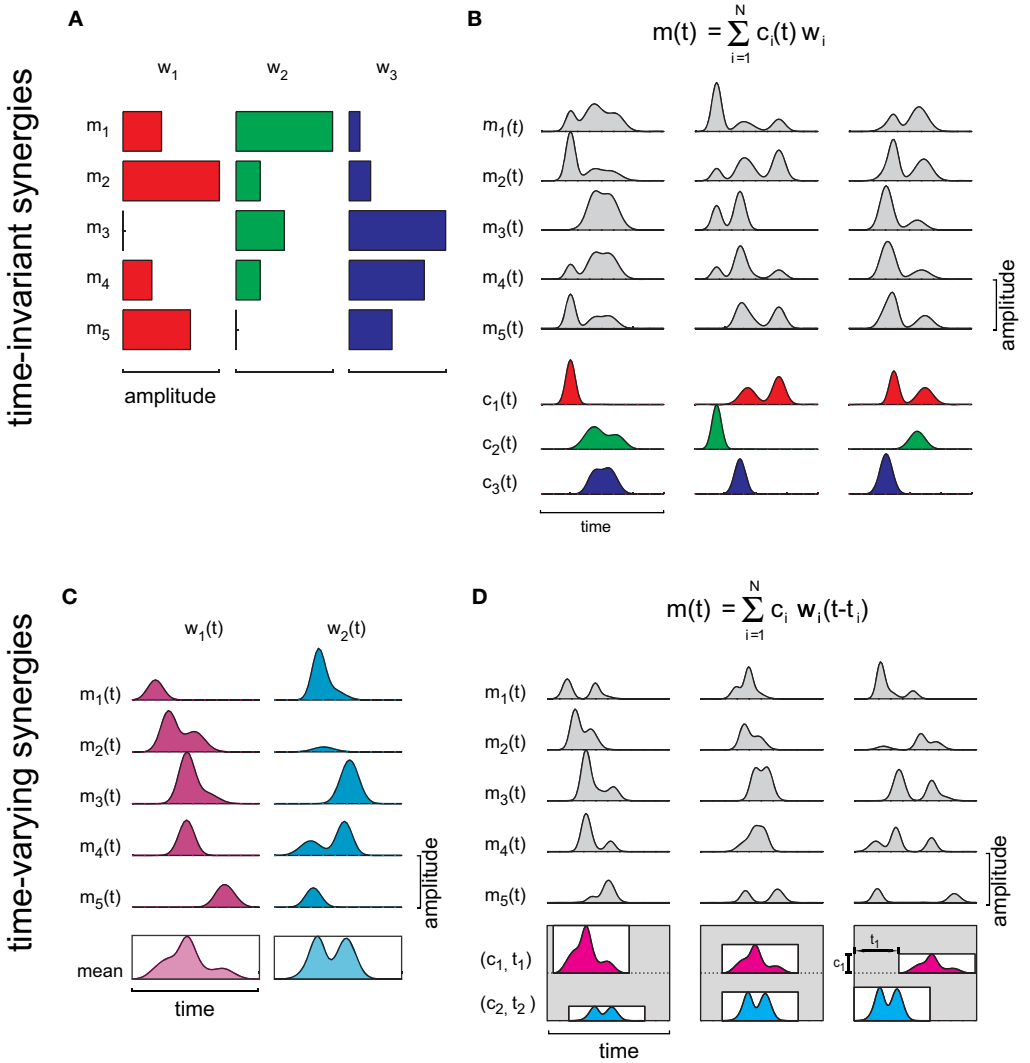

FIGURE 1 | Concept of time-invariant and time-varying synergies. **(A)** Three different activation balances among five muscles are expressed by three vectors ($\mathbf{w}_i$), whose components are represented by horizontal bars of different lengths. **(B)** A time-varying muscle pattern [$\mathbf{m}(t)$] is generated by combining the synergies with time-varying scaling coefficients [$c_i(t)$]. Different patterns can be obtained by changing the scaling coefficient waveforms. **(C)** Each one of the two time-varying synergies illustrated is composed by a collection of muscle activation waveforms. The profile inside the rectangle below each synergy represents the mean activation waveform for that synergy. **(D)** A time-varying muscle pattern [$\mathbf{m}(t)$] is generated by multiplying all waveforms of each synergy by a single scaling coefficient (c_i), shifting them in time by a single delay (t_i), and summing them together. Different patterns are obtained by changing two scaling coefficients and two delays.

deltoid in the third, fourth, and fifth synergy). The synergy waveforms show synchronous bursts of activation in many muscles as well as bi-phasic bursts (e.g., lateral head of triceps in the second synergy) and asynchronous bursts (e.g., long head of biceps in the second synergy). Some muscle waveforms have negative components, indicating an inhibitory drive that reduces the activation of that muscle due to excitatory drive from other synergies or tonic components.

The reconstruction of the muscle patterns by synergy combination for movements in different directions occurs by recruiting the synergies with different amplitude and at different times (**Figure 2B**). For example, the muscle patterns for a forward movement (*first column*) are generated by recruiting the second plus the third synergy, and the fourth synergy with smaller amplitude and later in time. The second and the third synergies are also recruited in a downward movement (*fourth column*), but with a different balance of activation and a different relative timing. Thus, different muscle patterns underlying reaching movements with different kinematics are captured by selecting a small number of parameters.

Plotting the dependence of the synergy amplitude coefficients on the movement direction in a polar plot (**Figure 2C**) clearly shows that synergy recruitment depends on movement direction (directional tuning) and that each synergy has a specific direction of maximal activation (preferred direction). In contrast to the dependence of individual muscles (Flanders et al., 1996), in most

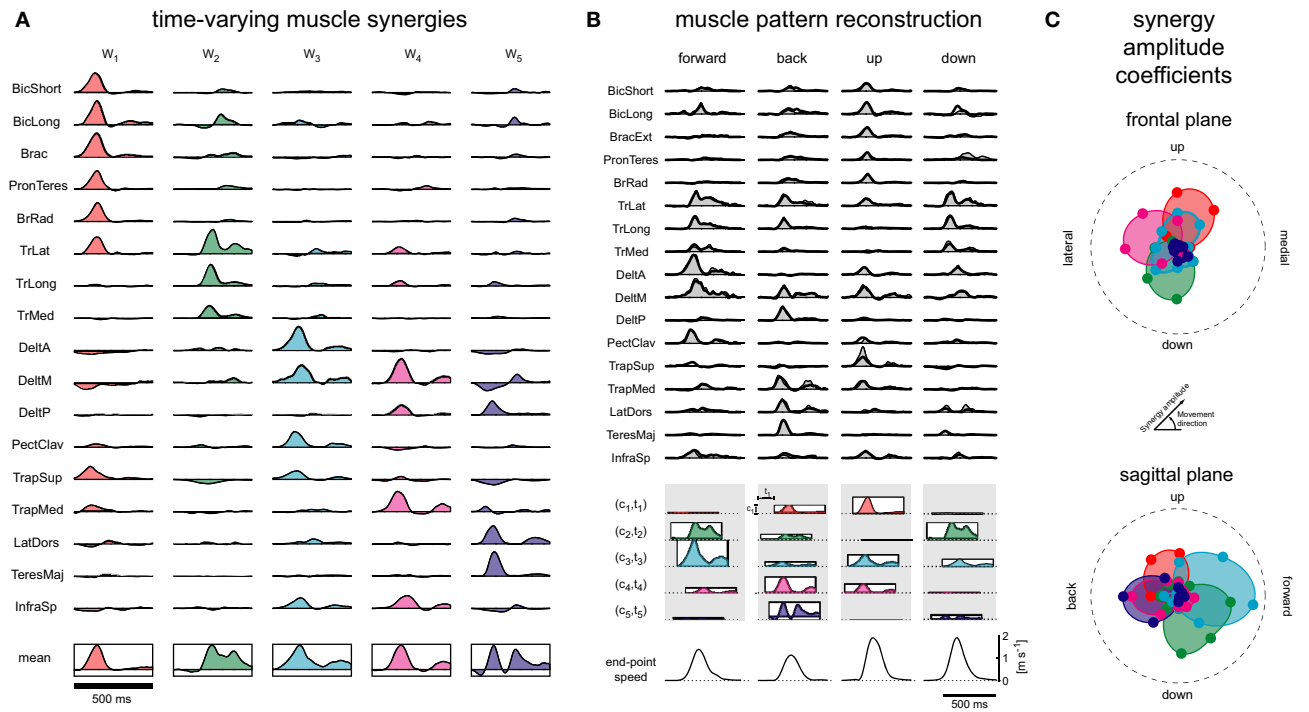

FIGURE 2 | Muscle synergies for fast reaching movement. (A) A set of five time-varying synergies, identified from the muscle patterns recorded during point-to-point movements between one central location and 8 peripheral locations in the frontal and sagittal planes with a movement duration below 400 ms. **(B)** The activation waveforms of 17 shoulder and arm muscles for four movement conditions (*columns*) are reconstructed by activating the five synergies with different amplitudes and at different times and then by combining, muscle by muscle, the amplitude-scaled and time-shifted muscle activation waveforms of each synergies. At the *top* of the panel the gray areas represent the averaged EMG activity and the solid black lines the synergy reconstruction. At the *bottom* of the panel, the amplitude scaling coefficient c_i of each synergy and movement condition is represented by the height of a rectangle and the onset latency t_i and the duration of the synergy is indicated by the horizontal position of the rectangle. The profile within each rectangle represents the mean muscle waveform of each synergy i.e., they are scaled versions of the waveforms shown below each synergy at the *bottom* of panel **A**. **(C)** The amplitude coefficients (c_i) for all five synergies (*color coded*) across all eight movement directions in the frontal (*top*) and sagittal (*bottom*) planes are shown in a polar plot. Thus, for each movement direction, the amplitude coefficient is indicated by the distance from the origin of a colored marker in the corresponding direction. Such polar plots clearly show that the amplitude coefficients are modulated by movement direction (directional tuning) and that each synergy has a specific preferred direction (direction of maximal activation). In most cases the directional tuning is well captured by a cosine function (corresponding to a circle in the polar plot). Adapted from (d'Avella et al., 2006) © 2006 by the Society of Neuroscience, with permission.

cases the synergy coefficients have a single peak and, remarkably, the directional tuning is well characterized by a simple cosine tuning (d'Avella et al., 2006). Cosine tuning is characteristic of neural activity in the motor system (Georgopoulos et al., 1982; Caminiti et al., 1991) and represents an optimal encoding of motor commands in terms of accuracy in presence of noise (Todorov, 2002) and minimum effort (Fagg et al., 2002). Thus, the observed cosine tuning of the synergy amplitude coefficients supports the role of muscle synergies as a mechanism for implementing a simple, direct mapping of movement goals into motor commands and suggests that their recruitment may be encoded in motor cortical areas (Overduin et al., 2012).

MODULATION OF PHASIC AND TONIC SYNERGIES WITH MOVEMENT DIRECTION AND SPEED

If movement direction can be controlled by modulating the recruitment of a few time-varying muscle synergies according to a cosine directional tuning, is movement speed also related to synergy recruitment in a simple way? The invariances observed in the arm kinematics and present in the equations of motions for an articulated arm suggest that a simple scaling rule might be used to control speed. Reaching movements between two given locations are executed at different speeds along an invariant path (Soechting and Lacquaniti, 1981) by scaling in time the entire motion (Atkeson and Hollerbach, 1985). Moreover, the arm motion equations have the property that a solution is invariant for changes in speed (i.e., the resulting joint motion follows the same trajectory with a different time scale) if the dynamic component of the torque profiles is scaled as the inverse of the square of the time scale (Hollerbach and Flash, 1982; Atkeson and Hollerbach, 1985). Thus, the CNS might control the speed of a reaching movement between two locations simply by scaling synergy activation according to movement duration. Such scaling rule would have to be captured by a close-to-quadratic function of the inverse of movement duration (notice, however, that joint torque is related non-linearly to muscle activation).

The analysis of the muscle patterns for reaching in different directions and with different speeds supports the notion of

a simple scaling rule for speed control (d'Avella et al., 2008). The patterns recorded during point-to-point movements in eight different directions on the frontal plane with five different movement durations, after scaling in time to equal movement duration, were reconstructed by the combination of three phasic and three tonic time-varying muscle synergies. Phasic synergies, similar in structure to the synergies identified only from the phasic patterns of fast reaching movements and with a similar directional modulation of amplitude and timing coefficients, were also scaled in amplitude by movement speed. The synergy amplitude coefficients for movements in its preferred direction scaled with the maximum speed of the movement according to a power law with an exponent close to two (range over all synergies of five subjects: 1.4–2.7, median 2.0), i.e., approximately in accordance to the torque scaling law. In contrast, tonic synergies, extracted from the muscle pattern without any time-shifts, showed directional modulation in their amplitude coefficients but either non-significant or weak speed dependence (exponent range: 0.1–0.6, median 0.3). Thus, the modulation of a small number of time-varying muscle synergies underlies the control of both direction and speed of point-to-point reaching movements.

SUPERPOSITION AND MODULATION OF SYNERGIES FOR MULTI-PHASIC MOVEMENTS

When reaching a set of different targets in sequence or a target whose location changes after movement initiation, movement kinematics may be complex, with curved paths, and multiple peaks in the tangential velocity. At the kinematic level, such multi-phasic movements can be decomposed as a sequence of superimposed sub-movements, each with the same features of point-to-point movements (Flash and Henis, 1991). As the muscle patterns for point-to-point movements are captured by the combination of a few time-varying muscle synergies, are multi-phasic movements constructed by a sequence of the same point-to-point synergies? If superposition holds at the kinematic level, because of the non-linear dependence of the muscle forces and torques on the arm posture, one expects a simple superposition of muscle patterns and muscle synergies not to hold. However, synergies may provide a simple mechanism for generating the muscle patterns underlying a multi-phasic movement by adjusting a small number of control parameters. To test this hypothesis, the muscle patterns recorded during reaching through a via-point (d'Avella et al., 2006) and to a target changing location after movement initiation (d'Avella et al., 2011) were analyzed using time-varying muscle synergies identified in point-to-point reaching. Indeed, the model of Equation 2 can be extended to allow for the same synergy to be recruited at different, multiple times. When multiple instances of point-to-point synergies were fit to multi-phasic muscle patterns, they reconstructed the muscle patterns with a level of accuracy comparable to that of the point-to-point patterns. However, the recruitment of the synergies, especially those underlying the second phase of the via-point or target change movements, was adjusted with respect to their recruitment in the corresponding point-to-point movement. Indeed, the simple superposition of two, appropriately aligned point-to-point patterns could not reconstruct the multi-phasic patterns with the same accuracy as the synergies. Thus, complex arm movements involving multiple phases appear to be constructed by the modulation and superposition of the same building blocks used for simple point-to-point reaching movements. As time-varying muscle synergies represent an invariant spatiotemporal component of a muscle pattern with a specific duration, the superposition of a set of synergies recruited at different times may be implemented by an intermittent controller.

MUSCLE SYNERGIES AND INTERMITTENT CONTROL

Sensory feedback is crucial for the control of accurate reaching movements and an internal model of the dynamics of the musculoskeletal system can be exploited to construct an optimal feedback controller (Todorov and Jordan, 2002). However, it might be challenging for the CNS to acquire such a model explicitly and to perform the necessary computations. In contrast, an internal model sufficient for constructing an open-loop controller may be acquired implicitly as a mapping from goals and initial states into motor commands, and feedback might be used for on-line adjustments and trial-to-trial adaptation. Muscle synergies may then provide the basis functions that allow acquiring and using such mapping quickly and efficiently by reducing the number of parameters to be adjusted, stored, and retrieved. An open-loop controller is used before feedback can be processed (Woodworth, 1899; Keele and Posner, 1968), e.g., in the initial phase or for brief movements. However, because of noise and inaccuracy in the model, feedback-driven corrections are required for accuracy. While it is often assumed that such corrections are performed continuously, sensory feedback might also be used intermittently to trigger discrete, open-loop corrections (Doeringer and Hogan, 1998; Gawthrop et al., 2011; Loram et al., 2011). In a synergistic controller, such intermittent corrections may be simply implemented by re-using the mapping of goals and states into synergy recruitment coefficients. Sensory feedback may be processed continuously to update an estimate of the current state and goal, necessary to prepare the synergy coefficients for the appropriate correction. In addition, sensory feedback may be used to construct an error signal which, possibly through a threshold process, triggers a correction by recruiting a set of time-varying synergies. As each synergy has a given duration, different synergies or multiple instances of the same synergy may partially overlap and generate a smooth movement that may appear to be continuously controlled. The fact that the same set of muscle synergies observed in fast point-to-point reaching movements also appear to be recruited in via-point and target-change movements, as reviewed above, supports the notion of a synergy-based intermittent controller.

CONCLUSIONS

Reaching muscle patterns are reconstructed by the combinations of a few time-varying muscle synergies. The complex changes of the activation waveforms of individual muscle across movement direction and speed are captured by the modulation in amplitude and timing of these synergies according to simple rules, such as amplitude cosine tuning for direction and time scaling for speed. Multi-phasic reaching movements, such as reaching through a via-point or toward a target whose location changes after movement initiation, appear to be generated by sequencing

and superimposing the same small set of muscle synergies identified in point-to-point movements. Thus, the regularities observed in the muscle patterns across movement conditions suggest that muscle synergies are building blocks used by the CNS to control goal directed movement. However, regularities may derive from optimization or task constraints (Todorov and Jordan, 2002; Tresch and Jarc, 2009; Kutch and Valero-Cuevas, 2012). Direct support for muscle synergies as centrally organized building blocks would come either from identifying their neural substrates or by testing the prediction that motor adaptation must be more difficult if it cannot be achieved recombining existing synergies (d'Avella and Pai, 2010). Recent results in frogs (Hart and Giszter, 2010) and monkeys (Overduin et al., 2012) support a neural organization of muscle synergies both at the spinal and cortical levels. Future investigations of adaptation after novel perturbations of the musculoskeletal system either compatible or incompatible with the synergies will help to clarify whether muscle synergies are merely low-dimensional approximations of the muscle patterns or building blocks organized by the CNS.

In this paper we review the works related to muscle synergies that have been carried-out in neuroscience and control engineering. In particular, we refer to the hypothesis that the central nervous system (CNS) generates desired muscle contractions by combining a small number of predefined modules, called muscle synergies. We provide an overview of the methods that have been employed to test the validity of this scheme, and we show how the concept of muscle synergy has been generalized for the control of artificial agents. The comparison between these two lines of research, in particular their different goals and approaches, is instrumental to explain the computational implications of the hypothesized modular organization. Moreover, it clarifies the importance of assessing the functional role of muscle synergies: although these basic modules are defined at the level of muscle activations (input-space), they should result in the effective accomplishment of the desired task. This requirement is not always explicitly considered in experimental neuroscience, as muscle synergies are often estimated solely by analyzing recorded muscle activities. We suggest that synergy extraction methods should explicitly take into account task execution variables, thus moving from a perspective purely based on input-space to one grounded on task-space as well.

Keywords: muscle synergies, modularity, task-space, dimensionality reduction, motor control, robotics, review

1. INTRODUCTION

One of the fundamental questions in motor control concerns the mechanisms that underlie muscle contractions during the execution of movements. The complexity of the musculoskeletal apparatus as well as its dynamical properties allow biological systems to perform a wide variety of motor tasks (Bizzi et al., 1992); on the other hand, such a complexity has to be mastered by efficient strategies implemented in the central nervous system (CNS). How does the CNS "choose" among the infinity of solutions of a given motor task (i.e., Bernstein problem) (Bernstein, 1967)? How are motor intentions translated into muscle activations? How can biological systems learn and plan movements so rapidly? A prominent hypothesis suggests that motor circuitries are organized in a modular fashion, so that muscle activations can be realized by flexibly combining such modules. Modularity has been observed in various forms such as kinematic strokes, spinal force fields and muscle synergies (Flash and Hochner, 2005); this paper provides an overview of the findings related to the so-called muscle synergies, as well as the application of such a concept in robotics and character animations.

Muscle synergies are defined as coordinated activations of a group of muscles[1]. It has been suggested that the CNS encodes a set of synergies, and it combines them in a task-dependent fashion in order to generate the muscle contractions that lead to the desired movement (muscle synergy hypothesis). Evidence for this organization relies on the spatio-temporal regularities observed in the EMG (Electromyography) activities of several species (Tresch et al., 2002; Bizzi et al., 2008). Since in many cases these regularities appear to be very similar across subjects and motor tasks (i.e., robustness of muscle synergies), scientists have proposed that they might reflect a modular organization of the

[1]The term *synergy* has also been used in the context of another motor control hypothesis, the uncontrolled manifold hypothesis (UMH) (Latash, 2010; Latash et al., 2010). In that context, the term refers to "a neural organization of a set of elemental variables (e.g., muscle contractions) with the purpose to ensure certain stability properties of a performance variable produced by the whole set (e.g., desired joint configuration)" (Latash et al., 2008). These studies are out of the scope of this paper, however, we will discuss the concept of M-modes, that has been introduced in the UMH but it is very similar to the definition of synergies we adopt in this manuscript.

underlying neural circuitries. Assuming that muscle activations represent the control input to the musculoskeletal system, in this context muscle synergies are implicitly defined as input-space generators (i.e., components that are able to generate the necessary input signals).

From a computational point of view, a modular organization based on muscle synergies is very attractive. The activations of many muscles is hypothetically implemented by modulating the contributions of a small set of predefined muscle synergies. Such a dimensionality reduction may simplify motor control and learning, and it may contribute to the adaptability observed in biological systems (Mussa-Ivaldi and Bizzi, 2000). This observation has recently motivated roboticists and control engineers to develop control strategies that are based on the same concept: combination of a small number of predefined actuations. In addition to the possible dimensionality reduction, the modularity of such scheme has the advantage that improved performance may be achieved incrementally by introducing additional synergies to the controller. The price to be paid is the restriction of the possible actuations to those that can be obtained by combining the synergies (i.e., synergies span set). This also implies a reduction of the possible movements that the controlled system can perform.

In the two fields of neuroscience and control engineering, research on muscle synergies is characterized by radically different goals and approaches (see **Figure 1**). In the context of controlling artificial systems, the main goal is the synthesis of a small set of synergies that instantiates an effective control strategy. The obtained controller, as such, is mainly evaluated in relation to task-accomplishment, and in particular it should be able to generate a set of feasible actuations that allows the agent to perform a wide variety of tasks. In neuroscience, on the other hand, the main goal is to validate or falsify the hypothesis of muscle synergy. The typical approach consists in analyzing a dataset of recorded muscle activities, and in verifying if such a dataset is compatible with the proposed modular decomposition; the hypothetical synergies are inferred by applying a decomposition algorithm to the dataset of EMG signals. Unlike in control engineering, the major focus of this line of research resides at the motor level (i.e., the input-space of muscle activations); the evaluation of the hypothesized modular organization at the level of task is not always considered and, from our point of view, it deserves more attention. Does the set of identified muscle synergies actually lead to the task performance observed experimentally? Does it generate feasible actuations? These issues have been investigated *a-posteriori* using realistic models of the musculoskeletal systems of different species (Berniker et al., 2009; Neptune et al., 2009; McKay and Ting, 2012). Additionally, novel methodologies to deal with these challenges are starting to emerge in experimental neuroscience as well (Chvatal et al., 2011; Delis et al., 2013). We believe that a shift of paradigm from an input-space to a task-space identification of muscle synergies, which seems to be already in progress, may contribute to a better understanding of the hypothetical modularity of the CNS, and of its relationship to human learning and control. In particular in this review we argue that task-space constraints could be directly integrated in the decomposition algorithm used to extract the synergies.

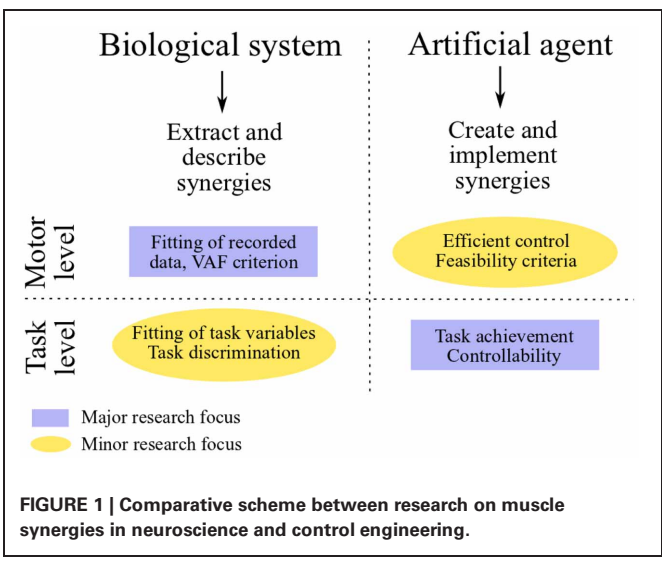

FIGURE 1 | Comparative scheme between research on muscle synergies in neuroscience and control engineering.

This paper reviews the studies that investigate the hypothesis of muscle synergies, as well as the methods to control artificial systems that have been developed taking inspiration from this hypothesis. The organization of the paper follows the rationale developed so far. Initially, in section 2, we provide a mathematical formulation of the concept of muscle synergies, we detail different synergy models (proposed as the mechanism to generate muscle contractions), and we analyze their computational implications. In section 3 we discuss the works that evaluate the hypothesis of muscle synergies solely in the space of input-signals, and the ones that seek more direct neural evidence. Then, in section 4, we present the studies that evaluate synergies also at the task-level; this section includes robotics, characters animation, as well as neuroscience. Finally, in section 5 we offer further discussions and concluding remarks.

2. MODELS OF MUSCLE SYNERGY

The concept of muscle synergy has been formalized in a variety of mathematical models. We will present these models in the context of controlling a generic dynamical system. This formulation is sufficiently generic to represent both the control of the musculoskeletal system and the control of an artificial agent. Furthermore, it is useful to explain the computational implications of the various synergy models, and to clarify the difference between input-space and task-space evaluation of a set of synergies.

The generic dynamical system we employ can be represented as follows:

$$\dot{\mathbf{x}}(t) = f(\mathbf{x}(t), t) + g(\mathbf{x}(t), t)\mathbf{u}(t),$$

where t represents time, $\mathbf{x}(t) \in \mathbb{R}^n$ is the system state variable at time t (e.g., angular positions and velocities of the joints), and $\mathbf{u}(t) \in \mathbb{R}^m$ is the system input at time t (e.g., muscle activations or joint torques). Within this framework, the variable to be controlled is denoted as $\mathbf{y}(t) \in \mathbb{R}^p$, and it is a generic function of the system state: $\mathbf{y}(t) = h(\mathbf{x}(t))$. The task is defined in terms of a set of

constraints applied on the time evolution of this variable. Typical examples of tasks include reaching ($\mathbf{y}(t_f) = \mathbf{y}_d$ where t_f is the desired reaching time), and tracking ($\mathbf{y}(t) = \mathbf{y}_d(t) \forall t$, where $\mathbf{y}_d(\cdot)$ is the desired trajectory to be tracked). We refer to the task-space, as the space where the task $\mathbf{y}_d$ is defined; similarly, the input-space is the space of the input signals $\mathbf{u}(\cdot)$. The relation between these two spaces is given by the dynamics of the system. It is now clear that a given control input should always be evaluated in relation to the error between the corresponding evolution of the controlled variable and the desired task; in other words, it should always be evaluated in task-space.

Classically, control inputs $\mathbf{u}(\cdot)$ belong to the infinite dimensional space of continuous functions. Under this assumption a number of interesting control properties (e.g., controllability and observability) can be proven. The idea behind modular control, is to significantly restrict the control input-space by constraining $\mathbf{u}(\cdot)$ to be a combination of modules, or muscle synergies. The various muscle synergy models can be distinguished based on the mathematical formalization of this combination, and they are described in the following (see **Figure 2** for a schematic representation). An empirical comparison of these models is proposed by Chiovetto et al. (2013).

2.1. TEMPORAL AND SYNCHRONOUS SYNERGIES

In these models, the control input is defined as a linear combination of k vectors $\mathbf{w} \in \mathbb{R}^m$, with 1-dimensional time-varying coefficients $a(t) : \mathbb{R}^+ \rightarrow \mathbb{R}$ (**Figure 2A**):

$$\mathbf{u}(t) = \sum_{j=1}^{k} a_j(t)\mathbf{w}_j. \quad (1)$$

Each vector $\mathbf{w}_j$ specifies a balance between the input variables (e.g., balance between muscle activations), and its coefficient $a_j(t)$ determines its temporal evolution. In the *temporal synergy model*, the coefficients $\{a_j(t)\}$ serve as the task-independent predefined modules, and the vectors $\{\mathbf{w}_j\}$ represent the new (task-dependent) control input. As a result, this model reduces the control space to $k \times m$ dimensions; i.e., the k m-dimensional vectors $\mathbf{w}_j$ have to be appropriately specified to fulfill the desired task $\mathbf{y}_d$. Synergies are thus interpreted as the temporal patterns that are recruited selectively by different muscles. In literature, temporal synergies are also referred to as temporally fixed muscle synergies. An important special case, the *premotor drive model*, is obtained by defining the temporal coefficients as $a_j(t) = A_j\phi(t - \tau_j)$. In this case, the time course of the vectors $\mathbf{w}_j$ are determined by a common function $\phi(t)$, called premotor drive or burst pulse, that can be modulated in amplitude and shifted in time. In contrast, the *synchronous synergy model* defines the task-independent synergies as the vectors $\mathbf{w}_j$. The the new control input $\{a_j(t)\}$ belongs to the infinite dimensional space of the one-dimensional real functions. Therefore this model, unlike the previous one, provides a dimensionality reduction only if the number of synergies is lower then the number of input variables, i.e., $k < m$. Synchronous synergies are co-varying group of muscles, and are also called time-invariant synergies, spatially fixed muscle synergies, or muscle modes.

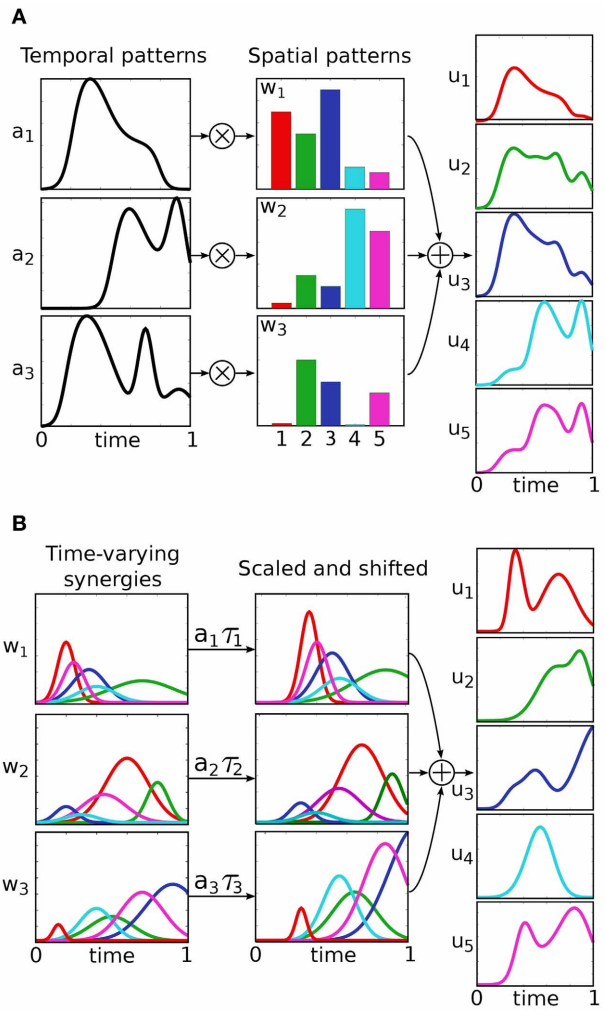

FIGURE 2 | Different models of muscle synergies. The temporal and the synchronous models explain motor signals as linear combinations of muscle balance vectors (spatial patterns), with 1-dimensional time-varying coefficients **(A)**. In the temporal model, these coefficients serve as task-independent predefined modules, and the spatial patterns as the new (task-dependent) control input. In the synchronous model, on the other hand, the control input is represented by the temporal patterns, while the spatial patterns act as predefined modules. Finally, time-varying synergies are spatio-temporal predefined motor patterns, which can be scaled in amplitude and shifted in time by the new input coefficients **(B)**.

2.2. TIME-VARYING SYNERGIES

This model defines the control input as the superposition of k task-independent vector-valued functions $\mathbf{w}(t) : \mathbb{R}^+ \rightarrow \mathbb{R}^m$ (**Figure 2B**):

$$\mathbf{u}(t) = \sum_{j=1}^{k} a_j\mathbf{w}_j(t - \tau_j). \quad (2)$$

Each synergy $\mathbf{w}_j$ can be scaled in amplitude and shifted in time by means of the coefficients $a_j, \tau_j \in \mathbb{R}$. These coefficients represent the new control input, and have to be chosen in order to accomplish the task $\mathbf{y}_d$. As a result, the new input-space is reduced

to a $2 \times k$ dimensional space. Neuroscientifically, these synergies are genuine spatiotemporal muscle patterns which do not make any explicit spatial and temporal separation. As such, according to this model, muscles within the same time-varying synergy do not necessarily co-vary.

3. SYNERGIES AS INPUT-SPACE GENERATORS

As discussed above, muscle synergies can be considered as input-space generators. Whether or not these generators are implemented in the CNS, and how they are eventually coordinated through the sensorimotor loops, is a main stream of research in motor neuroscience. To tackle this question, scientists have employed two main approaches. One of them is solely based on the analysis of EMG signals, therefore it can only provide indirect evidence of a modular neural organization. The other approach aims at locating the areas of the CNS where muscle synergies might be implemented, therefore providing a direct evidence. These methodologies as well as the obtained results are discussed in the following.

3.1. INDIRECT EMG-BASED EVIDENCE

The classical approach to evaluate the hypothesis of muscle synergies consists in searching spatio-temporal regularities (i.e., synergies) in a dataset of muscle activities (**Figure 3**, continuous green arrows). Such a dataset is obtained by recording the EMG signals from a group of subjects/animals that are performing some prescribed motor tasks. As such, this methodology is mainly based on considerations grounded at the input level. The possibility to discriminate the various task instances from motor signals represents the only (*a-posteriori*) task-related verification of the identified synergies (see **Figure 1**).

Linear dimensionality reduction algorithms are employed to identify a small set of components (i.e., synergies) that approximate the EMG dataset according to the chosen synergy model (see section 2). The number of synergies to be extracted has to be specified *a-priori* by the experimenter, as it constitutes an input parameter of the decomposition algorithm. The choice of the decomposition algorithm to be used depends on the assumptions made on the nature of the hypothetical muscle synergies (e.g., non-negativity, orthogonality, statistical independence etc.) (Ting and Chvatal, 2010). Principal component analysis (PCA) (Mardia et al., 1980) looks for orthogonal synergies that account for as much of the variability in the data as possible. Similarly, factor analysis (FA) (Darlington, 1968) seeks the smallest set of synergies that can account for the common variance (correlation) of a set of muscles. Independent component analysis (ICA) (Bell and Sejnowski, 1995) maximizes the statistical independence of the extracted components, thus it assumes that synergies represents independent information sources. Non-negative matrix factorization (NMF) (Lee and Seung, 1999) enforces the extracted synergies and their activation coefficients to be non-negative; this constraint reflects the non-negativity of neural and muscle activations ("pull-only" behavior). Additionally, NMF does not assume that the generators are statistically independent, thus it is more compatible with the observation that activations of multiple synergies are correlated (Saltiel et al., 2001). Finally, the extraction of time-varying synergies is performed by an NMF-based algorithm developed *ad-hoc* that allows the components to be shifted in time (d'Avella and Tresch, 2002).

To assess the quality of the extracted synergies, the so-called VAF (Variance Accounted For) metric is typically used

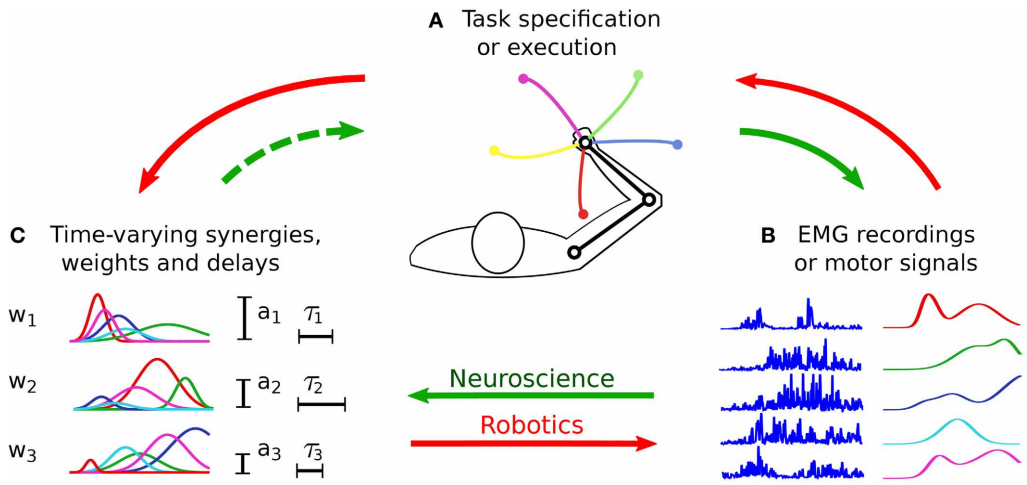

FIGURE 3 | Procedures for the identification and the testing of muscle synergies. In experimental neuroscience (green arrows), initially a group of subjects perform the tasks prescribed by the experimenter **(A)**. The EMG signals acquired during the experiments **(B)** are then analyzed, and a dimensionality reduction algorithm is applied to obtain the synergies **(C)**. Very often such synergies are not evaluated at the task-level (dashed arrow), therefore there is no guarantee that they lead to the observed task performance. In robotics (red arrows), synergies are synthesized **(C)** based on the requirements of the desired class of tasks **(A)**. Then they are appropriately combined to generate the motor signals **(B)** to solve a specific task instance. The quality of the synthesized synergies is finally tested in terms of the obtained task performance **(A)**. Without loss of generality, the figure presents the time-varying synergy model; however, the previous description holds for all the models.

(see **Figure 1**). VAF quantifies the percentage of variability in the EMG dataset that is accounted for by the extracted synergies. High values of VAF indicate good reconstruction of the recorded EMGs, which lends credit to the extracted synergy set; low VAF values cast doubt on the extracted synergies, indicating that they do not explain a large part of the EMG variance. This metric is also used for determining the dimensionality of the synergy space. The criteria used for this purpose rely on the assumption that most of the EMG variability is attributable to task-dependent muscle activations, whereas a small portion is due to several sources of noise. Under this assumption, the number of synergies is defined either by the point where the VAF-graph (i.e., the curve that describes the trend of the VAF as function of the number of synergies, which increases monotonically) reaches a threshold level (e.g., 90%) (Torres-Oviedo et al., 2006), or by its flattening point, i.e., the point where a drastic decrease of slope is observed. Such an "elbow" is in fact interpreted as the point that separates "structured" and noise-dependent variability, and therefore it can be used to define the minimum number of synergies that capture the task-related features (d'Avella et al., 2006; Tresch et al., 2006). Besides the VAF metric, other metrics [e.g., log-likelihood (Tresch et al., 2006)] have been proposed to evaluate the effectiveness of extracted synergies (still in input-space); a thorough discussion of these metrics is beyond the scope of the present review. As depicted in **Figure 1**, this indirect methodology is mainly restricted to the analysis of input-level data. A complementary metric based on single-trial task-decoding techniques has been proposed by Delis et al. (2013).

A significant amount of experiments has been conducted in frogs, cats, primates as well as humans in order to test the validity of the above-mentioned synergy models, and by extension, of the muscle synergy hypothesis itself. A pioneering study showed that a small set of synchronous muscle synergies could generate a large number of reflexive motor patterns produced by cutaneous stimulations of the frog hindlimb (Tresch et al., 1999). This study also demonstrated that microstimulations of the spinal cord produced very similar muscle synergies to the ones generated by the freely moving animal. Qualitatively similar synergies were also found by intraspinal microstimulation (Saltiel et al., 2001). The above analysis was then extended in order to identify spatiotemporal patterns of muscle activities (i.e., time-varying muscle synergies) (d'Avella et al., 2003). A few time-varying synergies were shown to underlie the muscle patterns required to let the frog kick in different directions, and their recruitment was directly related to movement kinematics. These findings were further generalized to a wide variety of frog natural motor behaviors such as jumping, swimming, and walking; evidence for both synchronous and time-varying synergies was reported (d'Avella and Bizzi, 2005). Additionally, this study revealed that some synergies are shared across motor behaviors, while others are behavior specific.

The synergy models described in section 2 do not include sensory feedback, however, the original experiments on animals involved sensory-triggered reflexive movements. In fact, only a few studies have systematically investigated the influence of sensory feedback in the muscle synergy organization. Cheung et al. (2005) analyzed the EMG signals collected from the bullfrog during locomotor behaviors before and after having interrupted its sensory pathways (i.e., deafferentation). Their findings support the existence of centrally organized synchronous muscle synergies that are modulated by sensory inflow. Further support was provided by showing that an appropriate modulation of the synergy activations could explain immediate motor adjustments, and that these synergies were robust across different dynamic conditions (Cheung et al., 2009a). A discussion on the role of sensory feedback is provided in section 5.

A number of studies have examined the generalization of the above results to other species. In primates, Overduin et al. (2008) found that three time-varying synergies described a large repertoire of grasping tasks. Shape and size of the grasped objects were shown to modulate the recruitment strength as well as the timing of each synergy. In this way, this study validated that time-varying synergies account for salient task differences, and their activations can be tuned to adapt to novel behavioral contexts. Along the same lines, Brochier et al. (2004) provided further support for such a robust and distinctive synergistic organization of primates' muscle patterns during grasping. Analysis of single-trial EMG signals demonstrated that the time-varying activation of three synchronous synergies was reproducible across repetitions of the same grasping task and allowed unequivocal identification of the object grasped in each single trial. In cats, Ting's group showed that muscle synergies could be mapped onto the control of task-level variables; such experiments will be detailed in section 4.2.

The framework of muscle synergies has been successful also in characterizing the spatio-temporal organization of muscle contractions during human reaching tasks. Muscle patterns observed during movements in different directions (d'Avella et al., 2006) and speed (d'Avella et al., 2008) were accurately reconstructed by appropriate linear combinations of synergies, which appeared very similar across subjects. The synergies that were extracted from muscle activities during unloaded reaching (i.e., subjects did not hold any load in their hands) accounted for the EMG signals obtained during loaded conditions. The recruitment of the individual synergies, as well as their onset time, were consistently modulated with movement direction, and did not change substantially with movement speed. This observation was further confirmed by Muceli et al. (2010); in this study a small set of specialized synchronous synergies was able to explain a large set of multijoint movements in various directions. Finally, visually guided online corrections during center-out reaching were tested recently. The synergistic strategy was shown to be robust and more effective in explaining the corrective muscle patterns than the individual muscle activities (d'Avella et al., 2011). Furthermore, it was shown that to correct ongoing reaching movements, the CNS may either modulate existing synergies (d'Avella et al., 2011), or reprogram new ones (Fautrelle et al., 2010).

Roh et al. (2012) showed that an appropriate set of synergies could reconstruct the average patterns of muscle activation observed during isometric forces production in humans. The EMG signals were obtained for different force magnitude, directions and initial postures. The extracted synergies were very similar across conditions, and they were able to explain the

corresponding datasets. Each synergy seemed to underly a specific force direction, while its activation coefficient appeared correlated to the force magnitude. In another series of experiments, a small set of synchronous synergies was able to explain static hand postures and discriminate the shapes of grasped objects (Weiss and Flanders, 2004). Moreover, a few time-varying synergies succeeded in revealing the spatiotemporal patterns of muscle activity during hand shape transitions, as in fingerspelling (Klein Breteler et al., 2007).

A relevant series of experiments showed that muscle activations involved in human postural control can be explained in terms of combinations of muscle synergies. A set of synchronous muscle synergies was able to explain muscle activations involved in postural stabilization; the EMG variation observed among trials and perturbation directions was accounted for by appropriate modulations of the synergies activation coefficients (Torres-Oviedo and Ting, 2007). In order to verify that the extracted synergies did not depend only on the specific biomechanical context, in a new experiment a set of subjects were asked to react to support perturbation from different postural configurations (Torres-Oviedo and Ting, 2010). The extracted synergies were very similar across the different conditions; however, in some cases task-specific muscle synergies needed to be added to the original synergy set to obtain a satisfactory EMG reconstruction. As the various postures lead to different patterns of sensory inflow, these results rule out the possibility that the observed synergies are only determined by specific patterns of sensory stimulations. On the contrary, they support the hypothesis that different muscle postural responses are generated by task-related modulations of the synergy activation levels. Such a hypothesis found evidence in the experiments performed by Safavynia and Ting (2012), where the temporal recruitment of the identified synchronous muscle synergies were explained by a mathematical model that explicitly takes into account the kinematic of the subject's center-of-mass (CoM). The authors then concluded that synchronous muscle synergies are recruited according to an estimate of task-related variables. The same model was previously used to fit the activations of each muscle independently during the same postural perturbation tasks (Welch and Ting, 2007). Related to postural control, Krishnamoorthy and colleagues analyzed the muscle activations that underly shifts of the centers of pressure (COP) of standing subjects (Krishnamoorthy et al., 2003a,b). In this experiment three "muscle modes," extracted by means of PCA, explained most of the variability of the integrated EMG signals. Such components are equivalent to synchronous muscle synergies as defined in section 2, and they are characterized by the authors as the independent elemental variables that are controlled synergistically (in the sense of the UMH) by the CNS to stabilize the COP. Specifically, the model assumes that the location of the COP is modified by linear combinations of the M-modes, and their mixing coefficients represent the independent variables controlled by the CNS. Perreault et al. (2008) examined the organization of reflexes involved in postural stabilization in both stiff and compliant environments; although reflexive responses are modulated by the direction of perturbation, they showed that the synchronous muscle synergies appear very similar across conditions.

Another scenario that provides evidence to the hypothesis of muscle synergies is human locomotion (Ivanenko et al., 2006a; Lacquaniti et al., 2012b). Ivanenko et al. (2004) showed that five temporal synergies could reconstruct the muscle activity involved in locomotion tasks. These patterns are robust across walking speeds and gravitational loads, and they relate to foot kinematics (Ivanenko et al., 2003). Additionally, the same temporal synergies (accompanied by additional ones) were observed during the coordination of locomotion with additional voluntary movements (Ivanenko et al., 2005). Similar results have been reported in other locomotor behaviors such as running (Cappellini et al., 2006) and pedaling (Hug et al., 2011).

Finally, some experiments have investigated how the hypothetical synergy organization of the CNS evolves during onthogenetic development (Lacquaniti et al., 2012a). Dominici et al. (2011) observed that the two temporal synergies identified in stepping neonates are retained through development, and they are augmented by two new patterns first revealed in toddlers. The final set of synergies was observed in several animal species, consistent with the hypothesis that, despite substantial phylogenetic distances and morphological differences, locomotion is built starting from common temporal synergies. This conclusion was also supported by the comparison of temporal synergies extracted from young and elderly people, which revealed no significant effect of aging on synergy compositionality and activation (Monaco et al., 2010).

3.2. DIRECT NEURAL EVIDENCE

The studies presented so far support the existence of synergistic muscle activations during the sensorimotor control of movements. However, these methods are indirect, in the sense that the presence of synergistic structures within the CNS can only be inferred. What remains to be tested is whether the uncovered muscle organization is neurally implemented in the CNS and, if so, in which areas. Alternatively, one could argue that the extracted synergies represent a phenomenological output of the motor coordination required for movement execution. For instance, recently Kutch and Valero-Cuevas (2012) designed carefully thought experiments and simulations to show that muscle synergies can be observed even if the nervous system does not control muscles in groups. The authors demonstrated that muscle synergies, as detected via dimensionality reduction methods (see section 3.1), may originate from biomechanical couplings and/or from constraints of the task. Similar conclusions were already reached by Valero-Cuevas et al. (2009), who showed that the observed within-trial variability of EMG data underlying the production of fingertip forces, was incompatible with the (unique) associated muscle synergy that would have been extracted. Although these findings do not directly falsify the muscle synergy hypothesis, they cast at least some doubts about the sole neural origin of modularity.

This underlines the need for a more critical assessment of the validity of the muscle synergy hypothesis. In this direction, a number of recent studies sought evidence for a neural implementation of muscle synergies, and examined which regions of the CNS may express synergies and their activations. This question has been addressed by attempting to relate neural activity with

simultaneously recorded muscle activity during performance of different motor tasks. Using such an approach, Holdefer and Miller (2002) provided direct support for the existence of neural substrates of muscle synergies in monkey's primary motor cortex. In particular, they studied the activity of neurons and muscles during the execution of a variety of reaching and pointing movements, and they found that the discharge of individual neurons represents the activation of functional groups of muscles. In addition, Hart and Giszter (2010) showed that some interneurons of the frog spinal cord were better correlated with temporal synergies than with individual muscles. Therefore, they suggested that these neural populations constitute a neural basis for synergistic muscle activations (Delis et al., 2010). Another study demonstrated that the sequential activation of populations of neurons in the cat's motor cortex initiates and sequentially modifies the activity of a small number of functionally distinct groups of synergistic muscles (Yakovenko et al., 2010). Similarly, Overduin et al. (2012) showed that microstimulations of specific regions of the motor cortex of two rhesus macaques corresponded to well-defined spatial patterns of muscle activations. These synchronous synergies were very similar to those extracted from the same animals during natural reaching and grasping behaviors. Extending this research line in the context of motor learning, Kargo and Nitz (2003) showed that early skill learning is expressed through selection and tuning of primary motor cortex firing rates, which specify temporal patterns of synergistic muscle contractions in the frog's limb. Finally, Roh et al. (2011) analyzed the muscle patterns of the frog before and after transection at different levels of the neuraxis: brain stem, medulla and spinal cord, respectively. They found that medulla and spinal cord are sufficient for the expression of most (but not all) muscle synergies, which are likely activated by descending commands from supraspinal areas. Similarly, Hart and Giszter (2004) examined the compositionality of temporal synergies in decerebrated and spinalized frogs. Their results indicated that in both cases temporal synergies consisted of pulsed or burst-like activations of groups of muscles. They also showed that brainstem frogs had more focused muscle groups and showed richer behaviors than spinalized equivalents.

In humans, the main approach to locate hypothetical muscle synergies has been to analyze brain-damaged patients. Comparing the synergies extracted from healthy and brain-damaged subjects could provide hints about the neural centers involved in the synergistic control of muscles. In this vein, examining motor tasks involving arm and hand movements, Cheung et al. (2009b) showed that the synchronous synergies extracted from the arm affected by a stroke were strikingly similar to the ones extracted from the unaffected arm, concluding that muscle synergies were located in regions of the CNS that were not damaged. In a second study involving subjects with more severe motor impairment (Cheung et al., 2012), they found that synchronous synergies may be modified according to three distinct patterns—including preservation, merging, and fractionation of muscle synergies—reflecting the multiple neural responses that occur after cortical damage. These patterns varied as a function of both the severity of functional impairment and the temporal distance from stroke onset. Similarly, Roh et al. (2013) found systematic alterations of the upper limb synergies involved in isometric force production in stroke patients with severe motor impairment. However, these alterations did not involve merging or fractionation of normal synergies. Clark et al. (2010) investigated the modular organization of locomotion in stroke patients. They found a coordination pattern consisting of fewer synchronous synergies than for the healthy subjects. These synergies resulted from merging of the synergies observed in healthy subjects, suggesting reduced independence of neural control signals. In contrast, Gizzi et al. (2011) demonstrated that the temporal waveforms of the synergy activation signals, but not the synchronous synergies, were preserved after stroke.

Finally, a different but worth-mentioning approach has been the attempt to map the activity of leg muscles onto the alpha-motoneuron pools along the rostrocaudal axis of the spinal cord during human locomotion (Ivanenko et al., 2006b, 2008). Using this procedure, the authors could infer the temporal and spatial spinal motor output for all the muscles of the legs during a variety of human walking conditions, and relate them to the control of task-relevant variables such as center of mass displacements. Overall, their findings support the existence of some spinal circuitry that implement temporal synergies. The strength of this approach resides in the explicit use of anatomical and clinical charts that document the innervation of the lower limb muscles from the lumbosacral enlargement (Cappellini et al., 2010).

4. SYNERGIES FROM THE PERSPECTIVE OF THE TASK-SPACE

4.1. FROM INPUT-SPACE TO TASK-SPACE: GENERAL RATIONALE

The methodology presented in section 3.1 undeniably led to many crucial insights, however, it does not guarantee that the extracted synergies account for the observed task performance. VAF-like metrics only measure the capability of the synergies to reconstruct/fit the dataset of recorded "input-signals" (i.e., EMG data). Moreover, in some studies, such signals are averaged across movement repetitions. In this case, the VAF constitutes an average indicator, and it does not quantify the capability of the synergies to reconstruct each individual trial (Ranganathan and Krishnan, 2012). Since the musculoskeletal apparatus is a non-linear system, these approximations of the recorded muscle activities may not lead to the observed task performance (Broer and Takens, 2011; section 1.1), a condition that would harm the validity of the hypothesized modular control structure. On a similar note, the extracted synergies might generate unfeasible joint torques. Finally, even if the dataset of muscle activity is very well approximated, additional muscles that are not recorded during the experiment might have a crucial role in the generation of the movement. These issues emerge because the dynamics of the musculoskeletal system (i.e., its input–output relation) is not directly taken into account in the synergy decomposition algorithms.

In this section we review those works that attempt to relate muscle synergies to performance variables defined in task-space. Initially, we present the concepts of functional synergies and spinal force fields. The former constitutes a valid strategy to

include the task variables into the classical EMG-based analysis; the latter provides task-based evidence for neurally implemented muscle synergies. Then, we discuss some studies that, in the context of biomechanics, employ plausible musculoskeletal models to test the movements obtained from experimentally extracted muscle synergies. Finally, we shift our attention to robotics and characters animation. In these fields, the main challenge is the synthesis of a small set of synergies that reduces the dimensionality of control and, at the same time, spans a subspace of actuations that allows the agent to perform a wide variety of tasks (**Figure 3**, red arrows). Ideally, the synthesized synergies should preserve controllability and reachability of the system. Loosely speaking, this means that any desired system state can be reached by an appropriate control input (i.e., combination of synergies) in a finite amount of time. At the motor level, it is important that the synergies generate feasible actuations; additional properties, such as the generation of optimal control signals, may also be desirable (see **Figure 1**).

4.2. FUNCTIONAL MUSCLE SYNERGIES AND SPINAL FORCE FIELDS

In most of the works presented so far, the functional role of muscle synergies is estimated *a-posteriori* by analyzing the dependence of the recruitment coefficients (i.e., gain and/or onset time) on the task conditions (e.g., reaching direction, force magnitude and direction, perturbation direction). Typically, each muscle synergy is assumed to underlie the task-level functionality observed in conjunction with the higher values of its activation coefficient. As an example, the analysis of directional tuning curves illustrated that some of the synergies were directly related to reaching in specific directions (d'Avella et al., 2008). A different approach is taken by a pool of studies which define the concept of functional synergies; i.e., components, typically extracted by means of NMF, of a dataset containing both EMG signals and measurements of defined task-related variables. As a result, each component consists of two elements: a balance of muscle contractions (i.e., synchronous muscle synergy), and the evolution of the task-related variables induced by such a muscle synergy (task-related vector). In our view, the concept of functional synergies provides a way to tackle the drawbacks of input-based extraction algorithms: if a set of functional muscle synergies extracted from a training-set is able to reconstruct both the EMG and, more importantly, the task-related signals observed in another set of data (testing set), then it is more likely that combinations of such muscle synergies will generate the appropriate control signals to perform the task successfully.

Functional muscle synergies were analyzed in the context of postural tasks in experiments with humans (Chvatal et al., 2011) and cats (Ting and Macpherson, 2005; Torres-Oviedo et al., 2006). The task-related variables were defined as the forces measured under the feet of the subject, which reacted to unexpected motions of the support surface. The experiments showed that each subject exhibited the same functional synergies for both stepping and non-stepping responses to perturbations (Chvatal et al., 2011), suggesting that a common pool of muscle synergies, with specific biomechanical functionalities, can be used by the CNS to drive the motion of the CoM independently of the subject's behavioral response. The functional synergies extracted from the non-stepping data were able to reconstruct the EMG signals, the CoM acceleration and the direction (not the magnitude) of the forces recorded during stepping responses; however, an additional stepping-specific muscle synergy was needed to increase the quality of EMG reconstruction. Generality and robustness of functional synergies were also analyzed in postural experiments with cats (Torres-Oviedo et al., 2006). In this study, a group of cats experienced both translations and rotations of the support surface. Functional muscle synergies were extracted from a dataset containing EMG signals and ground forces observed for different postural configurations (i.e., distances between the anterior and the posterior legs). The functional synergies extracted during surface translations for the most natural posture were able to reconstruct the data observed in all the other conditions (i.e., different postural configurations and surface rotations). Moreover, functional synergies appeared very similar across subjects. These results suggested that each muscle synergies implements a specific biomechanical functionality (Ting and Macpherson, 2005), which is general across tasks and robust across subjects.

The methodology proposed by Ting and colleagues is undoubtedly a valuable attempt to identify muscle synergies that are directly related to task execution, however, it presents some limitations. First, NMF extracts non-negative components and coefficients; while this constraint is well justified at the muscle activation level (see section 3.1), task variables may exhibit negative values. Second and more important, in addition to a linear superposition also at the task-level, this decomposition procedure assumes that both EMG signals and task-variables are generated with the same mixing coefficients. Although it is possible to obtain a good fit of a given dataset, due to the non-linearity of the musculoskeletal system, this assumption does not hold in general.

A radically different approach to investigate the modularity of motor circuitries consists in analyzing the so called spinal force fields. This method is grounded on the seminal discovery that electrical stimulations of individual regions of the frog's spinal cord produce peculiar isometric endpoint forces that depend on the posture of the limb; the direction of the force vectors within each of these fields is invariant over time, while their magnitudes are characterized by a specific time evolution. Additionally, each of these force fields features a specific point of convergence. Structures with these characteristics can be generated by groups of coactive and linearly covarying muscles (Giszter et al., 1993; Mussa-Ivaldi et al., 1994). In particular, only a small subset of all the possible muscle combinations leads to robust and convergent force fields (Loeb et al., 2000). Therefore, the observation of such characteristics in an experimentally measured force field can be regarded as an indirect evidence for spinally implemented temporal muscle synergies (see section 2). Kargo and Giszter (2000b) showed that rapid corrections of movements in wiping frogs can be explained as linear combinations of spinal force fields. Additional evidence was obtained by examining the force fields generated by frogs (Giszter and Kargo, 2000) and turtles (Stein, 2008) that exhibited deletion of motor patterns. Another method to investigate the nature of spinal circuits is the analysis of feedback mechanisms in relation to force fields. Different

external excitations of the frog's muscle spindles during wiping reflexes led to structurally invariant force fields across time. Furthermore, the bursts of muscle activity underlying the wiping behavior and the balance of activations across muscles were not altered by the spindle feedback. Instead, feedback regulated the amplitude and the timing of each single burst. Since these variables did not covary across the pulses, the authors concluded that individual premotor drive pulses and not time-varying synergies are the units of spinal activity (Kargo and Giszter, 2008). Such hypothetical neural organization is compatible with the synergy scheme proposed by Drew et al. (2008) and Krouchev et al. (2006) for locomotive behaviors. These schemes allow a sequential activation of coordinated groups of muscles, a mechanism that can be implemented in the premotor drive model by modulating the onset time of the bursts. Spinal force fields are effectively task-level representations of hypothetical neural modules, however, this methodology does not provide any estimate of what the corresponding muscle synergies may look like. Moreover, the relation between linear combinations of muscle synergies and linear combinations of force fields is far from being trivial.

4.3. NEUROMECHANICAL MODELING

Although many studies in experimental motor control provide support to the hypothesis of muscle synergies, it is hard to test whether the proposed control model can effectively lead to the task performance observed experimentally and generalize to other tasks. This issue can be tackled computationally by employing biologically plausible models of the musculoskeletal apparatus.

A pool of studies investigate if a modular organization like the synchronous synergy model can explain a complex task like human walking (Neptune et al., 2009; McGowan et al., 2010; Allen and Neptune, 2012). A set of synergies are identified from a dataset of recorded EMG signals by means of NMF. Such "modules" are then used to generate the muscle control inputs to a musculoskeletal model of the human legs. Using these synergies as a first guess, a numerical procedure optimizes the relative level of muscle activation within each module and the time course of the weighting coefficients; the objective is to minimize the difference between the results of the forward simulation and the values of the task variables measured experimentally. The walking kinematic and the ground reaction forces are well reproduced by 5 modules, if the motion is constrained in 2D (Neptune et al., 2009), and 6 modules for 3D walking (Allen and Neptune, 2012). Additional simulations reveal that the muscle groups identified during normal walking are able to emulate walking tasks with very different mechanical demands (i.e., change in mass and weight of the models) (McGowan et al., 2010). These results agree with the theoretical considerations formulated by Nori et al. (2008). Finally, this research shows that each module is associated to a specific biomechanical functionality (e.g., body support, forward propulsion, leg swing and balancing).

Related results are presented by McKay and Ting (2008, 2012). The goal of these studies is to predict the patterns of muscle activities and the ground reaction forces observed experimentally in unrestrained balance tasks with cats (Torres-Oviedo et al., 2006). Muscle contractions for an anatomically-realistic musculoskeletal model of the cat are computed; the used optimization procedure constrains task-related variables (i.e., center of mass) to the experimental results. Although many different cost functions are tested, the best predictions are achieved by minimizing control effort (i.e., total squared muscle activation). Predictions improve if muscle contractions are constrained to linear combinations of the experimentally derived synergies (Torres-Oviedo et al., 2006); however, the overall control effort increases, and the range of admissible ground forces reduces substantially. Furthermore, these studies validate the assumption made by Torres-Oviedo et al. (2006) that the ground reaction forces associated to each synergy rotate as a function of the limb axis. These results suggest that muscle synergies are feasible physiological mechanisms for the implementation of near-optimal or "good-enough" motor behaviors (de Rugy et al., 2012).

Kargo et al. (2010) employed a biomechanical model of the frog hindlimb to test whether the model of premotor drive could account for the wiping behavior observed experimentally (Kargo and Giszter, 2008). The parameters of the premotor drive model (i.e., muscle groups, pulse time course, and amplitude and phasing of the single synergies) are initially identified to reproduce experimental isometric forces and free limb movement kinematics. As expected, starting from different limb postures the derived feedforward control fail in driving the simulated limb toward the target. However, as showed by Kargo and Giszter (2008), appropriate feedback modulations of the amplitude and the phase shift of the drive burst, and the adjustment of muscle balance based on the initial configuration of the limb, are enough to generate successful muscle activations. Furthermore, the limb trajectories obtained with and without feedback are very similar to those observed in intact and deafferented (Kargo and Giszter, 2000a) frogs, respectively. These results support the model of premotor drives, in which feedback mechanisms preserve the duration of the pulses.

Berniker (2005) analyzed mathematically the control scheme of muscle synergies and proposed a principle for its formation (Berniker et al., 2009). A linear reduced-dimensional dynamical model that preserves (to the best extent possible) the natural dynamic of the original system is initially computed. Synergies are defined as the minimal set of input vectors that influence the output of the reduced-order model (Berniker, 2005), and that minimally restrict the commands (and the resulting responses) useful to solve the desired tasks (Berniker et al., 2009). Practically, this set is found by optimizing the synergy matrix over a representative dataset of desired sensory-motor signals. This method was able to synthesize a set of synergies for the model of the frog hindlimb that were very similar to the ones observed experimentally (Cheung et al., 2005). Furthermore, the synergy-based controller produced muscle activations and kinematic trajectories that were comparable with the ones obtained with the best-case controller (that can activate each muscle independently).

4.4. ROBOTICS AND CHARACTER ANIMATION

In the context of robotics and characters animation, the concept of muscle synergies is appealing as it provides a strategy to reduce

the number of variables to be controlled (synchronous synergy model), or more generically, the dimensionality of the control signals (time-varying synergy model). Animated characters are embedded in physical environments (i.e., dominated by physics laws) thus the associated control problem is totally equivalent to the control of a musculoskeletal model or of a humanoid robot. In this section we present the works that have been carried out in these fields of research.

The work proposed by Mussa-Ivaldi (1997) is one of the first attempts to develop a controller based on the modularity observed in biological systems (Mussa-Ivaldi and Giszter, 1992). The idea is that the motion of a kinematic chain can be determined by a force field applied to its end effector. Inspired by the experiments performed by Giszter et al. (1993), such a force-field results from the linear combination of basic fields, each characterized by a single equilibrium point in operational space. Results show that, for a simulated planar kinematic chain, an appropriate choice of the basis-field coefficients can produce a wide variety of end-effector trajectories. Similarly, Matarić et al. (1999) used force fields to drive joint torque controllers on a rigid-body animated character (Matarić et al., 1998a,b).

Although the concept of spinal-force field is very similar, Mussa-Ivaldi's work does not directly use the notion of synergy as defined in section 2. A step forward is taken by Nori and Frezza, who propose a mathematical formulation for a set of actuations (i.e., synergies) that comply with the hypothetical properties of spinal-force fields (Mussa-Ivaldi and Bizzi, 2000). The mathematical description of the synergies is derived from the closed-form solution of an optimal control problem. Additionally, a feedback controller assures that the system follows the desired trajectory toward the synergy equilibrium position. It is proved that the proposed formulation guarantees system controllability [2]. The synthesized synergies are successfully tested on a simulated two-degrees-of-freedom (dof) planar kinematic chain (Nori, 2005; Nori and Frezza, 2005).

The idea that each synergy solves a well-defined control problem [e.g., to lead the system to a specific equilibrium position (Nori and Frezza, 2005)], appears in several other studies (Chhabra and Jacobs, 2008; Todorov, 2009; Alessandro and Nori, 2012). Chhabra and Jacobs (2008) propose a method called Greedy additive regression (GAR). A library of task-specific actuations (synergies) are kept in memory. When a new task has to be performed, a suitable actuation is initially searched in the linear span of these synergies. If the lowest task-error is above a certain threshold, the task will be solved via traditional methods (e.g., feedback error learning), and the obtained actuation will be added to the library. If the library already contains the maximum number of synergies allowed, the least used one will be removed. The obtained results suggest that the synergies synthesized via GAR outperform primitives based on PCA if the dynamical system is non-linear (planar kinematic chain), and there is no statistical difference for linear systems. However, no theoretical explanation is provided.

[2]In control theory, a system is said to be controllable if an external input can move the system from any initial state to any final state in a finite time interval.

In the same vein, Todorov (2009) proved that, for a certain class of stochastic optimal control problems, an appropriate change of variable in the Bellman equation allows to obtain the optimal control policy as a linear combination of some primitives. These primitives are, in turns, solutions to other optimal control problems. Such a method has recently been tested in the context of character animation (da Silva et al., 2009). It is important to clarify that this theory provides a theoretical grounding to the compositionality of optimal control laws, but like GAR it does not provide a method to compute such primitives. In fact, although new efficient methods have been proposed recently, solving an optimal control problem remains quite computationally intense, and it might be unfeasible for systems with a large number of dof.

Another mathematical framework, that has recently been developed in the context of character animations, is based on the optimal anechoic mixture decomposition model, mathematically equivalent to the time-varying synergy decomposition. Specifically, complex kinematic animations are obtained by mixing primitive source signals that are learned from motion captured data (Mezger et al., 2005; Park et al., 2008a,b; Giese et al., 2009). Within this framework a number of interesting results have been achieved, including a mathematical proof of stability properties for groups of characters that interact in various ways (Mukovskiy et al., 2011).

The procedure presented by Alessandro et al. (2012) is grounded on a method to solve generalized reaching tasks called dynamic response decomposition (DRD). In this context, a task is defined as a list of constraints on the values of the state variables at given points of time. Initially, a state-space solution is computed by interpolating these constraints by means of a set of dynamic responses (i.e., evolutions of the state variables); then, inverse dynamics is used to obtain the corresponding actuations. Based on this technique, the following two-phase procedure allows to synthesize a set of synergies. An extensive collection of generic actuations are used to generate the system dynamic responses (exploration phase); in a second stage (reduction phase), they are used to interpolate a small set of tasks. The corresponding actuations proved to be effective synergies for additional reaching tasks on a simulated planar kinematic chain. Like GAR, this procedure generates synergies in the form of feedforward controllers, and it allows to modify incrementally the library of synergies. However, DRD provides a computationally fast method to solve the task. This technique has proved its efficacy empirically, but a solid theoretical grounding is still lacking.

Most of the methods presented so far require an accurate analytical model of the system dynamics. Such a model is not always available, and for certain robots, it might be difficult to identify. Todorov and Ghahramani (2003) propose a method to synthesize synergies by means of unsupervised learning. Their work emphasizes the role of muscle synergies in an hypothetical hierarchical control scheme similar to the one proposed by Safavynia and Ting (2012): receptive fields translate sensory signals to internal variables, and muscle synergies translate high-level control signals applied to these variables to actual muscle contractions. From this perspective, receptive fields along with

motor primitives must form an inverse model of the sensory-motor system. This mapping is learned by fitting a probabilistic model to a dataset of sensory-motor signals generated by actuating the robot with random pulses. The use of the learned synergies as low-level controllers substantially reduces the time needed to learn a desired policy, however, their capability to generalize to additional control laws is not explicitly tested.

Alessandro and Nori (2012) define synergies as parameterized functions of time that serve as feedforward controllers. The identification procedure consists in finding the values of the parameters such that appropriate linear combinations of the resulting synergies drive the dynamical system over a set of desired trajectories (training set). The synergies identified are then tested for generalization; the idea is to evaluate to which extent they can generate actuations that drive the system along a new group of trajectories (testing set). This procedure has been evaluated successfully in simulation and does not require the analytical form of the system dynamics. However, it is computationally very intense as it involves heavy optimizations. In essence, this work proposes a new formal definition of the concept of muscle synergies: elementary controls that are evaluated in terms of task-performance (i.e., tracking error), rather then in terms of approximation of the input-space.

Thomas and Barto (2012) formulate the problem of primitive (i.e., synergy) discovery within the framework of reinforcement learning. In this case, the problem that the agent has to solve is a Markov decision process (MDP), and each primitive is a parameterized feedback control policy. The idea is to identify the optimal parameters that maximize the expected reward for a given task, when the control is restricted to linear combinations of the learned primitives. This method is tested on a simulated planar kinematic chain actuated with artificial muscles. Primitives are identified on reaching tasks, and they are successfully tested in a scenario that involve reaching and avoiding obstacles. This work clearly shows the advantage of a synergy-based framework in terms of learning speed of novel control policies. This method is in essence similar to the one proposed by Alessandro et al. (2012), however, it identifies complete feedback control policies rather then single feedforward synergies.

The time-varying synergy model greatly reduces the dimensionality of the problems by encoding actuations with synergy-coefficients, however, at the same time it introduces a complication. As the new input variables are piecewise constant, it is difficult (although possible) to implement feedback loops. The synchronous model ameliorates this problem and, to some extent, it allows adapting traditional control strategies to the new reduced-dimensional control input.

Some researchers employ the synchronous synergy model to control the tendon-driven robotic ACT hand (Deshpande et al., 2013) in a reduced dimensional space (Rombokas et al., 2011; Zhang et al., 2011; Malhotra et al., 2012). Similarly to Todorov and Ghahramani (2003), dimensionality reduction is applied both in the sensory space and in the actuation space. The "observation synergies" transform sensory readings (tendon lengths) into a lower dimensional variable; the "control synergies" translates synergy-coefficients (as defined in section 2) to motor signals. Model adaptive control and PIDs are applied to the reduced dimensional input, and allow the robotic hand to perform tasks like writing (Rombokas et al., 2011; Malhotra et al., 2012) and playing piano (Zhang et al., 2011). The synergy matrices (observation and control) are computed by applying PCA and NMF to a dataset of tendon-lengths obtained as a result of defined hand motions. It is noteworthy that the more similar this motions are to the ones required to solve the task, the better the quality of the obtained synergy-based controller. This is clearly not surprising, but it highlights the importance of task-related variables in the formation of muscle synergies (Todorov et al., 2005).

Marques et al. (2012) identify synchronous synergies by means of an unsupervised Hebbian-like algorithm that captures the correlations between motor signals and sensory readings. Each synergy thus summarizes the levels of correlation between each motor and one of the sensors. The time modulation of each synergy to solve a given task is then obtained by means of a supervised learning procedure that aims at reducing the task error. Unlike many other works in robotics, the exploratory strategy proposed to generate the dataset of sensory-motor data does not exploit any prior information about the desired motor tasks, therefore muscle synergies are implicitly interpreted as patterns of motor coordinations that solely reflect the biomechanical constraints of the robot. This method has been tested on a single-joint tendon driven robot.

In the context of robotic hands, many researchers adopted the idea of postural-synergies, or eigengrasps. This concept derived by the observation that the variability of finger postures during human grasps can be explained by a few principal components (Santello et al., 1998), i.e., eigengrasps. Similarly, constraining the finger-joints positions of a robotic hand in such a way that the useful grasping postures can be obtained by superposing a small number of components, would result in a substantial simplification of the graphing problem. Ciocarlie and Allen (2009) derived a theoretical formulation of the problem of stable grasping in the low dimensional space of the postural-synergies; such a formulation is further improved by Gabiccini et al. (2011) for complain grasps. These studies are further analyzed and discussed by Bicchi et al. (2011), who presented them from the point of view of modeling the process of grasping and active touch. Finally, Brown and Asada (2007) proposed a direct mechanical implementation of the eigengrasps. In all these works, the quantitative details of the postural-synergies are taken from human experiments and adapted to the robot mechanical structure; the problem of finding a set of synergies that is optimized for a given robotic hand is left as future research.

Reduced dimensionality based on postural synergies is also explored by Hauser et al. (2011) for the task of balancing a humanoid robot. The authors propose a mathematical formulation, as well as a method to construct kinematic synergies (i.e., predefined balance between joint positions) that are directly linked to task variables (e.g., for balance control, the center of pressure). Additionally, the synergies are constructed in such a way that the mapping from synergy coefficients to task variables is linear (similar to the work proposed by Nori and Frezza (2005) but in kinematic space). This allows to use a simple

proportional-integral-derivative controller (PID) on the synergy coefficients to control the center of pressure of the robot, as long as the movements are slow enough to neglect dynamic disturbances. The proposed method is demonstrated both in simulation and in a real humanoid.

As a final note, it is important to say that the concept of modularity has been employed in robot control in many other ways. In most of these works modules are defined as kinematic-based controllers that are combined sequentially to obtain complex joint trajectories (Khansari-Zadeh and Billard, 2011; Ijspeert et al., 2013). In this regard, these works are more related to the concept of kinematic stroke than to muscle synergies (Pollick et al., 2009). These works are out of the scope of this paper, as we focus on controllers that, in accordance with the models of muscle synergies, are based on (parallel) superpositions of primitives in input-space.

5. CONCLUSIONS AND PERSPECTIVES

The hypothesis of muscle synergies, that proposes a modular organization of the neural circuitry involved in muscle coordination, has been proved very difficult to validate or falsify (Tresch and Jarc, 2009). As discussed in section 3, a substantial body of evidence in favor of this hypothesis comes from the observation that the main components of EMG recordings are robust across behaviors, biomechanical contexts, and individuals. In addition, the successful control of artificial agents confirm the computational feasibility of the hypothesized synergy-based controller (section 4). However, there also exist experiments that, for the case of the human hand, seem to disprove the hypothesis of muscle synergies (Kutch et al., 2008; Valero-Cuevas et al., 2009). As a matter of fact, there is no real consensus yet on whether muscle synergies effectively represent a modular organization of the CNS, or they merely result from the methodology employed during the experiments.

The works that are based on the control of artificial agents (e.g., musculoskeletal models, robots, and animated characters) clarify the importance of evaluating synergies in task-space. In this context, the idea is to synthesize a set of synergies that guarantees the accomplishment of the desired tasks (**Figure 3**, red arrows). On the contrary, the main focus of experimental motor control has been to identify the synergies that better reconstruct the recorded EMG dataset (**Figure 3**, continuous green arrows), and to understand their neural substrate. This approach implicitly assumes that a well reconstructed input signal leads to the observed task performance. Given the non-linear dynamics of the musculoskeletal system, this assumption might not hold. For this reason, in our view the hypothesis of muscle synergies should be tested by validating an input–output model (i.e., from muscle activations to task-variables), rather than fitting a model of the input data alone (**Figure 3**, dashed green arrow). In fact, we could speculate that muscle synergies encode a form of body schema (Hoffmann et al., 2010) that allows translating intentions to motor plans (i.e., the inverse dynamic model of the musculoskeletal system) (Torres-Oviedo and Ting, 2010).

The concept of functional synergies represents a first attempt to relate muscle synergies to task variables. However, as discussed in section 4.2, EMG and task-level components are assumed to be activated by the same coefficients. This assumption cannot hold in general because the musculoskeletal system is non-linear; rather, input-space and task-space coefficients should be related by a non-linear mapping (as described by Alessandro et al., 2012). To address this issue, one should go beyond the use of NMF, and develop novel techniques that do not impose a linear mapping between the two sets of coefficients. Additionally one could try to reconstruct the task-variables with more general non-linear methods instead of imposing a linear combination also at the task level. In the same spirit of the procedure used so far, such a technique should optimize the reconstruction error of the EMG signals, and constrain a good fit of the task-variables. In any case, the generality of the extracted functional synergies should be tested. To the best of our knowledge, the model of functional synergies was never used as a predictive framework. It would be extremely interesting to evaluate the extent to which functional synergies identified during the execution of a certain set of tasks, are able to predict the muscle activations observed during the execution of another task that involve the same task variables. If such prediction was unsuccessful, the experimenter could conclude that the identified muscle synergies do not really encode the hypothesized biomechanical functionalities, or that the same functionalities might be encoded by different synergies. In general, the model of muscle synergies has very seldom been used to make predictions.

An alternative strategy to verify the relationship between muscle synergies and task execution (**Figure 3**, dashed green arrow), is to evaluate if they can account for task-related variations of single movement executions (Delis et al., 2013). In practice, one might assess the capability of these synergies to decode each repetition of different motor tasks. In other words, one should be able to classify the motor tasks from the activation coefficients of the extracted synergies. If the decoding capability is satisfactory, one might conclude that the synergies not only constitute a low dimensional, but also a functional representation of the motor commands. This idea might be used to develop novel extraction algorithms that include task decoding objectives directly in the optimization procedure. The identified synergies would then maximize not only the reconstruction of the original motor patterns, but also the capability of disambiguating task-relevant trial-to-trial variations. Unlike the dimensionality reduction methods used so far, this approach would rely on supervised learning techniques to exploit information about the task. Possible alternatives to standard extraction algorithms include energy constrained discriminant analysis (Philips et al., 2009), the discriminant NMF (Buciu and Pitas, 2004), and the hybrid discriminant analysis (Yu et al., 2007).

The use of single-trial analysis, like the decoding strategy proposed above, may be useful for addressing some open problems that are relevant to this review. First, the development of such techniques may be useful to identify muscle activation components of relatively low amplitude that reflect unique information about the task (Quiroga and Panzeri, 2009); such components would be completely lost if an average across several trials is performed prior to the analysis. Second, such single-trial analysis techniques may be used to investigate the existence of trial-to-trial

correlations across synergy activations, and to evaluate their functional role in controlling and performing task-related movement (Golledge et al., 2003; Schneidman et al., 2003). Finally, approaches based on single-trial analysis of neural activity could also be instrumental in clarifying the existence of a neural basis for the muscle synergies (Hart and Giszter, 2004, 2010; Nazarpour et al., 2012; Ranganathan and Krishnan, 2012). For example, they could in principle be applied to decode the task from single-trial neural population patterns that regulate the activation of synergies, and also to determine which patterns encode task differences, and which carry additional or independent information to that carried by other patterns (Delis et al., 2010).

Finally, an important aspect that is worth discussing is the role of feedback loops. In the case of synchronous synergies, the time course of the mixing coefficients can be adjusted on-line by means of appropriate feedback controllers; this is the reason of the popularity of such a model in the context of robotics. On the contrary, the models of temporal and time-varying synergies, in which the actuation time course are directly embedded in the synergies themselves, naturally represent feedforward controllers. As a result, the evolution of the task-variables intimately depends on the initial condition of the dynamical system. Alternatively, these synergies might be defined as functions of both time and state-variables; such an approach would characterize temporal and time-varying synergies as generators of complete control policies (Nori and Frezza, 2005; Todorov, 2009; Thomas and Barto, 2012).

In conclusion, we believe that the evidence reviewed here provides support for the existence of muscle synergies. However, many issues are still unresolved. A deeper investigation of the relationship between synergies and task variables might help to address some of the open questions. In general, a closer coordination between experimental and computational research might lead to a more objective assessment of the muscle synergy hypothesis in task-space, and a better understanding of the modularity of the CNS.

Muscle synergies are neural coordinative structures that function to alleviate the computational burden associated with the control of movement and posture. In this commentary, we address two critical questions: the explicit encoding of muscle synergies in the nervous system, and how muscle synergies simplify movement production. We argue that shared and task-specific muscle synergies are neurophysiological entities whose combination, orchestrated by the motor cortical areas and the afferent systems, facilitates motor control and motor learning.

Keywords: motor primitive, spinal interneuron, motor module, non-negative matrix factorization, motor cortex

When the central nervous system (CNS) generates voluntary movement, many muscles, each comprising thousands of motor units, are simultaneously activated and coordinated. Computationally, this is a daunting task, and investigators since Bernstein (1967) have strived to understand whether and how the CNS's burden is reduced to a much smaller set of variables. In the last few years we and our collaborators have searched for physiological evidence of simplifying strategies by exploring whether the motor system makes use of low-level discrete elements, or motor modules, to construct a large set of movement. In this brief communication, we argue that there is convincing evidence that the discrete elements for such simplification are muscle synergies, neurophysiological entities whose combination is orchestrated by the motor cortical areas and the afferent systems.

EXPLICIT ENCODING OF MUSCLE SYNERGIES IN THE NERVOUS SYSTEM

The core argument for the neural origin of motor modules rests on studies of the spinal cord in several vertebral species, conducted using a variety of techniques such as microstimulation (Bizzi et al., 1991; Giszter et al., 1993), *N*-methyl-D-aspartate (NMDA) iontophoresis (Saltiel et al., 2001, 2005), and cutaneous stimulation (Tresch et al., 1999). With these approaches, we and others were able to provide the experimental basis for a modular organization of the spinal cord circuitry in the frog (with the studies cited above), rat (Tresch and Bizzi, 1999), and cat (Lemay and Grill, 2004). A *spinal module* is a functional unit of spinal interneurons that generates a specific motor output by imposing a specific pattern of muscle activation. The output of an activated module can be characterized as a force field, or the collection of isometric muscle forces generated at the limb's endpoint over different locations of the workspace. In the spinal frog and rat, different groups of force field were activated as the stimulating electrode was moved to different loci of the lumbar spinal cord in the rostro-caudal and medio-lateral directions. Following the initial description of the force field, Mussa-Ivaldi and others found that co-stimulation of two spinal sites led to vector summation of the forces generated at each site separately. When the pattern of forces resulting from co-stimulation were compared with those computed by linear summation of the two individual fields, the co-stimulation fields and the summation fields were found to be equivalent in 83% of the cases (Mussa-Ivaldi et al., 1994). Similar results were also obtained by Hogan and colleagues (Lemay et al., 2001), Tresch and Bizzi (1999), and Kargo and Giszter (2000). Vector summation of force fields led to the hypothesis that generation of movement and posture may be based on the combination of a few discrete motor primitives. A subsequent simulation study showed that the combinations of frog hind-limb muscles that produced stable force fields were similar to the muscle groups observed to be co-activated in spinal microstimulation studies (Loeb et al., 2000). These results together argue that the experimentally derived force fields are generated by discrete groups of muscles activated as individual units, or *muscle synergies*, from whose linear combination a vast repertoire of movement and posture could be generated.

Most voluntary movements are the result of the simultaneous activation of a few muscle synergies via descending or afferent pathways which produces a complex electromyographic (EMG) pattern in the limb's muscles. To retrieve the structures of muscle synergies from the variability of muscle activations, we and others have utilized a computational procedure, the non-negative matrix factorization algorithm (NMF), originally proposed by Lee and Seung (1999, 2001). The synergies identified by NMF are time invariant non-negative vectors whose linear combination is found, through an iterative update rule, to minimize the error of EMG

reconstruction, with the additional assumption that this error follows a Gaussian distribution (Cheung and Tresch, 2005). The extracted synergies thus reflect spatially fixed regularities (Kargo and Giszter, 2008; Safavynia and Ting, 2012) embedded within diverse muscle patterns. In addition to NMF, there exist other linear factorization algorithms, such as independent component analysis (Bell and Sejnowski, 1995) and independent factor analysis (Attias, 1999). For all of these algorithms, because each synergy can have components across any subset of muscles, any one muscle may belong to multiple synergies; this aspect makes the extracted synergies different from other formulations in which each muscle belongs to a single synergy. As Tresch et al. (2006) have shown, most of the algorithms, with the exception of principal component analysis (Jolliffe, 2002), perform comparably in simulated and experimental data sets. This observation suggests the extracted muscle synergies are likely not an artifact contingent upon the particular assumptions employed by the algorithm for separating the activations of the synergies, but reflect basic aspects of muscle activations.

Recent electrophysiological experiments in the lower vertebrates, cat, and monkey have provided evidence that the temporal activations of muscle synergies identified by computational algorithms are expressions of neural activities. In the frog, discharging neurons in the intermediate zone of the spinal cord were found to be significantly related to activations of muscle synergies rather than activities of individual muscles (Hart and Giszter, 2010). In the cat, activities of distinct groups of neurons in the forelimb motor cortex recorded during reaching coincided with activations of muscle synergies identified by a cluster analysis (Yakovenko et al., 2011). In the monkey, intra-cortical microstimulation of an area of the motor cortex with descending connections to the spinal interneurons evoked EMG patterns decomposable into muscle synergies that, remarkably, matched the ones observed during natural reach-and-grasp behaviors (Overduin et al., 2012). This finding directly support the idea that the expression of voluntary movement relies on a complex pathway connecting the motor cortex and the spinal interneurons; through this circuitry, the cortex selects and combines the appropriate spinal interneuronal modules, and supplies the modules with temporal patterns of activation appropriate for the behavior being executed.

There is emerging evidence suggesting that the above conclusions may also underlie production of voluntary movement in humans. In a group of mildly to-moderately impaired stroke survivors with lesions in the motor cortical areas, we observed that the muscle synergies extracted from the stroke-affected arm were similar to those of the unaffected arm despite marked differences in motor performance between the arms (Cheung et al., 2009b). This observation is compatible with the proposal that muscle synergies are structured in the brain stem or spinal cord, and after a stroke, altered descending commands from the supraspinal areas generate abnormal motor behavior through faulty activation of the spinal modules. Similar results for the lower limb have also been presented (Clark et al., 2010). It is of course entirely possible that in humans who have developed highly skilled movements, like pianists (Gentner et al., 2010) or professional athletes (Frère and Hug, 2012), the motor cortex may also encode muscle synergies (Gentner and Classen, 2006; Rathelot and Strick, 2006). How the CNS manages to involve both the cortex and the spinal interneurons from the earliest stage of movement preparation (Fetz et al., 2002), and to integrate sensory information that contains crucial postural information related to the initial limb position during motor planning, are questions that deserve to be systematically explored.

DO MUSCLE SYNERGIES HAVE A NON-NEURAL ORIGIN?

Kutch and Valero-Cuevas (2012) have recently proposed that the muscle synergies extracted from EMGs using factorization algorithms could have a non-neural origin. Through cadaveric experiments and computational models, these authors showed that constraints arising from the selected task and/or limb biomechanics could produce apparent couplings among muscles even when each muscle in the model is assumed to be independently controlled. This point of view that emphasizes non-neural constraints represents an important contribution to the ongoing debate on the provenance of the previously observed low-dimensionality of muscle activations (Tresch and Jarc, 2009), and offers important complementary insights. There are, however, a number of developmental and clinical studies that place the view of Kutch and Valero-Cuevas in a different light.

For instance, in a recent developmental study on human locomotor primitives, Lacquaniti and his colleagues (Dominici et al., 2011; Lacquaniti et al., 2012) demonstrated that the development of motor patterns from the neonatal to the toddler stages is primarily a result of the addition of new patterns to the few basic patterns present at birth. The precise temporal activations of all primitives are shaped gradually, over many years, as the individual grows from being a toddler to a preschooler, and finally to an adult. This progressive addition and fine-tuning of motor primitives could reflect how an infant, on his or her way to bipedal locomotion, "learns" new muscle synergies, presumably through mechanisms of associative learning and/or supervised learning, or one analogous to the mechanism responsible for the formation of ocular dominance columns in the developing visual cortex (Hubel and Wiesel, 1959). While the precise roles of genetic control in motor development remains to be established, it is conceivable that sensory feedback from muscles and tendons triggers adaptive changes in the spinal interneuronal circuitry to tune or create modules specifically tailored to the limb biomechanics of the individual, and informs other areas of the CNS of these modifications. At the termination of these developmental processes, the biomechanical properties of the limb are fully incorporated into the architecture of the motor modules, thus resulting in a match between the plant and its neural controllers that allows high-caliber motor performance. Since the limb biomechanics of different individuals are at least slightly different, it is not surprising that the precise structures of some muscle synergies are subject-specific (Torres-Oviedo and Ting, 2010). Thus, our argument that muscle synergies could have a neural origin is not incompatible with the idea that the precise structuring of each muscle synergy incorporates knowledge of both the musculo-skeletal dynamics (Berniker et al., 2009) and other biomechanical properties of the limb.

Ideally, a strong case supporting the neural origin of the muscle synergies extracted from the EMGs should come from a comparison between the number of experimentally derived synergies and

the dimensionality of the space of all muscle patterns suitable for the selected tasks. In a model of the human leg comprising 14 muscles, Kutch and Valero-Cuevas (2012) (their Figure 6C) showed that the set of all EMG patterns compatible with an isometric production of endpoint forces at 16 different directions, over three force magnitudes, defined an approximately seven-dimensional subspace (with 80% of the data variance explained). On the other hand, the number of leg muscle synergies for human locomotion, including running and walking at different speeds, was estimated to be between four and five (Ivanenko et al., 2004; Cappellini et al., 2006; Dominici et al., 2011). We do not know whether, for the human leg, isometric production of endpoint forces and locomotion define spaces of motor patterns with similar dimensionalities. But the fact that the dimensionality of the observed EMGs (4–5) was lower than that expected from the constraint of a related task (7) is not inconsistent with the notion that structures such as muscle synergies of neural origin exist to constrain possibilities of motor output (Andrea d'Avella, personal communication).

There is the additional possibility that muscle synergies extracted from EMG data sets reflect regularities in the reflex and other feedback-related activities of multiple muscles arising from fixed patterns of musculo-tendon length changes that are dictated by how the muscles are arranged around the joints (Kutch and Valero-Cuevas, 2012; their Figure 1B). This is certainly an important biomechanical constraint that can give rise to apparent muscle couplings. However, in the frog, the structures of both the spinal force fields (Loeb et al., 1993) and locomotor muscle synergies (Cheung et al., 2005) persisted even after complete hind-limb deafferentation.

Another related set of findings has come from studies of muscle synergies in human stroke patients. Briefly, using the NMF algorithm and a non-negative least-squares technique, we characterized post-stroke alterations of muscle synergies in the stroke-affected arm as reflecting either a merging or a fractionation of the unaffected-arm muscle synergies (Cheung et al., 2012). Remarkably, while the extent of synergy merging correlated with the severity of motor impairment (which reflects the extent of motor cortical damage), the degree of synergy fractionation varied with the temporal distance from stroke onset (which reflects how long the motor system had been influenced by post-stroke plasticity). Given that these two patterns of synergy change correlated with variables related to the state of the nervous system, and that the biomechanical structures of the stroke-affected and unaffected arms are expected to be similar, it is likely that neural constraint is a major contributor to the structures of the observed muscle synergies in the affected arm. Alterations and merging of both upper- and lower-limb muscle synergies in stroke survivors have similarly been reported in several other recent studies (Clark et al., 2010; Gizzi et al., 2011; Roh et al., 2013).

DO MUSCLE SYNERGIES SIMPLIFY MOVEMENT PRODUCTION BY DECREASING THE NUMBER OF DEGREES OF FREEDOM?

Muscle synergies may be conceived as representing elementary building blocks whose superposition allows the expression of a vast number of movements and postures. Similar concepts have been advanced by a number of laboratories with a variety of species ranging from *Aplysia* (Jing et al., 2004), to the frog (d'Avella et al., 2003; Hart and Giszter, 2004), rat (Tresch and Bizzi, 1999), cat (Ting and Macpherson, 2005; Ethier et al., 2006; Krouchev et al., 2006), monkey (Overduin et al., 2008), and humans (Krishnamoorthy et al., 2003; Torres-Oviedo and Ting, 2007; d'Avella et al., 2008; Monaco et al., 2010; Muceli et al., 2010). Taken together, these results indicate that *for each single task*, a reduction of the number of degrees of freedom relative to the number of muscles is a way to simplify the control of movement. In the frog, we and others have studied the activation patterns of all major hind-limb muscles collected during diverse natural motor behaviors, including jumping, in- and out-of-phase swimming, walking, kicking, and wiping. As shown by d'Avella and Bizzi (2005), each motor behavior results from a combination of both synergies shared between behaviors, and synergies specific to each or a few behaviors. While we do not know the maximum number of in-born and learned motor tasks each species may produce, it is conceivable that in any individual, the numbers of *all* task-specific and shared synergies combined may exceed the number of relevant muscles, in which case the EMGs recorded over all possible behaviors are not expected to exhibit a low dimensionality. This theoretical possibility raises the question of how muscle synergies of neural origin "simplify" movement control. We think muscle synergies simplify the production of posture and movement in the following senses. First, for tasks that can be executed by many possible trajectories or muscle activation patterns, a set of pre-existing muscle synergies can serve as a preferred channel through which the motor commands are specified. Muscle synergies thus effectively remove any musculoskeletal redundancy at the levels of posture (Santello et al., 1998; Weiss and Flanders, 2004; Bicchi et al., 2011), kinematics (Flash and Hochner, 2005), and muscle activation, by constraining how the muscles can be activated (Bernstein, 1967; Full and Koditschek, 1999; McKay and Ting, 2008).

Second, *for a single given task*, the total number of shared and task-specific muscle synergies needed for its execution is still expected to be smaller than the total number of muscles. The set of synergies thus reduces the volume of the space of possible motor commands that the CNS needs to search through by defining a subspace of a lower dimensionality. This is equivalent to a previous suggestion that preformed neural coordinative structures, such as muscle synergies, function to automatically eliminate muscle patterns that lead to uncoordinated or inappropriate movements (Tuller et al., 1982; Turvey et al., 1982). Such a reduction in search-space volume allows efficient transformation between task-level variables and muscle activations (Ting et al., 2012). This advantage conferred by a synergy-based control scheme may be particularly important for a task for which only a very small set of motor patterns is compatible with fulfilling the task requirements. For such a task, given the very large volume of the high-dimensional muscle-activation space defined by the many muscles of the limb, without any neural coordinative structures in place it would be very difficult for the motor system to discover, every time, a very small subspace of suitable motor patterns starting from any initial point in the space. The muscle synergies required could be a mixture of shared and task-specific muscle synergies

either acquired through motor learning, or inherited over the course of evolution of the species (Giszter et al., 2007). Generating motor outputs by activating these synergies ensures an efficient and robust execution of a difficult task.

Third, it has been shown that the activation of each muscle synergy can accomplish a certain kinematic (d'Avella et al., 2003) or biomechanical (Ting and Macpherson, 2005) goal which may or may not be shared between behaviors. The set of all muscle synergies may then be viewed as a compendium of coordinative patterns for executing different functions that the motor system can exploit either when executing a learned task under a different dynamic environment, or when learning a new task. In broader terms, muscle synergies may be essential components in the architecture of the motor system that allow generalization to occur (Poggio and Bizzi, 2004). Consistent with this interpretation, muscle synergies were observed to be robust across very different biomechanical or behavioral contexts (Cheung et al., 2009a; Torres-Oviedo and Ting, 2010; Chvatal et al., 2011). Also, human subjects were able to adapt much faster to a perturbation if the compensatory motor patterns required could be generated simply by tuning the activations of the existing muscle synergies (d'Avella and Pai, 2010). It remains to be seen to what extent difficult and unusual movements are also executed by recruiting the synergies utilized in well-practiced behaviors.

CAN MOTOR OUTPUTS BE GENERATED ONLY BY COMBINING MUSCLE SYNERGIES?

We have reviewed above experimental evidence that support the neural origin of muscle synergies, and argued how the combination of both shared and task-specific synergies could facilitate motor control and motor learning. We do not claim that neurally based muscle synergies are the only structures that can give rise to muscle couplings observed in experiments: feedback-related activities arising from limb biomechanics, for example, could lead to an observed coupling (Kutch and Valero-Cuevas, 2012). Nor do we claim that motor outputs can be generated only by combining a handful of spatially fixed muscle synergies. Monosynaptic stretch reflex, for instance, clearly contributes to the activities of each individual muscle. Also, at least for humans, with sufficient training even individual motor units of a single muscle could be voluntarily controlled (Basmajian, 1963). These and other additional mechanisms of motor-output generation further augment the flexibility of the motor system, and could conceivably play a role during the acquisition of motor skills (Kargo and Nitz, 2003).

One fruitful direction of future research is to determine precisely how the CNS integrates non-synergy-based mechanisms with the existing muscle synergies for the execution of a wide range of movements. In the higher primates and humans, there are two subdivisions of the primary motor cortex: a rostral, phylogenetically older region that contains descending efferents destined to the spinal interneurons, and a caudal, phylogenetically newer region that contains cortico-motoneuronal (CM) cells with monosynaptic innervations to the motoneurons of individual shoulder, elbow, and finger muscles (Rathelot and Strick, 2009). It is plausible that while the "old" motor cortex contributes to motor output by providing activation drives for the spinal modules, the "new" motor cortex further sculpts the activations of specific muscles by bypassing the spinal mechanisms through the CM cells. Controlling movement by combining muscle synergies and other proposals based on independently controlled muscles (Kutch et al., 2008; Valero-Cuevas et al., 2009) are not necessarily mutually exclusive.

Computational models of neuromotor recovery after a stroke might help to unveil the underlying physiological mechanisms and might suggest how to make recovery faster and more effective. At least in principle, these models could serve: (i) To provide testable hypotheses on the nature of recovery; (ii) To predict the recovery of individual patients; (iii) To design patient-specific "optimal" therapy, by setting the treatment variables for maximizing the amount of recovery or for achieving a better generalization of the learned abilities across different tasks. Here we review the state of the art of computational models for neuromotor recovery through exercise, and their implications for treatment. We show that to properly account for the computational mechanisms of neuromotor recovery, multiple levels of description need to be taken into account. The review specifically covers models of recovery at central, functional and muscle synergy level.

Keywords: functional recovery, cortical reorganization, motor skill learning, compensation, robot, slacking, muscle synergy

INTRODUCTION

In the nervous system, a cerebro-vascular accident (stroke) elicits a complex series of reorganization processes at molecular, cellular, neural population, behavioral (sensorimotor and cognitive) and social interaction levels, with temporal scales that range from hours, to months, to years (Schaechter, 2004; Barbay et al., 2006; Nudo, 2006, 2007). Alterations occurs well beyond the actual lesion, including a low-activity "penumbra" region in the surrounding areas and inter-hemispheric unbalance due to a decreased activity in the ipsilesional side (Hummel and Cohen, 2006).

Animal models and human studies suggest that functional recovery is mediated by use-dependent reorganization of the preserved neural circuitry. A key to neuromotor recovery, and the basis of neuro-rehabilitation interventions, is movement associated with a task (Nudo, 2006, 2007) and with volitional effort (Blennerhassett and Dite, 2004; Higgins et al., 2006; Timmermans et al., 2010). This process produces alterations in neuronal excitability (Ward and Cohen, 2004), leading to changes in neural circuitry, with a process resembling that occurring in the developing brain. Redundancy in the musculoskeletal system plays a key role in neuromotor recovery. It has long been suggested (Bernstein, 1967) that the nervous system has a modular control structure to deal with redundancy. According to this view, the nervous system adaptively controls combinations of motor primitives that are the "building blocks" of movement organization. The pressure toward re-gaining functional independence may lead to the development of compensatory strategies that, even when adequate for carrying out activities of daily life (ADLs), may be stereotypical or energetically inefficient so that they may ultimately prevent true recovery (Levin, 1996b; Cirstea and Levin, 2000). For instance, an excess use of the non-paretic limb can have a negative influence on the process of cortical reorganization (Avanzino et al., 2011) by further reinforcing the imbalance between the two hemispheres. Models of neuromotor recovery that explicitly take modularity into account might be the most appropriate level of description for these phenomena.

In summary, neuromotor recovery through exercise is the end result of a complex interplay between activity-dependent reorganization of the brain areas close to the lesion, the recruitment of new neural pathways and the development of novel motor strategies.

A deeper understanding of the functional and physiological mechanisms underlying recovery would have strong impact on approaches to neuromotor rehabilitation. Computational motor control and, more in general, computational models may greatly contribute to this understanding (Huang and Krakauer, 2009). Even more importantly, models may be directly incorporated into technological solutions, and can constitute the basis for personalized therapy. In fact, Marchal-Crespo and Reinkensmeyer (2009) pointed out that there is a specific need for "improved models of human motor recovery to provide a more rational framework for designing robotic therapy control strategies." However, while musculoskeletal models have a long history in the personalization of treatment of movement disorders (Fregly et al., 2012), computational models of neuromotor recovery through exercise are still in their infancy.

Here, we review the state of the art of computational models for neuromotor recovery and their implications for treatment. We then suggest directions for future research.

MODELS OF NEUROMOTOR RECOVERY

There have been several attempts to model the time course of recovery, either when it is spontaneous, or when is facilitated by some form of treatment, e.g., electrical stimulation or assistance by a robot. Here we specifically focus on models of activity-dependent recovery. Models of recovery may focus on different levels of description, ranging from cortical or subcortical lesions, to muscle control, to functional behavior in the context of a specific task.

Models of neuromotor recovery at the level of cortical circuitry (Goodall et al., 1997; Reinkensmeyer et al., 2003; Butz et al., 2009) address how focal cortical lesions elicit neural reorganization phenomena, and the way these lesions affect motor behavior.

Other models address the "functional" level of description, related to the ability to complete a specific task and to how it changes over time. For instance, Colombo et al. (2008, 2010) describe the temporal evolution of performance over training time. Only few models focus on how physical interaction affects voluntary control (Emken et al., 2007), and how such voluntary control changes with exercise (Casadio and Sanguineti, 2012).

Models of muscle control focus on characterizing the impairment in individual subjects in terms of altered muscle synergies (Cheung et al., 2012).

Only few models encompass multiple levels of description. Han et al. (2008), Reinkensmeyer et al. (2012a) and Takiyama and Okada (2012) address the mechanisms of cortical reorganization in the context of voluntary motor activity, in a skill learning scenario. The emphasis here is on how voluntary movements promote recovery through cortical and subcortical reorganization.

In the following sections we will review a number of computational models of neuromotor recovery—respectively, at central, functional and muscle level—that have recently appeared in the literature. For each model we provide a general description; we then discuss their main findings or predictions, their limitations and the implications for rehabilitation.

MODELS OF FOCAL CORTICAL LESIONS AND ACTIVITY-DEPENDENT REORGANIZATION

Several models of neuromotor recovery explicitly focus on the mechanisms of cortical reorganization following a focal lesion (models at central level).

In the work of Goodall et al. (1997), an existing computational model of the sensorimotor control of arm movements (Chen and Reggia, 1996), incorporating a model of both the somatosensory and the motor cortex, was used to investigate the reorganization processes that occur immediately after a focal cortical lesion; see **Figure 1**. The model assumes "mexican-hat" lateral cortical connections, a competitive activation dynamics and a Hebbian plasticity mechanism for incoming cortical connections. Lesions were modeled by setting the activation levels of selected units to zero, and by eliminating connections to and from those units.

The main prediction of this model is a two-phases reorganization process. Immediately after the lesion, lower activity is observed in the areas surrounding the lesion. A second phase is characterized by a gradual increase of the size of this area and by a general reorganization of the intact cortical regions. Both effects are mediated by activity-dependent synaptic changes. The low-activity peri-lesional area and its expansion over time are due to lack of activation. The model also predicts that a small uniform excitatory peri-lesional input may favor the participation of this area in the reorganization process.

The same group also studied the short- and long-term changes in lateralization that occur after a focal lesion, and investigated the possible contribution to recovery of the intact hemisphere and of inter-hemispheric communication (Reggia et al., 2000; Shkuro et al., 2000).

Here cortical reorganization is modeled in terms of synaptic changes (self-organization) of a topological map. In contrast, Butz et al. (2009) specifically addressed the mechanisms of activity-dependent synaptic rewiring that occur immediately after a focal cortical lesion. Synapse formation is accounted for by models of axonal and dendritic elements. On the pre-synaptic side, activity is assumed to promote axonal outgrowth. On the post-synaptic side, each neuron is assumed to change its input connectivity in an homeostatic manner, with the goal of keeping the firing probability within a specified range. In this framework, rewiring after a lesion can be seen as a form of compensation, driven by the need to regain a stable (homeostatic) regime.

The main prediction of this model is that neural populations that are already in homeostatic conditions (e.g., in adult individuals) are much less likely to compensate for lesions than networks that are still under development.

An additional prediction is that external stimulation may promote axonal outgrowth, thus accelerating rewiring. However, prolonged stimulation may induce a saturation effect, hence it can be detrimental to recovery or, anyway, less effective than paused stimulation. In terms of rehabilitation, these findings suggest that training with pauses in between may be more effective than continuous intensive training without pauses.

Varier et al. (2011) used the model proposed by Reggia and colleagues (Chen and Reggia, 1996) to examine the effects of focal and distributed lesions at various stages of development. In partial contrast with Butz et al. (2009), this model predicts that mature systems are relatively more robust to lesions than systems that are still under development. This apparent discrepancy may be a consequence of the different assumptions on structural plasticity—highly modifiable (Butz et al., 2009) vs hardwired (Chen and Reggia, 1996).

Reinkensmeyer et al. (2003) developed a model of cortical damage and its consequences on arm reaching movements. Different from the previous approaches, this model does not address intracortical connectivity and its reorganization. Based on experiments on non-human primates (Georgopoulos et al., 1982), neurons in the motor cortex are assumed to collectively encode the initial direction of the movement (population vector coding). Specifically, each neuron's firing rate is assumed to be a function (truncated cosine) of the difference between the actual direction and the "preferred direction" for that neuron plus a noise term, whose standard deviation is proportional to the deterministic part of the cell response (signal-dependent noise). The overall encoded direction is the sum of the preferred directions of each individual neuron, weighted by their activity levels.

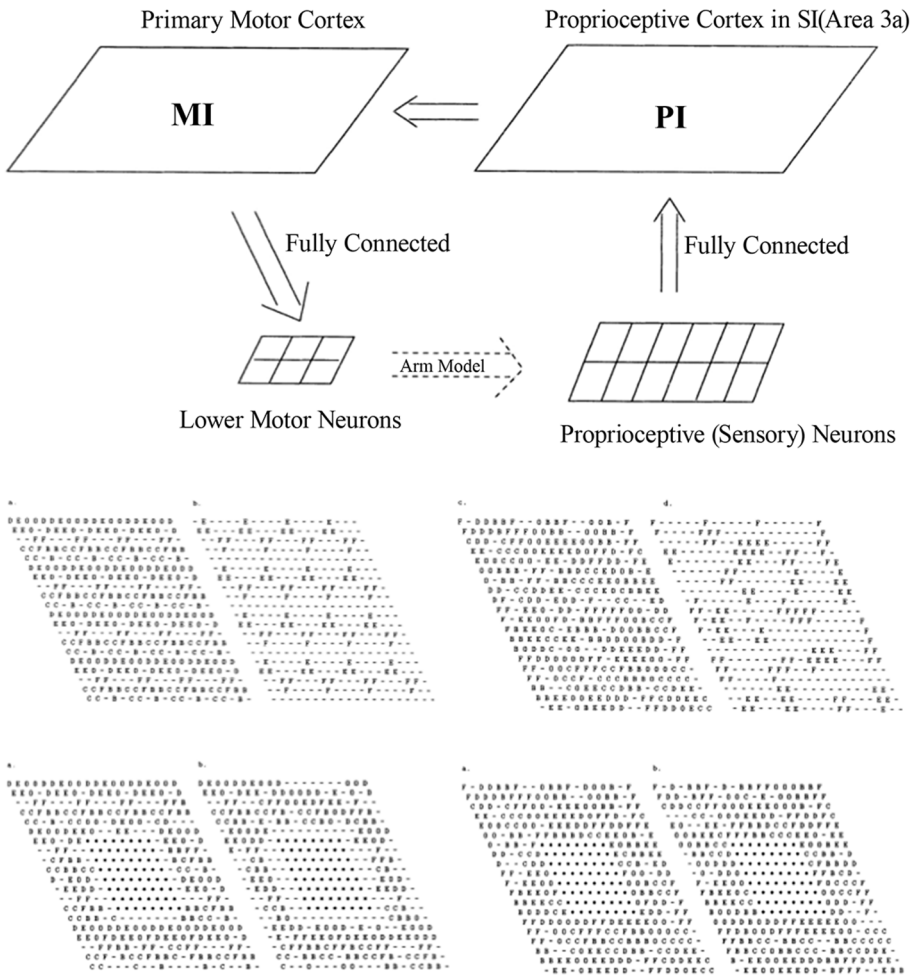

FIGURE 1 | Top: Sensorimotor control model, involving the primary motor cortex (MI) and the proprioceptive cortex (PI). Middle: Intact PI (left) and MI (right) maps. Letters indicate, for each neuron, the muscle groups of which that neuron encodes the activity (or stretch level). Bottom: PI (left) and MI (right) maps immediately after the lesion and after reorganization. Each map displays labels on all neurons (left) or only the neurons that are maximally activated by that muscle. From Goodall et al. (1997), reprinted with permission.

Cortical lesions were simulated by eliminating part of the neurons (cell death)—hence resulting in under-represented or non-represented preferred directions. Movement performance was measured in terms of the discrepancy between intended and encoded movement direction. They specifically looked at the variability of directional error within the same intended direction and across directions, and how these quantities are affected by cell death. They found that both types of error are inversely correlated with the fraction of surviving cells. In a number of experimental studies with stroke survivors, they found that the same indicators exhibit similar relationships with the subjects' clinical impairment score (Kamper et al., 2002; Reinkensmeyer et al., 2002; Takahashi and Reinkensmeyer, 2003).

This study addresses the problem of how cortical damage results in impaired movements. As such, it is a model of impairment, which does not explicitly address the mechanisms of recovery.

MODELS OF USE-DEPENDENT RECOVERY

Other models focus on cortical reorganization in the context of a specific motor task. Han et al. (2008) look at how lesions in cortical motor areas affect the mechanisms of arm selection to achieve a goal (reaching a target), and how impairment evolves through spontaneous arm use. The model accounts for motor cortical dynamics (both hemispheres) and action selection; see **Figure 2**. The cortex is modeled as in Reinkensmeyer et al. (2003), with the addition of a Hebbian learning mechanism to account for cortical reorganization. In addition, the process of deciding which arm to use is modeled as a form of reinforcement learning.

More specifically, the preferred directions for each neuron are assumed to adapt as a function of activity. Adaptation has two aims: (i) shifting the actual encoded direction closer to the desired direction (supervised component) and (ii) shifting the preferred directions of the individual neurons toward the desired direction (self-organizing component).

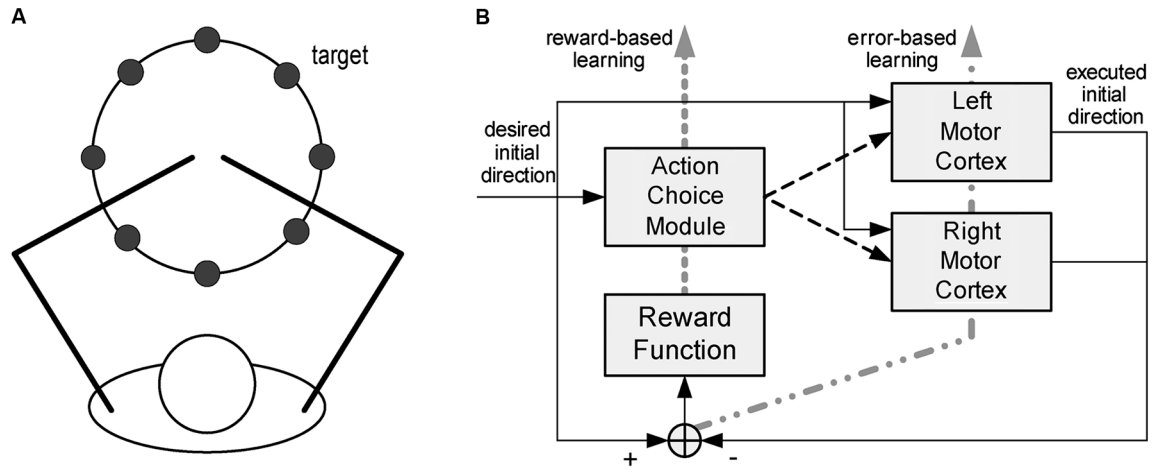

FIGURE 2 | Model of spontaneous recovery after stroke. The model focuses on reaching movements **(A)**, for which subjects spontaneously select what arm to use. The model **(B)** consists of a model of the motor cortex (both hemispheres) and an action selection module. From Han et al. (2008), reprinted with permission.

The action selection module accounts for the process of selecting the hand that will actually make the movement. A model of the action-value mapping, based on radial basis functions, generates the expected reward as a function of the direction of the actual movement. The hand whose expected reward is maximal is selected to execute the movement. This module is driven by a reinforcement learning mechanism. After every movement a reward signal is provided, defined as the sum of two terms, respectively reflecting (i) how close the cortex's encoded direction is to the desired movement direction, and (ii) the fact that the left hand is more likely chosen for leftward movements whereas the right hand is more likely selected for rightward movements. The action-value model is updated to minimize the difference between actual and expected reward.

As in Reinkensmeyer et al. (2003), the effect of a stroke was modeled by eliminating part of the neurons within one hemisphere's motor cortex. As a result, the impaired side is initially unlikely to be selected for movements on that side, and lack of use makes its selection even less likely. In contrast, its forced use induces reorganization, so that the intact portion of that hemisphere gradually shifts its preferred directions toward those that were once covered by the impaired portion of the cortex. In summary, the model addresses the mechanisms of interaction between activity-driven cortical reorganization and functional compensation, i.e., the change in the motor strategy (in this case, from the impaired to intact arm) that is driven by the need to preserve functional performance (e.g., a high reward).

Takiyama and Okada (2012) used a similar model, with emphasis on bimanual training. Their main prediction is that bimanual training facilitates the adaptation of the preferred directions of the unimpaired neurons in the ipsilesional cortical hemisiphere.

Han et al.'s (2008) model predicts that recovery will self-sustain if the amount of spontaneous use of the impaired arm reaches a certain threshold. If this is not the case, the impaired arm will be less likely to be selected, and recovery (if any) will gradually wash out. The model makes an important qualitative prediction—an activity threshold is a necessary condition for recovery to self-sustain. This can help explaining the mechanisms of action of rehabilitation strategies that rely on forced use of the impaired arm. As a matter of fact, observations from a rehabilitation trial based on constraint-induced movement therapy (CIMT) were found to be consistent with the "threshold" notion (Schweighofer et al., 2009). Aiming to achieve an "activity threshold" rather than providing a fixed amount of training, can be seen as a form of personalization of the therapy. Studies in this direction are currently under way, one first step being to quantify the amount of arm non-use in activities of daily living (Han et al., 2013).

More in general, the model is important because it is a first attempt to address the interplay between cortical reorganization and the development of compensatory strategies.

Although with different emphasis, all the above approaches focus on neural mechanisms of use-dependent reorganization. Impairment is only modeled qualitatively, and as such these models cannot immediately be related to the behavior of a specific subject, if not in qualitative terms.

Two related studies (Reinkensmeyer et al., 2009b, 2012a) focus on how reorganization of the preserved cortico-spinal (CS) pathways and the recruitment of new ones underlie the recovery of the ability to generate force. The proposed model—inspired by single-cell recordings of the neural correlates of wrist force generation in primates—specifically addresses the "residual capacity" phenomenon, i.e., the empirical evidence that additional motor training may still improve the movement capacities even years after a stroke.

Specifically, the model is based on the notion that experience of movement "practice" induces a re-optimization in the recruitment of the intact CS connections to motor-neurons (MNs). A pool of CS cells (see **Figure 3**) is assumed to receive a movement command as input. The activity of CS cells summates at the level of the MN pools in the spinal cord. Wrist force (aimed toward either flexion or extension) is determined by the difference between the activities of the "flexor" and "extensor" MN pools. This can be considered as the simplest muscle synergy. The synaptic weights of the CS-MN connections are assumed to

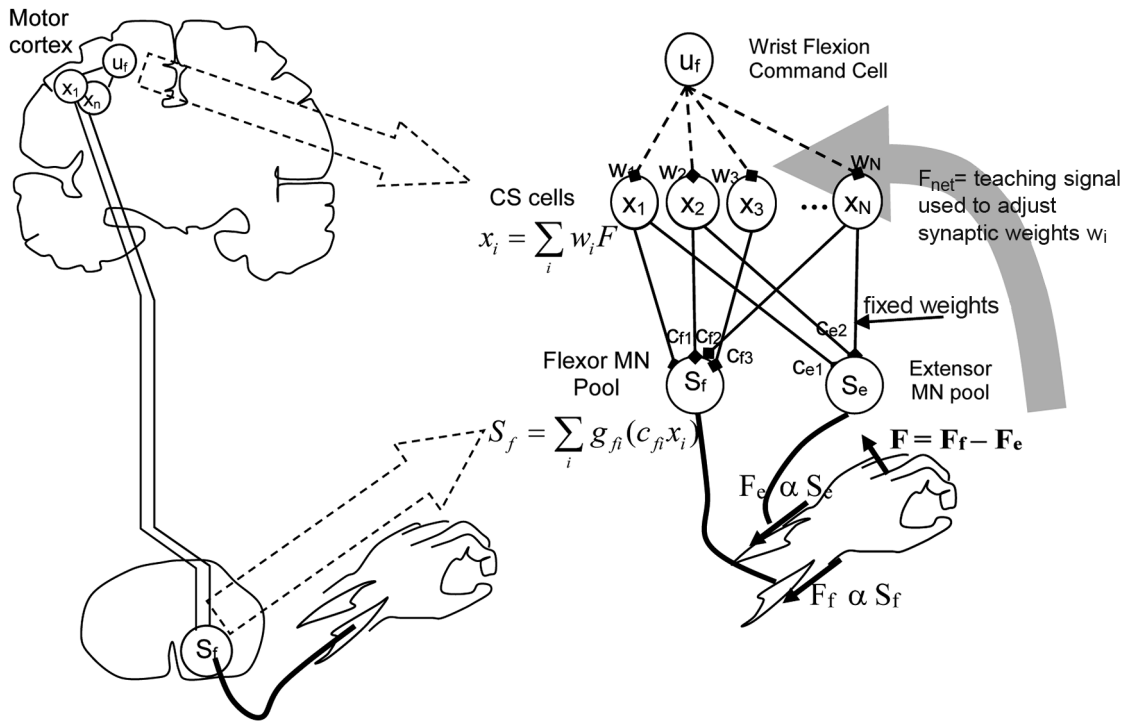

FIGURE 3 | Model of cortico-spinal reorganization after stroke. From Reinkensmeyer et al. (2012a), reprinted with permission.

be fixed, whereas the weights of the input connections to the CS cells are learned through a reinforcement mechanism, in which the experienced attempt to move the limb represents the reward signal that guides the refinement of activation.

Furthermore, the model assumes that if CS connections originating from the primary motor cortex (M1) are lacking, CS connections from the supplementary motor area (SMA) may be recruited as well.

Model simulations predict that the size of the residual CS population determines the maximum strength an individual stroke patient can achieve. This is consistent with observations based on Transcranial Magnetic Stimulation (TMS) and Magnetic Resonance-Diffusion Tensor Imaging (MR-DTI) (Stinear et al., 2007) suggesting a strong correlation between white matter integrity and maximum grip force. In addition, the model predicts that the same dose of exercise is more effective when administered to sub-acute subjects (as compared to chronic), and to less impaired subjects (as compared to more severe). Furthermore, severe M1 lesions are predicted to induce an increase in SMA activity. These predictions have been confirmed experimentally (Feydy et al., 2002; Ward et al., 2007).

This model has not been directly used in rehabilitation, but provides some hints on how to make rehabilitation more effective. The simulations show that recovery would be facilitated if noise level were decreased, or if noise were signal-dependent. Another prediction is that inhibition of the stronger connections, e.g., the residual connections originating from M1, would facilitate the recruitment of alternative pathways. The latter prediction is somehow consistent with, and actually provides a possible interpretation for, the empirical observation (Bolognini et al., 2009) that repetitive TMS of the intact cortical hemisphere facilitates recovery.

Like Han et al. (2008), this model only makes qualitative predictions and cannot describe the behavior of one specific subject. Further, apart from the M1-SMA shift of activity, the model does not directly address the compensation issue and does not provide new insight about the interplay between neural reorganization and task re-learning.

TEMPORAL EVOLUTION OF PERFORMANCE OVER TRAINING TIME

Variants of the power law of practice have often been used to describe the trial-by-trial evolution of motor performance during exercise, both within and between training sessions (the "functional" level of description).

In a widely used approach to robot-assisted rehabilitation (Krebs et al., 1998; Colombo et al., 2007), subjects are allowed a specific time interval to complete the task without assistance. After that, the robot completes the task through a high-stiffness position controller. In this way, the amount of robot intervention (fraction of the movement operated by the robot) automatically adjusts to subject's performance (more active performance, less robot intervention). However, to prevent movements from being totally passive, at least initially, this technique requires at least a minimum residual amount of voluntary control. In a systematic analysis of various performance indicators during robot-assisted rehabilitation based on this protocol, Colombo et al. (2008, 2010) used an exponential model to account for their temporal evolution.

The main finding of these studies was that some movement features, namely force control and movement smoothness, improved more quickly than parameters that relate to the fine-tuning of the movement, like speed. Specifically, speed improvement exhibited a much longer (2–3 times) time constant than force control and smoothness. Furthermore, in several subjects the path curvature exhibited a non-monotonic time course, with an initial increase until a peak, followed by a steady decrease.

These findings shed some light on the process of functional recovery. Subjects first explore the action space with the primary objective of exploiting their residual abilities to achieve the goal; then they undergo effort optimization to make the movement more efficient. The distinctive behavior of path curvature is a consequence of this two-phase process: the increase relates to the exploration phase, whereas the decay denotes the beginning of the effort optimization phase. The final step is the fine tuning of movement performance, denoted by the increase in movement speed (Colombo et al., 2012). These processes likely start at the same time and run in parallel, but have different time constants (faster the former, slower the latter).

A different, but related view of recovery is based on the notion that each movement is built by combining multiple sub-movements, and the empirical observation (Dipietro et al., 2009) that neuromotor recovery is characterized by a gradual decrease in the number of sub-movements—which results in an improved smoothness.

These mechanisms suggest that training-mediated recovery shares common features with motor skill learning.

In a subsequent study, Colombo et al. (2012) developed a control algorithm Progressive Task Regulation (PTR) that automatically adjusts various aspects of the task (amplitude of the movement, number of subtasks, assistance modality) according to the evolution of the different performance indicators. After each training epoch, performance is measured (moving average over the last three epochs), and the difficulty level of the task is modified according to a set of rules. Depending on the fraction of movement completed without assistance of the robot, exercise difficulty can switch to more challenging assistance modalities. The observed evolution of the different performance indicators was incorporated into the threshold values used to determine when the switch occurs. The decisions of switching task difficulty based on the PTR algorithm were found to be highly consistent with those based on subjective therapists' assessment.

This model only focuses on performance time series and only provides information on the temporal evolution of the recovery process. However, it does not attempt to describe the mechanisms underlying recovery. Specifically, the model describes the evolution of performance in non-assisted trials. The same modeling framework can address situations in which the degree of assistance is constant or changes slowly and monotonically, but cannot distinguish between the "robot" and the actual "voluntary" contributions in situations when they act together.

Recently, the same group proposed a dynamical model of recovery (Panarese et al., 2012), attempting to reproduce the mechanisms underlying the trial-by-trial evolution of performance. The model derives from a computational framework that was originally developed by Smith et al. (2004) in the context of associative learning in animal studies. In this model, an internal state variable denoting "motor improvement" is modeled as a random walk. This reflects the assumption that motor improvement builds up as the effect of many different factors. As an addition to the original model, at a given trial the logarithms of a number of observable performance indicators are assumed to be proportional to the amount of motor improvement. The model was found to reproduce the variety of time constants of the recovery observed in the different performance indicators. While interesting, this model is nothing more than a noisy version of the exponential model. In particular, the random walk assumption says little on what determines recovery.

THE ROLE OF ASSISTANCE

A few modeling studies have addressed the issue of how robot assistance affects recovery. Reinkensmeyer (2003) and Emken et al. (2007) focuses on adaptive changes in gait movements in presence of assistive forces. The study specifically addresses the trial-by-trial evolution of performance during adaptation to an assistive force field, and suggests that adaptation can be explained as an optimization process, which accounts for a combination of motor error and effort.

The resulting computational model is summarized in **Figure 4**. Similar to force field adaptation experiments (Thoroughman and Shadmehr, 2000; Scheidt et al., 2001; Donchin et al., 2003; Cheng and Sabes, 2006), the adaptation process is modeled as a linear autoregressive model. A controller receives as inputs the desired trajectory, the performance error and the motor command (muscle force) on the previous trial. The motor command on the next trial is the controller output. The controller includes two modules: (i) an inverse model of limb dynamics, which transforms a desired trajectory into an appropriate motor command; (ii) a "learning rule", which adapts the motor command to changes in the dynamics of the limb and/or of the environment. The output muscle force is applied to the body, whose movements are disturbed by an external perturbation.

The "learning rule" module (**Figure 4**, inset) relies on the notion that while dealing with assistive forces the motor system

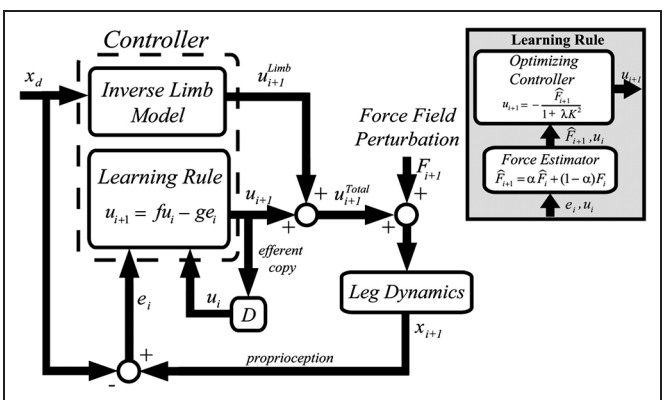

FIGURE 4 | Greedy optimizer model. The controller includes an inverse model of the limb and a "learning rule". The latter is based on a force estimator and an optimal controller. From Emken et al. (2007), reprinted with permission.

behaves as a "greedy" optimizer, so that these forces are quickly incorporated into the motor plan in order to minimize the effort while maintaining the required performance level (e.g., a small error). The force estimator predicts the disturbance on the next trial, and an optimizing controller generates the next motor command by minimizing a cost function on a trial-by-trial basis. In the model derived from this optimization framework, the "slacking" mechanism is captured by a decay term in the dynamics equation (the "f" term in the Learning Rule block, see **Figure 4**).

Emken et al. (2007) also suggested that slacking may have adverse effects on recovery. As a consequence, in robot-assisted rehabilitation, assistance should be kept to a minimum. Furthermore, it has to be decreased—manually or automatically—as performance improves. A variety of techniques have been proposed to adaptively regulate the magnitude of assistive force as a function of the observed outcome. In Casadio et al. (2009) the therapist manually selected the assistance level in order to keep it to the minimum level that evoked a functional response needed for accomplishing the task. In Vergaro et al. (2010) a linear controller continuously and automatically regulated the assistive force provided by the robot, depending on on-line performance measures. Similar mechanisms have been proposed in the context of upper limb—the Performance-based progressive robot-assisted therapy used by the MIT-Manus robot (Krebs et al., 2003)—and the lower limb—the patient-cooperative training modality used by the Lokomat system (Riener et al., 2005; Mihelj et al., 2007). Using a computational model of human-robot load sharing, Reinkensmeyer et al. (2007) suggested that to achieve assistance as needed, the robot controller should possess a slacking mechanism that resembles that observed in humans. Wolbrecht et al. (2008) designed a more complex adaptive control scheme, based on task performance, that automatically negotiates an error-reducing and an effort-enhancing component. The controller needs an explicit model of the subject's arm and its neural control. In this specific study, this model took the form of a radial basis function neural network, which was built by experience.

The "greedy optimizer" model has been highly influential to rehabilitation, but does not really address the recovery mechanisms. In fact, it has been derived from studies on healthy subjects and its implications for recovery are largely speculative. The slacking hypothesis has never been directly tested in clinical rehabilitation trials.

In a recent study, Casadio and Sanguineti (2012) developed a linear dynamical model to describe the trial-by-trial evolution of the motor performance of chronic stroke survivors who underwent a rehabilitation protocol based on a robot-assisted arm extension task.

The model is based on the notion that in robot-assisted exercise the robot device and the subject cooperate toward a common goal—a form of shared control. Specifically, the model assumes that task performance is a function of a voluntary, human-generated command (taken as the model's state variable) and of a robot-generated assistive force (taken as one of the model's inputs); see **Figure 5**, top right.

As regards the dynamics of the actual recovery process, the model assumes that the amount of voluntary control on the next trial is the sum of three components: (i) a "memory" or "retention" term—a fraction of the current amount of voluntary control; (ii) a "learning" component, proportional to a "driving" signal—a function of movement performance that can be interpreted as a reward—and (iii) an assistance-related component—proportional to the magnitude of the assistive force.

A distinctive feature of this model is that it posits separate mechanisms for "retention" and for the effect of assistance, i.e., the actual "slacking". These terms have often been used interchangeably; see Reinkensmeyer et al. (2009a) for a review that specifically covers slacking models.

The model was used to analyze the trial-by-trial time series of performance in nine chronic stroke survivors, who underwent a 10-sessions training protocol; see **Figure 5**, left. The estimates of the model parameters for each subject suggested that recovery is determined by a complex interplay of memory (retention), performance and slacking. One specific finding was that in severely impaired subjects recovery is greater when the driving (reward) signal is greater; hence, recovery improves when the performance—not the motor error—is greater. Another finding, which somewhat confirmed the observation of Emken et al. (2007), was that a greater assistive force has a negative impact on recovery (slacking). However, only a few subjects—the least impaired—exhibited a significant "slacking" effect. The single most important finding was that the retention rate (memory decay) parameter accurately predicts the long-term outcome of the rehabilitation trial (see **Figure 5**, bottom right). This finding is consistent with Han et al. (2008): the hypothesis that recovery must reach a threshold in order to self-sustain implies a buildup mechanism that integrates the effect of repeated motor activities. High retention is an essential prerequisite of this mechanism.

This model suggests that mechanisms of recovery may differ in different subjects. Again, this calls for an adaptive regulation of assistance, in which peculiarities of the individual subjects are to be taken into account.

Squeri et al. (2011) designed an adaptive Bayesian regulator that adjusts the magnitude of assistive force (or other task parameter) to keep the average performance around a target magnitude (performance clamp). In this way, as performance improved, the controller automatically reduced the amount of assistance. Squeri et al. (2012) used this model to analyze the temporal evolution of the subjects' voluntary control in a task that involved submovements in different directions. One single controller was used to adaptively regulate the degree of assistance in all submovements. The model suggested that the dynamics of recovery is direction-dependent, mostly due to the different sensitivity to assistance exhibited by the arm moving in different directions. These results suggest that modulation of assistance would better be made separately for each direction. More in general, they point at the need for therapy personalization.

While this model attempts to distinguish between recovery and slacking (i.e., adaptation to assistance), it remains purely descriptive and does not explicitly address the underlying mechanisms.

SYNERGY-BASED MODELS OF IMPAIRMENT

The characterization of compensatory strategies in stroke survivors is receiving an increasing attention. A number of studies

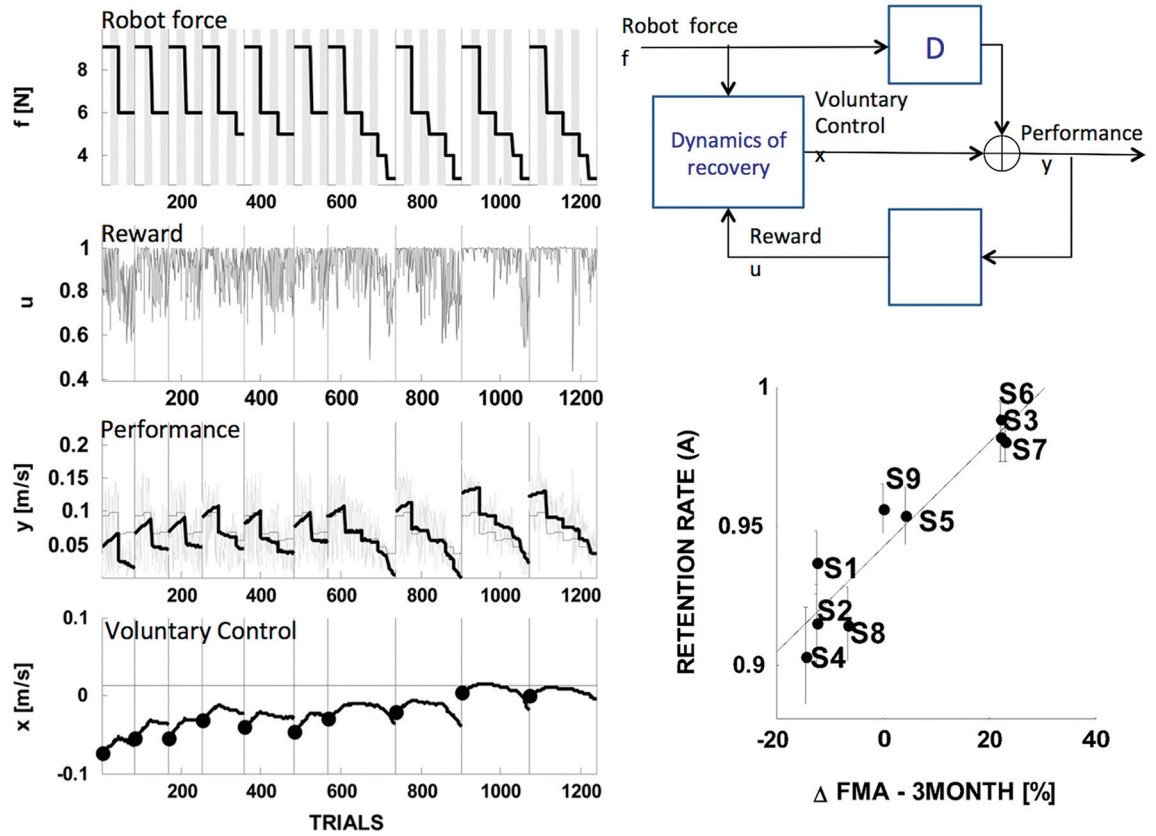

FIGURE 5 | State-space model of stroke recovery. Left: fitting performance. Right: model schematic (top) and the main result, that the model's rate of retention parameter predicts the long-term outcome—change in the Fugl-Meyer score (FMA) in the three months following the end of the treatment (bottom). Modified from Casadio and Sanguineti (2012).

look at movements in terms of their basic building blocks, or synergies (Ting and Macpherson, 2005; Tresch et al., 2006; Raghavan et al., 2010; Cheung et al., 2012). The notion of muscle synergy relies on the assumption that the nervous system recruits spinal inter-neural modules that activate groups of muscles as individual units.

Cortical lesions affect the organization of these modules, thus resulting in abnormal muscle activations (Twitchell, 1951; Brunnstrom, 1970), incorrect regulation of interaction torques, incorrect timing of action sequences (Archambault et al., 1999), decreased joint range of motion (Levin and Dimov, 1997), loss of inter-joint coordination (Levin, 1996a) and ultimately abnormal movements

To extract muscle synergies, Cheung et al. (2012) collected myoelectric signals (EMGs) from different muscles and applied a factorization algorithm—Non-negative Matrix Factorization (NMF)—to the rectified, integrated, and variance-normalized EMGs. Based on this factorization, the temporal pattern of activation of each muscle is expressed as the sum of a small number of (time-varying, task-dependent) signals. The relative contribution of each of these signals to each muscle is time-invariant and task-independent, and denotes groups of muscles that are recruited together.

These authors systematically analyzed the muscle synergies exhibited by stroke survivors with different levels of impairment (mild to severe) and different disease durations (post-acute to super-chronic). Subjects performed different tasks with each of their arms to allow a comparison of their muscle synergies in both the impaired and the unimpaired sides. A portion of the synergies observed in the impaired arm was found to be similar to those found in the intact arm of the same subjects ("preserved" synergies). The remaining synergies were altered. Specifically, the authors identified two distinct types of alterations, which they named "merging" and "fractionation". "Merging" refers to a situation in which in the impaired arm multiple synergies merge together. The amount of merging was found to correlate with the severity of the impairment. "Fractionation" refers to a situation in which the normal synergies split into multiple, novel patterns. The amount of fractionation was found to correlate with the disease duration (time since stroke onset), with suggest that it can be seen as a form of spontaneous reorganization.

Synergy models do not explicitly address the recovery process, but can be used to characterize impairment and the effects of treatment in individual subjects, in term of their repertoire of movement strategies at the articular and/or muscular level. In other words, muscle synergies are physiological markers of both

the degree of impairment and of the degree of recovery. Dipietro et al. (2007) observed that in chronic stroke survivors, robot-assisted exercise results in a more efficient control of shoulder and elbow joints. They suggested that these changes are due to a "tuning" of the existing abnormal synergies, not to their modification.

Latash and Anson (1996) suggested that in impaired individuals, the modified motor strategies should not be necessarily considered as pathological but, rather, they should be seen as forms of adaptation to the primary disorder. Therefore, their correction should not be the primary concern of the rehabilitative treatment. However, this view may be in contrast with the long-term goal of recovering motor functions (Levin, 1996b; Cirstea and Levin, 2000). Failure to modify the abnormal synergies may lead to incorrect postures, weakening of underutilized muscles. With time, it may worsen the chances of recovering other abilities (Levin, 1996b).

It is conceivable to design technological aids that drive the recovery toward preserving and/or facilitating the "normal" articular and muscle synergies while, conversely, reducing or preventing the "abnormal" ones. Recently, Crocher et al. (2012) demonstrated that in healthy subjects, training with an exoskeleton may induce changes in the arm-related synergies. In severe stroke survivors Ellis et al. (2005) demonstrated that training reduces abnormal isometric elbow and shoulder joint torque coupling.

Rehabilitation treatments built upon synergy models should be designed to emphasize the synergies that are silent or under-activated, while discouraging compensatory strategies in favor of new and more independent coordination patterns.

Synergy-based models are descriptors of impairment; they do not provide an explicit model of the recovery process, although they can be used for describing this process as a change at the level of muscle activity.

DISCUSSION

Computational models are widely used to investigate motor skill learning and sensorimotor adaptation. Similar models might potentially contribute to our understanding of the mechanisms of recovery after a stroke at "functional" level, and to the design of optimal, individualized rehabilitation strategies.

Neuromotor recovery is facilitated by exercise and is mediated by neural reorganization at cortical and sub-cortical levels, whose physiological substrate is synaptic plasticity and rewiring through axonal outgrowth.

On one hand, neural plasticity mechanisms constrain the way recovery proceeds. On the other hand, sensorimotor behaviors determine the patterns of neural activity, thus inducing specific, activity-dependent synaptic changes. Therefore, behavioral mechanisms and neural reorganization cannot be simply treated as different levels of description. Rather, both aspects need to be accounted for when modeling the neuromotor recovery process.

DO COMPUTATIONAL MODELS PROVIDE TESTABLE HYPOTHESES ON THE MECHANISMS OF RECOVERY?

It has been suggested (Krakauer, 2006; Dipietro et al., 2012) that neuromotor recovery shares at least some features with motor learning. The class of models focusing on the recovery of functions highlights this "motor learning" component.

To acquire (or re-acquire) a motor skill an individual must understand how to achieve the movement goal and, more in general, learn how to get high rewards, while minimizing the necessary muscle effort. Some of the models discussed in the previous sections unveil specific aspects of this process. The observation (Colombo et al., 2010) that different aspects of motor performance exhibit a different temporal evolution, which may not be monotonic, reflects the notion that recovery is a complex multifactorial process, in which maximization of performance is only one of the components. Another aspect is generalization, from simpler to more complex movements (Dipietro et al., 2009).

Other models (Han et al., 2008; Reinkensmeyer et al., 2012a) describe neuromotor recovery within a reinforcement learning paradigm. Casadio and Sanguineti (2012) suggest that in severe chronic stroke survivors, improvements in voluntary control are determined by performance, not error—another indication that recovery has much in common with motor skill learning.

Other models focus on the "central" level, and describe cortical reorganization in terms of Hebbian and/or self-organization principles. These models highlight a number of physiological mechanisms of recovery. The model of Goodall et al. (1997) predicts an initial increase of the size of peri-lesional "silent" areas immediately after the lesion, followed by overall reorganization. Another specific prediction is that tonic stimulation of the lesioned side would limit the size of peri-lesional "silent" areas. A similar effect is obtained by limiting the activity of the contralateral hemisphere. Butz et al. (2009) focuses on axonal outgrowth driven by the push toward restoring the homeostatic inter-hemispheric balance. Its main prediction is that stimulation may facilitate axonal outgrowth but, because of a saturation effect, paused stimulation is more effective than sustained stimulation.

Still other models address reorganization mechanisms either at the level of the musculoskeletal system or at the level of CS circuitry. Reinkensmeyer et al.'s (2012a) model includes a basic form of reorganization, based on the recruitment of corticospinal pathways that originate from cortical areas (e.g., the SMA) that in the intact brain are normally not used because they are less efficient, and therefore more "costly", in contributing to force generation.

In Han et al.'s (2008) model, the activity of the impaired limb induces a reorganization of the ipsilesional cortical areas, which in turn makes this same hand more likely to be selected for movement. Its main prediction is that for recovery to self-sustain, activity of the impaired hand must reach a threshold. The hand selection (Han et al., 2008) model suggests that if there is too much emphasis on performing the task but there is too little pressure toward reorganization—for instance, if the affected arm is not likely to be selected and hence the impaired hemisphere is not active enough to undergo reorganization—recovery of the paretic side functions will not self-sustain and will possibly wash-out. One testable prediction is that techniques that facilitate reorganization independent of motor learning—e.g., by increasing cortical excitability, as with trans-cranial direct

current stimulation (tDCS) (Reis et al., 2009) might lower the "threshol" activity level that allows recovery to self-sustain. The model of Takiyama and Okada (2012) is very similar. It predicts that the inter-hemispheric activation induced by bimanual exercise facilitates cortical reorganization on the ipsilesional side.

A complementary view of the recovery process is provided by the attempts to characterize muscle synergies in a quantitative way (Ting and Macpherson, 2005; Tresch et al., 2006; Raghavan et al., 2010; Cheung et al., 2012). These models do not directly address the recovery mechanisms, but provide a window into the way muscle groups are recruited in different phases of the recovery process, and allow to distinguish whether recovery occurs through structural changes in muscle synergies, or as a tuning of existing synergies.

Only few models address the facilitatory role of assistive forces. In principle, assistive forces enable achieving the same motor performance with less voluntary contribution (Emken et al., 2007), but how this mechanism plays a role in the recovery process has not been extensively investigated. The "slacking" hypothesis predicts that reduced voluntary commands have a detrimental effect on recovery. A recent study confirmed this prediction, by demonstrating that subjects undergoing passive training exhibit less recovery than subjects that are actively involved in the exercise through an electromyography-driven robot. Hu et al. (2009) and Casadio and Sanguineti (2012) found that this effect may not be equally important in all subjects.

CAN COMPUTATIONAL MODELS PREDICT THE RECOVERY ON A PATIENT-BY-PATIENT BASIS?

By "predicting the recovery" we mean estimating the future evolution—either spontaneous or induced by treatment—of the impairment and/or the functional performance of a specific subject, measured in terms of clinical scales and task-specific performance indicators. A number of mathematical models, e.g., Chaudhuri et al. (1988), Saeki et al. (1994), Oczkowski and Barreca (1997), Stineman et al. (1997), Lofgren et al. (2000) and Mirbagheri et al. (2012), have been proposed to predict the recovery outcome within different time scales. These models use different types of information, such as the initial degree of impairment and the nature, size or location of the lesion. In contrast, computational models explicitly account for the mechanisms by which recovery takes place, namely use-dependent neural reorganization and motor learning.

Some computational models focus on general principles, but do not address the dynamics of the recovery process of a specific individual. All models of the central level account for brain areas, CS circuitry and neural plasticity mechanisms in a way that cannot be immediately associated to empirical observations on individual subjects.

However, some comparison of these models with empirical data is still possible. For instance, in Reinkensmeyer et al. (2003) the lesion is modeled as a reduction in the number of available direction-tuned cells in the motor map. The size of the lesion can be related to the degree of impairment, a correlation that has been observed empirically. In principle it would be possible to personalize the model in terms of location and size of the lesion, or fraction of intact CS pathways (e.g., from imaging data), but the general focus is on quantities (e.g., the activity and the changes of the spatial tuning individual cortical columns) that are hard to associate to empirical measures.

Other models allow inferring how recovery would take place in a specific individual. These include all functional models and synergy-based models.

Specifically, Colombo et al. (2010) predict the time constant of the recovery process by fitting the time course of the performance data during the rehabilitation treatment. Casadio and Sanguineti (2012) predict the long-term retention of the recovery by using a state space model and by looking at the memory decay of the learning process. These models directly refer to observable quantities, so that it is relatively easy to identify subject-specific model parameters. Model parameters capture the modality with which one subject undergoes recovery. For instance, a model may allow estimating the subject's rate of spontaneous recovery, or may provide information on his/her peculiar response to mechanical perturbations (mechanical impedance).

All the above models enable significant, but limited predictions. All focus on limited aspects of the recovery process (cortical, muscular, functional) and only provide a limited account of their complex interplay. The importance of such interplay is exemplified by the prediction that the possibility that recovery will self-sustain can be inferred by evaluating if the amount of spontaneous use of the impaired arm reaches a certain threshold (Han et al., 2008).

In conclusion, multiple levels of description would be necessary. One important issue is whether these models can incorporate the specific features of one patient (nature, size and location of the lesion; type and degree of impairment). This is particularly important for the cortical level, for which there is a need for descriptions that are based on observable quantities.

DO MODELS ALLOW DESIGNING PATIENT-SPECIFIC "OPTIMAL" THERAPY?

Computational models may enable designing patient-specific therapy, aimed at maximizing speed and amount of recovery of that patient.

Patient-specific models provide a description of his/her status and characteristics, e.g., impairment, articular and muscular synergies, residual movements and force generation abilities etc. They also provide a better understanding of what determines the recovery of that patient. This information can be used to define specific goals for treatment, and to assess its efficacy in terms of progress of the subject's status (motor strategies and functional behavior) toward the treatment goals.

Colombo et al. (2012) designed and tested a controller PTR that automatically selects exercise parameters (amplitude of the movement, number of sub-movements, assistance modality) based on their previous work on modeling the evolution of different performance indicators (Colombo et al., 2010).

Reinkensmeyer et al. (2007) proposed a robot controller based on the assist-as-needed principle, with a slacking mechanism similar to the one observed in humans. In several other applications, the magnitude of assistive force is adaptively regulated as a function of the observed outcome, in both the upper limb (Krebs et al., 2003; Vergaro et al., 2010) and the lower limb (Riener et al., 2005; Mihelj et al., 2007).

Bayesian regulation of robot-generated assistance (Squeri et al., 2011) is a direct derivation of the model of recovery proposed by Casadio and Sanguineti (2012).

The success of the above mentioned approaches suggests that an even greater advantage would come from the much more ambitious goal of designing treatment modalities that directly rely on patient-specific recovery models. In principle, if a model allows predicting evolution and final outcome of a specific rehabilitation intervention, it should be possible to use this same model as a basis for an optimal planning of the intervention. This may include the timing of the individual exercise sessions, the specific exercises to be administered, the trial-by-trial regulation of the degree of assistance, and the online planning of assistive or resistive forces (or other forms of stimulation, like Functional Electrical Stimulation (FES)).

Only few examples of model-based robot controllers for treatment have been proposed so far (Wolbrecht et al., 2008; Reinkensmeyer et al., 2012b). One major difficulty is that to incorporate recovery models in the robot controller requires to achieve a dual goal: the controller should select the goal and the difficulty level of the exercise based on the subject's state as predicted by the model and, at the same time, the model should be continuously adjusted, on the basis of the observed subject and robot performance while the treatment proceeds. Therefore, the resulting treatment protocol has to be a trade-off between exploitation (of the model) and exploration (of the treatment control space to keep the model up to date).

DIRECTIONS FOR FUTURE RESEARCH

Computational approaches to the study of neuromotor recovery after stroke are innovative and promising, but still in their infancy. The models described in this review open a new view of the recovery process, and along these lines there is still a lot to understand, to discover, and to integrate in the clinical practice.

We can identify the following directions for future research: (i) multi-level models; (ii) the role of modularity in neuromotor recovery, and (iii) new modeling approaches.

The models reviewed in this paper capture important and complementary aspects of the recovery process at central, muscular, functional level. With few exceptions, the focus is on one single level of description. Convergence toward multiple levels of description may provide a more comprehensive representation of the different aspects of the recovery process and of their interconnections. Multi-level models are being successfully used in other related fields such as musculo-skeletal disorders—see Fregly et al. (2012) for review—and are of great importance both for a more comprehensive understanding of the mechanisms related to the observed phenomenon—in our case, neuromotor recovery—and for planning the most appropriate intervention.

The well-established notion of modularity in the motor system has been getting a renewed attention in computational motor control. In the context of neuromotor recovery, the view of motor strategies as the combination of a repertoire of muscle synergies may be the key to unveil the role of mechanical redundancy in counteracting the effects of a central focal lesion, either toward compensation or true recovery. A recent study (Overduin et al., 2012) highlighted the neural correlates of muscle synergies in two rhesus macaque monkeys. However, more work is needed to understand how a focal lesion affects muscle synergies and how they evolve over time as a consequence of spontaneous recovery and/or exercise-based therapy.

One main difficulty in this application domain is our limited understanding of the physiological mechanisms underlying synaptic plasticity and neural reorganization. Moreover, these phenomena are hard to monitor and quantify experimentally, so that models at central level are difficult to identify from empirical observations and have poor predictive power. Novel modeling approaches, relying on quantities that can be observed with simple and non-invasive procedures, like fMRI and EEG would facilitate progress in this respect. Novel modeling approaches can also be beneficial to the study of the functional level of description. Novel computational approaches used for describing the neural control of movements and motor learning might find insightful application in the study of the recovery process. Optimization is a particularly viable concept to describe neuromotor recovery. Given the available sensory information and the constraints that derive from the actual impairment (sensory, motor), it may suggest how the next voluntary command is selected. Bayesian inference, optimal control and reinforcement learning may play a role here.

Computational models have been successfully applied to the study of motor learning and adaptation, providing important insights with respect how brain controls movement and react to the environment or task variables changes. Their application to the rehabilitation field is fairly new and the first approaches suggest that they will lead to a deeper understanding of the mechanisms underlying neuromotor recovery.

Human locomotor movements exhibit considerable variability and are highly complex in terms of both neural activation and biomechanical output. The building blocks with which the central nervous system constructs these motor patterns can be preserved in patients with various sensory-motor disorders. In particular, several studies highlighted a modular burst-like organization of the muscle activity. Here we review and discuss this issue with a particular emphasis on the various examples of adaptation of locomotor patterns in patients (with large fiber neuropathy, amputees, stroke and spinal cord injury). The results highlight plasticity and different solutions to reorganize muscle patterns in both peripheral and central nervous system lesions. The findings are discussed in a general context of compensatory gait mechanisms, spatiotemporal architecture and modularity of the locomotor program.

Keywords: compensation, plantarflexor weakness, spinal cord injury, stroke, EMG activity, modularity, locomotor pattern generation

INTRODUCTION

Investigating locomotor responses after neurological lesions is fundamental to the development of improved rehabilitation strategies and to explore the mechanisms involved in improving locomotor function. The problem of motor neurorehabilitation is significant and complex. Numerous studies have shown that motor activity after brain damage plays an essential role in anatomo-physiological reorganization, which may occur in the areas adjacent to the damage (Cao et al., 1998; Nelles et al., 1999). Nevertheless, the building blocks with which the central nervous system constructs the motor patterns can be preserved in patients with neurological disorders. In particular, several studies highlighted a modular burst-like organization of muscle activity.

While biomechanical and neural aspects of human locomotion have been documented in many studies both in normal and pathological gait, the architecture of neural circuits and the nature of descending neural signals that are involved in locomotor control remain elusive in humans. To date, little work has been completed on characterizing the neural substrates for modularity in both healthy individuals and in neurological patients with different sensory-motor disorders. A number of studies explored the bases of central motor programming by decomposing muscle activation patterns as a means to look backward from the periphery to the CNS (Davis and Vaughan, 1993; Prentice et al., 1998; d'Avella and Bizzi, 2005; Ivanenko et al., 2006; Giszter et al., 2007; Tresch and Jarc, 2009; Chvatal and Ting, 2012; Bizzi and Cheung, 2013; Lacquaniti et al., 2013). While different studies use different decomposition techniques, the common message is the emphasis on modular architecture of the motor output. Furthermore, these computational techniques often converge to a similar solution (Ivanenko et al., 2005; Tresch et al., 2006). The data and concepts discussed here offer a new approach to characterizing the mechanisms underlying control of human locomotion that may potentially benefit the study of pathological gait and the ability of current therapeutic exercises to improve patient outcomes.

In patients, the mechanisms involved in locomotor improvements may rely on the inherent spatiotemporal organization of neural circuitry and its adaptability. The question arises as to whether the rhythmic patterning elements are invariant when muscle activation patterns can be compromised by spinal cord lesions, brain damage and other motor disturbances. Compensatory strategies for plantarflexor weakness or after distal limb segment amputation also represent important examples of locomotor adaptations. Several recent studies provide some clues on this topic. We will consider and discuss these examples in the following sections.

LOCOMOTOR PATTERNS IN HEALTHY SUBJECTS

Muscle activity during normal locomotion has both invariant and variant features. In each step, the control system needs to compensate for body weight, provide forward and lateral stability and maintain forward progression. The coordination of the musculoskeletal system with non-linear properties and multiple degrees of freedom is complex and requires activity of tens of leg muscles. Major muscle activity during walking tends to be organized in bursts at specific moments of the gait cycle (**Figure 1A**) to perform specific functions dictated by the biomechanics of bipedal walking (Winter, 1989; Zajac et al., 2003; Lacquaniti et al., 2012). For instance, in early stance hip and knee extensors contribute to weight acceptance at heel contact (**Figure 1B**). Ankle

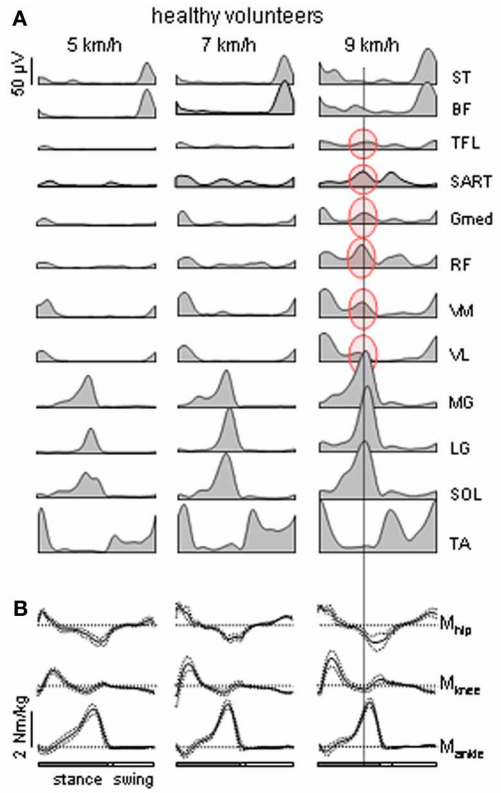

FIGURE 1 | Motor patterns in healthy volunteers. (A) Ensemble-averaged EMGs ($n = 8$ subjects) recorded from 10 ipsilateral leg muscles during walking on a treadmill at 5, 7, and 9 km/h. At 9 km/h, there is an "atypical" burst of activity in several thigh muscles that is synchronous with the peak activity in the calf muscles [the data are illustrated from Ivanenko et al. (2008)]. ST, semitendinosus; BF, biceps femoris; TFL, tensor fascia latae; SART, Sartorius; Gmed, RF, rectus femoris; VM, vastus medialis; VL, vastus lateralis; MG, gastrocnemius medialis; LG, gastrocnemius lateralis; SOL, soleus; TA, tibialis anterior. **(B)** ensemble-averaged (±*SD*) ankle, knee and hip moments of force (normalized to the subject's weight) of the right leg during overground walking at about the same speeds (as in panel **A**) in one representative healthy subject.

plantar flexors provide body support and forward propulsion in late stance while ankle dorsiflexors and hip flexors contribute to foot lift-off in early- to mid-swing. Simultaneously, erector spinae muscles activate at this time to stabilize the trunk. In late swing, hamstrings decelerate the leg in preparation for heel contact and then stabilize the pelvis. Throughout the entire step cycle, adductor muscles contribute to the control of medio-lateral accelerations of the center of body mass. However, it is worth noting that most leg muscles that are involved in the control of forward progression in the sagittal plane have a noticeable lateral component of force production and thus are also involved in the control of motion in non-sagittal planes. Even though there is a relationship between the neural and biomechanical control of the gait cycle, evidentially the system is much more complex due to the dynamic coupling of multiple body segments (e.g., Zajac et al., 2003).

Whereas this "invariant" picture of muscle activation (**Figure 1A**) has been documented in healthy subjects, there are also variant features of muscle activity depending on the context and differences between individuals. If one aims at reactivating the "normal" motor patterns in patients and extrapolating them to any walking condition, this may not be of benefit to the patient due to the specific pathology or individual differences that occur in pathological as well as healthy subjects. Muscle activity in healthy subjects may show very non-linear changes in both amplitude and temporal envelope, e.g., with changing the speed or body weight support even while kinematics patterns remain similar (Ivanenko et al., 2002; Lacquaniti et al., 2002). For instance, the amplitude of EMG activity of "anatomical" synergists may diverge remarkably in these conditions: lateral and medial gastrocnemius muscles at different walking speeds (Huang and Ferris, 2012), soleus and gastrocnemius muscles at different levels of limb loading (McGowan et al., 2010). With body weight unloading (Ivanenko et al., 2002), most muscles (e.g., gluteus maximus and distal leg extensors) decrease their activity, while other muscles demonstrate a "paradoxical" increment of activation (e.g., quadriceps) or considerable changes in the activation waveforms (hamstring muscles). In addition, muscle activity patterns are shaped by the direction of progression (e.g., forward vs. backward, Grasso et al., 1998, or walking along a curved path, Courtine et al., 2006). In particular, such studies suggest that a comparison of normal and pathological gait should be preferably performed in the same stepping conditions.

There is also notable inter-individual variability in muscle activity during walking (Winter and Yack, 1987). The most variable patterns are observed in the proximal and bi-articular muscles especially at lower walking speeds. For example, quadriceps activity is virtually silent in some subjects at low speeds (<4 km/h), whereas it is still present in others (Ivanenko et al., 2002). Finally, notable systematic changes in the EMG activity during walking occur with age, e.g., co-contraction of leg muscles in infants (Forssberg, 1985; Teulier et al., 2012; Ivanenko et al., 2013b) and widening of EMG patterns in elderly (Monaco et al., 2010).

Nevertheless, a number of recent studies using statistical analyses of EMG suggest that the nervous system may adopt a relatively simple control strategy (e.g., Ivanenko et al., 2005; Cappellini et al., 2006; Clark et al., 2010; McGowan et al., 2010; Monaco et al., 2010). Using pattern recognition mathematics, both the stereotypical activation patterns and across-stride variability of these patterns can be accounted for by combining and scaling a small set of basic activation components. Such tendency for a few basic patterns to account for about 90% of variance indicates that leg muscles tend to group their activity in order to perform specific biomechanical functions during gait.

While intuitively one would expect some changes in the EMG activity in patients, the present question is whether the basic modular patterns or the functional grouping of muscles are conserved in pathological participants. Below we summarize various examples of motor patterns in patients with both peripheral and central lesions. The main focus is placed on the studies that analyzed multi-muscle EMG patterns.

LOCOMOTOR PATTERNS IN PERIPHERAL LESIONS

Compensatory strategies for plantarflexor weakness or after below-knee amputation represent an important example of gait adaptation. The human bipedal gait and heel-to-toe rolling pattern are unique (Bramble and Lieberman, 2004) and require a specific inter-segmental coordination (Lacquaniti et al., 2002), balance control and walking experience for acquisition of plantigrade gait at the beginning of independent walking (Forssberg, 1985; Ivanenko et al., 2007). Plantarflexor muscles are an important muscle group that regulates the gait speed, compensates for body weight and provides the vertical and horizontal (anterior-posterior shear) forces during the push-off phase. Weakness of the plantarflexors is considered as one of the limiting factors that prevents humans from walking at faster speeds (Nadeau et al., 1999; Brunner and Romkes, 2008).

In addition to the development of extensor forces in the distal antigravity muscles, there is an important sensory feedback from these muscles and from numerous foot receptors. Peripheral neuropathy and aging may result in muscle weakness and substantial impairments of sensory feedback and balance control (Nardone et al., 2000, 2006; Nardone and Schieppati, 2004; Mazzaro et al., 2005). For instance in older adults, ankle plantarflexor work remains relatively constant at increasing speeds, in contrast to the systematic increase in ankle work output with walking speed in young adults (Winter et al., 1990; Judge et al., 1996).

PATIENTS WITH LARGE FIBER PERIPHERAL NEUROPATHY

Weakness of distal extensors in patients with large-fiber neuropathy can be observed after acute nerve compression in the sciatic notch associated with a reduced level of motor and sensory function. After sciatic nerve compression there may be a loss of reflexes, movement skills, sensation in the affected area, and atrophy of the affected muscles can occur (Hagiwara et al., 2003). Sciatica commonly refers to pain that radiates along the sciatic nerve and is typically felt in the back of the leg and possibly to the foot, and is one of the most common forms of pain caused by compression of the spinal nerves.

We analyzed adaptations of gait patterns at different walking speeds in four patients with a unilateral large-fiber neuropathy of S1 innervation resulting from acute nerve compression in the sciatic notch. Plantarflexor weakness on the affected side was evidenced by subjective difficulty to lift and support the body weight on the forefoot region (forefoot-standing) by plantarflexing the ankle joint during standing. Reflexes and sensory thresholds were all normal in the contralateral leg. **Figure 2** illustrates EMG patterns in these patients during walking and slow and fast speeds. After acute nerve compression in the sciatic notch, the patients walked somewhat slower (even their self-selected fast speed was <5 km/h) than healthy individuals. The EMG patterns differed from healthy individuals walking at the same speeds (**Figure 1A**) and were variable between the patients as well as between left and right leg muscle activities (**Figure 2**). A part of these differences may originate from slightly different EMG electrode placements and/or skin impedance. Nevertheless, we found an interesting cooperation of distal and proximal extensors (**Figure 2**, marked in red) and discuss its general functional significance for bipedal gait adaptations (Dickey and Winter, 1992; Beres-Jones and Harkema, 2004; Nene et al., 2004; Ivanenko et al., 2008, 2013a).

The "atypical" burst of activity in the proximal leg muscle was more prominent in patient 1 (**Figure 2**) on the affected side, while it could be observed also in other patients on the contralateral side. To understand better it's link to the kinematics and kinetics of gait, we recorded patient 1 again during overgound (**Figure 3B**) and treadmill walking (**Figures 3A,C**). The second time (1 year later, session 2) the patient had recovered all reflexes and reduced sensation was limited to the lateral, plantar surface of the foot. The patient was now able to fully support his body weight on the left leg during "forefoot standing," although some weakness still remained. The most prominent decrements in angular oscillations and angular velocities were observed in

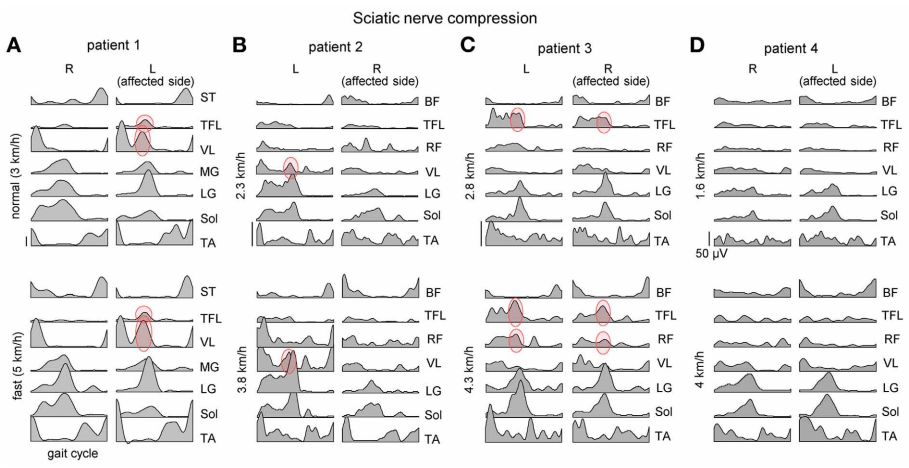

FIGURE 2 | Ensemble-averaged bilateral EMG activity of leg muscles during overground walking at slow and fast speeds in four patients (panels A–D) with unilateral sciatic nerve compression. Note an "atypical" activation of proximal extensors during late stance (marked in red) and its variability across patients and depending on the affected side.

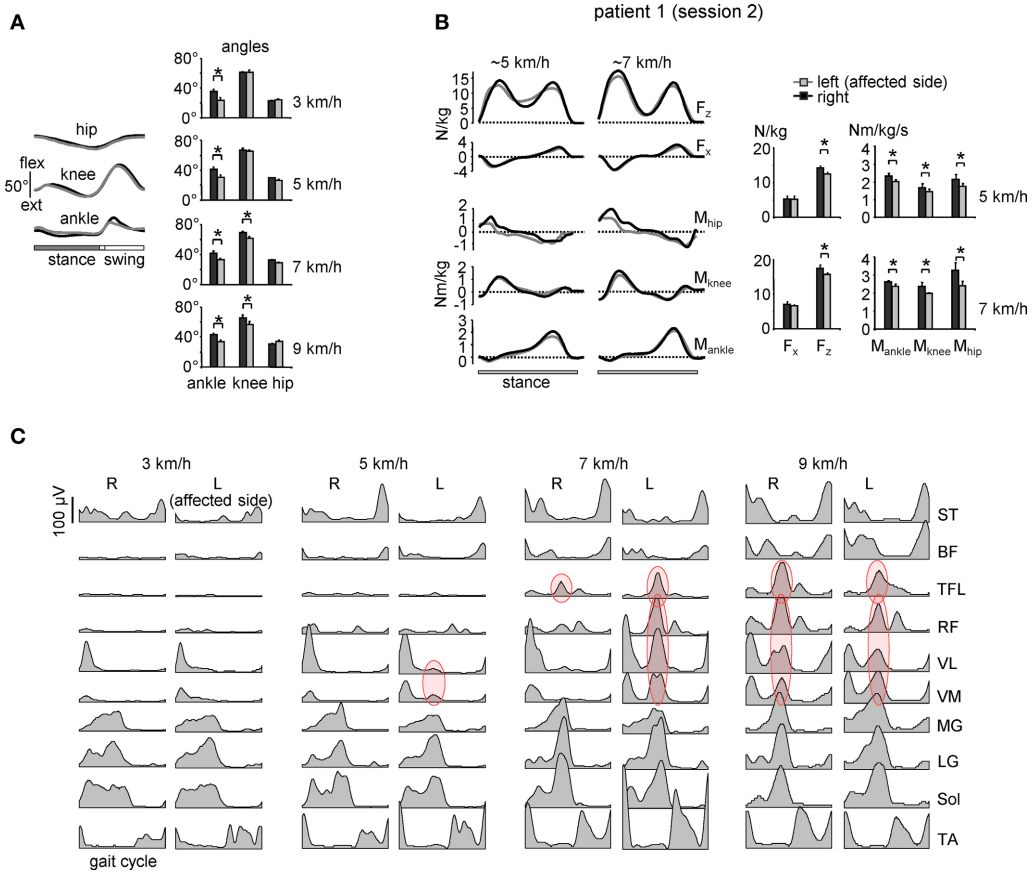

FIGURE 3 | Motor patterns in a patient with sciatic nerve compression [the same patient as in Figure 2A but recorded 1 year later (session 2)]. **(A)** ensemble-averaged (across 12 consecutive steps) joint angular displacements (left panel, mean ± *SD*) and amplitudes of angular joint motion (right panel) during walking at 3 km/h. Asterisks denote significant differences. Note significantly smaller distal joint oscillations on the affected (left) side. **(B)** ensemble-averaged ($n = 5$ steps) vertical (F_z) and horizontal anterior-posterior (F_x) ground reaction forces, and ankle, knee and hip joint moments of force normalized to the patient's weight during overground walking at ~5 and 7 km/h in session 2 (left panels). The patterns are plotted vs. normalized stance. On the right—peak-to-peak amplitudes. **(C)** Ensemble-averaged bilateral EMG activity of leg muscles during walking on a treadmill at different speeds. In session 1 (**Figure 2A**), the patient could walk only at speeds up to 5 km/h due to plantarflexor weakness, while in session 2 we recorded walking in a wide range of speeds (3–9 km/h). Adapted from Ivanenko et al. (2013a). Note a prominent burst of activity (marked in red) in the proximal extensors during late stance on the affected (left) side at low speeds in the session 1 (**Figure 2A**) and only at higher speeds (>5 km/h) in session 2. Furthermore, at 9 km/h the "atypical" burst of activity was present in both legs, as in healthy subjects (see **Figure 1A**).

the ankle joint motion (**Figure 3A**). In the knee joint, angular motion asymmetry was significant only at higher speeds (7 and 9 km/h). When the plantarflexor strength and/or reflexes were compromised in one leg, the primary compensatory mechanism was an increase in activity of proximal extensor muscles (VL, RF, VM, TFL evidenced by red circles in **Figure 2**) during late stance. This compensatory effect was observed at all recorded walking speeds in patient 1 in session 1 (**Figure 2A**) but only at the higher speeds (>5 km/h) in session 2 (**Figure 3C**) which required greater propulsion forces. This suggests a possible link to the extent of the weakness in the ankle extensors.

Healthy volunteers typically do not show activity in the proximal extensor muscles during late stance in normal walking (Nilsson et al., 1985; Winter, 1989; Prilutsky and Gregor, 2001; Nene et al., 2004; Cappellini et al., 2006). However, the atypical proximal burst was present in all healthy subjects at high, non-preferred walking speeds (**Figure 1A**, right panel). The proximal muscles involved (RF, VM, VL, SART, Gmed, TFL) were activated synchronously with the distal extensors (MG, LG, SOL) as was observed for the patient. At the higher speeds, the muscle gain, or force produced for a given level of activation, may be lower due to the muscle force-velocity relationship (Neptune and Sasaki, 2005), so the force produced by ankle extensors alone may be insufficient to initiate lift-off or to provide appropriate limb stiffness. The proximal activation may be recruited to compensate by supplying additional extensor torque and stiffness.

Similarities can also be noted between this type of adaptation and unilateral acute pathologies such as hemiplegia (Knutsson and Richards, 1979), below-knee amputation (Winter and Sienko, 1988) or unilateral ischemic block of distal leg muscles in healthy subjects (Dickey and Winter, 1992). Co-activation of distal and proximal extensors during stance in each leg was also observed in the clinically incomplete spinal cord injury individuals during weight-bearing treadmill stepping (Beres-Jones and Harkema,

2004, see also below) and in healthy adults during walking on a slippery surface (Cappellini et al., 2010). Such similarity indicates that this kind of adaptation seems not to depend on the location of the lesion of the neuronal system but may be related to the activation of existing basic activation patterns or muscle synergies.

Nevertheless, despite a potential broad-spectrum functional significance of this compensatory response to plantarflexor weakness, its biomechanical nature remains puzzling. One would perhaps expect the cooperation of distal and proximal extensors during knee-flexed locomotion, e.g., as it happens during digitigrade gait requiring a significant positive (anti-gravity) knee torque during stance. However, in our case (**Figure 3B**) there was no generation of positive knee moments of force in response to extra activation of knee extensors, likely reflecting dynamic coupling between body segments (Zajac et al., 2003). Moreover, biomechanical simulations of the compensatory strategies in response to muscle weakness do not seem to predict the appearance of "atypical" burst of activity in the proximal extensors (Goldberg and Neptune, 2007). Perhaps a complete consideration of all factors affecting gait optimization is necessary, including a 3D rather than 2D musculoskeletal gait model (e.g., Gmed, TFL, and SART may generate a noticeable trunk torsion or lateral force component, Dostal et al., 1986) and taking into account the mechanisms that regulate leg stiffness during walking (Fiolkowski et al., 2005).

Whatever the exact biomechanical reasons for the observed phenomenon (**Figure 3**), it is important to emphasize that the timing of the reaction in the proximal muscles corresponded to the timing of the calf muscle activation. This supports the idea of a temporal architecture of the locomotor program linked to specific kinematic events (Ivanenko et al., 2005, 2006; Giszter et al., 2007; McGowan et al., 2010) or critical points in the processing of sensory information (Saltiel and Rossignol, 2004) in the gait cycle.

TRANSTIBIAL AMPUTEES

Various efforts have been made to restore the normal EMG patterns in patients, presumably by reactivating the CPG (central pattern generator) circuitry or more directly by functional electrical stimulation (FES) (Thrasher et al., 2006; Solopova et al., 2011) or when implementing myoelectric control of powered limb prostheses in amputees (Au et al., 2008; Huang et al., 2011). For instance, transtibial amputees can learn to volitionally activate residual leg muscles (Au et al., 2008; Ha et al., 2011; Hargrove et al., 2011) that can be used for movement intent recognition in the myoelectric control of powered limb prostheses. However, such strategies and their underlying hypotheses are often based on the assumption that the motor patterns are relatively invariant across different walking conditions, for instance, when using FES for gait rehabilitation (Thrasher et al., 2006). Below we consider a reorganization of EMG activity in transtibial amputees.

Below-knee amputation represents a severe damage of the neuromuscular apparatus of the leg and impaired sensory feedback. As a result, the EMG activity in amputees may be compromised by these factors. Indeed, below-knee amputation may result in the EMG patterns different from those in healthy subjects. For instance, co-activation of distal and proximal extensors during stance, similar to that described in the previous section (**Figures 2**, **3C**), was also observed in below-knee amputees (Winter and Sienko, 1988).

Of particular interest is residual lower leg muscle activation following such an amputation. For instance, if the CPG output were relatively fixed (e.g., providing an alternating activity of flexors and extensors, Zehr, 2005) one would not expect major changes in residual muscle activation profiles. **Figure 4** illustrates the results of a recent study on multi-muscle EMG activity in both proximal and residual leg muscles during walking in transtibial amputees (Huang and Ferris, 2012). In the upper leg muscles, the data showed that amputee subjects had greater inter-subject variability in their biceps femoris and gluteus medius muscle activation profiles compared to control subjects during walking, as well as a different BF activation profile shape (**Figure 4**, right panels). Amputee subjects also demonstrated reliable muscle recruitment signals from residual lower leg muscles recorded within the prosthetic socket during walking. However, the grouping of muscles activated together differed from that in controls (see, for instance, "atypical" co-activation of Gmed, BF and MG in the A02 subject or TA, BF and Gmed in the A10 subject). Overall, muscle activation profile variability was higher for amputee subjects than for control subjects (Huang and Ferris, 2012). Nevertheless, it is interesting to note that muscle recruitment signals in amputees tended to be locked to particular phases of the gait cycle (**Figure 4**).

LOCOMOTOR PATTERNS IN CENTRAL LESIONS

Contrary to impairments in the peripheral sensory feedback or neuromuscular apparatus, nervous system lesions may essentially affect central controllers and thus provide some insights into the spatiotemporal organization of neural circuitry. In particular, if muscle modules are indeed mechanisms by which task level biomechanical goals are implemented, one would expect that impairments to the neural control of such modules would directly result in impaired biomechanical outputs (Cheung et al., 2009; Ivanenko et al., 2009; Clark et al., 2010). In addition, lesion at different levels of the neuraxis could differentially affect locomotor control. Adaptation of gait after cortical, subcortical or spinal cord damage might thus represent the experimental field in which one might test such hypotheses and the therapeutic relevance of different interventions.

STROKE PATIENTS

Post-stroke locomotor impairments are often associated with abnormal spatiotemporal patterns of muscle coordination (Knutsson and Richards, 1979; De Quervain et al., 1996; Mulroy et al., 2003; Den Otter et al., 2007). Furthermore, impaired locomotor coordination in post-stroke may be accompanied by fewer modules (Clark et al., 2010; Safavynia et al., 2011), though in a recent study Gizzi et al. (2011) have argued that impulses of activation rather than muscle synergies are preserved in the locomotion of subacute stroke patients (**Figure 5**). The discrepancies could be accounted for by a different set of recorded muscles or different populations of patients. The authors of both studies hypothesized that identification of motor modules may lead

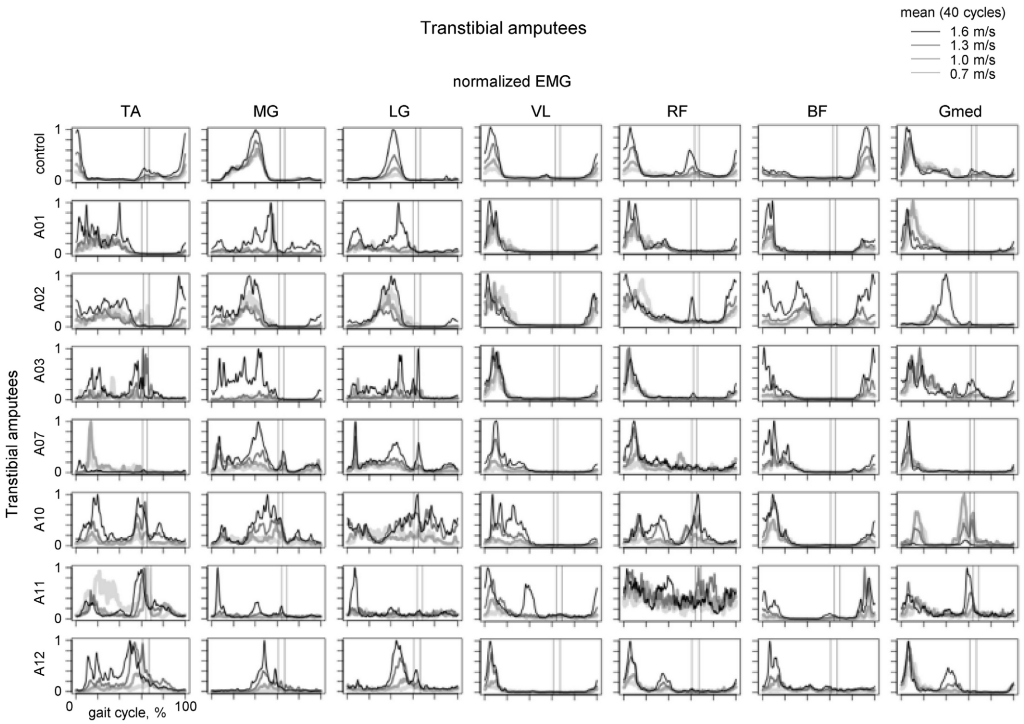

FIGURE 4 | Ensemble-averaged EMG activity of leg muscles during walking at different speeds in the control group (upper panels) and seven amputee subjects. Adapted from Huang and Ferris (2012) with permission of the authors. Vertical lines show average toe-off events for the fastest and slowest walking speeds.

to new insight into how nervous system injury may alter the organization of motor modules and their biomechanical outputs. Furthermore, entraining appropriate motor modules can be of a major importance for neurorehabilitation of gait in these patients since many of them develop an abnormal stereotype of movement during walking, which is difficult to correct.

A similar conclusion has been reached in recent studies on the upper limb control (Cheung et al., 2009, 2012). All patients studied suffered from a mostly unilateral cortical and subcortical lesion resulting from either an ischemic or a hemorrhagic stroke. The robustness of muscle synergies observed in that study supports the notion that descending cortical signals represent neural drives that select, activate, and flexibly combine muscle synergies specified by networks in the spinal cord and/or brainstem and suggest an approach to stroke rehabilitation by focusing on those synergies with altered activations after stroke. Nevertheless, despite higher variability in muscle activation patterns, all these studies suggest a modular organization of muscle coordination underlying motor control in both healthy and post-stroke subjects.

In fact, one of the effective approaches to gait rehabilitation after stroke consists in using step synchronized FES of leg muscles (Yan et al., 2005; Tong et al., 2006; Ferrante et al., 2008). FES has been shown to be an effective tool for muscle strength augmentation, increase in the range of motion in joints and improvements in walking in neurological patients (Popovic et al., 2009). FES is delivered in reference to the timing of natural muscle excitation during movement and it provides additional sensory reinforcement which ultimately improves learning. As a result, the locomotor centers or networks are excited or released from inhibition in phase with their expected activity and thus may be accessible for correction or stimulating effects (Yan et al., 2005; Tong et al., 2006; Popovic et al., 2009; Solopova et al., 2011). Thus, this approach takes advantage of the spatiotemporal architecture of the locomotor program and increases the patient's functional abilities and the effectiveness of rehabilitation.

SPINAL CORD INJURY

Flexibility and adaptability of locomotor patterns are evident from monitoring and analyzing the spatiotemporal spinal segmental output after spinal cord injury. For instance, in motor incomplete paraplegics who recovered independent control of their limbs, an additional activation burst is present in the lumbosacral enlargement at full loading (**Figures 6A,C**). The presence of this burst is related to abnormal activation of the quadriceps muscle during this time. Patients can be trained to step with body weight support unassisted, but they use activity patterns in individual muscles that were often different from healthy individuals.

A number of clinical trials have suggested the possible beneficial effects of locomotor training in SCI patients (Edgerton and Roy, 2012). In patients with severe SCI disorders, initial training is performed while being supported by a harness or with their body partially unloaded. As well, assistance of leg movements by the therapist (or robotics) may be required. These patients frequently show EMG patterns different from those of healthy

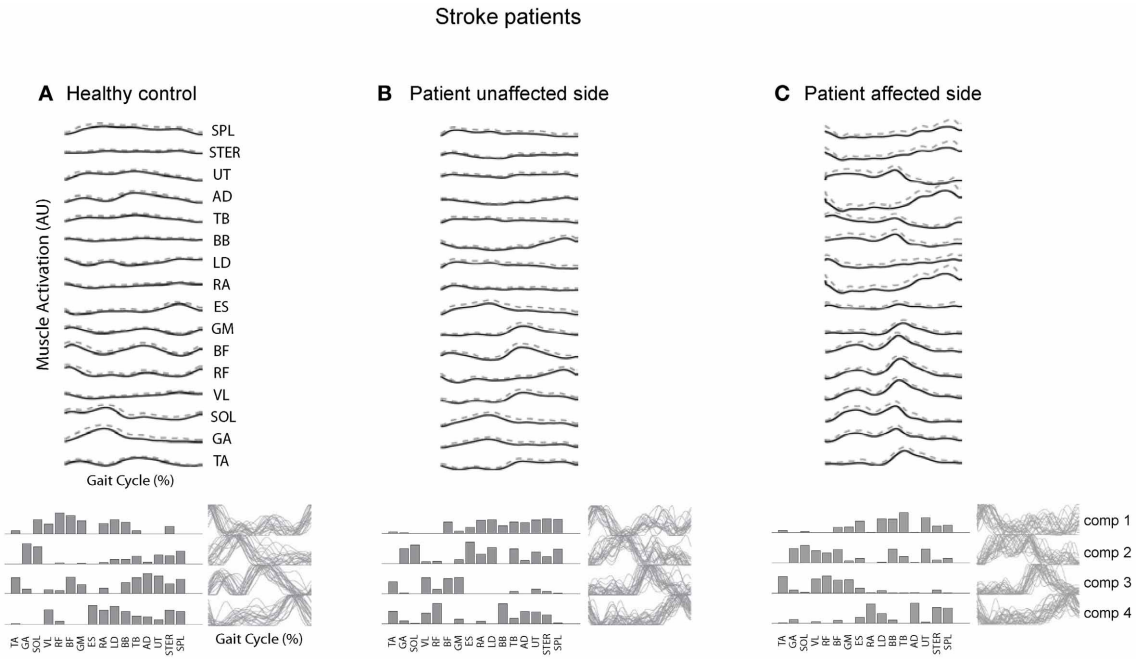

FIGURE 5 | Surface electromyogram (means and *SD*), motor modules (bottom, left), and activation signals (bottom, right) for a representative healthy control subject (A) and for the unaffected (B) and affected side of a stroke patient. (C) Adapted from Gizzi et al. (2011).

individuals suggesting that human spinal cord can interpret differently loading- or velocity-dependent sensory input during stepping (Beres-Jones and Harkema, 2004). One method used to study such variability involves reconstructing the total output pattern of motoneuron activity of the lumbosacral enlargement of the spinal cord by mapping the recorded EMG waveforms onto the known charts of segmental localization (Ivanenko et al., 2006). Spatiotemporal maps of motoneuron activity are generally different from those of healthy subjects (**Figure 6C**; Grasso et al., 2004). The legs may also show muscle activity which is not-systematically synchronized with the gait cycle on the most affected side (**Figure 6B**; marked in red). Although training of stepping in patients with body weight support can be facilitated in a laboratory setting, often new coordinative strategies appear. Training can be utilized in order for patients to relearn foot kinematics of healthy individuals, but the muscle activation patterns used to generate these kinematics differ from that of a healthy group (Pepin et al., 2003; Grasso et al., 2004). While most incomplete paraplegics can recover independent control of leg muscles sufficient to propel the limbs in swing and to support body weight in stance, complete paraplegics, were unable to and they typically used their arms and body to assist the leg movements. SCI patients largely relied on proximal and axial muscles to lift the foot and to project the limb forward.

It is though that spinal lesions may trigger plasticity including modified synaptic strengths, sprouting and anatomical development of new circuits as well as plasticity of unlesioned descending pathways, including both subcortical and cortical motor areas. Stepping may also depend more heavily on cortical (and voluntary) control after severe spinal lesions (Van den Brand et al., 2012) than it does in healthy subjects, where locomotion may be more automatic. The spinal cord itself does also contribute to the proposed adaptation mechanisms. Indeed, experiments on both animals and SCI patients suggest that the spinal cord is capable of adaptive locomotor plasticity with training after spinal lesion (Hodgson et al., 1994; Belanger et al., 1996; Heng and de Leon, 2007) or after peripheral motor nerve lesions (Bouyer et al., 2001).

Modular pattern generator elements (or burst synergies), nevertheless, tend to be conserved after spinal cord injury (Fox et al., 2013; Giszter and Hart, 2013). Our previous work in SCI patients (Ivanenko et al., 2003) has shown a similar set of temporal components from EMG activity (**Figure 6D**). In addition, muscles both rostral and caudal to the lesions could be strongly weighted on a given component. However, some patients do exhibit a smaller number of basic components during walking (Ivanenko et al., 2003; Hayes et al., 2011; Fox et al., 2013) although these results may be dependent on the number and selection of muscles recorded during stepping. Nevertheless, similar activation timings in SCI patients (**Figure 6D**) may be ultimately related to the global kinematic goal (a motor equivalent solution; Grasso et al., 2004) or the necessity to apply forces at particular phases of the gait cycle (Lacquaniti et al., 2012). These data highlight the importance of understanding the modular structure of motor behaviors to best provide principled therapies after central nervous system lesions (Giszter and Hart, 2013).

CONCLUDING REMARKS

Taken together, the data support the idea of plasticity and distributed networks for controlling human locomotion (Scivoletto

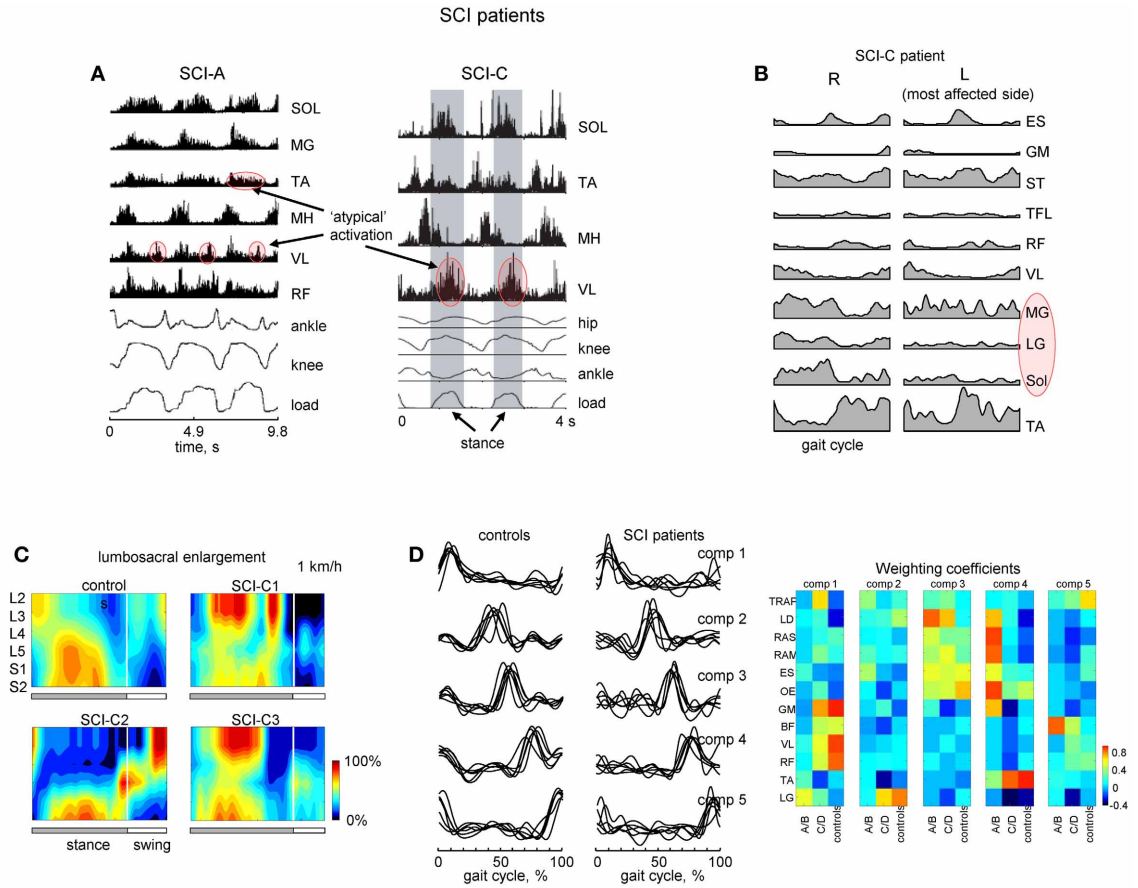

FIGURE 6 | Motor patterns in SCI patients. (A) An example of weight-bearing stepping in a clinically complete (at 0.22 m/s, left panel) and incomplete (at 0.89 m/s, right panel) SCI individuals [modified from Beres-Jones and Harkema (2004) and Maegele et al. (2002) with permission of the authors]. The stance phase in the right panel is evidenced by the elevation in the ground reaction force trace and indicated by the shaded region. MH, medial hamstring; load, vertical ground reaction force. **(B)** Ensemble-averaged (across 5 strides) EMG patterns in the SCI-C patient during walking at a natural speed (~3.1 km/h). Note variable and weaker muscle activity on the most affected side (marked in red). **(C)** Examples of spatiotemporal patterns of α-motorneuron activity in the lumbosacral enlargement in controls and three SCI-C patients during walking on a treadmill at 1 km/h. Output pattern for each segment was reconstructed by mapping the recorded EMG waveforms (normalized method, see Ivanenko et al., 2006) onto the known charts of segmental localization. White vertical lines denote stance-to-swing transition time. **(D)** Time course of the temporal components in controls and patients for stepping at 2 km/h, 0–75% body weight support. The components extracted by factor analysis from individual subjects. Right panel illustrates weighting coefficients of the temporal components in individual activity patterns of 12 muscles for all groups of subjects in a color coded scale. Adapted from Ivanenko et al. (2003). Note similar basic EMG components in controls and patients as opposed to quite different EMG patterns and weighting coefficients.

et al., 2007). Tens of muscles participate in the control of limb and body movements during locomotion, and redundancy in the neuromuscular system is an essential element of gait adaptability (Winter, 1989; Cai et al., 2006; Noble and Prentice, 2006; Ivanenko et al., 2009; Molinari, 2009; Duysens et al., 2013). Indeed, experimental studies performed on individuals with well-identified pathologies have demonstrated distinct adaptations. Due to muscle redundancy, various neuromotor strategies may exist to compensate for decreased muscle strength and joint stiffness (Grasso et al., 2004; Goldberg and Neptune, 2007; Ivanenko et al., 2009; Gordon et al., 2013).

A modular motor organization may be needed to solve the degrees of freedom problem in biological motor control (Giszter et al., 2010). Nevertheless, there are still many open questions related to the choice of appropriate modules, their task dependence, influence of sensory input and adaptation to the malfunctioning of neural networks in the case of different gait pathologies. While many studies succeeded in a decomposition of motor patterns into a few "motor modules," nevertheless, the way in which the central nervous system combines them together, how and where the weighting coefficients are encoded are not understood. Often it is difficult to distinguish what primarily comes from pathology and what comes from compensatory mechanisms. We suggest that many adaptive features in various neurological disorders are likely compensatory, including modified EMG patterns during walking. In view of task dependence of muscle synergies, it would be interesting also to compare them in different behaviors and examine whether plasticity in muscle patterns originates from sharing these common modules or by creating new muscle synergies.

An impulsive (burst-like) controller made of a low-dimensional set of time-delayed excitation pulses has been also thoroughly considered in a simulation study from the biomechanical viewpoint (Sartori et al., 2013). In particular, simulated gait motions based on a few modular activation patterns were successfully produced (see also Neptune et al., 2009; Allen and Neptune, 2012; Allen et al., 2013). Once calibrated, the musculoskeletal model could work in open-loop, approximating joint moments over multiple degrees of freedom using only the recorded kinematics and the internal impulsive controller. The accuracy of estimation of the joint torques was comparable when using the low-dimensional activation signals (Sartori et al., 2013). This approach has substantial implications for the design of human machine interfaces for prosthetic and orthotic devices.

Uncovering a common underlying neural framework for the modular control of human locomotion and its development represent an interesting avenue for the future work. Motor primitives may reflect in a way how the nervous system develops, by building up or modifying modules as it matures. Some functional units are likely inborn, others may develop later or be dependent on individual body size/proportions or experience (Dominici et al., 2011). Such investigations may have important implications related to the construction of gait rehabilitation technology.

The observation that the activity of multiple muscles can be well approximated by a few linear synergies is viewed by some as a sign that such low-dimensional modules constitute a key component of the neural control system. Here, we argue that the usefulness of muscle synergies as a control principle should be evaluated in terms of errors produced not only in muscle space, but also in task space. We used data from a force-aiming task in two dimensions at the wrist, using an electromyograms (EMG)-driven virtual biomechanics technique that overcomes typical errors in predicting force from recorded EMG, to illustrate through simulation how synergy decomposition inevitably introduces substantial task space errors. Then, we computed the optimal pattern of muscle activation that minimizes summed-squared muscle activities, and demonstrated that synergy decomposition produced similar results on real and simulated data. We further assessed the influence of synergy decomposition on aiming errors (AEs) in a more redundant system, using the optimal muscle pattern computed for the elbow-joint complex (i.e., 13 muscles acting in two dimensions). Because EMG records are typically not available from all contributing muscles, we also explored reconstructions from incomplete sets of muscles. The redundancy of a given set of muscles had opposite effects on the goodness of muscle reconstruction and on task achievement; higher redundancy is associated with better EMG approximation (lower residuals), but with higher AEs. Finally, we showed that the number of synergies required to approximate the optimal muscle pattern for an arbitrary biomechanical system increases with task-space dimensionality, which indicates that the capacity of synergy decomposition to explain behavior depends critically on the scope of the original database. These results have implications regarding the viability of muscle synergy as a putative neural control mechanism, and also as a control algorithm to restore movements.

Keywords: aiming movement, muscle coordination, motor control, biomechanics, optimal control

INTRODUCTION

There is now considerable evidence from a broad range of tasks and contexts that the activity of multiple muscles can appear to be well-approximated by only a few muscle synergies, each defined as a set of fixed relative levels of muscle activation (d'Avella et al., 2003, 2006; Torres-Oviedo et al., 2006; Tresch and Jarc, 2009; Dominici et al., 2011; Roh et al., 2012). Although many view this as a sign that muscle synergy is an important principle used by the nervous system to control movement, we believe that the viability of synergies as control elements needs to be evaluated in relation to task achievement rather than only to accuracy in accounting for observed muscle activity. All synergy decomposition procedures (including, for example, those based on convenient optimization algorithms such as the non-negative matrix factorization; Lee and Seung, 2001), care only about explaining as much variance of muscle activity as possible. These procedures are therefore completely blind to any consideration of task achievement, ignoring the functional significance of the (typically modest) muscle-space errors that are inevitably introduced when approximating an original muscle pattern using fewer synergies than muscles. However, because the musculoskeletal system has complex and highly non-linear properties, statistical methods that minimize errors in the input signal (muscle activity) may result in unacceptably large errors in the output (limb kinematics). A careful assessment of behavioral errors introduced by synergy decomposition therefore appears necessary to evaluate the viability of synergy as a potential biological control principle. Such errors would also affect the utility of synergy decomposition as a potential control strategy to restore movement artificially such as with functional electrical stimulation (FES) or myoelectric controls (Davoodi et al., 2003; Parker et al., 2006; Hargrove et al., 2009).

Neptune and colleagues evaluated whether muscle synergies extracted during human walking would actually produce well coordinated locomotion (Neptune et al., 2009; Allen and Neptune, 2012). They found that the activations of muscle synergies required substantial fine-tuning based on their consequences in task-space (i.e., minimizing difference between actual and simulated walking kinematics and ground reaction forces) to achieve satisfactory motor behavior. This suggests that relatively small errors produced by muscle synergies in reproducing muscle activation patterns can lead to important functional deficits. Other studies demonstrated the capacity to generate functional

movements with a limited number of muscle synergies (McKay and Ting, 2008, 2012; Berniker et al., 2009; Kargo et al., 2010). These also required fine-tuning of synergy activation to produce reasonable behavior, a requirement that might result from discrepancies between the real and modeled biomechanics. None evaluated the functional consequence of synergy decomposition by comparing the movements predicted by the extracted synergies with those actually occurring when the basis-set of electromyograms (EMG) signals was recorded.

A likely reason for the lack of attention that has been devoted to the functional consequences of synergy approximation is the complexity of the mapping between muscle activities and their resulting effects on the limb. In addition to an accurate biomechanical model, effective forward simulation of limb kinematics from EMG requires an accurate measurement of the activation of each muscle. However, EMG are subject to crosstalk (i.e., contamination by nearby muscles) and representativeness issues (e.g., regional segregation of early recruited, slow-twitch motor units vs. late-recruited, fast-twitch units; Chanaud et al., 1991b), and are therefore imperfect measures of muscle activation (Staudenmann et al., 2010; Hug, 2011). To accommodate for this, we designed a practical forward simulation approach whereby a virtual representation of muscle biomechanics is defined that best reconstructs force when driven by EMG recordings (de Rugy et al., 2012c). This "virtual biomechanics" technique offers a unique opportunity to map the functional consequences of synergy approximation: Because the mapping between muscle and force is explicitly defined and used to control the task, the mapping between muscle synergies and force is also explicit and enables unambiguous assessment of the functional consequences of using extracted synergies compared to the original EMG signals in order to account for the motor behavior actually measured during those EMG recordings.

Another advantage of the explicit representation of muscle biomechanics defined with this technique is that it provides an experimental basis from which we can compute muscle activity according to the principles of optimal control theory; to achieve the task while minimizing a cost such as effort or variability of movement. Optimal control theory has been shown to reproduce patterns of muscle recruitment that are consistent with the existence of motor synergies (Todorov, 2004; Chhabra and Jacobs, 2006; Diedrichsen et al., 2010), and muscle synergies have been used to simplify the computational cost of optimization in several optimal control schemes (Todorov et al., 2005; Lockhart and Ting, 2007; Berniker et al., 2009). Here, we compared directly synergy decomposition and the resulting task performance between real data and simulated optimal muscle patterns for the same task. This comparison should indicate whether synergies similar to those extracted from real data can result from an optimal control scheme, and whether we can use simulated optimal muscle patterns in place of unavailable EMG to explore functional consequences of synergy decomposition in arbitrary biomechanical systems. First, we evaluated the functional consequences of synergy decomposition using previous data obtained when subjects performed force-aiming in two dimensions at the wrist, with force reconstructed online from EMG recordings (de Rugy et al., 2012c). Then, we computed the optimal muscle pattern that minimized the summed squared muscle activities (Fagg et al., 2002; Diedrichsen et al., 2010) for the virtual biomechanics extracted for each subject, and compared synergy decomposition on this simulated pattern with that obtained on real data. We also assessed synergy decomposition on the optimal muscle pattern for the higher dimensional elbow-joint complex (13 muscles), and explored reconstruction from an incomplete set of muscles as this represents the vast majority of cases for which recordings are available from only a subset of contributing muscles. The idea that sampling of muscle degrades the estimate of muscle synergies has been addressed in the literature (Clark et al., 2010; Ting and Chvatal, 2010; Allen and Neptune, 2012), but here we additionally determined the influence of the redundancy of the muscle selection on both synergy approximation and task performance. Finally, we explored the implications of increasing the dimensionality of the task (i.e., from 2-d to 3-d) for synergy decomposition of the optimal muscle pattern for an arbitrary biomechanical system. The scope of the original database is known to influence the results of synergy decomposition (Macpherson, 1991; Ting and Chvatal, 2010; Burkholder and van Antwerp, 2012), and we wanted to evaluate the influence of task dimension on synergy decomposition of optimal muscle patterns.

MATERIALS AND METHODS

WRIST EXPERIMENT

We re-analyzed data from Experiment 1 in de Rugy et al. (2012c), applying synergy decomposition methods and measures, and additionally assessed their consequences in task space.

Participants

Six healthy, right-handed subjects (all men, aged 23–38) volunteered for this study. All had normal or corrected to normal vision and gave informed consent prior to the experiment, which was approved by the local ethics committee and conformed to the Declaration of Helsinki.

General procedure

Subjects sat 80 cm from a computer display positioned at eye level. The right hand was maintained in a custom-made manipulandum with the forearm in a neutral position (midway between pronation and supination, as displayed **Figure 1**). The elbow was kept at 110° with the forearm parallel to the table and supported by a custom-built device. The wrist was fixed by an array of adjustable supports, contoured to fit the hand at the metacarpal-phalangeal joints (12 contacts) and the wrist just proximal to the radial head (10 contacts). This allowed wrist forces to be applied without the need for a gripping force. Wrist forces were recorded using a 6-df force/torque transducer (JR3 45E15A-I63-A 400N60S, Woodland, CA) coupled with the wrist manipulandum.

Real-time visual feedback of either the real wrist forces or the reconstructed wrist forces was presented on the visual display. Targets were presented at 16 radial positions around the center of the display (i.e., 22.5° apart). Flexion/extension corresponded to the horizontal axis (flexion left) and radial/ulnar deviation corresponded to the vertical axis (radial deviation up).

A block of 32 maximal voluntary contraction (MVC) trials was first conducted for each subject. This block was used to normalize

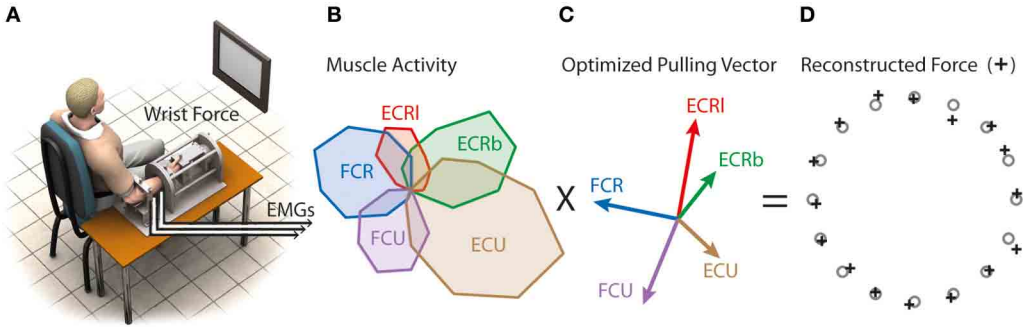

FIGURE 1 | Virtual biomechanics. (A) Subjects produced force at the wrist to 16 targets. **(B)** Example of muscle tuning curves obtained by averaging EMGs from five trials per target in the initial force-driven task. **(C)** Virtual muscle pulling vector optimized to produce the best aiming performance when combined with muscle activity. **(D)** Aiming force reconstructed by combining **(B)** and **(C)**.

the activity of each muscle during the aiming task to the maximal EMG obtained in that muscle during MVC toward any target direction. Each of the 16 target directions was presented twice in a randomized order. For each direction, subjects were asked to raise their force rapidly to the maximal extent while maintaining the force direction within a delineated range of ±8° of target direction. Maximal forces were held for approximately 2 s. Fifteen seconds were allowed for rest before the next target appeared in another direction.

The experiment contained a "force-driven" block in which the visual cursor used to reach targets represented the real force, followed by an "EMG-driven" block in which the cursor represented the reconstructed force. The force-driven block consisted of 96 trials (six trials for each of the 16 target directions) in which a low level of force (i.e., 22.5 N, which represents approximately 20% MVC for the subjects tested) was required to reach targets. This level of force was identical across all subjects, and chosen to reduce the possibility of fatigue. Each trial began only if the cursor was maintained less than 5% of the target distance from the origin continuously for 200 ms. The origin was calibrated to zero force along both axes (wrist relaxed) prior to each block. A random delay (1–2 s) elapsed before a single target appeared coincident with a brief tone. Participants were asked to move the cursor to the target with a movement time of between 150 and 250 ms, defined as the time between 10 and 90% of the radial distance to the target, and to hold the cursor continuously for 1 s within the target zone (a trapezoid ±8° from target direction by 10% of radial distance to target). A high-pitched tone signaled that the target had been acquired. If the target was not acquired within 2 s of target presentation, a low-pitched tone indicated the end of the trial. A second tone (200 ms after the first) indicated whether the movement time was correct (high tone) or not (low tone), and a bar graph provided visual feedback of the movement time in relation to the prescribed time window. Both the target and cursor disappeared at target acquisition or trial end, and at least 1 s elapsed before the start of the next trial. For each block, six consecutive trials were conducted for each one of 16 randomly ordered targets. The "EMG-driven" block was identical to the "force-driven" blocks, with the only exception that the real force feedback was replaced by the reconstructed force.

EMG procedure

Bipolar electromyographic signals were recorded from extensor carpi radialis longus (ECRl), extensor carpi radialis brevis (ECRb), flexor carpi radialis (FCR), flexor carpi ulnaris (FCU), and extensor carpi ulnaris (ECU) muscles, with self-adhesive surface electrodes. Signals were band-pass filtered from 30 Hz–1 KHz, amplified 200–5000 times (Grass P511, Grass Instruments, AstroMed, West Warwick, RI, USA), and sampled at 2 KHz. Electrode locations were determined according to procedures previously reported (Selvanayagam et al., 2011).

Data reduction and analysis

Muscle tuning curves, or the time-independent muscular activity ($\mathbf{a}$) for the different target directions, were determined for each muscle as the mean rectified EMG during the hold-phase of the task (i.e., in a time window from 300 to 1000 ms after movement onset), averaged over five trials to each target (the first of the six consecutive trials to each target was discarded to prevent the uncertainty about target direction from contaminating the data).

Virtual biomechanics, the representation of muscle biomechanics that best reaches the target when combined with EMG data, was extracted from muscle tuning curves obtained from the "force-driven" block as indicated in de Rugy et al. (2012c). A coordinate descent was used to determine the set of pulling vectors $\mathbf{P}$ (**Figure 1**) that resulted in the best aiming performance, i.e., that minimizes endpoint errors $E = \left\|\mathbf{x}_{\text{targ}} - \mathbf{x}\right\|^2$ between cursor positions $\mathbf{x}$ ($\mathbf{x} = \mathbf{P}\ \mathbf{a}$) and target positions $\mathbf{x}_{\text{targ}}$. This coordinate descent used the following steps: (1) Assign random values to the initial set of pulling vectors in the physiological range of muscle force and direction. (2) Pick a muscle at random and modify its pulling vector by changing its endpoint by a step in four orthogonal directions. The target errors associated with each of the five pulling vectors (i.e., the original and the four modified for that muscle) was then calculated as the summed squared error between targets and reconstructed reaches, and the pulling vector that produced the lowest cost was retained. (3) One iteration of the model was said to be completed when each muscle had been optimized once. (4) The whole model was iterated until the overall cost converged to a low value.

The resulting set of pulling vectors was then multiplied online by the rectified filtered EMG of the five muscles to reconstruct force used as a feedback in the "EMG-driven" condition. This virtual biomechanics was also used to compute the optimal muscle pattern, as explained below. We showed previously that muscle tuning curves for this data set were not different in the "force-driven" and in the "EMG-driven" blocks (de Rugy et al., 2012c).

Synergy extraction was conducted using the non-negative matrix factorization algorithm (Lee and Seung, 2001) on muscle tuning curves obtained in the "EMG-driven" block, for which we unambiguously know the mapping between muscle activity and task space. The muscle activation pattern **a** was first normalized such that each muscle has unit variance, and the normalized pattern **a*** was approximated with N muscle synergies according to

$$\mathbf{a}^* \approx \hat{\mathbf{a}}^* = \mathbf{c}\,\mathbf{w}$$

where **a*** is a matrix with each component representing the normalized activation of a specific muscle for a specific target direction, $\hat{\mathbf{a}}^*$ is the approximated muscle pattern, **w** is a matrix with each component representing the activation of a specific synergy for a specific target direction, and **c** is a matrix of non-negative scaling coefficients.

The goodness of synergy approximation was calculated as a multivariate R^2 (Mardia et al., 1979; d'Avella et al., 2006):

$$R^2 = 1 - \frac{SSE}{SST} = 1 - \frac{\left\|\mathbf{a}^* - \hat{\mathbf{a}}^*\right\|^2}{\left\|\mathbf{a}^* - \overline{\mathbf{a}}^*\right\|^2}$$

where *SSE* is the sum squared residuals and *SST* is the summed squared residual from the mean normalized activation vector ($\overline{\mathbf{a}}^*$). We also computed the variance accounted for (VAF), a related measure where *SST* is simply the summed squared activation, i.e., calculated on uncentered data (Cheung et al., 2005; Roh et al., 2012):

$$\mathrm{VAF} = 1 - \frac{SSE}{SST} = 1 - \frac{\left\|\mathbf{a}^* - \hat{\mathbf{a}}^*\right\|^2}{\left\|\mathbf{a}^*\right\|^2}$$

For each synergy decomposition, an associated aiming error (AE) was computed as the distance between targets $\mathbf{x}_{\mathrm{targ}}$ and the force vector produced by combining the pulling vectors with the (un-normalized) muscle activity approximated by the synergies ($\hat{\mathbf{x}} = \mathbf{P}\hat{\mathbf{a}}$):

$$\mathrm{AE} = \left\|\hat{\mathbf{x}} - \mathbf{x}_{\mathrm{targ}}\right\|^2$$

For each subject and synergy number ($N = 1 - 5$), the synergy decomposition was conducted 10 times and averaged values were obtained for each of the three measures (R^2, VAF, and AE).

WRIST SIMULATIONS

We computed the optimal muscle pattern $\mathbf{a}_{\mathrm{opt}}$ for the set of pulling vectors extracted individually for each subject using the procedure described in Fagg et al. (2002). This procedure minimizes the following composite cost *C*, which ensures task achievement by minimizing target errors while simultaneously minimizing the summed squared muscle activations:

$$C = \frac{1}{2}\left\|\mathbf{x}_{\mathrm{targ}} - \mathbf{x}\right\|^2 + \frac{\lambda}{2}\left\|\mathbf{a}_{\mathrm{opt}}\right\|^2$$

where λ is a regularization parameter set to 0.02 to represent allowable errors on the order of 2% of movement magnitude. Synergy decomposition was applied on the optimal muscle pattern as on experimental data, and differences between experimental and simulated data were tested using a two way [data type (experimental vs. simulated) × number of synergy (1–5)] repeated measures ANOVAs for the three measures (R^2, VAF, and AE). Differences between AEs produced with different number of synergies were also tested on experimental data using a paired sample *t*-test. The significance level was set to $\alpha = 0.05$.

ELBOW SIMULATIONS

The optimal muscle pattern was also computed on an existing biomechanical model of the arm for a similar center-out isometric task performed at the elbow joint complex in the flexion/extension and supination/pronation workspace (de Rugy et al., 2009; de Rugy, 2010). The biomechanical model developed by Davoodi and colleagues (**Figure 4A**; Davoodi et al., 2002a,b; de Rugy et al., 2008; de Rugy, 2010) was used to extract the pulling vectors of 13 arm and forearm muscles in this workspace (**Figure 4B**): Supinator (SUP), the short and long heads of Biceps Brachii (BIC ln and sh), Brachialis (BRA), Brachioradialis (BRD), Pronator Teres (PT), Pronator Quadratus (PQ), the long, medial, and lateral heads of Triceps (TRI ln, m, and lt), and three wrist muscles (FCR, ECRl, and ECRb; please note that the two remaining wrist muscles, FCU, and ECU, were not included because their moments are negligible in that workspace).

Synergy decomposition was conducted on the optimal muscle pattern according to the method described above for the wrist, and the procedure was repeated 100 times to obtain the mean and standard error of the three measures (R^2, VAF, and AE).

To account for the vast majority of cases in which recordings are limited to an incomplete set of muscles, we also explored reconstructions from a limited number of muscles. In particular, we considered two qualitatively different selections of eight muscles amongst the 13 muscles: a "redundant" selection (**Figure 5A**, BIC ln and sh, BRA, BRD, TRI ln, lt, and m, PT), and a "less redundant" one (**Figure 5B**, BICln, BRA, TRIln, PT, SUP, PQ, FCR, ECRb). The idea behind this choice of qualitatively different sets of muscles was that the level of biomechanical redundancy might translate into relationships between activation of muscles that would be visible through synergy decomposition. R^2 and VAF were calculated as before for these incomplete sets of muscles, and AE was computed on the basis of the virtual biomechanics reconstructed from these eight muscles only (i.e., based on the set of pulling vectors that best achieve targets when combining the activity of the eight muscles rather than on the true pulling vectors). This was designed to assess the quality of the reconstruction in both muscle space and task space for common situations in which recordings are only available from fewer muscles than those contributing the task.

SIMULATIONS WITH ARBITRARY PULLING VECTORS IN 3 AND 2 DIMENSIONS

We explored the implications of changing the dimensionality of the task-space for synergy decomposition using the optimal muscle pattern for an arbitrary biomechanical system represented by a set of 13 pulling vectors in three and two dimensions. A set of 13 unit vectors approximately uniformly distributed in three dimensions was first defined using a repulsive iterative algorithm (**Figure 6A**). Then the same iterative algorithm was used to generate a set of 200 targets approximately uniformly distributed on a sphere (**Figure 6B**), and the optimal muscle pattern for these pulling vectors and targets was determined that minimized the same cost function as for the wrist and elbow (i.e., composite cost with target errors and summed squared muscle activations). The corresponding simulations in two dimensions were conducted using the original set of 16 targets used for the wrist and elbow, and the same set of 13, 3-dimensional pulling vectors by ignoring the third dimension (Z on **Figure 6B**, 2-d pulling vector shown **Figure 6C**). The optimal muscle pattern was computed as before (**Figure 6D**). Synergy decomposition and the mean and standard error of the three main measures (R^2, VAF, and AE) were conducted and obtained as for the elbow system.

RESULTS

SYNERGY DECOMPOSITION ON REAL AND OPTIMAL DATA AT THE WRIST

Figure 2A shows how synergy decomposition approximates the original muscle pattern for one subject, and **Figures 2B,C** show how this approximation translates into AEs for the same subject (**B**) and for all six subjects (**C**). This figure illustrates that the muscle pattern reconstructed with synergy only starts to resemble the real pattern with three or four synergies, but also that the remaining muscle-space differences translate into substantial AE. These errors disappear only when five synergies have been extracted, which reflects the unreduced dimensionality of the complete musculoskeletal system.

Figure 3 shows that the goodness of the muscle reconstruction increases as expected with the number of synergies, and that AEs decrease accordingly. It is worth noting that a VAF of approximately 0.5 is obtained with only one synergy, where the cursor hasn't moved from the center of the workspace toward any target (**Figure 2C**). This illustrates that 50% of the variance in muscle activity is accounted for by a synergy decomposition that is doing no better at reaching targets than simply not activating any muscles. **Figures 2B,C** also illustrate that synergy decomposition systematically results in undershoot errors. The reason for this is obvious with one synergy, where the solution found by the non-negative matrix factorization algorithm takes the form of muscles that co-contract to their average activity level in the original muscle pattern. For other number of synergies, the muscle pattern approximated with fewer synergies than muscles similarly results in wider muscle tuning curves, which produces undershoot errors when summing muscle contributions at the joint.

Figure 3 shows that the reconstruction with four synergies explained most of the variance of the muscle pattern (VAF = 0.95 and $R^2 = 0.91$) while still producing considerable task errors (averaged error of 13.5 % of target distance, visible **Figure 2C**), that are significantly higher than errors produced by the original muscle pattern (3.6% averaged error; $t = 8.11$ $p < 0.0005$).

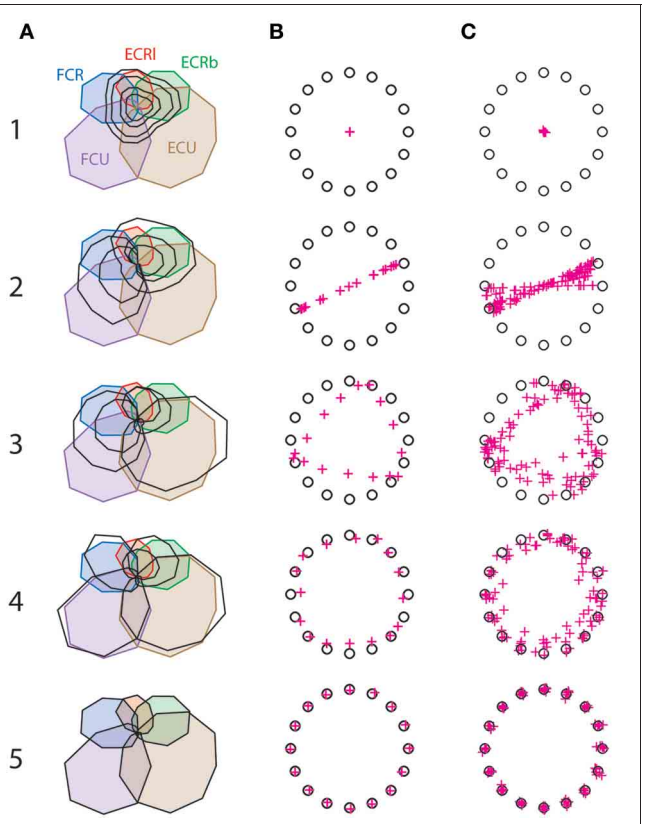

FIGURE 2 | Synergy decomposition at the wrist. (A) Actual muscle pattern (colored) with the muscle pattern reconstructed with 1–5 synergies (black) for a representative subject. **(B)** Corresponding targets (circles) and reconstructed aiming force (crosses) for the same subject. **(C)** Targets (circles) and reconstructed aiming force (crosses) for all subjects.

Figure 3 also shows that synergy decomposition conducted on optimal muscle patterns computed for the virtual biomechanics extracted from individual subjects generated similar results to synergy decomposition of real data. There were no differences in R^2 or AE values calculated on real vs. simulated data [$F_{(1,\ 5)} < 4.98$, $p > 0.08$], although VAF values were slightly higher when calculated on real data than optimal data [$F_{(1,\ 5)} = 9.19$, $p = 0.03$]. These results indicate that synergy decomposition of optimal muscle recruitment patterns produces results similar to those obtained from real EMG signals. This makes it possible to explore the inherent consequences of synergies interacting with realistic musculoskeletal dynamics without the potential confounds introduced by missing, poorly sampled or noisy EMG signals.

SYNERGY DECOMPOSITION ON OPTIMAL DATA AT THE ELBOW JOINT COMPLEX

Figure 4 shows that synergy decomposition conducted on the optimal muscle pattern (**C**) computed for the 13 muscles of the biomechanical arm model provides results (**D**) closer to those usually reported in the literature; i.e., a goodness of the

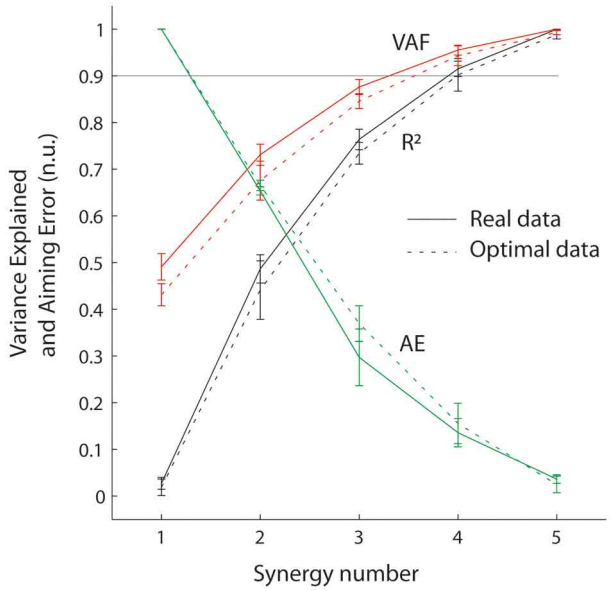

FIGURE 3 | Goodness of muscle and aiming force reconstructions at the wrist, evaluated through VAF, R^2, and AE. Sold lines correspond to real data and dotted lines correspond to simulated data (optimal muscle pattern). Error bars represent standard errors.

reconstruction (both VAF and R^2) that quickly rises to reach an asymptotic level at which most muscle variance is explained with substantially fewer synergies than muscles. For instance, the 90% variance level is reached with only four synergies (VAF = 0.94 and $R^2 = 0.90$) and almost the entire variance is explained with five synergies (VAF = 0.98.5 and $R^2 = 0.97.5$). However, the associated AEs are still substantial (14.6% and 7.5% of target distance with four and five synergies, respectively), and at least six synergies are needed to generate AEs below 5% of target distance (i.e., 4.1% with six synergies).

The situation changes when only an incomplete selection of muscles is available to perform the synergy decomposition and the force reconstruction, reflecting the common experimental situation in which recordings are not available from all contributing muscles. **Figure 5** shows that the goodness of muscle approximation is better for the selection of redundant muscles than for the selection of less redundant muscles. For instance, at least 90% of the variance is explained with three and four synergies with the set of redundant muscles, but this degree of variance explained requires an additional synergy with the set of less redundant muscles. Inversely, the AE reconstructed by combining synergy approximation with the virtual biomechanics extracted on the incomplete set of available muscles is much higher for the redundant muscles than for the less redundant muscles. In particular, the reduction of error saturates above 30% from 4 to 8 synergies for the set of redundant muscles, but monotonically decreases to a minimum of 3.8% for the less redundant muscles.

It is worth noting that if AEs associated with synergy decomposition are better for the set of less redundant muscles, they are still substantially higher than with the complete set of muscles. For instance, AEs for 5–7 synergies are 29, 17.5, and 8% for the set of less redundant muscles, and 14.6, 7.5, and 4.1% for the complete set of muscles. This indicates that aiming performance suffers more from synergy approximation with an incomplete set of muscles.

SYNERGY DECOMPOSITION ON ARBITRARY BIOMECHANICS IN 2 AND 3 DIMENSIONS

Figure 6E shows that synergy decomposition conducted on the optimal muscle pattern computed on the 13 muscles of the arbitrary biomechanical model provides different results for the two- and three-dimensional versions of the task. As for the elbow system, the optimal muscle pattern for the 13 two-dimensional pulling vectors (**Figures 6C,D**) reaches the 90% variance level with only four synergies (VAF = 0.94, $R^2 = 0.90$, AE = 14.6%). In contrast, nine synergies were required to reach the same 90% variance level for the three-dimensional version of the task (VAF = 0.94, $R^2 = 0.91$, AE = 12%). For both cases, an additional synergy is required for the averaged AE to drop below 10% (i.e., 8% with five synergies and 9.8% with 10 synergies for the two- and three-dimensional cases, respectively). This indicates that the capacity of synergy to explain optimal muscle patterns and their functional outcome depends critically on the scope of the original database, where higher dimensional behaviors will require more synergies or will produce poorer fits.

DISCUSSION

The purpose of this study was to assess the functional consequences of approximating an actual pattern of muscle recruitment with fewer synergies. We first used previous data obtained when people performed a force-aiming task in two dimensions at the wrist, where force was reconstructed online from EMG recordings (de Rugy et al., 2012c), to show that despite successfully explaining muscle activities, synergy-approximated EMG data would introduce substantial errors in task space. Then, we showed that synergy decomposition on the optimal muscle pattern that minimizes summed-squared muscle activities for a representation of muscle biomechanics produces similar muscle approximations, with the same functional consequences. We also assessed the influence of synergy decomposition on the optimal muscle pattern computed for the more redundant elbow-joint complex, to show that when selecting an incomplete set of muscles, the redundancy of that selection has opposite effects on the goodness of muscle approximation and on task achievement: higher redundancy is associated with better muscle approximation, but with higher AEs. Finally, we showed that increasing the dimensionality of the task-space from 2 to 3 dimensions also increases the number of synergies required to approximate the optimal muscle pattern and produce low AEs.

If synergies are used only as a tool to summarize observed muscle activation patterns, then they are no different from regression analysis, in which the goodness of fit depends simply on the number of free parameters and the complexity of the source data. Instead, synergies were introduced originally by Bernstein (1967 translation of 1934 book) and continue to be offered as a theory for how the nervous system solves a very specific control problem known as redundancy. The musculoskeletal system

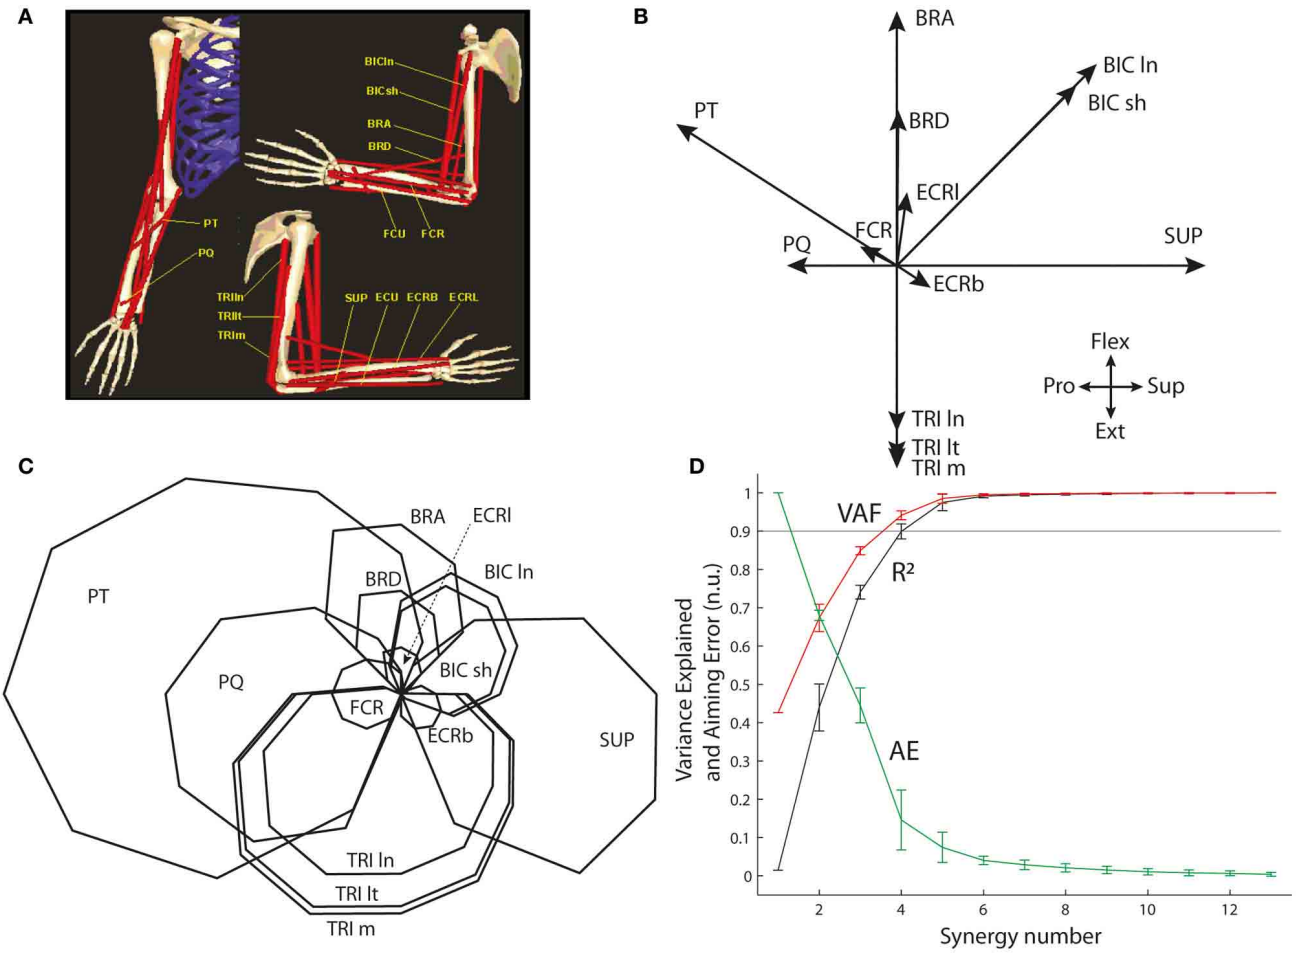

FIGURE 4 | Synergy decomposition at the elbow joint complex. **(A)** Musculoskeletal model. **(B)** Pulling vectors of muscles in the two-dimensional space of flexion/extension and supination/pronation. **(C)** Optimal muscle pattern for this system. **(D)** Goodness of muscle and aiming force reconstructions, evaluated through VAF, R^2, and AE.

contains more degrees of mechanical freedom and more muscles than required to perform tasks successfully. If the nervous system must compute the pattern of muscle activations required to perform a given task, how does it decide which of many solutions to use? One solution is to add performance criteria that can be optimized by one and only one solution (e.g., minimize trajectory errors in the face of noise or minimize effort to conserve energy). Computing or discovering such optimal solutions tends to be extremely difficult for systems with the complexity of a typical limb (reviewed by Valero-Cuevas et al., 2009 and Loeb, 2012). An alternative solution is for there to be arbitrary restrictions on the available patterns of muscle recruitment, either as a consequence of hard-wired neural circuits or learned motor habits. The synergies extracted by decomposition of observed EMG patterns would then be indicative of this control strategy at work. The validity of synergies as a neural control strategy thus depends on its necessity (what are the alternatives?) and its utility (what are the consequences?), which are discussed below.

MUSCLE SYNERGIES INTRODUCE AIMING ERRORS

The importance of considering error introduced in the task space when assessing the usefulness of muscle synergies is clearly illustrated by the fact that in our wrist isometric task, about 50% of muscle variance is accounted for (i.e., VAF) by only one synergy. In this case, the solution found by the non-negative matrix factorization algorithm takes the form of muscles that co-contract to their average activity level in the original muscle pattern. When summing muscle contributions at the joint, this resulted in zero net force, which therefore translated in no movement whatsoever toward the force targets. This extreme case might indicate that centered data should be preferred when calculating the goodness of muscle approximation (i.e., use R^2 instead of VAF) to avoid over-interpreting spurious results arising from the nature of the statistical method. However, both R^2 and VAF are relatively insensitive to the functional consequences of the synergy approximation of muscle activity. For instance, approximating the activity of the five wrist muscles with four synergies explained most of the muscle variance (R^2 and VAF > 0.9), while still

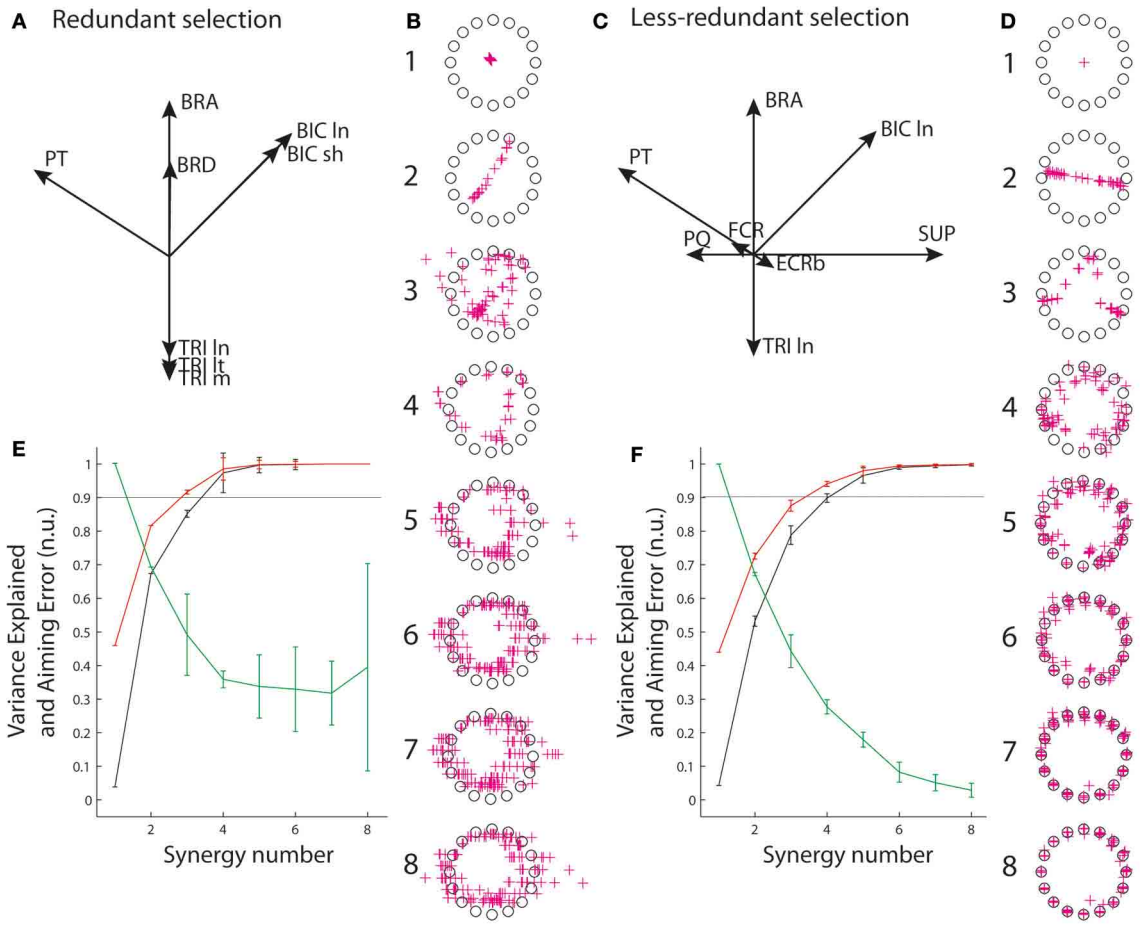

FIGURE 5 | Reconstruction from incomplete set of muscles. (A,C) Muscle pulling vectors for the redundant **(A)** and less redundant **(D)** set of muscle. **(B,D)** Reconstructed aiming force. **(E,F)** goodness of muscle and aiming force reconstructions evaluated through VAF, R^2, and AE.

missing the force targets by 13.5% of target distance. This is important because this order of magnitude of explained muscle variance has been considered as an accurate description in different contexts [e.g., R^2 of 0.85 in reaching (Muceli et al., 2010) or VAF of 0.88 for locomotion (Oliveira et al., 2012)]. It is interesting to note that synergy decomposition systematically resulted in undershoot errors (**Figure 2**) because it inevitably produces inappropriate cocontraction.

The assessment of the functional consequences of muscle approximation by synergies was possible here because for the isometric task at relatively low force (approximately 20% of MVC), the relationship between muscle activity and task space is likely to be close to linear. Although we have not tested our virtual biomechanics technique in contexts where this might not be the case, this linear relationship might be required for subjects to perform the task similarly well with either the real force or the force reconstructed online from EMG recordings (de Rugy et al., 2012c). Because the synergy decomposition was conducted on data obtained when the task was performed with reconstructed force, the mapping between EMG and task space was known, and we applied this mapping directly to calculate errors introduced by synergy decomposition in task space. It remains that the mapping between muscle activity and task space is likely to be far more complex in broader dynamic contexts that include strongly nonlinear relationships between muscle force and velocity for a given level of activation (Brown et al., 1999), which might introduce more errors. For example, the final positions of center-out reaches will depend more on the relatively small EMG signals but large forces that stop the movement on target than on the larger EMG signals but smaller forces in the agonists that accelerate the limb at the beginning of the task. This illustrates that an important part of the control problem might reside in an arbitrarily small proportion of unexplained muscle activation variance.

As mentioned in the introduction, we believe that the complexity of the mapping between muscle activity and the resulting action is the primary reason for the scant attention that has been devoted to the functional consequences of synergy approximation. Although Neptune and colleagues found that synergies were a useful starting point, they required substantial fine-tuning based on their consequences in task-space to produce well coordinated locomotion (Neptune et al., 2009; Allen and Neptune, 2012). There is no question that the statistical methods used to extract

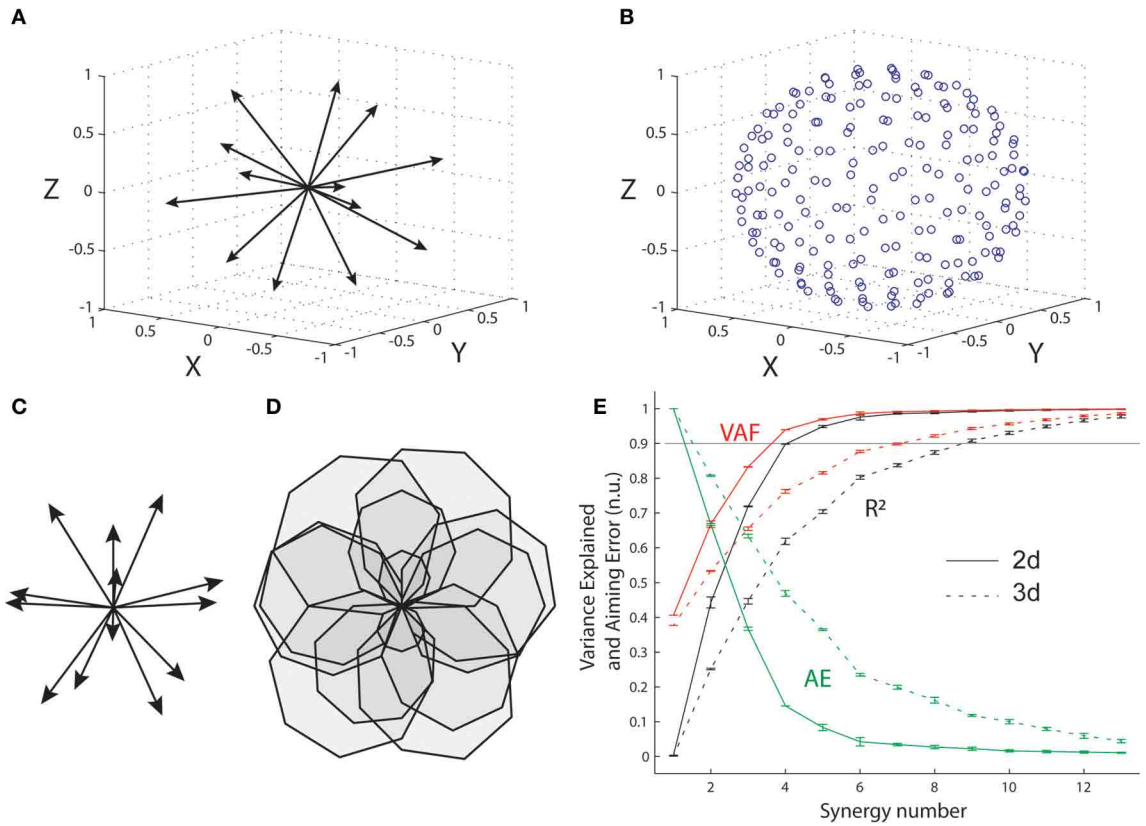

FIGURE 6 | Synergy decomposition from arbitrary muscle pulling vectors in 3-d and 2-d. (A) Unit pulling vectors representing 13 muscles approximately uniformly distributed in the three-dimensional space. **(B)** Set of 200 approximately uniformly distributed targets on the surface of a sphere. **(C)** Corresponding pulling vectors in the two-dimensional space, obtained by suppressing the Z-dimension to the original set of 13 pulling vector. **(D)** Optimal muscle pattern in 2-d. **(E)** Goodness of muscle and aiming force reconstructions evaluated through VAF, R^2, and AE, for both the 3-d and the 2-d simulated data sets.

synergies from EMG recordings must capture substantial features of the very behavior from which the recordings were obtained. The question of whether these synergies reflect an organizing principle of neural control depends on their capacity to sufficiently account for behavior. This condition was not met in either the walking studies or in the wrist task presented here.

MUSCLE SYNERGIES MIGHT ARISE FROM, OR SUBSERVE OPTIMAL CONTROL

Despite the shortcomings mentioned above in relation to AEs generated with the wrist system, we found that synergy decomposition produces similar results on real and simulated (optimal) data. This direct comparison extends previous reports that optimal control schemes produce synergy-like properties (Todorov, 2004; Chhabra and Jacobs, 2006) by showing both qualitative and quantitative matches within the same protocol. Because the deleterious effects of synergy decomposition in terms of AEs at the wrist might relate to the relatively low muscle redundancy of that system, we also explored the more redundant elbow-joint complex. We show that synergy decomposition on the optimal pattern for the 13 muscles of that system produces results that correspond to those typically reported in muscle synergy studies (d'Avella et al., 2006, 2008; Roh et al., 2012), with a goodness of muscle approximation that quickly rises to reach an asymptote level at which most muscle variance is explained with substantially less synergies than muscles. Thus, properties that are typical of the muscle synergy hypothesis arise from the inherent principles of optimal control, highlighting the obvious possibility that synergy might just be a by-product of an alternate control scheme rather than a control principle in itself (Todorov, 2004; Chhabra and Jacobs, 2006; Diedrichsen et al., 2010). One such control scheme that could result in muscle activations that resemble the output of muscle synergies involves the online computation of optimal task solutions by feedback control laws (i.e., optimal feedback control; Todorov, 2004; Diedrichsen et al., 2010). However, muscle synergies have also been suggested to subserve optimal feedback control as a possible neural control element to reduce the high computational cost associated with online optimization (Todorov et al., 2005; Berniker et al., 2009) or to implement a simple feedback rule at task level (Lockhart and Ting, 2007; Ting and McKay, 2007).

Alternatively, muscle synergies might prevail over optimal control schemes. Similarities between real and optimal muscle patterns might reflect behaviors that have developed and evolved

to minimize biologically relevant costs, and whose production is mediated by muscle synergies that are relatively less flexible at shorter time scale. In fact, we showed recently that when faced with novel biomechanics, participants adapted by scaling their original muscle patterns linearly rather than re-optimizing them (de Rugy et al., 2012b), which could at first glance appear in favor of the existence of hard wired synergies. However, we also found that muscle patterns observed when simulating the biomechanics of a posture different from the real posture were better described by a linear scaling of the muscle pattern associated with the real posture than with the simulated posture (de Rugy et al., 2012a,b). This result is not consistent with a re-optimization of activation signals to a set of fixed muscle synergies, as this should have enabled reproducing the optimal muscle pattern associated with the simulated posture. This result could potentially be explained by posture- or feedback-specific synergies (Cheung et al., 2005; d'Avella et al., 2008), but this would be inconsistent with the definition of muscle synergy as a fixed, linear combination of muscle activations, and the associated potential benefits in terms of dimensionality reduction for higher level controllers. Indeed, if synergies are allowed to vary depending on the task or context, these variations would become additional degrees of freedom requiring both additional circuits that can produce the additional synergies and control circuits to select among them. Alternatively, the observed limitation of flexibility of posture-dependent muscle patterns could conceivably pertain to stored and recalled activation signals to synergies rather than to the synergies themselves. However, this would be difficult to distinguish from alternative control schemes involving stored motor programs that would be based on an equal or higher number of control signals than muscles. The concept of synergies might be defined broadly to reflect any tendency to use muscles in learned patterns rather than requiring the existence of specific circuits that generate fixed combinations of muscle activations. But in that case, it is really a neologism for regression analysis that has no predictive value as a reductionist theory of motor control.

THE NUMBER OF SYNERGIES INCREASES WITH TASK DIMENSION

Our simulations show that when going from aiming in two to three dimensions with the same (arbitrary) biomechanical system, more synergies are required to well-approximate the optimal muscle pattern and to generate sufficiently small errors (**Figure 6E**). This illustrates that the capacity of synergy to explain behaviors depends critically on the scope of the original database, where more diverse behaviors will require more synergies or will produce poorer fits. In other word, the seemingly high capacity to account for most activity of numerous muscles with only few linear synergies might hold in restricted experimental contexts (Loeb, 2000), but is expected to deteriorate for more diverse natural behaviors (Macpherson, 1991).

The need to study sufficiently rich behavioral sets has been well-recognized in EMG studies of behaving animals, in which it is possible to surgically implant selective and precisely positioned recording electrodes (Loeb and Gans, 1986). A monkey can learn gradually to selectively modulate muscles that appear to be closely synergistic on both anatomical and electrophysiological grounds if some mechanical advantage can thereby be attained (Cheng and Loeb, 2008). Cats walking on a treadmill exhibit stereotypical patterns of synergy in some major muscles but appear to have learned idiosyncratic patterns of use for smaller muscles (Loeb, 1993), which patterns depend on the musculoskeletal mechanics of the limb rather than genetically specified spinal pattern generators for locomotion (Loeb, 1999). Even within anatomically singular muscles, neuromuscular compartments that have somewhat different mechanical actions on the skeleton can be differentially recruited for some but not all tasks (Chanaud et al., 1991a,b; Pratt et al., 1991; Pratt and Loeb, 1991). These refinements of neural control are likely to go unappreciated in the EMG databases obtainable from surface electrodes, but they seem likely to be present nonetheless in humans.

IMPLICATIONS FOR THE USE OF SYNERGY IN ARTIFICIAL CONTROL

FES typically requires the transformation of a motor goal into control signals designed to stimulate muscles in order to achieve that goal (Davoodi et al., 2003; Loeb and Davoodi, 2005). We illustrated previously that the nervous system does not seem to re-optimize activation signals to a set of muscle synergies (de Rugy et al., 2012b), but this does not mean that the principle of low dimensional control modules cannot be useful to restore movements artificially with FES. For instance, optimal muscle patterns computed for the biomechanics of a particular limb could be decomposed into fewer synergies, that could be used to enable online optimization onto fewer control signals (Todorov et al., 2005), or to implement of simple feedback rules at task-level without requiring to solve complex redundancy problems (Lockhart and Ting, 2007; Ting and McKay, 2007). The value of such schemes, however, remains contingent upon whether their benefits in reducing computational cost outweigh task-space errors introduced by the original approximation into fewer synergies.

Myoelectric control is another important area where muscles are used to restore movement artificially, although in this case muscles are used to generate control signals rather than to receive them. In contrast to traditional myoelectric prostheses where muscle activities are translated into velocity about a joint, the goal of contemporary myoelectric control research is toward the simultaneous and proportional control of multiple degrees of freedom (Parker et al., 2006; Jiang et al., 2009). In this context, a recent technique that involves transferring residual nerves to alternative muscle sites targeted motor reinnervation (TMR) has increased the number of muscle signals available to control a prosthetic device in amputees (Kuiken et al., 2007, 2009). Although promising, this re-innervation technique is unlikely to restitute the complete set of original control signals. Similar recording limitations obtain in intact musculoskeletal systems. This is why we explored simulations with incomplete sets of muscles. The first consideration, before synergy decomposition, is to reconstruct the motor output from the available muscles. We showed previously that this could be done with our virtual biomechanics technique, which empirically finds a representation of muscle biomechanics that best reconstructs force when driven by EMG recordings (de Rugy et al., 2012c). Here, we additionally show that on simulated (optimal) muscle patterns, the reconstruction is better for an incomplete set of muscles that are less redundant than for a set of more redundant muscles. Then,

irrespective of how good or bad this reconstruction is, synergy decomposition would add additional errors on the top of it. From that perspective, applying synergy decomposition onto the set of available muscles appears of little use, and it seems rather more appropriate to make full use of all available muscles to best reconstruct the motor output in task space. This is essentially what is now done with the method of principal components analysis of TMR recordings (Jiang et al., 2009).

Nevertheless, synergy decomposition might suggest a useful, although paradoxical way to decide which muscles to record from in the case of myoelectric controllers in which the number of available myoelectric channels is limited. Those muscles that are most difficult to decompose into a small number of synergies should be accorded the highest priority for obtaining command signals.

A HIGH DIMENSIONAL ALTERNATIVE TO SYNERGY

Finally, we ask whether there really is a redundancy problem to be solved at all. The notion that the nervous system might control movement through a limited number of synergies seems at odds with the high number of neurons available to process the transformation between sensory information and motor commands, as well as with the numerous divergent pathways that have been suggested by some as a possible basis for the implementation of muscle synergies. For instance, the processes of sensorimotor transformation and adaptation are well described by gain fields, or population codes formed by numerous basis neurons each responding to a particular range or combination of inputs (Andersen et al., 1985; Salinas and Abbott, 1995; Pouget and Snyder, 2000; Baraduc et al., 2001). Although decoding algorithms such as those developed for neural prosthetics involve a great deal of dimensionality reduction to extract motor goals from neuronal populations (Musallam et al., 2004; Hauschild et al., 2012), there seems to be no compelling reason to believe that the nervous system should operate a comparable dimensionality reduction into muscle synergies before increasing the dimensionality again to pools of motor units that have mechanically distinct actions. It has been suggested that the nervous system may actually encode more muscle synergies than muscles, but that only a subset of the entire synergy library is used in any given task (Chiel et al., 2009). Such a scheme clearly does not alleviate redundancy, and although it could conceivably simplify control within the context of a given task, it would require an additional control process to select appropriate synergies for each task. It would also appear to be impossible to generate testable hypotheses regarding the existence of an unlimited number of unrealized synergies.

If the nervous system does not control movements through a limited number of synergies, then how does it decide which of many good-enough (i.e., redundant) motor programs to use? Recent modeling work that includes the spinal cord circuitry provides interesting insight into this question. Indeed, a system with a large number of control inputs to a realistic set of interneuronal pathways was found to enable a simple learning algorithm to rapidly converge to physiological solutions (Raphael et al., 2010; Tsianos et al., 2011). Instead of reducing the dimensionality of control signals to assist computation of an unlikely global optimum, the nervous system might take advantage of the high probability of finding good-enough local minima within the high dimensional space of low-level circuitry (Loeb, 2012). A system that learned and stored such motor habits would appear to be limited to the synergies that it happened to have learned, but not as a result of any fundamental mechanism. Such a system might tend to get stuck in motor habits that could become suboptimal if the musculoskeletal system were to change its properties. This is exactly what we found when we applied our virtual biomechanics methodology (de Rugy et al., 2012c) to studies of wrist control in human subjects (de Rugy et al., 2012b).

ACKNOWLEDGMENTS

One theory for how humans control movement is that muscles are activated in weighted groups or synergies. Studies have shown that electromyography (EMG) from a variety of tasks can be described by a low-dimensional space thought to reflect synergies. These studies use algorithms, such as nonnegative matrix factorization, to identify synergies from EMG. Due to experimental constraints, EMG can rarely be taken from all muscles involved in a task. However, it is unclear if the choice of muscles included in the analysis impacts estimated synergies. The aim of our study was to evaluate the impact of the number and choice of muscles on synergy analyses. We used a musculoskeletal model to calculate muscle activations required to perform an isometric upper-extremity task. Synergies calculated from the activations from the musculoskeletal model were similar to a prior experimental study. To evaluate the impact of the number of muscles included in the analysis, we randomly selected subsets of between 5 and 29 muscles and compared the similarity of the synergies calculated from each subset to a master set of synergies calculated from all muscles. We determined that the structure of synergies is dependent upon the number and choice of muscles included in the analysis. When five muscles were included in the analysis, the similarity of the synergies to the master set was only 0.57 ± 0.54; however, the similarity improved to over 0.8 with more than ten muscles. We identified two methods, selecting dominant muscles from the master set or selecting muscles with the largest maximum isometric force, which significantly improved similarity to the master set and can help guide future experimental design. Analyses that included a small subset of muscles also over-estimated the variance accounted for (VAF) by the synergies compared to an analysis with all muscles. Thus, researchers should use caution using VAF to evaluate synergies when EMG is measured from a small subset of muscles.

Keywords: muscle synergy, electromyography, simulation, nonnegative matrix factorization, musculoskeletal model

INTRODUCTION

The human musculoskeletal system is complex, providing a robust and flexible system for executing tasks of daily life. A primary challenge for researchers, clinicians, and others seeking to evaluate human movement is to understand how we control this complex system. The musculoskeletal system is highly redundant, with more muscles than degrees of freedom. Thus, there are many different ways that muscles can be recruited to execute a given task. Understanding the control strategies used during movement can provide insight into pathologic conditions, optimize performance, and inspire the design of novel robotics.

One theory of the control of human movement suggests that muscles are activated in groups, commonly referred to as synergies or modes (Lee, 1984; Tresch et al., 1999; Krishnamoorthy et al., 2003; Ting and Macpherson, 2005; Ivanenko et al., 2006). Activating multiple muscles with a single control signal is theorized to provide a simplified system compared to controlling each muscle individually. Previous studies have shown that muscle activity during a variety of tasks in humans (Ting and Macpherson, 2005; Ivanenko et al., 2007; Cheung et al., 2012) and animals (Tresch et al., 2002; d'Avella and Bizzi, 2005) can be described by a low-dimensional space thought to reflect synergies. In these experiments, electromyography (EMG) is measured during a variety of tasks and matrix factorization algorithms, such as nonnegative matrix factorization (NNMF), are used to determine a subset of vectors, or synergies, which describe the EMG signals. For postural control, gait, and upper-extremity tasks in humans, a lower dimensional space of four to six synergies have consistently been shown to describe muscle activity (Ivanenko et al., 2006; Torres-Oviedo et al., 2006; Roh et al., 2012).

Using NNMF or other algorithms to identify synergies relies upon measuring EMG from the muscles used to execute a task. However, due to constraints on time, resources, and subject comfort, EMG can usually only be measured for a subset of the muscles involved in the task. For example, in the human arm, there are over twenty muscles that may contribute to movement and force generation. Previous studies of synergies in the human arm typically only measure EMG from eight to nineteen

muscles (d'Avella et al., 2006; Cheung et al., 2009; Roh et al., 2012). Researchers typically try to include as many muscles as possible within the constraints of their experimental set-up and often choose larger muscles thought to contribute to the task and from which it is easier to record surface EMGs. However, no rigorous analysis has been performed to determine how the number and choice of muscles included affects the results of synergy analyses.

A few studies have been able to measure EMG from all muscles involved in a task such as Valero-Cuevas et al. (2009) who evaluated human index finger force generation. This study determined that when EMG was measured from all muscles involved in the task, more synergies were required to describe the variance in EMG activity and a lower percentage of variance in EMG activity was explained by the synergies compared to prior studies that included EMG for a subset of muscles. Furthermore, studies that have tried to use synergies to drive musculoskeletal simulations have found that the synergies identified from EMG are often inadequate for controlling motion. For example, an experimental analysis of synergies during gait did not include EMG of the iliopsoas, a deep muscle that is difficult to measure with EMG. Simulations indicated that a synergy that included the iliopsoas was required to control gait (Neptune et al., 2009). However, even from this analysis it was not possible to determine if the number of synergies was incorrect (i.e., an extra synergy for the iliopsoas was required) or the structure of the synergies was incorrect (i.e., the iliopsoas should have been included in one of the original synergies). These results suggest that synergies identified from a subset of muscles involved in a task may be inaccurate or incomplete. Understanding the sensitivity of synergy analyses to the number and choice of muscles will enable researchers to understand the limitations of these methods, design experimental protocols, and critically analyze the results of these analyses.

The aim of this study was to evaluate how the number and choice of muscles included in synergy analyses impact synergies calculated from EMG. We created a musculoskeletal model of an isometric force task in the upper-extremity and evaluated the effect of using different combinations of muscles to calculate synergies. By comparing the similarity of synergies from different combinations of muscles, we determined that synergies were affected by the number and choice of muscles included in the analysis. We also were able to identify methods, such as selecting the largest muscles, which can be used to design experimental protocols and decrease the sensitivity of synergy analyses to the number and choice of muscles.

MATERIALS AND METHODS

MUSCULOSKELETAL MODEL

A previously developed model of the upper-extremity (Holzbaur et al., 2005) with 30 muscles (**Table 1**) was used to recreate an upper-extremity isometric force task that has previously been used to evaluate synergies (Roh et al., 2012). The upper-extremity model included seven degrees of freedom including three degrees of freedom at the shoulder (flexion/extension, abduction/adduction, and internal/external rotation), wrist flexion/extension, forearm supination/pronation, and two degrees of freedom at the wrist (flexion/extension and radial/ulnar deviation). The model was positioned according to the experimental protocol of Roh et al. (2012) with the hand at half an arms-length in front of the shoulder, the shoulder and elbow flexed, and the forearm and wrist in neutral positions. Muscle activations required to generate isometric forces in various directions at the hand were estimated by minimizing the sum of squared activations. Similar to the experimental protocol, the muscle activations to hold the force were examined and the periods ramping up or down from each force target were not included in the analysis. In the experimental protocol, the subjects generated forces in 54 or 210 directions evenly distributed in a sphere around the hand. Since, with a musculoskeletal model, we did not have the constraints of time, attention, or fatigue of the subject, we included 1000 force directions randomly distributed in a sphere around the hand. For each force direction, we solved for the muscle activations required to generate a ten newton force. The musculoskeletal model and analysis were executed using OpenSim, an open source software platform for musculoskeletal modeling and simulation (Delp et al., 2007).

FCU	Flexor carpi ulnaris	128.9

**Maximum isometric force (Holzbaur et al., 2005)*

SYNERGY ANALYSIS

The muscle activations estimated from the musculoskeletal model during the upper-extremity isometric force task were used to calculate synergies. The muscle activations from all force directions were combined into an $m \times t$ matrix, V, where m was the number of muscles (i.e., 30) and t was the number of force directions (i.e., 1000). The activations for each muscle were normalized to unit-variance to ensure that the synergies were not biased toward high-variance muscles (Roh et al., 2012). NNMF was used to calculate synergies (Lee and Seung, 1999; Tresch et al., 1999, 2006) such that $V = W^*C$ where W is the $m \times n$ matrix with n synergies and C is the $n \times t$ matrix of synergy activation coefficients. Thus, each column of W represents the weights of each muscle for one synergy, and each row of C represents how much the corresponding synergy was activated or used to generate force in each direction. The number of synergies, n, was set at four to compare to the prior experimental study. The NNMF algorithm was implemented within an iterative optimization which tested random initial estimates of W and C and selected the muscle weights and activation timings that minimized the sum of squared error between V and the muscle activations.

To demonstrate that our simulation was consistent with experimental observation, we first compared the synergies estimated from the musculoskeletal model to the synergies from the experimental protocol reported by Roh et al. (2012). The experimental protocol included EMG from eight muscles: the brachioradialis, biceps brachii, triceps brachii (long and lateral heads), deltoid (anterior, medial, and posterior fibers), and pectoralis major (clavicular fibers). Thus, for this comparison, we used the activations from the musculoskeletal model for the eight muscles with EMG to calculate synergies using NNMF. We compared the synergies from the musculoskeletal model to the experimental synergies from eight unimpaired subjects. We calculated the similarity of the synergies as the average correlation coefficient. To evaluate if the synergies from the simulation were within the inter-subject variability, we compared the synergies from the musculoskeletal model to the experimental synergies of each subject. We calculated the similarity of the experimental synergies from each subject to one another to evaluate the inter-subject variability. Each subject's synergies were then compared to the simulated synergies to evaluate the similarity between the experimental and simulated synergies. We used an equivalence test to determine if the similarity of the experimental and simulated synergies were within the inter-subject similarity with a significance level of 0.05. For both the inter-subject similarity and similarity between experimental and simulated, we report the 95% confidence intervals.

IMPACT OF NUMBER OF MUSCLES ON SYNERGIES

To evaluate the impact of the number of muscles included in the analysis on the resultant synergies, we compared the synergies calculated from random subsets of muscles to the "master set" of synergies (**Figure 1**). The master set of synergies was determined from the activations of all 30 muscles and 1000 force directions using NNMF. We then calculated synergies from the muscle activations of random subsets of muscles. We evaluated subsets that included odd numbers of muscles between 5 and 29. For each number of muscles (e.g., five muscles), we selected 1000 random combinations, or as many combinations possible given 30 muscles, and calculated synergies from the activations of these muscles using NNMF. The synergies from each subset were then compared to the same subset of muscles isolated from the master set. For each combination, the synergies were normalized to unit length and similarity was evaluated as the average correlation coefficient between the subset of the master set and the synergies calculated from the subset of muscle activations. The average correlation coefficient was determined by matching the pairs of synergies from the master set and subset that had the greatest similarity and averaging the correlation coefficients across the pairs. The correlation coefficient was normalized from zero to one

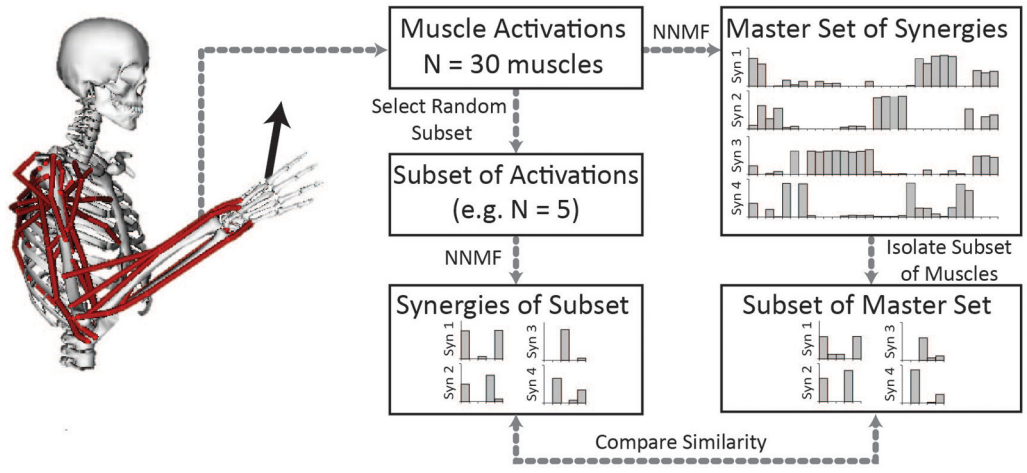

FIGURE 1 | Synergies calculated from a subset of muscles were compared to the master set of synergies calculated from all 30 muscles. The master set of synergies was calculated using NNMF from the activations of all 30 muscles required to perform the isometric upper-extremity force task. Random subsets of muscles (varying between 5 and 29 muscles) were then selected and four synergies were calculated from the subset of muscle activations. The same subset of muscles was isolated from the master set and the similarity of the synergies was compared as the average correlation coefficient.

where zero is the similarity expected by chance and one is perfect similarity (Tresch et al., 2006). The similarity expected by chance was calculated as the average correlation coefficient comparing each set of synergies to 25 randomly generated sets of synergies of the same size (i.e., same number of muscles and force directions). Across all analyses, four synergies were calculated from NNMF.

To evaluate the impact of changes in synergy weights, W, on the recruitment of synergies, C, we compared the directional tuning of synergies. The directional tuning was calculated as the dot product of the activation level of each synergy and each force direction. The resulting direction indicates the force direction for which a given synergy was highly recruited. The impact of the number of muscles on synergy recruitment was evaluated as the average angle between the directional tuning of the synergies from each subset of muscles and the master set.

Experimental EMG is commonly a noisy signal. To evaluate the impact of noise on synergies we repeated the analysis for each number of muscles between 5 and 29 with varying levels of noise. Noise was added to the estimated activations as a random normal distribution with a signal-to-noise ratio (SNR) between 0 and 20 dB, adjusted for the level of activity in each muscle. The similarity of the estimated synergies with noise was compared to the master set, as described above.

IMPACT OF THE CHOICE OF MUSCLES ON SYNERGIES

To improve the similarity of synergies estimated from a subset of muscles to the master set, we evaluated different methods for choosing which muscles to include in the analysis. We evaluated two protocols for choosing muscles and compared the protocols to randomly selected subsets of muscles. We first evaluated the impact of selecting random sets of muscles from the dominant muscles of the master set of synergies. Dominant muscles were defined as muscles whose weight was within twenty percent of the maximum weight for each synergy, of which 22 of the 30 muscles met this criterion in at least one synergy. We varied the threshold for defining dominant muscles from 5 to 30% and found similar results for the similarity. To select a subset of muscles from the group of dominant muscles, an equal number of muscles were chosen from the dominant muscles of each synergy. For example, for combinations of five muscles, one dominant muscle was selected from each of the four synergies and then the final muscle was randomly selected from all the remaining dominant muscles. We compared the similarity of random combinations of 5–21 muscles selected from the dominant muscles to the similarity of the random combinations of muscles described above.

Selecting dominant muscles based on a synergy analysis of all relevant muscles requires that researchers have access to a musculoskeletal model appropriate for simulating their experimental protocol. For cases when this requirement may not be practical, we also evaluated the impact of selecting muscles according to size. We selected the largest muscles, according to maximum isometric force (**Table 1**), and determined the similarity to the master set for subsets that included from 5 to 29 of the largest muscles. These methods were evaluated to provide guidance for experimental protocols and to assist researchers in deciding which muscles to measure EMG from for synergy analyses.

RESULTS

COMPARISON OF EXPERIMENTAL AND MODEL SYNERGIES

Synergies estimated from a musculoskeletal model of an upper-extremity isometric force task were similar to synergies calculated from experimental EMG (**Figure 2**). From the experimental EMG, the average similarity of synergies between subjects was 0.79 ± 0.10 (95% CI: 0.75–0.82). We also calculated synergies from the musculoskeletal model using the activations of the eight muscles that had EMG in the experimental protocol. The average similarity of the synergies from the musculoskeletal model to the eight subjects' experimental EMG was 0.72 ± 0.10 (95% CI: 0.65–0.78). Thus, the similarity of synergies estimated from the musculoskeletal model to the experimental synergies was slightly less than the inter-subject similarity of synergies from experimental EMG, but not significantly different. From **Figure 2**, the primary difference between the model and experimental synergies was the grouping of the posterior deltoid. In the synergies from the model, the posterior deltoid (DELT3) was grouped with the triceps while, in the synergies from the experimental EMG, the posterior deltoid was grouped with the other compartments of the deltoid. This may be due to the simplified shoulder (i.e., ball and socket) used in the model which does not include the posterior deltoid's role in controlling other shoulder degrees of freedom.

SYNERGIES CALCULATED FROM ALL MUSCLES

The relative weightings and grouping of muscles in the synergies calculated from all 30 muscles differed from the synergies

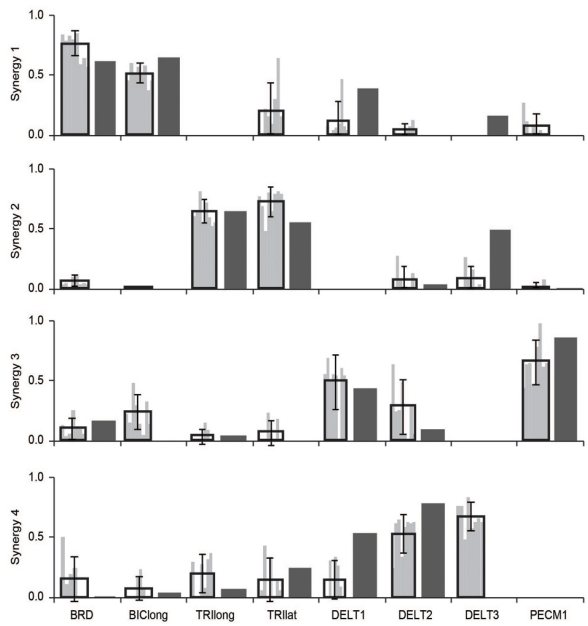

FIGURE 2 | Comparison of synergies calculated from the musculoskeletal model (dark gray bars) and experimental EMG (black outlined bars showing average ± one standard deviation and light gray bars showing synergies of individual subjects). The similarity of the synergies from the musculoskeletal model and the experimental EMG were not significantly different from the inter-subject similarity of synergies.

calculated from the eight muscles included in the experimental protocol (**Figure 3**). When all 30 muscles were included in the analysis, four synergies described 88% of the total variance in muscle activity. Similar to the analysis with eight muscles, one synergy was dominated by the biceps (**Figure 3**, see Synergy 1) and another synergy was dominated by the triceps (see Synergy 2); however, the dominant muscles of the other synergies included muscles that were not included in the experimental analysis such as the latissimus muscles (see Synergy 3) and shoulder rotator cuff muscles and forearm muscles (see Synergy 4). Additionally, the grouping and relative weights of muscles differed with thirty versus eight muscles. For example, in the analysis with eight muscles, the deltoids dominated Synergy 4 and were also coupled with the pectoralis major clavicular (PECM1) in Synergy 3. However, when all 30 muscles were included in the analysis, the deltoids did not dominate one of the synergies and were no longer coupled with PECM1, suggesting fundamental differences in the grouping of muscles. The changes in the synergy weights, W, also altered the synergy activations in the C matrix. The directional tunings of synergies calculated from all 30 muscles were different from synergies calculated from the subset of eight muscles used experimentally, with differences in direction ranging from 12.2° to 74.5° (**Figure 4**).

If 5 synergies were included in the analysis, the variance accounted for increased to 92% and included four synergies with the same dominant muscles as the analysis with four synergies. The dominant muscles of the fifth synergy included the posterior deltoid and supraspinatus. To maintain consistency with the prior experimental analysis, four synergies were used for all subsequent analyses.

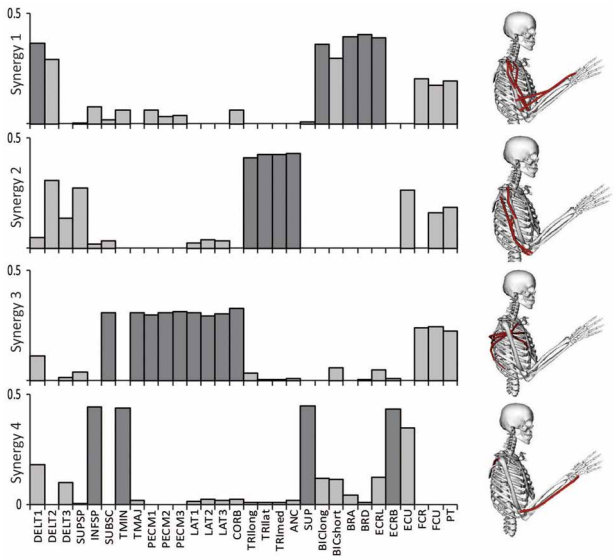

FIGURE 3 | Synergies calculated from all 30 muscles included in the model during an upper-extremity isometric force task. The dominant muscles of each synergy (defined as within 20% of the maximum value of each synergy) are shown in dark gray and on the musculoskeletal models.

THE IMPACT OF NUMBER OF MUSCLES ON SYNERGIES

The number of muscles included in the synergy analysis impacted the results from the NNMF algorithm (**Figure 5**). We compared the similarity of the synergies calculated from random subsets that included between 5 and 29 muscles to the synergies calculated from all 30 muscles (the master set). The average similarity of the random subsets to the master set was greater than 0.8 for all subsets that included between 5 and 29 muscles (**Figure 5A**). However, the similarity expected by chance increased when fewer muscles were included in the analysis. When only five muscles were included in the analysis, the similarity expected by chance was 0.63 (see dark bars, **Figure 5A**). Thus, the average normalized similarity (with 0 equal to similarity expected by chance) was only 0.57 ± 0.54 with five muscles (**Figure 5B**) and remained below 0.8 when less than 11 muscles were included in the analysis. When a small number of muscles were included in the analysis, the variance in similarity was also greater between subsets. For example, with five muscles, the average normalized similarity was 0.57 but some combinations of muscles approached perfect similarity while the similarity of other combinations was not different from similarity expected by chance. The set of five muscles with the greatest normalized similarity (0.999) included the triceps lateral head, teres major, supinator, latissimus dorsi inferior, and

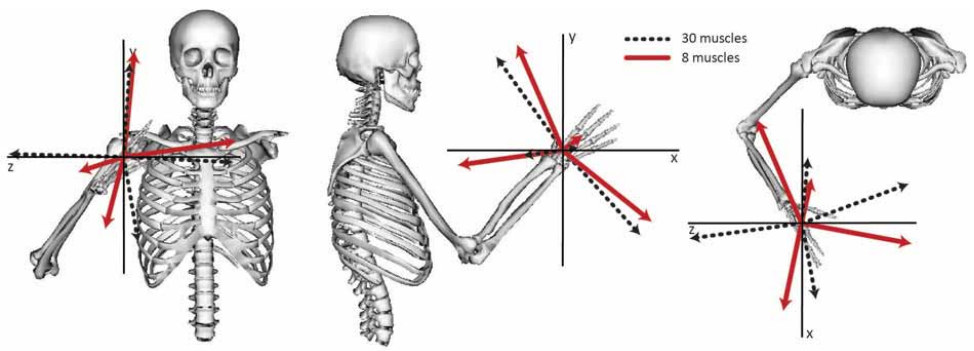

FIGURE 4 | Directional tuning of the four synergies calculated from all 30 muscles and the subset of eight muscles included in the experimental analysis. The direction for each synergy was calculated from the activation level of each synergy across all force directions and normalized to unit length.

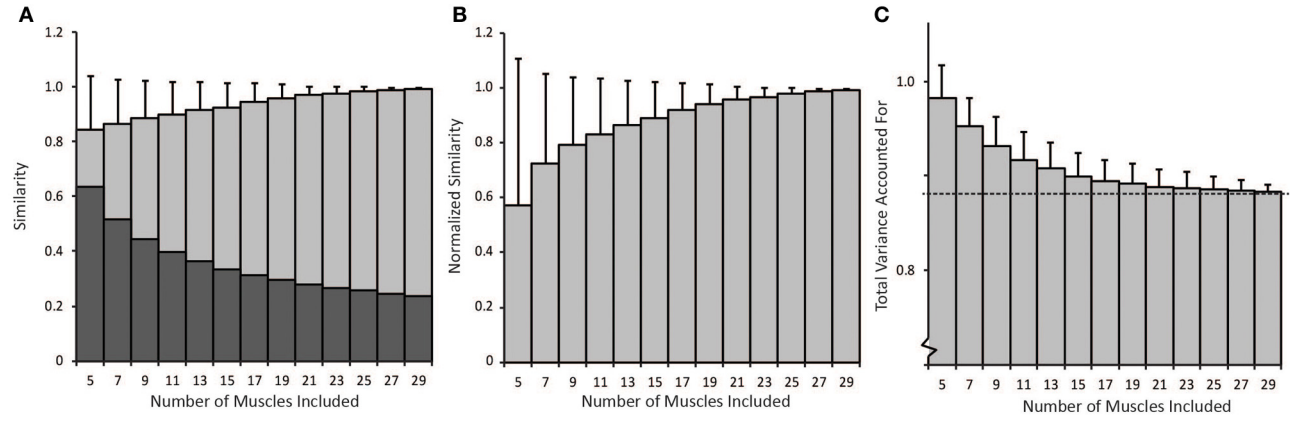

FIGURE 5 | (A) Non-normalized similarity calculated as the average correlation coefficients of synergies calculated from random subsets that included between 5 and 29 muscles to the synergies calculated from all 30 muscles (light gray bars − average ± 1 standard deviation). The dark gray bars show the similarity expected by chance for each number of muscles included in the analysis. **(B)** Average similarity of synergies from random subsets to synergies calculated from all 30 muscles normalized by similarity expected by chance. **(C)** Average total variance accounted for by synergies from random subsets. As the number of muscles in the analysis increased, the total variance accounted for approached the variance accounted for when all 30 muscles were included in the analysis (dotted line).

brachioradialis. The normalized similarity of the subset of eight muscles used in the experimental protocol to the master set of synergies was 0.52.

The difference in directional tunings of the synergy activations (C matrix) between subsets of muscles and the master set decreased as more muscles were included in the analysis. The average difference in directional tuning compared to the master set of synergies was 26.2° (±15.3°) when only five muscles were included; however, the difference in directional tuning decreased to 12.7° (±11.0) when 15 muscles were included and approached zero degrees as the number of muscles increased. Differences in directional tuning would indicate errors in interpreting how synergies are recruited to produce force in various directions.

Total variance accounted for is often used to determine the number of synergies to include in an analysis and to evaluate how well a set of synergies reproduces muscle activity. The average total variance accounted for decreased with the number of muscles included in the analysis (**Figure 5C**). Thus, the average total variance accounted for was 0.98 ± 0.03 when only five muscles were included in the analysis and decreased to approach the total variance accounted for by the master set of synergies, 0.88 (see dotted line, **Figure 5C**) as more muscles were included in the analysis. Four synergies could more easily describe the variability in muscle activity when fewer muscles were included in the analysis. These results demonstrate that experimental analyses that include fewer muscles may over-estimate the total variance accounted for compared to an analysis that included all muscles involved in a task.

The task simulated in this analysis included 1000 force directions; however, the experimental protocol included either 54 or 210 force directions. We evaluated the impact of the number of force directions on the normalized similarity and total variance accounted for. The total variance accounted for was not sensitive to the number of force directions; however, the normalized similarity was reduced when fewer than 100 force directions were included. Additionally, there was greater variability in the normalized similarity between trials when fewer force directions were included depending upon the choice and dispersion of the force directions.

THE IMPACT OF NOISE ON SYNERGIES

Surface EMG is an inherently noisy signal; however, the activations from a musculoskeletal model estimate muscle activity without noise. Thus, we sought to determine the impact of noise on the similarity of synergies to the master set of synergies. Increasing noise decreased the average normalized similarity (**Figure 6**), especially for combinations that included less than 15 muscles. Noise with an SNR greater than 10 dB had minimal effect on combinations of muscles that included more than 15 muscles. These results emphasize the importance of maintaining high SNR, especially when fewer muscles are included in the analysis.

PROTOCOLS TO IMPROVE SIMILARITY OF SYNERGIES

To aid researchers in selecting muscles to include in an experimental protocol for synergy analyses, we evaluated several methods that could minimize the impact of measuring EMG from a subset of muscles. The most successful method involved selecting a subset of muscles evenly distributed across the dominant muscles from the master set of synergies (**Figure 7**). The dominant muscles were defined as muscles that were within 20% of the maximum for each synergy; however, the effectiveness of this method remained similar if the cut-off for defining dominant muscles was varied between 5 and 30%. This protocol resulted in a normalized similarity to the master set greater than 0.95 for subsets including between 5 and 29 muscles.

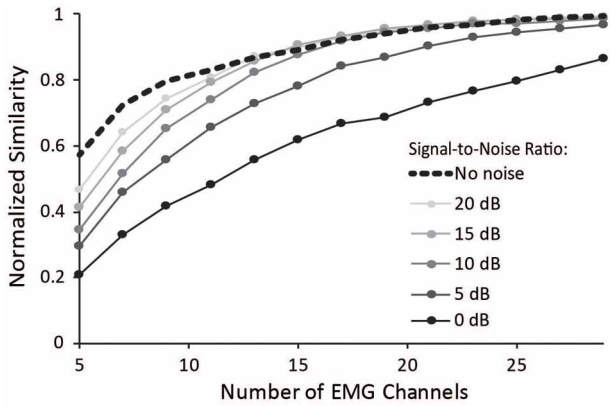

FIGURE 6 | Average normalized similarity vs. number of muscles included in the synergy analysis for varying levels of noise. Noise was specified according to a signal-to-noise ratio between 0 and 20 dB.

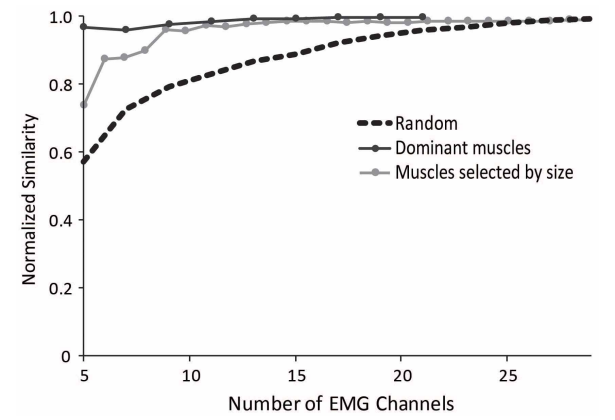

FIGURE 7 | Average normalized similarity of subsets of muscles chosen randomly (dotted black line), muscles chosen from subsets of dominant muscles from the master set (dark gray line), and muscles selected by size starting with the largest muscles (light gray line).

We also evaluated a method in which the subset of muscles was selected based on muscle size, using the maximal isometric force of each muscle. Such a method might be useful for the general situation where a musculoskeletal model is not available but overall muscle sizes might be. Selecting the largest muscles significantly improved the similarity to the master set. The normalized similarity of synergies calculated from the five largest muscles was 0.75 and all combinations with more than seven muscles had an average normalized similarity greater than 0.9.

DISCUSSION

In this study we sought to determine if the number and choice of muscles with EMG in an experimental protocol will impact the synergies identified using matrix factorization algorithms, such as NNMF. We found that the number and choice of muscles does impact the structure of synergies and the amount of variance in muscle activity accounted for by a given set of synergies. However, we were also able to identify several strategies that can be used to minimize the impact of using a subset of muscles. We also compared our results from the musculoskeletal model to experimental results and found similar synergies, suggesting that results from musculoskeletal modeling were comparable to experimental conditions and can provide a platform for investigating muscle synergies.

The average similarity of synergies to the master set dropped below 0.8 when fewer than eleven muscles were included in the analysis. Prior studies of synergies during upper-extremity tasks have included between 8 and 19 muscles and thus may be significantly impacted by the choice of muscles. For example, our comparison to synergies from eight muscles used in the experimental protocol by Roh et al. (2012) had a low normalized similarity to the master set of only 0.52. Although the structure of two of the four synergies, dominated by the biceps and triceps, were similar, the other two synergies identified from the master set were dominated by muscles not included in the experimental protocol. Furthermore, the relative weighting and grouping of muscles also changed significantly when all 30 muscles were included in the analysis. Although synergies identified from a subset of muscles may be able to describe the variance in EMG activity, they may not correctly reflect how muscles are recruited or activated together which can impact the functional interpretations of synergies. Previous studies of similar tasks have also identified synergies with different structures and dominant muscles which may be due to the different muscles included in the experimental protocols (e.g., Cheung et al., 2012; Roh et al., 2013). Evaluating muscle synergies from a subset of muscles may still be valuable for comparing populations, such as unimpaired individuals and individuals after stroke, if the same subset of muscles is used for all groups. However, the limitations of using a subset of muscles involved in a task should be considered in analyzing the results of synergy analyses and in generalizing results to the over-arching neuromuscular control strategy.

Variance accounted for is also commonly used as a measure to evaluate the results of muscle synergy analyses and to determine the number of synergies used in a given task. However, the results of this study highlight that when fewer muscles are included in the analysis, the variance accounted for is over-estimated. Using variance accounted for to determine the number of synergies may result in fewer muscle synergies being selected than if all muscles were included in the analysis. The impact of the number of muscles included on variance accounted for suggests that complementary methods, such as using the ability of synergies to discriminate between tasks (Delis et al., 2013), should be used to determine the number of synergies in experimental protocols that include a small subset of muscles.

To assist with future experimental design, we identified several strategies to select muscles which can improve similarity when only a subset of muscles is included due to experimental constraints. Selecting from the dominant muscles of the synergies identified from musculoskeletal simulation was the most successful method. By selecting an equal number of dominant muscles from each synergy in the master set, the average similarity

increased to over 0.95, even for cases with only five muscles. This approach worked well because it identified important muscles from each synergy of the master set which translated to similar synergies identified from NNMF. However, since musculoskeletal simulation may not always be available for analysis, we determined that selecting the largest muscles, as determined by maximum isometric force, also improved similarity. The largest muscles have the greatest contribution to movement and force generation and overlap with the dominant muscles identified with musculoskeletal simulation. These strategies for choosing which muscles to include in an experimental protocol are important for decreasing the sensitivity of synergies to experimental constraints and improving our understanding of the generalizability of synergy analyses.

The synergies calculated from the musculoskeletal model were similar to the experimental synergies; however, it is important to note that the muscle activations from the model were determined without reference to synergies. Similar to previous studies, we determined the muscle activations required to perform the task by minimizing the sum of squared activations. Thus, no synergies or other coupling between muscles was incorporated into the musculoskeletal model. Previous studies have suggested that the lower-dimensional subspace determined from matrix factorization algorithms may be more reflective of biomechanical or task constraints rather than the underlying neuromuscular control strategy (Valero-Cuevas et al., 2009; Kutch and Valero-Cuevas, 2012; Burkholder and Van Antwerp, 2013). The similarity between the synergies calculated from the model and experiment in this study further reinforce this theory since we could recover similar synergies as the experimental task in the absence of a control strategy based upon synergies.

This study also demonstrated how musculoskeletal simulation can be used to complement and optimize experimental design for muscle synergy analyses. Based upon the posture, kinematics, and external forces for an experimental protocol, musculoskeletal simulation can be used to estimate expected muscle forces and test a priori the impact of experimental constraints such as the number of muscles with EMG. Musculoskeletal simulation can also be used to predict the functional impacts of altered synergies or test if synergies identified from matrix factorization algorithms can control movement (Neptune et al., 2009; Allen and Neptune, 2012). Free musculoskeletal simulation platforms such as OpenSim (Delp et al., 2007) provide a variety of human and animal models as well as the simulation algorithms that can be used for these analyses.

Matrix factorization algorithms provide a valuable tool for evaluating neuromuscular control of movement through the framework of synergies. Synergy analyses can provide insight into lower-dimensional subspaces that describe muscle activity during a variety of tasks and may reflect the underlying strategies for controlling the complexities of the neuromuscular and musculoskeletal systems. Muscle synergy analyses are increasingly being used to evaluate altered neuromuscular control in clinical populations, such as individuals after stroke (Clark et al., 2010; Cheung et al., 2012; Roh et al., 2013). As the applications of muscle synergy analysis reach the clinical realm, it is even more important to understand the limitations and generalizability of these methods. Understanding if the structure of synergies is altered in clinical populations because of different control strategies, altered biomechanics, or other factors will be critical for using synergy analyses to improve treatment and will require careful experimental design. This study has demonstrated that, although synergies estimated from NNMF are sensitive to the number and choice of muscles, there are multiple strategies that can be employed to improve experimental design and decrease the sensitivity of these analyses to experimental constraints. Researchers should especially note the increased risk of over-estimating the variance accounted for by synergies when fewer muscles are used in an experimental analysis. Combining simulation and experimental studies provides a complementary platform to address these challenges and continue to refine our knowledge of how humans control movement and interact with the world.

Muscle synergies, i.e., invariant coordinated activations of groups of muscles, have been proposed as building blocks that the central nervous system (CNS) uses to construct the patterns of muscle activity utilized for executing movements. Several efficient dimensionality reduction algorithms that extract putative synergies from electromyographic (EMG) signals have been developed. Typically, the quality of synergy decompositions is assessed by computing the Variance Accounted For (VAF). Yet, little is known about the extent to which the combination of those synergies encodes task-discriminating variations of muscle activity in individual trials. To address this question, here we conceive and develop a novel computational framework to evaluate muscle synergy decompositions in task space. Unlike previous methods considering the total variance of muscle patterns (VAF based metrics), our approach focuses on variance discriminating execution of different tasks. The procedure is based on single-trial task decoding from muscle synergy activation features. The task decoding based metric evaluates quantitatively the mapping between synergy recruitment and task identification and automatically determines the minimal number of synergies that captures all the task-discriminating variability in the synergy activations. In this paper, we first validate the method on plausibly simulated EMG datasets. We then show that it can be applied to different types of muscle synergy decomposition and illustrate its applicability to real data by using it for the analysis of EMG recordings during an arm pointing task. We find that time-varying and synchronous synergies with similar number of parameters are equally efficient in task decoding, suggesting that in this experimental paradigm they are equally valid representations of muscle synergies. Overall, these findings stress the effectiveness of the decoding metric in systematically assessing muscle synergy decompositions in task space.

Keywords: muscle synergies, reaching, arm movement, task decoding, single-trial analysis

INTRODUCTION

The question of how the central nervous system (CNS) coordinates muscle activity to produce movements is central to the understanding of motor control (Tresch et al., 1999). The human brain has to deal with a redundant musculoskeletal system comprising of approximately 600 muscles actuating approximately 200 joints. It has been suggested that the CNS reduces the complexity of this control problem by exploiting various types of modularity present in the motor system (Bizzi et al., 2002, 2008; Flash and Hochner, 2005; Berret et al., 2009). A prominent example of such modularity is given by muscle synergies (D'Avella et al., 2003; Ting and McKay, 2007), loosely defined as stereotyped patterns of coordinated activations of groups of muscles. According to this hypothesis, the muscle patterns driving movements originate from linear combinations of a small number of synergies presumably recruited by a premotor drive generated by some neuronal population (Delis et al., 2010; Hart and Giszter, 2010).

A relatively standard approach to individuate putative muscle synergies from EMG recordings of multiple muscles (**Figure 1B**) while subjects perform a variety of motor tasks (**Figure 1A**) is to first apply dimensionality reduction techniques to decompose the recorded EMGs into a set of synergies (**Figure 1C**), and then to assess validity of the decomposition using measures of goodness of approximation such as the Variance Accounted For (VAF) (D'Avella et al., 2006; Torres-Oviedo et al., 2006). This analytical approach has held valuable insights and hypotheses about the structure of modularity in muscle space.

Yet, actions are defined in task space and evaluation of the functional role of muscle synergies requires relating them explicitly to the execution of motor tasks (Todorov et al., 2005; Nazarpour et al., 2012; Ting et al., 2012). For this reason, the

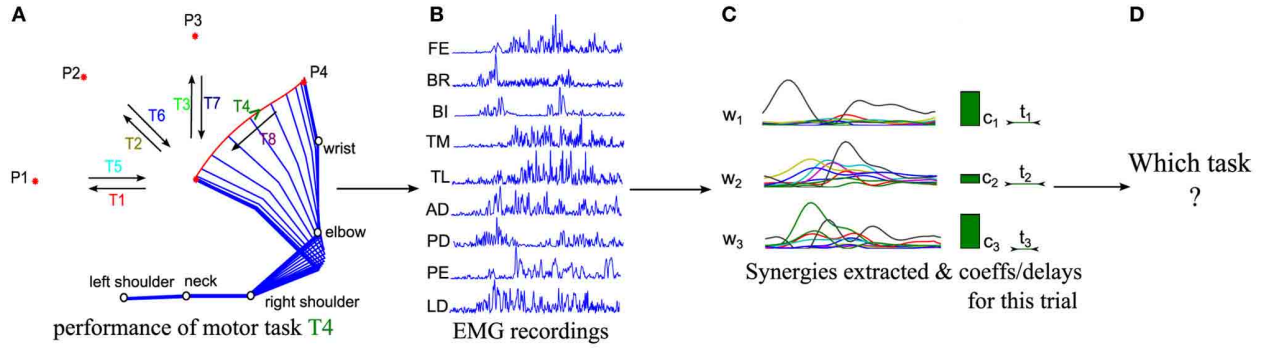

FIGURE 1 | Schematic representations of the logics of our procedure. **(A)** Sketch of the kinematics of five joints during the execution of a center-out movement to target P4 (referred to as task T4 in the following). **(B)** EMG signals from 9 muscles are recorded in each trial with surface EMG devices during movement execution. **(C)** Muscle synergies are extracted from the whole dataset and the corresponding synergy parameters are computed for each trial. **(D)** We finally decode which motor task is performed in each trial from the extracted synergies and activation coefficients.

analytical framework needed to critically test synergy decompositions on empirical data should include additional elements that are currently not considered systematically. First, synergies must constitute not only a low dimensional but also a functional representation of a variety of motor tasks (Overduin et al., 2008). Thus, to evaluate how well muscle synergy recruitment relates to differences across motor tasks, we ought to quantify how well the executed motor tasks can be distinguished on the basis of the synergy activation coefficients (Brochier et al., 2004; Torres-Oviedo and Ting, 2010; Chvatal et al., 2011).

Second, the CNS generates appropriate motor behaviors on single trials, thus synergy recruitment must accurately describe single-trial muscle activations (Tresch et al., 1999; Torres-Oviedo and Ting, 2007; Roh et al., 2011; Ranganathan and Krishnan, 2012). Third, to evaluate the extent to which muscle synergies implement a dimensionality reduction, the number of synergies that discriminate among different task-related movements must be correctly identified and compared to both the degrees of freedom of the musculoskeletal system (e.g., number of muscles) and/or the number of tasks (Ting and McKay, 2007). The estimation of which synergies are needed to fully describe all the task-discriminating movement variations is therefore crucial. Moreover, muscle synergies can contribute to motor function even if their activations do not depend on the task at hand (e.g., if they relate to body posture or reflect biomechanical constraints). To understand the function of a putative set of synergies, it is important to be able to easily tease apart task-dependent and task-independent synergies.

In practice however, not only the identity of these synergies, but also their number and their contribution to task discriminating variations, is unknown a priori. To select the number of synergies, the most widely used criteria rely on the dependence of the amount of variance explained upon the number of synergies. However, criteria solely based on VAF depend substantially also on factors not related to task execution, such as noise (neural variability, measurement fluctuations etc.) and preprocessing (filtering, averaging of EMG signals etc.) and cannot distinguish synergy that describe task-to-task variations from synergies that do not. We argue that synergy model selection should reflect not only the reconstruction of the dataset but also include a way to assess the reliability of the associated mapping from synergy recruitment to motor task identification.

To address these needs, here we propose, implement and validate on EMG data a method (schematized in **Figure 1**) for predicting, on a single-trial basis, the motor task from the synergy activation parameters. The method is based on quantifying the task discriminability afforded by one or more synergies, and then using this for an automated objective selection of the minimal set of synergies containing all information about such salient task-related differences in synergy activation patterns. We validate the robustness and applicability of the method using simulated EMG datasets. We finally apply it to real EMG recordings during a reaching task to illustrate how this method may be used for individuating synergy sets relevant for the execution of a given set of tasks, and for evaluating in task space the effectiveness of different types of muscle synergy decompositions.

MATERIALS AND METHODS

MUSCLE SYNERGY EXTRACTION

To identify muscle synergies, we used the time course of EMG activity of all recorded/simulated muscles in all individual trials for each task. We considered two well-established mathematical models for the representation of muscle patterns as synergy combinations: synchronous and time-varying.

Synchronous synergy model

We used the Non-negative Matrix Factorization (NMF) algorithm (Lee and Seung, 1999) to extract synchronous synergies. In this model, the EMGs are represented as a linear combination of a set of time-invariant activation balance profiles across all muscles activated by a time-dependent activation coefficient:

$$\boldsymbol{m}^s(t) = \sum_{i=1}^{N} c_i^s(t)\boldsymbol{w}_i + \varepsilon^s(t) \quad (1)$$

where $m^s(t)$ is again the EMG data of all muscles at time t; w_i is the synergy vector for the i-th synergy; $c_i^s(t)$ is the scalar coefficient for

the *i*-th synergy at time *t*; *N* is the total number of synergies composing the dataset; and $\varepsilon^s(\tau)$ is the residual (e.g., noise). *N* is an input to the NMF algorithm, so we varied the number of extracted synergies from 1 to 8. In this case, the sample-independent muscle synergies are time-invariant vectors and the parameters that have to be modified in each sample *s* are the time-varying waveforms $c_i^s(t)$ (Cheung et al., 2005)-the superscript *s* is used to denote sample-dependent quantities.

Time-varying synergy model

We used the time-varying synergies model first introduced in (D'Avella and Tresch, 2002). According to it, a muscle pattern recorded during one sample *s* is decomposed into *N* time-varying muscle synergies combined as follows:

$$\boldsymbol{m}^s(t) = \sum_{i=1}^{N} c_i^s \boldsymbol{w}_i(t - t_i^s) + \varepsilon^s(t) \tag{2}$$

where $m^s(t)$ is a vector of real numbers, each component of which represents the activation of a specific muscle at time *t*; $w(\tau)$ is a vector representing the muscle activations for the *i*-th synergy at time τ after the synergy onset; t_i^s is the time of synergy onset; c_i^s is a non-negative scaling coefficient; and $\varepsilon^s(\tau)$ is the residual (e.g., noise). This is a linear model providing a very compact representation of the muscle activity during one sample, since it has only two free parameters (one amplitude and one time coefficient) for each synergy (D'Avella et al., 2006). Note that the synergies w_i are sample-independent, whereas the parameters t_i^s and c_i^s must be adjusted for each sample (i.e., trial or task).

We fed the dataset to the time-varying synergies extraction algorithm to identify a set of muscle synergies and their activation coefficients that reconstructed the entire set of muscle patterns with minimum error. The number of extracted synergies *N* is a parameter of the model, and thus we repeated the extraction with a number of synergies ranging from 1 to 8. In order to minimize the probability of finding local minima, for each *N*, we ran the algorithm 10 times using different random initializations of the synergies and coefficients and selected the solution with the lowest reconstruction error. We used a convergence criterion of ten consecutive iterations for which the average error was decreased by less than 10^{-6}. After extraction, the synergies (and the corresponding coefficients) were normalized to their maximum muscle activations.

Synergy similarity

We assessed the robustness of the synergy sets extracted from different experimental datasets as done in (D'Avella et al., 2003). In brief, we quantified the similarity between pairs of synergies as their correlation coefficient. For evaluating the similarity of the whole ensembles of synergies recorded in different datasets, we started by selecting the pair with the highest similarity, and then the synergies in that pair were removed from their sets. We then computed the similarities between the remaining synergies and repeated this procedure until all synergies in the smallest set had been matched. In the case of time-varying synergies, we computed the correlation coefficient of the two synergies over all possible delays and selected the delay that maximized similarity (see D'Avella et al., 2003 for details).

CLASSICAL VAF-BASED CRITERIA FOR ASSESSING THE VALIDITY OF SYNERGY DECOMPOSITIONS AND FOR SELECTING THE SMALLEST SET OF SYNERGIES

The purpose of this study is to develop a methodology to select, in a considered dataset, the smallest set of synergies that accounts for all task-discriminating variability in the recorded EMG dataset. Before we describe this new methodology, in this Subsection we briefly summarize the current methodology to choose the set of synergies used to decompose a dataset.

Synergy selection can be cast as a model selection problem, because different synergy decompositions are obtained when varying the number of extracted synergies. In the literature, there are typically *ad-hoc* criteria to assess the number of synergies, all based on the dependence of the amount of explained variance on the number of synergies extracted (*N*). This VAF is a measure of how well the actual muscle patterns can be fitted with a given set of synergies. The VAF of each synergy decomposition (D'Avella et al., 2006) is defined as follows:

$$VAF = 1 - \frac{\sum_{s=1}^{S}\sum_{t=1}^{T}\left\{\boldsymbol{m}^s(t) - \hat{\boldsymbol{m}}^s(t)\right\}^2}{\sum_{s=1}^{S}\sum_{t=1}^{T}\left\{\boldsymbol{m}^s(t) - \bar{\boldsymbol{m}}\right\}^2}. \tag{3}$$

where *s* indexes samples and *t* indexes time steps; $\hat{\boldsymbol{m}}^s(t) = \sum_{i=1}^{N} c_i^s \boldsymbol{w}_i(t - t_i^s)$ for the time-varying synergies and $\hat{\boldsymbol{m}}^s(t) = \sum_{i=1}^{N} c_i^s(\boldsymbol{t})\mathrm{w}_i$ for the synchronous synergies model and $\bar{\boldsymbol{m}}$ is the mean (over samples and time steps) activation vector.

To detect the correct number of synergies from the VAF, there are four main existing criteria all based on the "VAF curve," i.e., the function quantifying the dependence of the VAF on the number of synergies extracted (*N*): (a) the point in the VAF curve at which a threshold (usually 0.9) is exceeded ("VAF-T" criterion) (Torres-Oviedo et al., 2006), (b) the point at which the highest change in slope (the "elbow") is observed ("VAF-E") (Tresch et al., 2006), (c) the point at which the curve "plateaus" to a straight line ("VAF-P") (Cheung et al., 2005) and (d) the point at which any further increase in the number of extracted synergies yields a VAF increase smaller than 75% of that expected from chance ("VAF-S") (Cheung et al., 2009b). VAF-S is implemented by first shuffling the EMG data across muscles and time steps and then extracting synergies from this "randomized" dataset. The VAF curve obtained from this decomposition exhibits an almost linear increase. Comparison of its slope with the slope of the real VAF curve at its point gives the selected number of synergies.

NEW TASK-DECODING BASED CRITERION FOR ASSESSING THE VALIDITY OF THE SYNERGY DECOMPOSITION AND FOR SELECTING THE SMALLEST SET OF SYNERGIES

In this section, we present an additional method to quantitatively evaluate muscle synergies in task space and to automatically identify the smallest set of synergies that captures all the variance describing single-trial task-to-task variations in the dataset.

To this aim, we first used a single-trial decoding analysis to quantify how well the single-trial coefficients of individual synergies or groups thereof discriminate between different tasks. A similar analysis has been implemented in the past in the context of muscle synergies (Brochier et al., 2004; Weiss and Flanders, 2004; Overduin, 2005) and in studies of modularity in the kinematics space (Santello and Soechting, 1998; Santello et al., 1998; Jerde et al., 2003). Intuitively, our reasoning is that VAF includes both the "interesting variance" (the one related to variations in synergy recruitment across tasks) and the "less interesting variance" (the one unrelated to variations in synergy recruitment across tasks and in some cases reflecting various sources of noise). In some condition, the presence of the latter variance may make difficult the selection of the correct number of synergies. Also, the removal of "noise" variance using VAF requires the experimenter's intuition and partly arbitrary or *ad-hoc* criteria (see section "Classical VAF-Based Criteria for Assessing the Validity of Synergy Decompositions and for Selecting the Smallest Set of Synergies" above). Our synergy evaluation method overcomes this problem by singling out (by single-trial task decoding) only the task-discriminating variance and then studying the dependence upon the number of synergies of this part of the variance.

Task decoding based metric

For a given set of synergies extracted via classical dimensionality reduction techniques (e.g., NMF), we defined the new metric as the decoding performance, i.e., the percentage of correct decoding of individual trials, based on the single-trial measure of their activation coefficients (or some parameters of them). To avoid inflating artificially the decoding performance because of data over-fitting, each trial was decoded based on the distribution of all other trials (decoding with leave-one-out cross-validation).

The task-decoding metric for determining the minimal set of synergies potentially depends on the choice of an algorithm used to decode the stimuli. Thus, to test the consistency of the results with respect to the details of the underlying calculations, we evaluated the performance of different decoding algorithms.

Here we used the following algorithms: (i) A linear discriminant algorithm (LDA), which worked as follows. For each pair of classes (i.e., motor tasks to be decoded), it first projects the N-dimensional values onto a hyperplane (i.e., a linear decision boundary) where the samples of each class are optimally separated. The direction of this line is the one that maximizes the ratio of the between-class over the within-class distances. Then, the trial to be predicted is assigned to one of the two classes by taking the one that has the minimum Euclidean distance in the direction of the decision boundary. An example of the decoding procedure using 2 pairs of synergies to decode the eight different motor tasks is given in **Figure 6E**. The LDA has determined the decision boundaries for classifying the trials to the motor task performed, and as a result, has separated the 2-dimensional space into eight regions, one for each task. Each point is assigned to the class represented by the colored region on which it lies. (ii) The quadratic discriminant (QDA), i.e., a discriminant algorithm that assumes unequal variances across classes leading to quadratic decision boundaries. (iii) The Naive Bayesian classifier (NB) which assumes that data points are independent with Gaussian in-class distributions and calculate the most likely class using Bayes theorem. (iv) The k-Nearest-Neighbors classifier with Euclidean distances (k-NN) (Duda et al., 2001). We set the number of neighbors k (a free parameter) to $k = 10$ because empirical investigations revealed that this selection maximized decoding performance for the dataset examined.

Unless otherwise stated, in this paper we relied on decoding using a LDA, because of its high computational speed and performance on the datasets considered here.

Automated procedure for selecting the minimal number of synergies based on task decoding

From the proposed decoding based metric, we developed an automated procedure to select the minimal number of synergies. This model selection technique is based upon the progressive evaluation of the statistical significance of the task-discriminating information added when progressively increasing the number of synergies in the decomposition model. After evaluating decoding performance with $N = 1$ synergy, the number of synergies in the decomposition model increases step by step, until the increase of synergies does not gain any further statistically significant increase of decoding performance. The procedure is automatic because of this statistical test of significance. In this way, the chosen set of N synergies is the smallest decomposition that captures all available task-discriminating variance within the synergy space.

Crucial to this selection procedure is the test to determine if adding one more synergy significantly increases decoding performance. We needed to ensure that the different dimensionality of two models with N and $N + 1$ synergies does not lead to any artifactual difference in the computed percent correct values. Thus, we designed the statistical test as follows. For a given value N, we compare the decoding performance of the synergy parameters when using the N synergies with the decoding performance of the parameters of all subsets consisting of $N - 1$ synergies plus the parameters of the N-th synergy pseudo-randomly permuted ("shuffled") across conditions. We repeat this shuffling procedure a number of times (100 in our implementation) to obtain a non-parametric distribution of decoding performance values in the null hypothesis that the additional synergy does not add to the decoding power of the synergy decomposition. In the following we evaluated this significance at the $p < 0.05$ threshold. The statistical threshold for significant increase of decoding performance was graphically highlighted in the plots of the decoding performance (% correct) as a function of the number of synergies as a shaded area indicating the 95% confidence intervals constructed using this bootstrap procedure (**Figure 2C**). In this way, if the original decoding performance curve enters in the shaded area at the N-th synergy, the N-th dimension does not increase significantly the decoding performance and therefore this suggests that $N - 1$ synergies should be selected. The selected number of synergies can be simply visualized as the smallest value of N for which decoding performance lies above the no-significance (shaded) area.

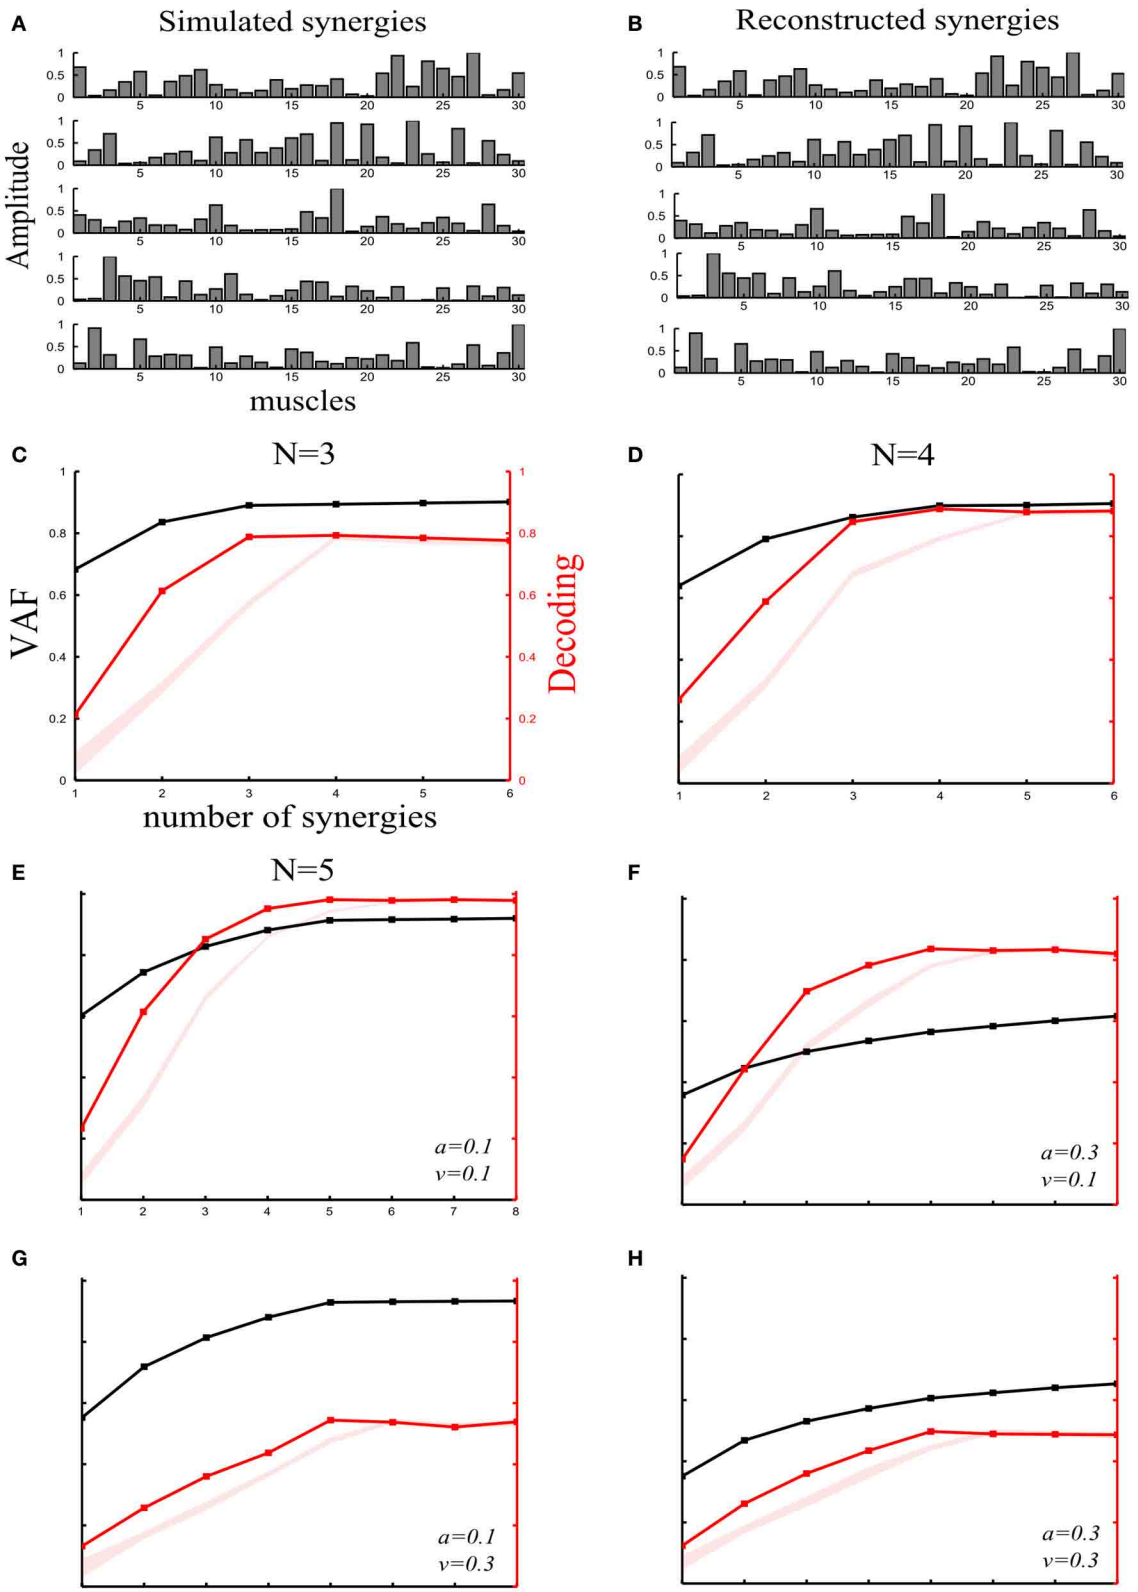

FIGURE 2 | Robustness of our method applied to synchronous synergies when varying the number of "ground-truth" synergies and the sources and levels of noise. curves (red curves whose scale is indicated in right *y*-axes) for datasets generated from 3**(C)**, 4**(D)**, and 5**(E)** "ground-truth" synergies. For noise levels, we used the "reference" values ($a = 0.1$ and $v = 0.1$). The red shaded areas represent the 5–95% confidence intervals of the bootstrap test for decoding. **(F–H)** VAF and decoding performance curves [plotted with the same conventions as in panels **(C–E)**] when generating data from five synergies and varying the simulated noise parameters as follows: increased signal-dependent noise ($a = 0.3$, $v = 0.1$) **(F)**; increased trial-by-trial variability of the activation coefficients ($a = 0.1$, $v = 0.3$) **(G)**; increased signal-dependent noise and trial-by-trial variability of the activation coefficients ($a = 0.3$, $v = 0.3$) **(H)**.

Choice of the synergy coefficients' parameters

In practice, task decoding is applied in synergy space, thus it requires working with synergy activation variables. The nature of such activation coefficients depends on the synergy model considered. After the decomposition into N synergies, the pattern of synergy activation in each trial can be described by a set of scalar parameters, vectors and temporal waveforms. To illustrate the method clearly, we first restricted our analysis to only one single-trial parameter per synergy for both models (time-varying and synchronous synergies), so each trial was represented by N values. The time-varying synergy model has two single-trial parameters (one scaling coefficient and one time delay) per synergy. We used the scaling coefficients which were shown to be more task-informative than the time-delays (see section "Results"). In the case of the synchronous model, we had to extract the single-trial parameters from the time-varying activation coefficient. We decided to use the time integral of the activation coefficient over the entire task period because preliminary investigations (not shown) revealed that integral measures largely outperformed the decoding performance obtained with other measures based on single points such as timing and amplitude of first or second activation peak (Karst and Hasan, 1991; Flanders et al., 1996) and measures based on Principal Component Analysis of the activation time course (Optican and Richmond, 1987). The use of the integrated EMG activity is standard and has been extensively used in biomechanical studies (e.g., Winter, 2009).

Then, we went on to investigate whether taking more single-trial parameters into account would increase the task identification power of each type of synergy decomposition. For the time-varying model, we evaluated the decoding performance using both single-trial parameters (scaling coefficients and time delays). For the synchronous model, the time-varying activation coefficients of the synergies add a large number of extra parameters (up to an independent parameter per time point if activation varied fast enough) that could potentially carry more task-discriminating information. To test for the possibility that complex multi-parameter single descriptions of the time course of activation of synchronous synergies carry more information, we progressively refined the parameterization of the single-trial activation coefficients by binning them in smaller bins and we computed the decoding performance as a function of the number of bins.

EMG RECORDING PROCEDURES

To validate the analytical methods developed here, we applied them to a set of EMGs recorded during the execution of a reaching task, as described in the following.

Four healthy right-handed subjects (AM, AB, AK, and ES) participated voluntarily in the experiment. The experiment conformed to the declaration of Helsinki and informed consent was obtained from all the participants, which was approved by the local ethical committee ASL-3 ("Azienda Sanitaria Locale," local health unit), Genoa. The protocol consisted in executing reaching multijoint movements (flexions and extensions of the shoulder and elbow joints) in the horizontal plane (**Figure 1A**). The subjects sat in front of a table and were instructed to perform fast one-shot point-to-point movements between a central location (P0) and 4 peripheral locations (P1-P2-P3-P4) evenly spaced along a circumference of radius 40 cm. Subjects were supporting the weight of their arm by themselves; no device was used to remove static gravitational effects. The upper trunk was not restrained, but analysis of the kinematics data showed that its movement during the investigated tasks was negligible. The subjects made center-out (fwd) and out-center (bwd) movements (**Figure 1A**) to each one of the 4 targets. In total, the experimental protocol specified 8 distinct motor tasks denoted by T1, . . . , T8, each one of which was performed 40 times, thus the entire experiment consisted of 8 tasks $\times$ 40 trials $=$ 320 samples. The subjects were asked to perform such a relatively high number of repetitions of each task because this was useful for the validation of the single-trial algorithms and of the impact of trial-to-trial variability on the generation of muscle activation patterns. This experimental design can be viewed as a variant of the one proposed in (D'Avella et al., 2006, 2008) since performance of each one of the 8 motor tasks requires executing movements to 8 different directions. The main difference with respect to this previous work is that instead of considering movements from the center of a circle to 8 points on its circumference, we analyze forward and backward movements between the center and 4 of these points. The order with which the movements were performed was randomized.

Electromyographic (EMG) activity was recorded by means of an Aurion (Milano, Italy) wireless surface EMG system. The EMG signals were recorded with a sampling rate of 1 kHz from the following muscles: (1) finger extensors (FE), (2) brachioradialis (BR), (3) biceps brachii (BI), (4) triceps medial (TM), (5) triceps lateral (TL), (6) anterior deltoid (AD), (7) posterior deltoid (PD), (8) pectoralis (PE), (9) latissimus dorsi (LD) (**Figure 1B**). The EMGs for each trial were digitally full-wave rectified, low-pass filtered (Butterworth filter; 20 Hz cutoff; zero-phase distortion), their duration was normalized to 1000 time steps and then the signals were integrated over 20 time-step intervals yielding a final waveform of 50 time steps. This is a standard EMG treatment in muscle synergy studies (see D'Avella et al., 2006). Body kinematics was recorded by means of a Vicon (Oxford, UK) motion capture system with a sampling rate of 100 Hz. Six passive markers were placed on the fingertip, wrist (over the styloid process of the ulna), elbow (over the lateral epicondyle), right shoulder (on the lateral epicondyle of the humerus), back of the neck and left shoulder.

The kinematics data were low-pass filtered (Butterworth filter, cut-off frequency of 20 Hz) and numerically differentiated to compute tangential velocity and acceleration. Movement onset and movement end were identified as the times in which the velocity profile of the fingertip superseded 5% of its maximum. The mean movement duration varied across subjects from 370 to 560 ms. We verified that for all the subjects included in this analysis none of the muscles showed a systematic change in signal amplitude across the recordings sessions, which would be an indication that the EMG sensors were partially detached from the skin.

GENERATION OF SIMULATED EMG DATASETS

To demonstrate the validity of our method and investigate its robustness, we tested it on simulated single-trial EMG responses in which the "ground truth" about which synergy set actually generated the data was known by construction, and that contained physiologically plausible sources of single-trial variance. We constructed two synthetic datasets by linear summation of a small number (from 2 to 5, depending on the simulation) of either synchronous or time-varying synergies and corrupted them with different physiologically plausible sources of single-trial variance: motor noise on the synergy activations and additive signal-dependent noise. The amount of each type of noise was parameterized by two separate free parameters: v and a respectively.

The first EMG dataset (simulation of synchronous synergies) was generated as a weighted combination of set of synchronous synergies according to Equation 2. The data simulated the activation of $M = 30$ muscles used for executing $R = 40$ repetitions of each one of $T = 15$ motor tasks, i.e., $40 \times 15 = 600$ simulated samples in total (**Figure 2A**). The M-dimensional synergies were drawn from exponential distributions with mean 10 were then normalized to each synergy's maximum muscle activation (Tresch et al., 2006). Their number was varied from $N = 3$ to 5 and their corresponding activation coefficients were assumed time-invariant for simplicity (Tresch et al., 2006). The use of time-invariant activation coefficients is common in the synchronous synergy framework (Ting and Macpherson, 2005; Torres-Oviedo et al., 2006). Typically, such time-invariant activations result from the preprocessing of the EMG signals to reduce dimensionality in the time domain (e.g., time-averaging of the muscle activities). However, the model can readily incorporate temporal variability too. In our simulations, we assumed that, to execute a motor task, each one of the N synergies was activated by a scalar coefficient drawn from a uniform distribution in the [0,1] interval. So, each task was represented as an N-dimensional vector of activation coefficients. The variability in the neural motor command, which in turn leads to trial-to-trial variations of the synergy coefficients in each task, was modeled as additive white Gaussian noise with covariance matrix $v^2\mathbf{I}$. Hence, we varied the parameter v to modulate the trial-to-trial variability of the synergy recruitment for each task.

To construct the second simulated dataset (simulation of time-varying synergies), we used the time-varying synergies (from $N = 2$ to 4) and the corresponding scaling coefficients extracted from the single-trial experimental data of the typical subject (**Figures 3A,B**). Importantly, this simulated dataset was built such that, without any source of task-unrelated variability, the underlying set of synergies is theoretically sufficient to produce the EMG patterns of 9 muscles for the execution of 8 motor tasks and such that, even with other sources of noise added, all task-discriminating variations are described by the scaling coefficients of the "ground-truth" synergies. We computed the means of the extracted coefficients for each motor task and fitted their distributions with N-dimensional Gaussians. Based on these data, we modeled the motor noise that corrupts the coefficients and delays as a Gaussian whose standard deviation (SD) is a fraction v of the SDs measured on real EMGs. A value $v = 1$ corresponds to the amount of variability empirically found on real data, whereas $v > 1$ corresponds to trial-to-trial synergy recruitment variability larger than that of the experimental data. From the resulting Gaussian distributions, we generated 40 sets of activation coefficients c_i^s per task which scaled the extracted synergies $\mathbf{w_i}(t)$ according to Equation 1 to generate the simulated EMG dataset consisting of 9 muscles and 40 trials $\times$ 8 tasks $=$ 320 samples. The duration of each sample was 50 time steps.

For both simulations, the resultant data were then corrupted by task-unrelated variability during movement execution. This was done by adding the noise term $\varepsilon^s(t)$ in Equations 1, 2. Muscle activation patterns have been reported to be corrupted by noise that scales with the amplitude of the motor signal, termed as signal-dependent noise (Tresch et al., 2006). Such noise whose SD is proportional to the amplitude of the noiseless EMG was added on each muscle's simulated EMG activity. In summary, the two types of variability included in the generation of the simulated data set are:

- Additive noise (i.e., trial-to-trial variability) on the activation coefficients and delays (free parameter v). This is a motor noise that affects the synergy recruitment itself. This variability corresponds to the one depicted thereafter in **Figure 4A** bottom.
- Signal-dependent noise, i.e., additive noise whose SD is proportional to the magnitude of the noiseless activation pattern of an individual muscle $m(\sigma^{(m)} = a^{(m)} \sum_{i=1}^{N} c_i \mathbf{w}_i^{(m)}(t)$, free parameter a). This noise affects all the muscles independently and could typically represent variability arising from motor neurons activity, but also noise related to signal pre-processing and measurement. This type of variability will generally affect dimensionality of the data set and corresponds to the one depicted thereafter in **Figure 4A** top (actually, it is even more general because it is not necessarily orthogonal to the synergy space).

The above simulation parameters were varied to test the robustness of the proposed method to all sources and different levels of noise. In all cases, the maximal values of these parameters were chosen as the largest values that allowed accurate reconstruction of the original synergies by the synergy extraction algorithms.

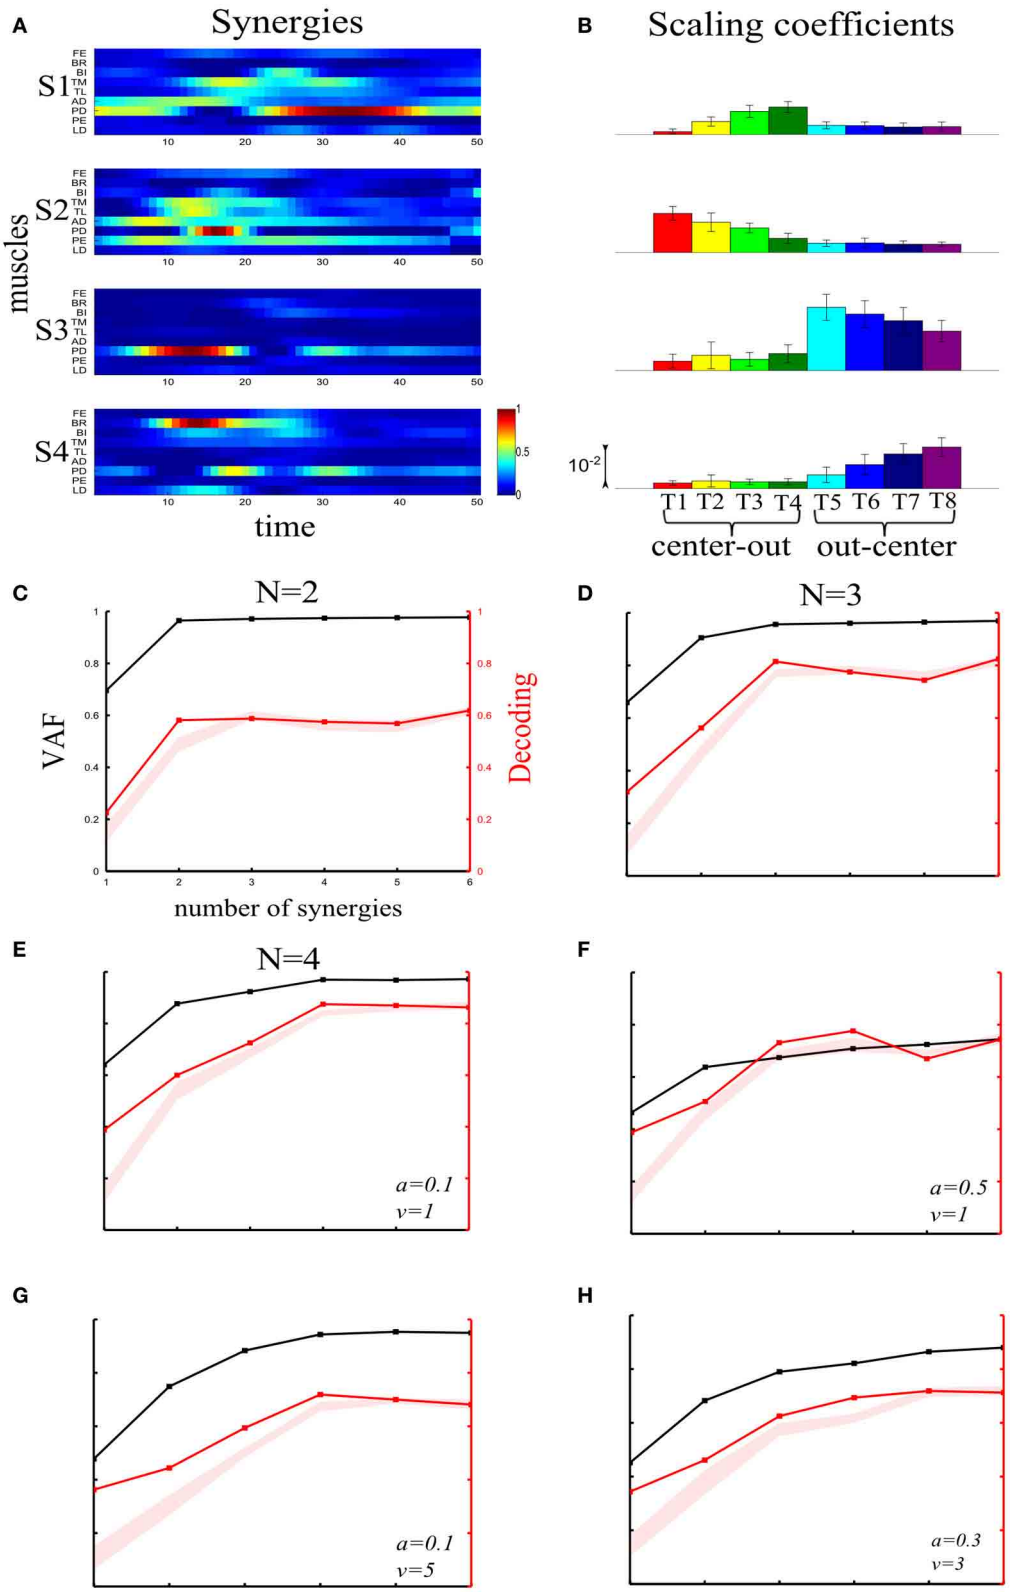

FIGURE 3 | Robustness of our method applied to time-varying synergies when varying the number of "ground-truth" synergies and the sources and levels of noise. coefficients activating the four synergies across the 8 motor tasks performed. Histograms are plotted as means ± SDs across all trials to the given task. **(C–E)** VAF and decoding performance curves for datasets generated from 2**(C)**, 3**(D)**, and 4**(E)** "ground-truth" synergies. For noise levels, we used the "reference" values ($a = 0.1$, $v = 1$). **(F–H)** VAF and decoding performance curves when generating data from four synergies and varying the simulated noise parameters as follows: increased signal-dependent noise ($a = 0.5$, $v = 1$) **(F)**; increased trial-by-trial variability of the activation coefficients ($a = 0.1$, $v = 5$) **(G)**; increased signal-dependent noise and trial-by-trial variability of the activation coefficients ($a = 0.3$, $v = 3$) **(H)**. Conventions as in **Figure 2**.

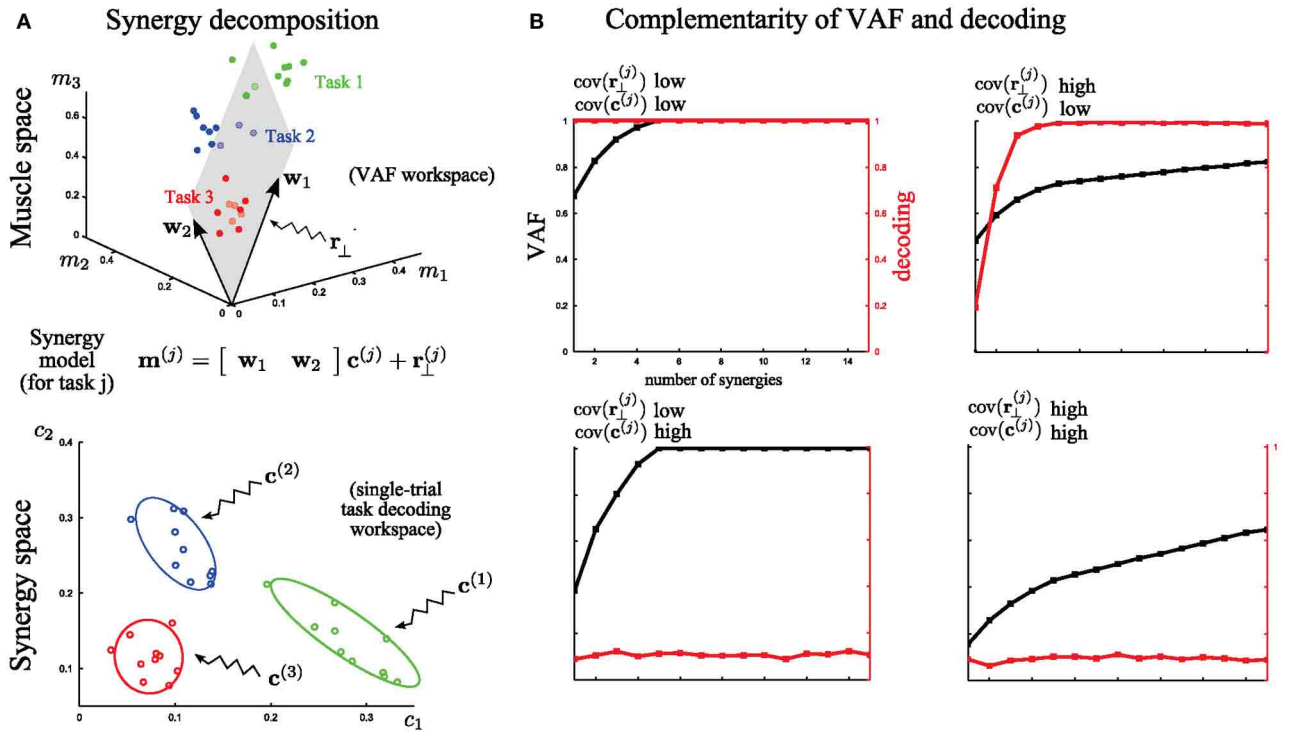

FIGURE 4 | A simple illustration of problems faced in assessing the quality of muscle synergy models. (A) Top: Identification of 2 muscle synergies ($\boldsymbol{w_1}$ and $\boldsymbol{w_2}$) from the activities of 3 muscles executing 3 motor tasks. The 3-dimensional muscle space is approximated by a linear 2-dimensional synergy space. Bottom: Distributions of the synergy activation coefficients across trials for the three tasks. The variability of these distributions determines how reliably synergy recruitment maps onto task accomplishment. **(B)** Illustration of the behavior of VAF (black curves and left *y*-axes) and decoding performance (red curves and right *y*-axes) as a function of the number of extracted synergies under four cases of extreme (either high or low) levels of variability. The dataset was generated by combining five synchronous synergies. These examples indicate that the two metrics assess the role of two different types of variance in the dataset.

RESULTS

COMPLEMENTARITY OF VAF AND DECODING METRICS FOR ASSESSING THE VALIDITY OF SYNERGY DECOMPOSITIONS

Before we proceed to a detailed validation of the newly proposed decoding metric, we begin discussing and exemplifying the complementarity between our decoding metric and the traditionally used VAF metric (Ting and Chvatal, 2011). This is useful to both illustrate our methodology and justify the need for complementing the current evaluation of muscle synergy models with a task-space metric.

For this illustration, we simulated the activity of three muscles executing three different tasks (**Figure 4**; red, blue, green). For simplicity, we assume that muscle activation is described by a time-invariant scalar in this preliminary example. In each trial, the activation of these three muscles can be represented as a point in the 3-dimensional muscle space [as done in (Tresch et al., 2006) in simulations and in (Torres-Oviedo et al., 2006; Torres-Oviedo and Ting, 2007) with real data]. In **Figure 4A** (top), we show a total of 30 sample points (10 for each task). Muscle synergy identification consists in finding basis vectors spanning a lower-dimensional linear space in which the original data can be accurately described: in this case we extracted two synergies with non-negativity constraints (the arrows $\boldsymbol{w}_1$ and $\boldsymbol{w}_2$) that approximate at best the data by a 2-dimensional hyperplane defined by the 3-dimensional synergy vectors (**Figure 4A** top). This representation is considered good if the approximation error (i.e., the residual error $r_\perp^{(j)}$), defined as the distance of the data points from the hyperplane, is low. The currently most exploited metric to determine the set of synergies best describing a dataset is the VAF measure, which quantifies the proportion of variability in the EMG data set that is accounted for by the muscle synergy decomposition (see Equation 3 in section "Materials and

Methods" for the exact definition). This metric is defined in muscle space. Thus, a high value of VAF means a high quality of reconstruction of the original muscle pattern (i.e., a relatively low $r_{\perp}^{(j)}$). In this part of the analysis, unsupervised learning only is performed and the available knowledge about the task is ignored.

However, as outlined in section "Introduction," VAF alone cannot tell if, or how well, activations of these synergies describe variations of movement across different tasks in individual trials, and if two different synergies describe a different or the same type of task-discriminating variations. In other words, there is a second and equally important type of variability in the synergy decomposition that cannot be addressed by the VAF, which concerns trial-by-trial differences in the recruitment of muscle synergies. To analyze this, we move to coordinates in the synergy space (**Figure 4A** bottom). This variance reflects the spread of the synergy activation coefficients $c^{(j)}$ for the execution of the same task. The extent to which this latter variance affects task discrimination (and thus likely also task execution) can be assessed by quantifying the identifiability of the task performed on every trial in the synergy space. This is because executing a motor task using muscle synergies requires a well-defined mapping from synergy recruitment to task identification (i.e., one possible outcome associated with a given synergy activation). To quantify the reliability of this mapping on a single-trial basis we introduced (see section "Task Decoding Based Metric") the decoding metric which measures the percentage of times the task j is correctly predicted by the single-trial activation coefficients $c^{(j)}$. This additional metric is necessary for the evaluation of muscle synergy representations with respect to task identification.

We further illustrate in **Figure 4B** the *complementarity* of the two metrics (VAF and decoding based) by considering EMG datasets corrupted with extreme levels (either high or low) of both types of variability described above. These datasets were generated from the five synchronous synergies shown in **Figure 2A** (see section "Materials and Methods" for details) and in all cases the noise levels were restricted so that the original synergies could be recovered from the synergy extraction algorithm (**Figure 2B**). Note that with very large noise, the original synergistic structure can be hidden or lost and therefore the extraction algorithm may fail to extract the correct synergies. Therefore, our analysis relies on the assumption that NMF's algorithms were able to recover the correct synergies (at least for the correct N, which was checked a posteriori).

First, we considered low levels of both types of variance for each task (the variance in muscle space, assumed to lie on a plane that is orthogonal to the synergy space, which characterizes how the actual muscle pattern varies across trials and the variance in synergy space, which characterizes trial-to-trial variations in the synergy recruitment). Note that the distinction between these two sources of variability is not unrealistic as it may reflect actual neural noise acting at different levels of the CNS. With low variance, the VAF metric reveals that five synergies reconstruct accurately all the muscle patterns and the decoding metric validates that all the tasks are perfectly discriminable from the activation coefficients of these synergies (**Figure 4B**, top left). Then, we tested the case of very high variance only in $r_{\perp}^{(j)}$. Because such variability cannot be written as synergy decomposition (by hypothesis), the VAF by the extracted synergy decomposition is never sufficiently high: the high levels of unstructured noise do not allow a good approximation of the data in a low-dimensional space. Nevertheless, decoding performance proves that 5 synergies describe all task-to-task differences; therefore these synergies constitute the minimal set of synergies that guarantees a reliable mapping between their activation and task identification (**Figure 4B**, top right). On the other hand, when there is a very high variability in the synergy activations $c^{(j)}$ then the synergy decomposition cannot distinguish between different tasks even though the dimensionality reduction is not affected. This is shown by the decoding performance curve that never exceeds significantly chance level. Hence, although all the data points still lie on a 5-dimensional space ($VAF = 1$ exactly for $N = 5$), there is no way to guarantee what task will be executed at fixed activation of the synergies (in this extreme case, the mapping is even a uniform random variable –chance level) (**Figure 4B**, bottom left). Finally, we consider high variance for both $r_{\perp}^{(j)}$ and $c^{(j)}$ simultaneously. As expected, VAF exhibits no saturation point and decoding performance is at chance level. So, in this case, the identified synergy decomposition neither reconstructs well the original (i.e., recorded) muscle activities nor discriminates between tasks (**Figure 4B**, bottom right). This "worst case" scenario would typically invalidate the synergy decomposition because both metrics yield low scores.

These extreme but theoretically plausible cases exemplify well the usefulness of a systematic methodology that evaluates quantitatively not only the approximation of the muscle space by the synergy space (addressed by the VAF) but also the mapping between synergy activation and task identification (addressed by single-trial task decoding). Such an approach will allow an objective and automatic assessment of muscle synergy models/decompositions and thus, it can serve as a model selection criterion.

It is useful to consider other possible conceptual cases in which concurrent evaluation of VAF and task decoding may provide valuable insights. First, consider a case when VAF individuates a larger set of synergies than that individuated by decoding. The extra synergies identified by VAF explain a useful amount EMG variance but do not add any task-discriminating information. This may happen either because such extra synergies are activated always in the same way in all tasks (something that can be tested by verifying that when considered individually they lead only to random task decoding) or that they do not add any task discrimination to that already carried by the minimal set of synergies determined by the decoding metric. Careful decoding analysis of the individual extra synergies contributing to VAF but out of the minimal task-decoding set may be useful to individuate synergies (e.g., postural synergies) that may be important for generating the appropriate movements even if their activation is constant across tasks. A second possibility is that decoding selects a larger set of synergies than VAF. This case indicates that some synergies (because e.g., they have little signal amplitude) do not explain a large part of the variance of the dataset, yet they provide unique information about task-to-task differences not carried even by other synergies in the set with larger amplitude.

These considerations suggest the potential value and complementarity of the insights provided by the joint use of VAF and decoding metrics.

In the following, we aim to show how our new method is crucial in this respect. We will illustrate how the VAF and decoding curves behave when muscle synergies are extracted from real data and verify that the method is reliably applicable to a variety of realistic EMG datasets with different properties giving robustly correct results.

SIMULATION STUDIES OF THE ROBUSTNESS OF THE DECODING-BASED METHOD

To demonstrate and test our novel method for selecting the set of synergies that describe all task-related differences at best, we used two types of simulated datasets (one for each type of muscle synergy model, see section "Materials and Methods" for details). Importantly, in both simulated datasets, which contain both task-discriminating and non-discriminating ("noise") variance, we know by construction the number of synergies sufficient to describe the entire task-discriminating part of the EMG variance. This allows a direct evaluation of the performance of the method against a ground truth. Moreover, by manipulating the parameters (such as the level of noise, or the number of true synergies, or the number of samples recorded), we can investigate how these variables affect the quality of synergy detection. In the following, we first validate the methodology by implementing various tests on the dataset generated by synchronous synergies and then show that its application extends naturally to the time-varying synergy model.

Assessment of the method's performance when applied to synchronous synergies

Varying the number of "ground truth" synergies. First, we checked the extent to which our method could identify the correct set of synergies that generated the data, by varying the number of ground-truth synergies from which we generated the simulated EMG data. More precisely, we simulated three, four or five synchronous synergies (see section "Materials and Methods") and corrupted them with both types of noise ($a = 0.1$ and $v = 1$). After extracting muscle synergies from the simulated datasets, we obtained the VAF and decoding curves reported in **Figures 2C–E**. In all three cases, the ground-truth sets of synergies that explain the task-discriminating variations were correctly individuated, indicating that our method reliably detects synergy sets independently of the precise number of synergies.

Varying the sources and levels of noise. We then estimated the effect of varying the amount of the two types of physiological noise. In these further investigations, we generated the data using all 5 simulated synchronous synergies (plotted in **Figure 2A**). In particular, we tested how noise differentially affects the selection of synergies with our decoding method and with standard VAF criteria. (The threshold for the VAF-T criterion was set to 0.9 in all subsequent simulations).

We started by generating an EMG dataset with a set of "reference" values of the noise parameters ($a = 0.1$ and $v = 0.1$) on which we performed the subsequent synergy-identification and decoding analysis. **Figure 2E** shows that the decoding method correctly identified the number of synergies expressing task-discriminating variance. This already suggests that the decoding metric is quite robust to the presence of task-irrelevant variance in the data set.

In the subsequent simulations, we increased the level of one noise parameter at a time in order to gain some intuition about the dependence of the VAF and percent correct metrics on these different sources of noise and also examine the robustness of our method to higher levels of noise.

First, we examined the impact of increasing the signal-dependent noise. We increased the signal dependent noise parameter to $a = 0.3$ keeping v unchanged. The VAF drastically decreased indicating its susceptibility to the unstructured additive noise (**Figure 2F**). In fact, in the limit of very large additive noise (e.g., due to very noisy recordings), the VAF curve exhibited an almost linear increase with low slope implying that a large number of synergies would be required to explain the variance of the dataset (see e.g., **Figures 2F,H**). These findings highlight a degree of arbitrariness in selecting synergy sets by setting thresholds purely based on VAF criteria, as VAF contains also noise variance and thus choice of a good threshold crucially depends on the amount of noise in the considered dataset. More specifically, in the high additive noise case, the VAF-based criteria select a very large number of synergies because the curve neither reaches the 0.9 threshold nor plateaus. On the other hand, the percent correct metric exhibited robustness to additive noise demonstrating only a slight decrease (**Figure 2F**). Hence, by attempting to decode the task performed, we can discount task-unrelated variance and we can still identify the synergies that account for task-discriminating variability in a general way and separate them from those explaining unstructured noise in the data.

Second, increasing signal-dependent noise ($v = 0.3$) does not change the VAF curve (**Figure 2G**)- meaning that the whole dataset can still be reconstructed with low error- but produces synergies whose activations are more variable across trials, i.e., the motor tasks are performed in a less stereotyped way, which causes the decoding performance of the extracted synergies to decrease. However, although the decoding ability of the extracted synergies is decreased, our method is still able to detect the four synergies that explain all the task-relevant variability in the dataset (**Figure 2G**). Note that in the limit of very large motor noise, decoding would tend to chance level while the VAF would still be near 100% (see e.g., **Figure 4C**). In such an extreme case, our decoding algorithm would correctly detect that the synergies (though they explain the variance of the data) cannot be used for identifying and selecting the task-discriminating movement features. In fact, the mapping between synergy activations and tasks executed would be completely random, proving the non-usability of this synergistic structure for accurate motor control.

Finally, we increased both types of noise simultaneously ($a = 0.3$ and $v = 0.3$). Consequently, both curves fell to lower values. However, although the VAF curve did not exhibit any elbow or saturation point, the decoding curve had a clear peak at $N = 5$ demonstrating the robustness of our approach to high levels of any type of variability (**Figure 2H**).

Varying the number of samples. Because the datasets that can be obtained experimentally are composed of a limited number of trials, we investigated how this limitation may affect the performance of our method. Our aim was to assess the smallest number of repetitions of each motor task that can guarantee reliable selection of the set of muscle synergies that account for all the task identification power. In these simulations we used the same noise levels as the ones in **Figure 2E** ($a = 0.1$ and $v = 0.1$). We generated 5 repetitions of each simulated motor task, i.e., 5 trials $\times$ 8 tasks $=$ 40 samples, and corrupted them with 20 different instances of noise yielding 20 different simulated datasets. On these datasets we implemented our decoding-based method and computed how many times it gave the correct result (five). We repeated the same when simulating 10 and 20 repetitions of every motor task. **Figure 5A** shows that 10 trials per task were sufficient to determine the five synergies in the vast majority of the algorithm runs, while when 20 trials were used the algorithm identified the number of synergies always correctly. In general, we found (results not shown) that increasing the number of samples caused a reduction of both the variance of the decoding performance at fixed number of synergies and of the confidence

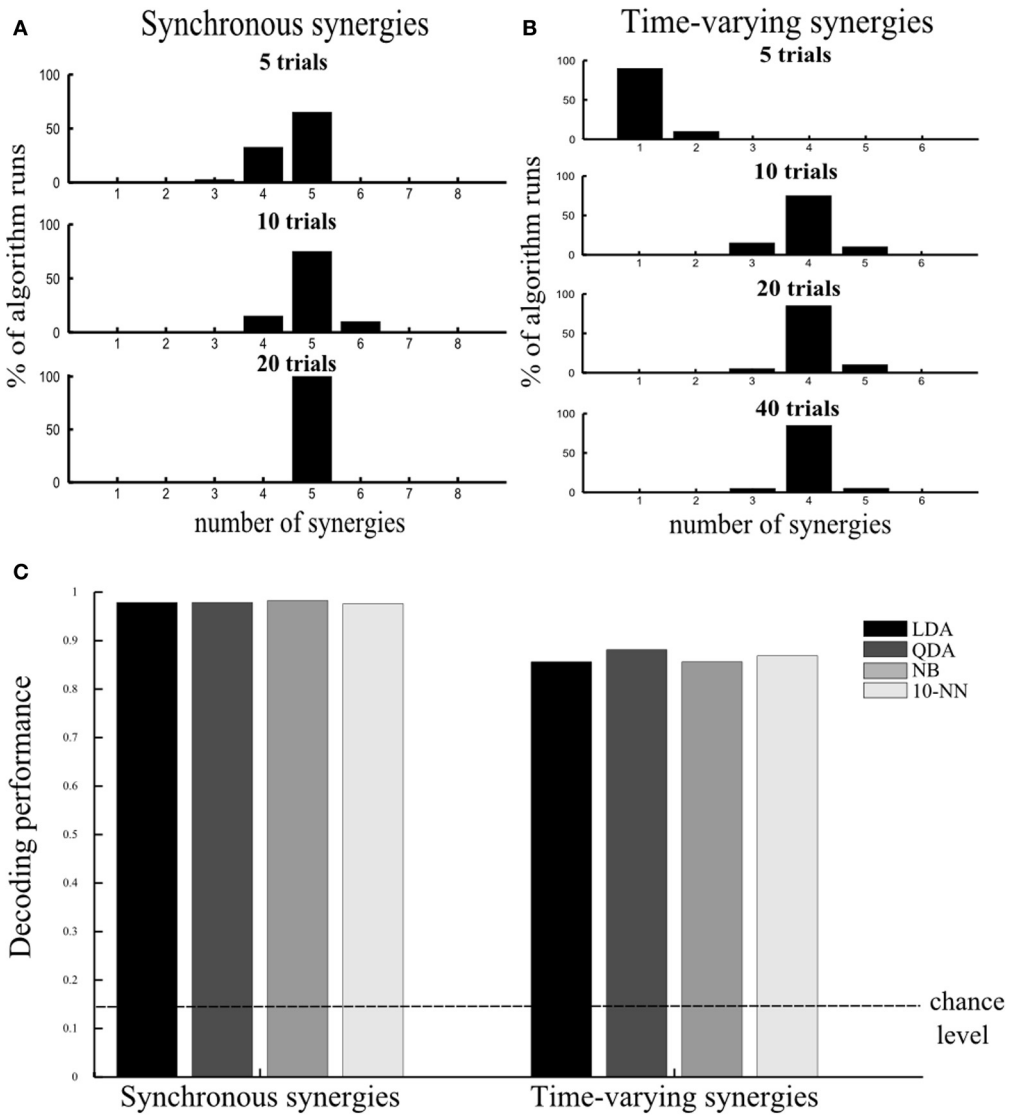

FIGURE 5 | Assessing robustness of results. (A,B) Assessing the number of repetitions per motor task required to guarantee robustness of our method. Histogram of the distribution of number of selected synergies across 20 algorithm runs using 5, 10, 20, and 40 trials per task (plotted from top to bottom) for the synchronous **(A)** and the time-varying synergies **(B)**. **(C)** Robustness of results to choice of single-trial decoding algorithm. Histogram of the percent correct values computed using four different decoding algorithms for the synchronous (left) and the time-varying synergies (right). The discrimination power of the selected synergy set was preserved across all decoding algorithms. In all tests, we used the "reference" noise values ($a = 0.1, v = 0.1$).

intervals of the "null hypothesis" (indicated as a shaded red area in **Figures 2**, **3**), which in turn both contribute to increasing the stability of the method. In the case of five trials, although the correct number was found in most cases, sometimes the algorithm underestimated the number of underlying synergies because relying on only 5 trials per task rendered our test of statistical significance not reliable. So, the synergies contributing the least to describing task-related differences were often falsely excluded.

Using different decoding algorithms. To validate that our results do not depend on the specific choice of single-trial decoding algorithm (LDA) we applied our methodology to the simulated dataset constructed from the five synergies (**Figure 2A**) corrupted with the "reference" noise values ($a = 0.1$ and $v = 0.1$) and 40 simulated trials per task using a wider range of classification algorithms (see section "Materials and Methods" for details). We used these noise levels and number of trials because they reflect the corresponding values used/computed in our experiment. We tested other three standard decoding algorithms (QDA, NB, and 10-NN) and found that all of them identified correctly the set of (five) synergies describing all information about the task. Moreover, the discrimination power of the synergy decomposition was revealed to be robust to the assumptions underlying the classification procedure as the decoding performance was almost identical for all algorithms (**Figure 5C** left) (also when we varied the number of trials and levels of noise, results not shown).

Extension of the method's applicability to time-varying synergies

So far, we validated our method on EMG data described by synchronous synergies. However, it is readily applicable to any type of representation of muscle activation patterns. To demonstrate its robustness independently of the underlying model, we repeated all the tests performed above with simulated data generated from four physiologically plausible time-varying synergies (see section "Materials and Methods"). The reference values of the noise parameters $v = 1$ and $a = 0.1$ used in these simulations were set so that the amount of task-discriminating and non-discriminating variability in the simulated data matched those measured in the experimental data based on which we built the simulations. We note that in all cases adding realistic amounts of noise—as the ones expressed by the parameter values used in all subsequent simulations—allowed accurate reconstruction of the shape of the underlying synergies (shown in **Figure 3A**).

First, we validated that the method identifies correctly the set of synergies that generated all task-to-task differences independently of the original synergy set dimensionality (**Figures 3C–E**). Then, using all four synergies, we examined the method's robustness to higher levels of both types of variability. Again, the number of synergies explaining all task-discriminating variations was reliably specified (**Figures 3F–H**). The slightly larger confidence intervals of the "null hypothesis" (shaded red area) result from the larger variance of the estimates of this decomposition with respect to the synchronous synergies. This can arise from the non-guaranteed convergence of the time-varying synergy extraction algorithm and its sensitivity to the initial guess, two factors that make the output of time-varying decompositions less stable across simulations.

Following this, we aimed at estimating the minimal number of trials required to guarantee reliable synergy set selection. Five trials appeared to be too few for our proposed test of statistical significance (**Figure 5B**). In this case, the assessment of the number of synergies was not reliable because the distribution of the shuffled surrogates had a very big variance. As a result, any increase of dimensionality did not increase significantly (with respect to the shuffled surrogates) the decoding performance and thus, our method yielded usually one synergy. Therefore, we suggest a minimum of 10 repetitions of each motor task for potential future studies evaluating the importance of trial-to-trial variability in time-varying synergy extraction.

We note that the minimum of trials required to individuate correctly the synergy set may depend upon both the number of muscles recorded by the EMG setup and the level of noise in a current session. The number of trials needed to identify the synergy set is likely to increase with the number of recorded muscles (because decoding in a higher dimensional space with small dataset is more difficult) and with the level of noise (due to the difficulty in detecting patterns in noisy conditions). Whereas our simulations demonstrate that our method can detect reliably the synergy set with feasible amounts of data, for the reasons indicated above it is valuable to evaluate the minimum number of trials at a preliminary stage using simulated data (such as those considered here) constructed with statistical properties as similar as possible to the actual experimental data of interest.

Finally, we examined whether other decoding algorithms yield the same results for the time-varying synergies too (**Figure 5C** right). Indeed, both the identified number of synergies and their decoding performance were robust once more indicating the applicability of our method independently of the properties of the dataset or the details of the mathematical implementation.

IDENTIFICATION OF THE SMALLEST SYNERGY SET THAT ACCOUNTS FOR ALL TASK-DISCRIMINATING VARIABILITY IN SINGLE-TRIAL SYNERGIES EXTRACTED DURING CENTER-OUT POINTING.

To illustrate the ability of our methodology to identify synergy sets on real data, we applied it to a dataset of EMG activity recorded during an experimental protocol (fully described in section "Materials and Methods") comprising of many repetitions of a variety of point-to-point reaching movements. For each one of the four subjects tested, we formed an EMG matrix of dimensions 9 muscles × (50 time steps × 320 samples) consisting of all the movement-related EMG activity (rectified and filtered) of the 9 muscles for all samples recorded. In order to illustrate our methodology first, we present extensive results from the analysis of only one ("typical") subject's EMG dataset. In such realistic situation, the correct number of synergies is unknown and the amount of the different types of noise is not available. Here we test the extent to which extracted synergies can express single-trial task-related differences and how many synergies are selected by our method (compared to the VAF-based criteria). A summary

of the results of all four datasets is reported at the end of the following section.

Synchronous synergy identification

We first illustrate the application of our method to recorded synchronous synergies. We extracted using the NMF algorithm (see section "Materials and Methods") single-trial synchronous synergies from the experimental EMG data, beginning with the typical subject (**Figure 6**). These synergies consist of constant vectors of levels of muscle activations (**Figure 6A**) recruited by time-varying activation coefficients. Note that the synergies and coefficients shown in this figure were obtained using $N = 4$ in

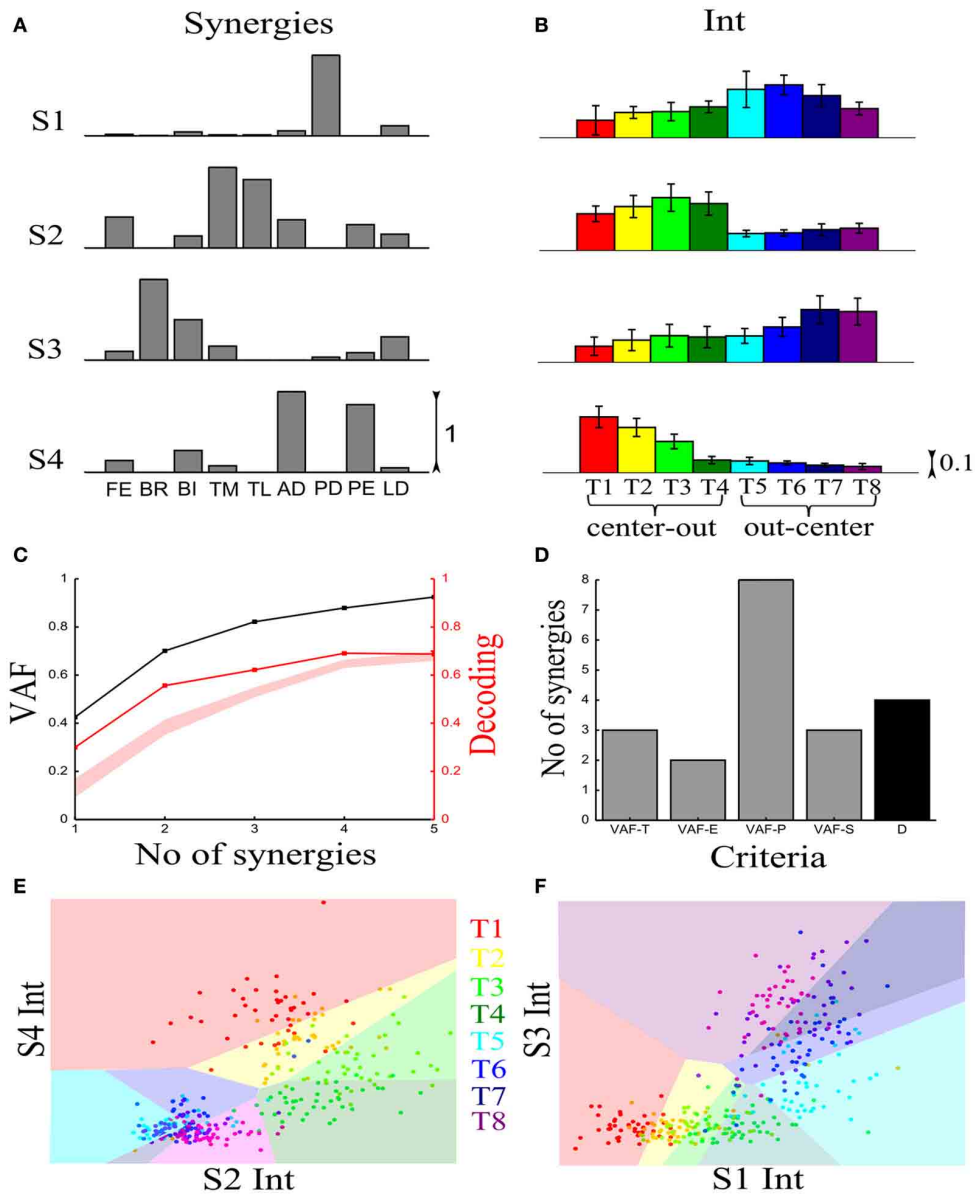

FIGURE 6 | Application of our decoding method to the synchronous synergies extracted from the EMG data of a typical subject recorded during the execution of an arm pointing task. (A) The four synchronous synergies obtained from the experimental data of the example subject as four vectors of activation levels of 9 shoulder and elbow muscles. **(B)** Histograms of the integral of the activation coefficient (Int) across the 8 motor tasks performed. **(C)** VAF (black curve whose scale is indicated in left *y*-axis) and percent correct curve (red curve whose scale is indicated in right *y*-axis). The shaded area represents the 5–95% confidence interval of the bootstrap test for decoding. **(D)** Histogram of the number of synergies selected by each one of the existing criteria (gray bars) and our proposed one (black bar). **(E,F)** Decoding the 8 motor tasks using the integral of the 4 synchronous synergies' activation coefficients. For a given trial to be decoded, the activation coefficients of 2 synergies are represented as a point in the 2-dimensional space. The color of each point indicates the actual task which this trial corresponds to. The linear discriminant algorithm has divided the space into 8 regions, one for each class (motor task). The trial is assigned to the class indicated by the color of the region on which the point lies. **(E)** Classification using the integral of activation of synergies S2 and S4. **(F)** Classification in the S1–S3 space.

the synergy extraction algorithm because we found (see next sections) that this is the minimal set of synergies explaining all task-discriminating variations. However, the four most task-discriminating synergies and their coefficients obtained assuming more synergies were quantitatively and qualitatively very similar to those presented in **Figure 3** (results not shown). The resulting muscle groupings had a straightforward anatomical and functional interpretation: Synergy1 describes mainly the activation of two shoulder flexors; Synergy2 has strong activations of elbow extensors; Synergy3 has strong activations of elbow flexors and Synergy4 is primarily composed of shoulder extensors (**Figure 6A**).

In order to assess how synchronous synergies allow decoding the task on single trials, we computed the time integral of the synergies' activation coefficients, which represents the magnitude of the synergy activation (see section "Materials and Methods"). The magnitude of each synergy clearly depended upon the task. More precisely, S1 is primarily activated for out-center movements starting from the left; S2 is recruited for center-out leftward movements; S3 is recruited for out-center movements starting from the right and S4 for center-out rightward movements (**Figure 6B**).

Figure 6C plots the VAF curve as a function of the number of synergies (black curve) and **Figure 6D** shows the selected number of synergies that would be selected according to each one of these criteria. It is clear that these VAF-based criteria do not yield a consistent number of synergies for this dataset, and selecting the correct set of synergies in this way necessarily relies partly on a somewhat arbitrary choice. We attempted to resolve this problem by complementing the VAF curve with the decoding performance afforded by the single-trial parameters of the model. We applied our proposed decoding-based method on the magnitude of the extracted synchronous synergies. The decoding performance curve (red curve in **Figure 6C**) obtained by varying the number of synergies (N) saturates at $N = 4$ indicating that the task discrimination power added by the magnitude parameters of any additional synergy is negligible. Thus, application of our model selection algorithm gave 4 synergies (last point on the curve lying above the red shaded area).

To gain more insights on how these 8 motor tasks are decoded using the magnitude parameters of the extracted four synergies, we visualized the decoding procedure. In **Figures 6E,F**, we show scatter plots of the parameters on a 2-dimensional space that has been split by the LDA into 8 different classes, one for each task. Each point is colored according to the actual class which this trial corresponds to and is assigned by the decoding algorithm to the class represented by the colored region on which it lies. Thus, the trial is decoded correctly only if these two colors coincide. From **Figure 6E**, it is clear that activations of synergies S2 and S4 can discriminate well the forward tasks (T1-T2-T3-T4), but the backward ones(T5-T6-T7-T8) are much less discriminable (larger overlap of the data points). This is why only two synergies are not sufficient to distinguish all the simulated tasks. We may expect that adding the other two synergies will resolve this problem. Indeed, **Figure 6F** shows that in the S1-S3 space, even though tasks T1-T2-T3-T4 are poorly classified, there is a clear improvement in the classification of tasks T5-T6-T7-T8. So, to get maximal discrimination of the 8 motor tasks four synergies are required, two of them encoding the forward movements and the other two the backward ones.

We then examined the results from the single-trial analysis of the synchronous synergies extracted from all four recorded subjects. The overall decoding performance afforded by synchronous synergies ranged from 63% to 73% for the LDA decoding algorithm across subjects. The set of synergies needed to explain all task-discriminating variability consisted of four synergies in two subjects and three in two other subjects. In general, the synchronous synergies extracted from different subjects were qualitatively and quantitatively similar. The average similarity between the synchronous synergies extracted from different subjects is shown in **Figure 8** (lower left part). In the two subjects that needed four synergies to capture all task-discriminating variations, muscle groupings were similar to the ones shown in **Figure 6A**. In the two subjects that needed only three synergies, the elbow extensors (S2 in **Figure 6A**) were either grouped with the shoulder extensors (S4 in **Figure 6A**) to form one synergy or activated by all three remaining synergies at lower levels (results not shown). Hence, S1, S3, and S4 were identified in all subjects, whereas S2 was present only in the two subjects that used four synergies to perform the tasks. In all subjects the decoding performance of the selected synergies was significantly higher-than-random for all tasks ($p < 0.05$, bootstrap test). We also tested the decoding performance of each one of the four synchronous synergies separately and found higher than random decoding for all of them (ranging from 31% to 46%). This implies that each synergy in the set exhibits a degree of tuning to all task directions.

Time-varying synergy identification

To characterize the spatiotemporal organization of the recorded muscle patterns, we fed the EMG matrix to the time-varying synergy extraction algorithm and extracted sets of time-varying synergies (see section "Materials and Methods"). Each EMG pattern in each sample was then described by the coefficients specifying the amplitude (scaling coefficient) and time delays of the activation of each synergy. The extracted synergies, the mean activation coefficients and delays across tasks are shown for the typical subject in **Figure 3**.

We then examined how these single-trial parameters were modulated by the task (**Figure 3B**). We considered the distribution across tasks of the scaling coefficient and found that it exhibited a clear task-dependence (**Figure 3B**) (D'Avella et al., 2008) similar to the one found for the integral of the synchronous synergies model. The corresponding delays are dependent on the task performed but their relationship with motor tasks is less apparent than that of the coefficients (results not shown). Then, we implemented the decoding-based method opting for the set of time-varying synergies that explain all task-discriminating variability. Our method yielded four synergies (**Figure 7A**) also for this model. We further asked if we could reach the same result using the VAF-based criteria. **Figure 7B** shows that each one indicated a different number of synergies rendering such an assessment inconclusive and pointing out the arbitrariness of any selection made using these criteria.

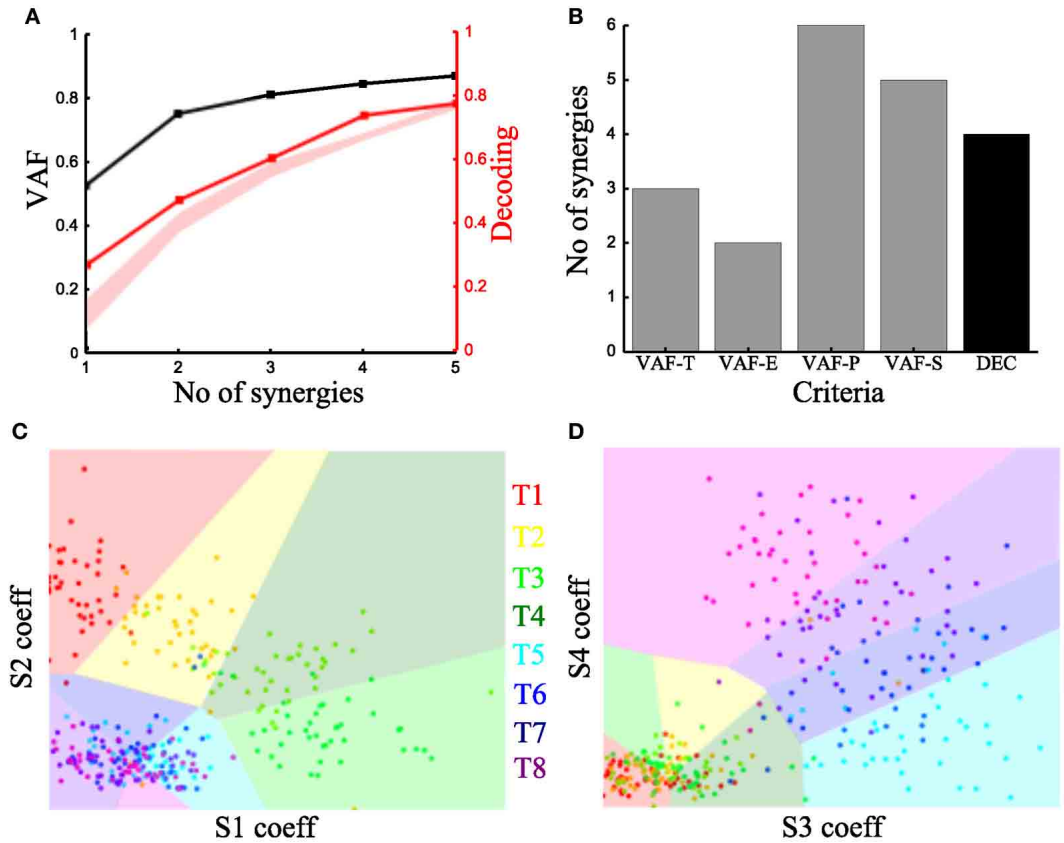

FIGURE 7 | Application of our method to the time-varying synergies of the typical subject. (A) VAF (black curve whose scale is indicated in left *y*-axis) and decoding performance curve (red curve whose scale is indicated in right *y*-axis) for the example subject. The red curve represents the percent correct values using the scaling coefficients of the time-varying synergy model. The shaded area represents the 5–95% confidence interval of the bootstrap test for decoding. **(B)** Histogram of the number of synergies selected by each one of the existing criteria (gray bars) and our proposed one (black bar). **(C,D)** Decoding the 8 motor tasks using the 4 time-varying synergies' scaling coefficients. **(C)** Classification using the coefficients of synergies S1 and S2. **(D)** Classification in the S3–S4 space. Region and marker color conventions as in **Figures 6E,F**.

As we did for the synchronous synergies, we examined the discriminability of the motor tasks also in the time-varying synergy activations space (**Figures 7C,D**). Again, we found the activations of two synergies (S1-S2) describing the differences across the forward tasks (T1-T2-T3-T4) and the other two (S3-S4) were used to distinguish the backward ones (T5-T6-T7-T8).

We note that with respect to previous studies of the role of synergies upon goal-directed reaching movements (D'Avella et al., 2006, 2008), our method individuated in this subject synergies spanning all four cardinal directions in planar reaching space. This may be due to specific subject-to-subject or task setup differences between our experiments and those previously published. Another possibility is that some synergies encoding specific directions carry relatively little EMG variance (such as those pointing right in right-handed movements, e.g., synergy S4 in **Figure 3A**, which expresses out-center movements starting from the right) and may thus be discarded according to VAF-based criteria. However, our method picks these synergies because they express degrees of freedom of movement relevant for the task and not expressed by other synergies and so must necessarily be included in a task-decoding analysis.

Similar results held for all four recorded subjects. The overall decoding performance afforded by the scaling coefficients of time-varying synergies ranged from 64% to 74% (for the LDA algorithm) across subjects (for comparison, chance level is 12.5%). The number of time-varying synergies needed to explain all task-discriminating variability was the same as the number of synchronous synergies for all four subjects. The shape of synergies (i.e., the time course and the relative levels of muscle activations) was similar for each subject, as indicated by the high similarity index obtained for all pairs of subjects (**Figure 8** upper right part). The main difference across subjects was that in the two subjects that needed only three synergies the muscle activations that constitute the fourth (non-significant) synergy was either included in one of the other three synergies or distributed across all of them (results not shown). The resulting scaling coefficients were modulated accordingly so as to produce movements to all task directions and describe identifiably all motor tasks. Indeed, in all subjects the scaling coefficients of the selected synergies had significantly higher-than-random decoding performance ($p < 0.05$, bootstrap test) for all reaching directions. Furthermore, we found that all time-varying synergies too exhibit some degree of tuning

to all task directions (individual decoding performance ranged from 33,75% to 38,75 %).

In sum, a small set of time-varying or synchronous synergies described all task-related differences in the examined EMG datasets. This set of synergies would have been hard to select relying on VAF-based criteria, because some of the standard criteria would exclude synergies that express task-discriminating muscle activations and contribute to the generation of each task, while others would include synergies that explain only task-irrelevant variations reflecting different sources of noise in the recorded data.

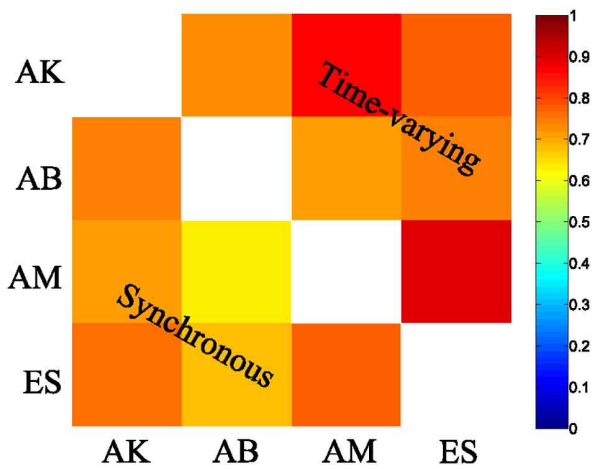

FIGURE 8 | Synergy similarity matrix across all tested subjects. The synergy sets extracted from all subjects that were selected by our method exhibited a high similarity either when the synchronous (bottom left) or when the time-varying synergy (top right) model was used.

USING THE DECODING FORMALISM FOR COMPARING THE ABILITY OF MUSCLE SYNERGY MODELS TO ENCODE TASK-DISCRIMINATING INFORMATION

We further note that the overall decoding performance of a synergy model may be used as a criterion to decide which type of synergy decomposition is most suitable to describe a set of tasks and which (and how many) parameters of such a representation carry information about the task effected at hand. To illustrate this point, we compared the decoding performance of both time-varying and synchronous synergies with comparable number of parameters per synergy for all subjects tested.

We first examined decoding performance when using one parameter per synergy. We started by assessing the discrimination power of the two single-trial parameters of the time-varying synergies (i.e., scaling coefficients and time delays). Although decoding with the time delays is significantly above chance level ($1/8 = 12.5\%$) for all subjects, the scaling coefficients afford a significantly higher decoding performance ($37.3 \pm 4.3\%$ vs. $70.5 \pm 2.2\%$ respectively, **Figure 9A**) ($p < 0.05$, paired t-test). Comparing the scaling coefficients of the time-varying synergies with the integral of the activation coefficients of the synchronous synergies (**Figures 9A,B**), we found that the time-varying and the synchronous model had comparable performance ($70.5 \pm 2.2\%$ vs. $69 \pm 1.9\%$ respectively). The corresponding VAF values for these synergy decompositions were $81 \pm 2.1\%$ vs. $89 \pm 1.4\%$ respectively. Consistent with previous findings (D'Avella and Bizzi, 2005), the synchronous synergy decomposition captures a significantly higher percentage of the variability of the data ($p < 0.05$, paired t-test).

Then, we evaluated the decoding performance gain obtained when combining two parameters per synergy. For the time-varying synergies, using both parameters yielded a significantly better decoding than with the scaling coefficients alone

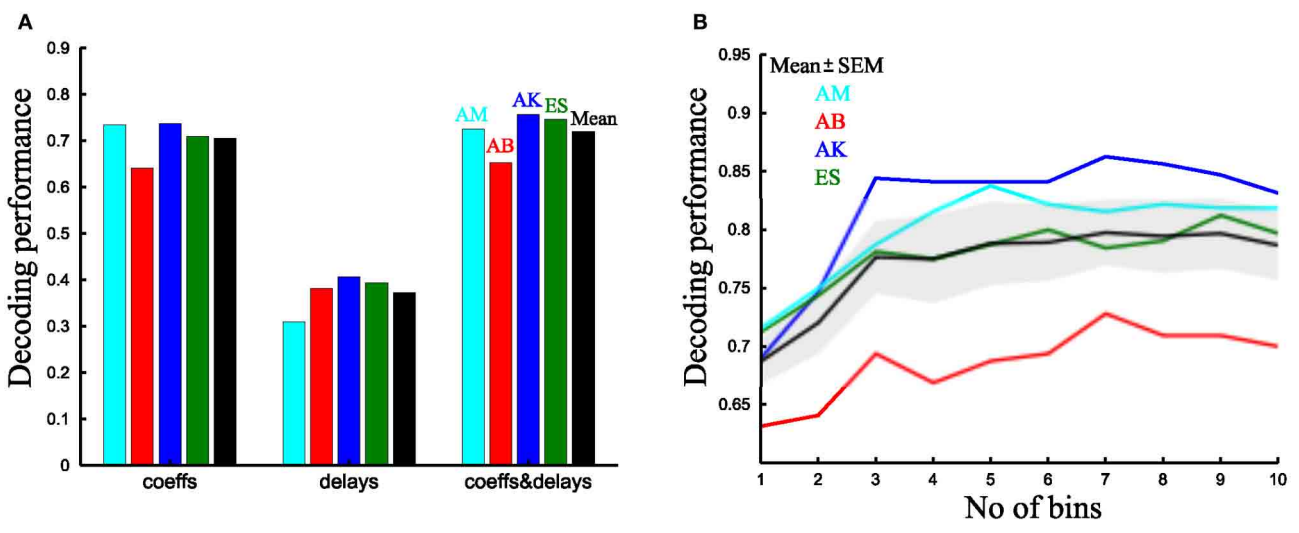

FIGURE 9 | Comparison of the decoding performance of synchronous and time-varying synergies. (A) Percent correct values of the time-varying synergy decomposition for all four subjects tested using only the scaling coefficients (left), only the delays (middle) and both single-trial parameters per synergy (right). The last column (black) is the mean across subjects. **(B)** Decoding performance as a function of the number of bins in which the integral of the activation coefficient is split for all subjects. The black curve and shaded area represents the mean ± SEM across subjects.

($72 \pm 2.7\%$ vs. $70.5 \pm 2.2\%$ respectively, **Figure 9A**) ($p < 0.05$, paired t-test). For the synchronous synergies, we divided the movement duration in two phases; we computed the integral of the synchronous synergy activation coefficients for each one of them and used these values as the decoding parameters. Also for this model, decoding using two parameters was significantly higher than with one ($72 \pm 2.6\%$ vs. $69 \pm 1.9\%$ respectively) ($p < 0.05$, paired t-test). Then, we compared the task discrimination power of the two models. We found that, when using two parameters per synergy (scaling and delay coefficients for the time-varying model and the integral in two equal bins for the synchronous), the decoding performance of both types of synergy decomposition was $72 \pm 2.7\%$ vs. $72 \pm 2.6\%$ respectively (**Figure 9B**). Thus, for this particular set of tasks and muscles, both synergy decompositions seem equally adequate and equally compact in describing the task-discriminating variations in muscle activation signals. Indeed, equal decoding performance is obtained when using the same number of parameters in both approaches ($p < 0.05$, paired t-test).

Finally, we tested whether adding more single-trial parameters per synergy adds more information about the task. As the time-varying synergies have only two single-trial parameters, we had to restrict the analysis to the synchronous synergy model. By binning the activation coefficients in gradually shorter time bins and computing the corresponding integrals, we progressively increased the number of parameters used for decoding. **Figure 9B** depicts the decoding performance for all subjects as a function of the number of bins. Decoding performance saturated quickly for all subjects at approximately three bins, meaning that all task-discriminating information can be described by considering three basic phases of one-shot rapid movements. This is reminiscent of the well-known triphasic pattern observed during the control of ballistic single joint rotations but also during whole-body actions (a first agonist burst followed by an antagonist burst followed by a second agonist burst) (Berardelli et al., 1996; Chiovetto et al., 2010). This result points out that despite the potentially high number of free parameters describing the activation time course of synchronous synergies, the task being performed may be encoded by a much more compressed set of parameters without loss of information about task-discriminating variations in synergy recruitment.

In sum, in this particular dataset the synchronous synergy model was slightly more effective at describing task-discriminating variability than the time-varying one when the time course of synchronous synergies was modeled by three or more parameters. This corresponds to a slight increase in model complexity with respect to the use of time-varying synergies whose single-trial activation is described by two parameters per synergy. However, when using the same number of parameters, time-varying and synchronous synergies explained the same amount of task-discriminating variability.

DISCUSSION

In this article we proposed and implemented an automated method, based on single-trial task decoding, to evaluate the extent to which muscle synergy recruitment can be mapped onto motor task identification. We showed how this new metric complements the VAF metric commonly used to test the validity of muscle synergy decompositions and can be used to address questions related to movement execution in task space. Quantifying the degree of validity of muscle synergies in task space is fundamental since synergies (as extracted from dimensionality reduction techniques) are assumed to be the building blocks of movement production that can be reused across tasks, while the synergy combination coefficients represent the task-dependent motor features. This study presents a systematic procedure to measure the degree of feasibility of such a modular and hierarchical control scheme by means of a single-trial task decoding technique. The significance of our conceptual and computational developments is discussed in the following.

CONCEPTUAL FOUNDATIONS OF THE METHOD

Fundamental to the method is the fact that motor behaviors are produced on single trials and therefore should be analyzed on such a basis (Ranganathan and Krishnan, 2012; Ting et al., 2012). Even though single-trial analysis is not new in the study of muscle synergies (Tresch et al., 1999; Torres-Oviedo and Ting, 2007, 2010; Kutch et al., 2008; Valero-Cuevas et al., 2009; Chvatal et al., 2011), it appears to be a necessary and rational component in our methodology (otherwise task-decoding would be trivial with data averaged per task). Thus, exploiting single-trial analysis tools, we came up with a computational procedure that quantifies the task identification power afforded by different synergy decompositions. Our method uses this formalism to separate out trial-to-trial variations in synergy space that reflect task-discriminating variability (and hence increase decoding performance) from those that do not account for task-related differences. The latter can be regarded as "noise" as far as task discrimination is concerned, even if they reflect neurophysiological processes. This conceptualization mirrors the one often used in single-trial neural literature to separate signal from noise and identify the most informative components of neural responses (Quian Quiroga and Panzeri, 2009). The advantage of this method is that it allows the user to focus on task-discriminant aspects of variability using an objective and useful scale in a user-defined "task space" rather than measuring variability on a scale related only to the amplitude of the EMG signals (Quian Quiroga and Panzeri, 2009; Tolambiya et al., 2011).

As exemplified by our application to real data, one potential advantage of the decoding metric is that it can identify muscle activation components of relatively low amplitude (and accounting for a small amount of the VAF) but reflecting unique information about the task. Furthermore, a comparison of synergy sets determined by VAF or by decoding metrics may be useful to tease apart synergies that provide unique information about task-to-task differences (such as the synergy set individuated by decoding) from synergies that are task invariant but contribute an important part of variance because they e.g., implement muscle activation for maintaining posture. Such important task invariant synergies are likely to appear as "extra" synergies selected by VAF method (because they carry variance) but not from the decoding method (because they do not add much task discriminating power).

Interestingly, in the experimental data we found that our method revealed relatively high decoding scores for relatively small synergy sets, supporting the idea that a small set of synergies are recruited in different ways during the execution of a larger number of different motor tasks. This finding is compatible with the idea of muscle synergies as intermediate low-dimensional representations of the mapping between motor commands and task goals and the associated theory of hierarchical motor control (Ting and McKay, 2007; Todorov, 2009).

The hierarchical view of motor control implies that a desired motor behavior can be mapped onto specific recruitment of muscle synergies whose activation leads to the expected behavior (Bizzi et al., 2000; Tresch and Jarc, 2009). Due to the nonlinearities of the musculoskeletal plant, even small variations in the muscle pattern could lead to very different behaviors at the end-effector level and thus could affect task achievement. Therefore, evaluating the effectiveness of synergies in terms of motor task performance is crucial. Ultimately biomechanical modeling/simulation is needed to achieve this (Neptune et al., 2009; Kargo et al., 2010). Task-decoding is a useful additional metric to validate (or invalidate) a certain chosen synergy decomposition before or simply without this step. High task-decoding scores lend credit to a synergy decomposition. In contrast, low task-decoding scores (e.g., decoding performance that is robustly around chance level for different decoding algorithms) may falsify a given synergy decomposition, even if VAF is close to 100%. Generally speaking, the decomposition/model yielding concurrently the highest VAF and the highest decoding score could be viewed as the most likely representation of neural synergies implemented in the CNS. In practice, the decoding metric was shown to be more robust to various sources of noise than the VAF. As such, it provides a more stable reference to inter-subject or inter-study comparisons. Concretely, this approach can be useful to reduce side effects on VAF values related to the different material, subjects or signal pre-processing used by different researchers.

Previous studies have proposed to separate task-discriminating from non-discriminating variations by evaluating VAF within each task separately (Torres-Oviedo and Ting, 2010; Chvatal et al., 2011; Roh et al., 2011) or identifying task-specific muscle synergies (Cheung et al., 2009a). These methods are very effective when some tasks in the examined set are executed using synergies that are not shared with other tasks. On the contrary, our method is more effective when muscle activations in different tasks differ not because of the highly specific activation of synergies only in particular tasks, but rather because of different activation coefficients of the same group of synergies. In this latter case, application of synergy decompositions separately in each individual task would lead to the identification of a larger set of synergies than those actually generating the task-discriminating muscle activations (we verified this intuition also by extracting synergies in one task at a time in our simulated datasets, which invariably led to incorrect identification of a larger set of synergies with lower task-discrimination power than the synergy set determined by our method; data not shown).

Our findings parallel results recently obtained in frogs' experimental and modeling studies (Kargo and Giszter, 2000, 2008; Kargo et al., 2010). In these studies, the authors varied the initial configurations as well as the level of muscle vibrations applied to the frog's hindlimb and showed that flexible combinations of a small set of invariant muscle patterns can produce successful accurate targeting of the frog's hindlimb from a large range of starting positions. It would be of interest to apply our method to this dataset in order to assess quantitatively the reliability of the correspondence between such task variables or feedback stimuli and muscle pattern activations. We believe that our method could serve to determine the functional role of the identified muscle patterns and further evaluate the significance of their coupling under different experimental conditions.

ON THE COMPUTATIONAL METHOD AND ITS USE

Critical comparison of the validity of different synergy models

An advantage of the derived decoding metric is that it allows a direct comparison of performance of different synergy decompositions in terms of task execution when using the same number of parameters in all decompositions. This is useful for testing the validity of various hierarchical motor control schemes or various mathematical representations of muscle synergies. For example, the synchronous synergy model may account for more variance than the time-varying synergy one (as happens in the EMG dataset considered here) but this may be due to the fact that synchronous synergies are potentially characterized by a larger number of parameters than time-varying synergies (because the former report the full time course of activation, whereas the single-trial activation of the latter is described by two parameters per synergy) (D'Avella and Bizzi, 2005; D'Avella et al., 2006). Specifically, by applying this metric to our dataset we found that the two decompositions decode tasks equally well when using the same number of parameters. Moreover, our formalism can be used to evaluate the loss of task-discriminating information due to simplification of the time course of synergy activation. In our example dataset, our analysis suggested that a full representation of the temporal pattern of activation patterns of synchronous synergies is not crucial to encode the goal of the task. Only the average activation during two or three temporal phases seems sufficient to know what target will be reached.

To shed more light onto the effectiveness of synergies as low-dimensional structures for motor control, future research could aim at extending our formalism to quantify the predictability of kinematic movement features in continuous time (Corbett et al., 2010) rather than just decoding which task (out of many) was performed. This would enable a proper comparison between the dimensionality of the instantaneous kinematics needed to perform tasks and the dimensionality of the muscle representations that explain all the kinematic range elicited by task execution. Furthermore, it would be of interest to apply our methods to experimental datasets containing a wider range of complex movements to determine which synergy decomposition is more effective in general and particularly in more "daily-life" situations. For example, in an entire reach-and-grasp motor task, we could

expect that the time-shifts of the time-varying synergy model or a more detailed consideration of the temporal profile of the synchronous synergy activations would be more relevant to task discrimination.

Automated selection of the minimal number of synergies

Since our framework allows critically evaluating any muscle synergy model, it can be used in particular to select the minimal number of synergies at fixed synergy representation. Assuming, for example, time-varying synergies as the model from which movements are generated, the simple question of how many synergies are required to describe distinctly the entire set of motor tasks under consideration is usually difficult to answer. The empirical and intuitive VAF-based methods are not automatic or lack objective rationale. Even more problematic is the fact that a synergy accounting for a large or small amount of the total VAF might have no implication with respect to the task goal. We proposed a recursive and automated method to compare synergy set of N elements with synergy set of $N-1$ elements. The basic argument is that if adding a synergy improves significantly task decoding performance then increasing the dimensions by one is worthwhile. We showed that this procedure is effective on simulated data sets for various levels of noise. However, examining decoding alone might be insufficient in some cases: for some data sets, one synergy could allow perfect decoding even though the muscle pattern cannot be reconstructed accurately (very low VAF). To cope with such cases, a potential variation of our method may imply choosing first a lower bound for N based on an inspection of the VAF graph, and then running our automated procedure from this N to refine the selection of the number of synergies. More generally, considering both VAF and decoding seems important to fully understand he function of the computed synergies, as a consequence of the above discussed complementarity of the two metrics.

POSSIBLE APPLICATIONS AND EXTENSIONS

There is evidence that the activity of motor cortical neurons in the monkey (Holdefer and Miller, 2002) and the cat (Yakovenko et al., 2010) during reaching movements as well as spinal interneurons in the frog during reflex motions (Hart and Giszter, 2010) correlates with muscle synergies and/or their recruitment. These studies suggest that the physiological basis of muscle synergy structures, which is observed in the motor output and assumed to simplify motor control, may rely on a focused selection of a set of neurons. We note that our decoding approach could be in principle applied to decode from single-trial neural population patterns activating synergies, to determine which patterns encode the task and which patterns carry additional or independent information to that carried by other patterns. Application of our method to simultaneous recordings of neural activity and EMGs during the execution of different movements could therefore lead to the determination at the same time of the minimal set of synergies and the minimal set of neural activity patterns that explain all task-discriminating neural and muscle activity, and to the specification of an explicit link between these two sets. These considerations suggest that the work presented here lays down the foundations for a deeper understanding of the relationships between single-trial neural activity and the resulting recruitment of muscle synergies.

More generally, this investigation could reveal itself useful for human-machine interfaces and neuroprosthetics (Nazarpour et al., 2012; Ting et al., 2012). Assuming it is possible to decrypt movement intention (e.g., what target a subject wants to reach to), a set of synergies could be recruited in accordance and, if our metric showed good task-decoding performance of the synergy decomposition considered, we could ensure that a coordinated multijoint arm movement would be generated to the expected target. Recent works aimed at exploiting synergies to control arm and hand motion (Jackson et al., 2006; Radhakrishnan et al., 2008; Vinjamuri et al., 2011) and assessing the validity of muscle synergies in task space appears to be a basic prerequisite for the effectiveness of such techniques.

ACKNOWLEDGMENTS

We acknowledge the financial support of the SI-CODE project of the Future and Emerging Technologies (FET) programme within the Seventh Framework Programme for Research of The European Commission, under FET-Open grant number: FP7–284553. We are deeply indebted to E. Chiovetto for participating in the first stage of this project and to M. Jacono for technical assistance.

Muscle synergies have been hypothesized to be the building blocks used by the central nervous system to generate movement. According to this hypothesis, the accomplishment of various motor tasks relies on the ability of the motor system to recruit a small set of synergies on a single-trial basis and combine them in a task-dependent manner. It is conceivable that this requires a fine tuning of the trial-to-trial relationships between the synergy activations. Here we develop an analytical methodology to address the nature and functional role of trial-to-trial correlations between synergy activations, which is designed to help to better understand how these correlations may contribute to generating appropriate motor behavior. The algorithm we propose first divides correlations between muscle synergies into types (noise correlations, quantifying the trial-to-trial covariations of synergy activations at fixed task, and signal correlations, quantifying the similarity of task tuning of the trial-averaged activation coefficients of different synergies), and then uses single-trial methods (task-decoding and information theory) to quantify their overall effect on the task-discriminating information carried by muscle synergy activations. We apply the method to both synchronous and time-varying synergies and exemplify it on electromyographic data recorded during performance of reaching movements in different directions. Our method reveals the robust presence of information-enhancing patterns of signal and noise correlations among pairs of synchronous synergies, and shows that they enhance by 9–15% (depending on the set of tasks) the task-discriminating information provided by the synergy decompositions. We suggest that the proposed methodology could be useful for assessing whether single-trial activations of one synergy depend on activations of other synergies and quantifying the effect of such dependences on the task-to-task differences in muscle activation patterns.

Keywords: muscle synergies, correlations, information theory, task decoding, single-trial analysis

INTRODUCTION

The central nervous system (CNS) is capable of performing a wide repertoire of motor tasks despite the high complexity of the musculoskeletal system (Bizzi et al., 1998). A possible strategy for achieving this accuracy despite the difficulties of controlling so many degrees of freedom may rely on generating movement as combination of a small number of invariant muscle patterns, commonly referred to as muscle synergies (Tresch et al., 1999; D'Avella et al., 2003; Bizzi et al., 2008). Muscle synergies are presumably recruited by neural motor commands—the so-called synergy activations—to produce the muscle activities required for task execution (Ting and McKay, 2007). However, how the appropriate synergies are combined and their corresponding activation levels are selected in single trials is still an open question.

An important empirical observation is that, although the CNS is able to generate a reliable and consistent motor behavior in each single trial, synergy activations are highly variable across trials: repeated executions of the same motor task rely on different activations of muscle synergies (Tresch and Jarc, 2009). The impact of such trial-to-trial variability on task performance remains to be understood. A question of particular interest is whether activations of different synergies in the same trials are correlated—in other words, whether recruitment of a given synergy may depend not only on the task at hand but also on the activation of other synergies—and what the potential roles of such correlations among synergy activations may be (Saltiel et al., 2001; Tresch et al., 2006). These trial-to-trial correlations of synergy activations are often neglected in studies that report

for example only the mean of each synergy activation coefficient independently of the other. Investigating such correlations requires, of course, ways to quantify their joint distributions across different trials.

From the theoretical point of view, these correlations may arise from different factors or serve a number of different purposes. Because individual synergies are presumably recruited by different neural drives that are not necessarily synchronous, it is conceivable that information about the recruitment of one synergy may be utilized for the activation of complementary synergies. In the same vein, the brain could rely on such correlations to cope with neural noise by reinforcing the relationships between the recruitment of the different synergies. Moreover, the correlation between synergy activations could be an emergent constraint of the task execution and its identity. For example, variations of speed in a set of arm pointing movements to a given spatial target could naturally lead to such correlations. Alternatively, these correlations may not serve a purposeful function, but rather arise from limitations of the neural-musculoskeletal systems and be detrimental to task performance. In such latter case, a useful strategy would be to minimize such correlations rather than using them as part of the motor strategy.

Here we introduce an analytical methodology to address the nature and functional role of trial-to-trial correlations between synergy activations. This method, which takes inspiration from methodologies derived for studying neural population codes, is designed to quantify how these correlations may contribute to generating appropriate motor behavior in single trials. The algorithm we propose first divides correlations between muscle synergies into types (noise correlations, quantifying the trial-to-trial covariations of synergy activations at fixed task, and signal correlations, quantifying the similarity of task tuning of the trial-averaged activation coefficients of different synergies). Then, building on recent work designed to quantify single-trial task discriminability of EMG data (Delis et al., 2013) the method employs single-trial methods (task-decoding and information theory) to quantify the overall effect of correlations between synergy activations on the task-to-task differences in patterns of muscle activation. We show that the methodology is readily applicable to any type of synergy decomposition and demonstrate its use for addressing the functional role of coordinated synergy recruitment on a task-by-task basis. To illustrate the method, and to begin to reason about the existence and potential function of cross-synergy correlations in real EMG data, we finally implement the method on muscle synergies extracted from an electromyographic (EMG) dataset recorded during the execution of a variety of reaching tasks (Delis et al., 2013). This application reveals the robust presence of information-enhancing patterns of signal and noise correlations among pairs of synchronous synergies, and shows that they contribute to enhance by approximately 9–15% (depending on the set of tasks considered) the task-discriminating information provided by synchronous synergy decompositions. Activations of time-varying synergies were instead much more weakly correlated and their correlations had a more limited impact on task information (0–5%).

MATERIALS AND METHODS

MUSCLE SYNERGY EXTRACTION

The extraction of muscle synergies relies on dimensionality reduction algorithms that determine stereotyped muscle activation patterns from the EMG data by modeling muscle activities as linear combinations of the extracted synergies (D'Avella et al., 2003; Tresch et al., 2006; Tresch and Jarc, 2009). There exist two influential models for describing muscle patterns as synergy combinations: the time-varying synergies (D'Avella and Tresch, 2002), which are genuine spatiotemporal patterns of muscle activation, with the EMG output specified by the amplitude and time lag of the recruitment of each synergy; and the synchronous synergies, which are co-varying groups of muscle activations, with the EMG output specified by a temporal profile defining the timing of each synergy during the task execution (Tresch et al., 1999; Cheung et al., 2005). Here, we implemented both models using algorithms based on Non-negative Matrix Factorization (NMF).

We selected this dimensionality reduction technique over alternatives, such as Principal Component Analysis (PCA) or Independent Component Analysis (ICA), because of two reasons. First, it imposes a non-negativity constraint to the extracted synergies (Tresch et al., 2006). Such a constraint reflects well the properties of muscle activation signals, as muscles cannot be activated "negatively." Second and more importantly for this study, PCA and ICA make specific assumptions about the dependencies among the extracted synergies (orthogonality and statistical independence respectively), which impose constraints on the relationships between the corresponding synergy activations as well. NMF does not impose such constraints and thus seems more suitable for studying the trial-to-trial relationships of synergy activations.

Synchronous synergy model

We used the NMF algorithm (Lee and Seung, 1999) to extract synchronous synergies. In this model, the EMGs are represented as a linear combination of a set of time-invariant activation balance profiles across all muscles activated by a time-dependent activation coefficient:

$$\boldsymbol{m}^s(t) = \sum_{i=1}^{N} c_i^s(t)\boldsymbol{w}_i + \boldsymbol{\varepsilon}^s(t) \tag{1}$$

where $\boldsymbol{m}^s(t)$ is again the EMG data of all muscles at time t; $\boldsymbol{w}_i$ is the synergy vector for the i-th synergy; $c_i^s(t)$ is the scalar coefficient for the i-th synergy at time t; N is the total number of synergies composing the dataset; and $\boldsymbol{\varepsilon}^s(\tau)$ is the residual (e.g., noise). The exponent s indicates the trial-dependence of the variables.

Time-varying synergy model

We used the time-varying synergy model first introduced in D'Avella and Tresch (2002). According to it, a muscle pattern recorded during one sample s is decomposed into N time-varying muscle synergies combined as follows:

$$\boldsymbol{m}^s(t) = \sum_{i=1}^{N} c_i^s \boldsymbol{w}_i \left(t - t_i^s\right) + \boldsymbol{\varepsilon}^s(t) \tag{2}$$

where $\boldsymbol{m}^s(t)$ is a vector of real numbers, each component of which represents the activation of a specific muscle at time t; $\boldsymbol{w}(\tau)$ is a vector representing the muscle activations for the i-th synergy at time τ after the synergy onset; t_i^s is the time of synergy onset; c_i^s is a non-negative scaling coefficient; and $\boldsymbol{\varepsilon}^s(\tau)$ is the residual (e.g., noise). To implement this model, we used the NMF-based time-varying synergy extraction introduced in D'Avella et al. (2003).

In the following, our purpose is to develop a mathematical procedure for quantifying the single-trial correlations among synergy activations and in particular their contribution to the task-discriminating information carried by the synergy decompositions.

SINGLE-TRIAL DECODING OF MOTOR TASKS IN THE MUSCLE SYNERGY SPACE

In our previous work, we introduced an approach for predicting the motor task performed in every single-trial using muscle synergy activation parameters (Delis et al., 2013). In this study, our aim is to examine the functional role of the correlations between muscle synergy activations in each single trial. For simplicity, we restricted our decoding analysis to one single-trial parameter per synergy. We use as decoding parameters the time-integral of the synergy activation coefficient for the synchronous synergies and the scaling coefficient for the time-varying synergies. Decoding was performed using a quadratic discriminant algorithm (QDA) (Duda et al., 2001). QDA assumes that the probability of obtaining the synergy activation vector given that task t is performed follows a Gaussian distribution for each task. Based on this assumption, the algorithm attempts to decode the task by determining the decision boundaries that maximize the ratio of the between-task over the within-task distances. In contrast to the linear discriminant algorithm that we used previously, QDA assumes unequal covariance matrices across tasks and this difference leads to quadratic instead of linear decision boundaries (Duda et al., 2001). Although the differences between these two algorithms in terms of task decoding were relatively small, the use of QDA can in principle better handle the differences between correlated and uncorrelated data, as strong correlations may lead to curved decision boundaries (Duda et al., 2001; Averbeck and Lee, 2006).

To validate decoding results, we implemented the "leave-one-out" cross-validation (Kjaer et al., 1994; Quian Quiroga and Panzeri, 2009), in which each trial is predicted based on the distribution of all other trials. Hence, in each step of this cross-validation procedure the training set consists of $M-1$ trials, while the test set consists of 1 trial. This process is repeated until all M trials have been tested. The "leave-one-out" approach maximizes the number of trials used for optimizing the decoder (training set) as well as for assessing its performance (test set).

QUANTIFYING INFORMATION FROM THE CONFUSION MATRIX

Once decoding is performed, we need to choose a measure of decoding performance. The simplest possibility, which we used in our earlier work, is to use the percentage of correct decoding (Delis et al., 2013). A potential problem with using percent correct is that it may fail to capture all task-discriminating information even when using an optimal decoding algorithm. Synergy coefficients may convey information by means other than just reporting the most likely task given the muscle synergy activation pattern: for example, they can provide the information that some tasks are utterly unlikely based on the synergy activations (Quian Quiroga and Panzeri, 2009).

A way to include in our calculation more ways to encode information is to use the mutual information $I(T; T^P)$ between the actual and the predicted tasks from the decoding outcomes (Shannon, 1948). The information $I(T; T^P)$ is a measure of the overall information about which task out of a set is gained by the prediction of the most likely task from the single-trial muscle synergy activations, and is defined as the mutual information between the rows and columns of the so called "confusion matrix" (i.e., the matrix quantifying the probability of predicting a given task given the presentation of a certain task):

$$I\left(T; T^P\right) = \sum_{t,t^p} P\left(t, t^P\right) \log_2 \frac{P\left(t, t^P\right)}{P(t)P\left(t^P\right)} \tag{3}$$

where t is the motor task performed, t^p is the one predicted by our decoding algorithm, $P(t)$ is the probability of execution of task t, $P(t^p, t)$ is the confusion matrix, i.e., the joint probability of predicting task t^p and executing task t, and $P(t^p)$ is the probability of predicting task t^p across all tasks in the considered set. Such measure of information $I(T; T^P)$ is not an absolute property of the synergy set, but it depends on the specific set of tasks considered (because it measures discriminability between tasks belonging to the specific set considered). In this article we will compute information about three possible task sets: the set of all eight different reaching tasks; the set of all four center-out tasks, and the set of all four out-center tasks. All quantities are computed from Equation (3), but summing over the appropriate set or subset of tasks.

It is useful to remind that information is measured in bits. Every bit of information reduces the overall uncertainty about the task by a factor of two. Perfect knowledge about the task from the synergy decomposition gives maximum mutual information of $\log_2 K$, where K is the number of tasks. For a given percent correct value, more information can be obtained if incorrect predictions are concentrated into clusters around the correct stimulus rather than distributed randomly (Panzeri et al., 1999b; Samengo, 2002). This information measure can reveal the effect of such systematic errors in the decoder and thus capture also this form of information that may be carried by muscle synergy activations. Information values were computed using the Information Breakdown Toolbox (Magri et al., 2009) available at www.infotoolbox.org. To eliminate the systematic bias from which information measures suffer when computed from small datasets, we used the Panzeri-Treves (PT) bias-correction method (Panzeri and Treves, 1996; Panzeri et al., 2007).

In Results, for simplicity we will abbreviate $I(T; T^P)$ simply as I.

SELECTING THE SET OF SYNERGIES THAT CARRY ALL TASK-DISCRIMINATING INFORMATION IN THE MUSCLE SYNERGY SPACE

The number of synergies (N) used to perform a set of motor tasks and their contribution to task-discriminating variations, is

unknown a priori. To address this, we developed an automated procedure to select the minimal number of synergies that carry all information about task-to-task differences. This model selection technique is based upon the progressive evaluation of the statistical significance of the task-discriminating information added when progressively increasing the number of synergies in the decomposition model. After evaluating the information carried by $N = 1$ synergy, the number of synergies in the decomposition model increases step by step, until the increase of synergies does not gain any further statistically significant information. The test of statistical significance was designed as follows. For a given value N, we compare the information carried by the synergy parameters when using the N synergies with the decoding performance of the parameters of all subsets consisting of $N - 1$ synergies plus the parameters of the N-th synergy pseudo-randomly permuted ("shuffled") across conditions. We repeat this shuffling procedure a number of times (100 in our implementation) to obtain a non-parametric distribution of decoding performance values in the null hypothesis that the additional synergy does not add to information carried by the synergy decomposition. In the following we evaluated this significance at the $p < 0.05$ threshold. The statistical threshold for significant increase of decoding performance was graphically highlighted in the information curves as a function of the number of synergies as a shaded area indicating the 95% confidence intervals constructed using this bootstrap procedure (**Figure 1C**). The selected number of synergies can be simply visualized as the smallest value of N for which information lies above the no-significance (shaded) area. In this way, the chosen set of N synergies is the smallest decomposition that captures all available task-discriminating information within the synergy space.

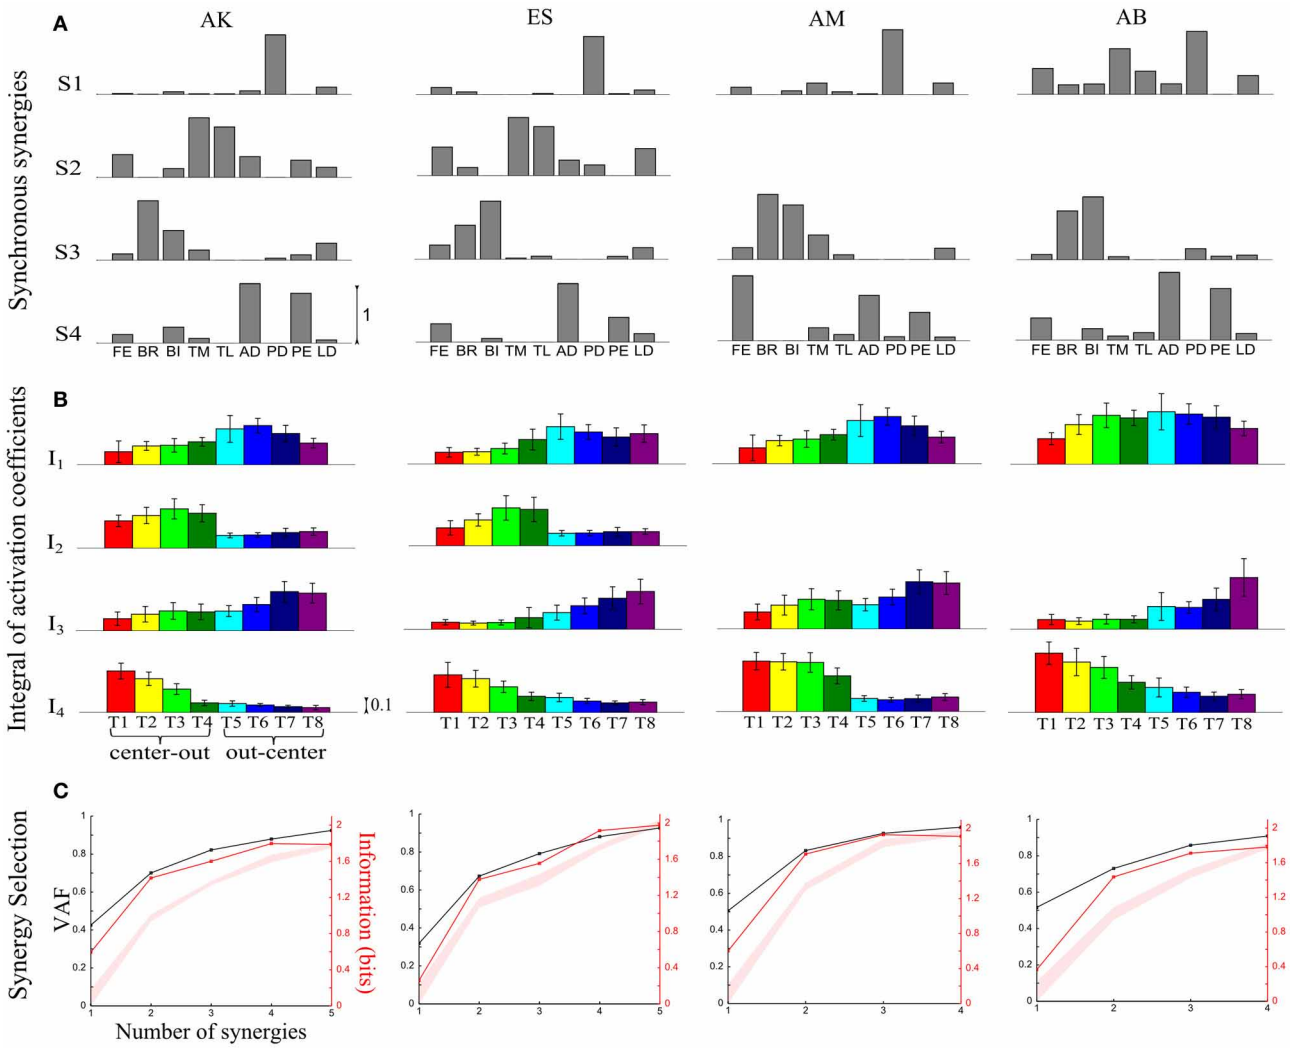

FIGURE 1 | Application of our information-based method to the synchronous synergies extracted from the EMG data of all four subjects recorded during the execution of an arm pointing task. (A) The sets of synchronous synergies obtained from the experimental data of four subjects as vectors of activation levels of nine shoulder and elbow muscles for each subject. **(B)** Histograms of the integral of the activation coefficient (I) across the eight motor tasks performed. **(C)** VAF (black curve whose scale is indicated in left y-axis) and information curves (red curve whose scale is indicated in right y-axis). The shaded area represents the 5–95% confidence interval of the bootstrap test for decoding (see Materials and Methods).

We verified, by means of generation of realistically simulated EMG datasets [based on linear combination of realistic synchronous and time-varying synergies with the addition of various kinds of physiologically-relevant noise—see (Delis et al., 2013)] that the method needed only a small number of trials per task (10 or more) to individuate correctly the set of synergies generating the data and to evaluate correctly their information content [data not shown, but see (Delis et al., 2013) for similar evaluations of robustness of decoding algorithms].

DEFINING AND QUANTIFYING SIGNAL AND NOISE CORRELATIONS AMONG SYNERGY ACTIVATIONS

Before we present our methodology based on the metrics defined so far, we explain what we mean by correlations among activations of muscle synergies, how we can quantify these correlations and how they may impact on the information about the task. In general, we would like to distinguish between different kinds of correlations ("signal" and "noise"—see below) that, as shown in previous studies of neural population codes and reviewed below, are known to have different impacts on information about the task (Averbeck and Lee, 2006; Averbeck et al., 2006; Ince et al., 2010).

To separate out the contribution of task modulation and of variability not attributable to task-to-task differences, it is useful to characterize the activation of each synergy in each trial as "signal plus noise" (Gawne and Richmond, 1993; Panzeri et al., 1999a; Averbeck et al., 2006), where we refer as the "signal" the trial-averaged synergy activation coefficients for each task and took as the "noise" the trial-by-trial fluctuations of the activation response around their averaged across trials at fixed task. We stress that such "noise" does not necessarily reflect only noise in the real sense, but comprises all types of variations at fixed task, which may well include the effect of various types of potentially important contributions such as modulations arising from variations across trials of the movement kinematics.

We performed a linear analysis of correlations across synergies of both the signal and the noise, as follows. The correlation of the averaged (across all trials to the same task) synergy activation coefficients across different tasks of two given synergies are called "signal correlations" (Gawne and Richmond, 1993; Panzeri et al., 1999a; Averbeck et al., 2006) because they are entirely attributable to task-to-task variations. The signal correlation coefficient was computed, for each synergy pair and channel, as the Pearson correlation across stimuli of the trial-averaged responses. Positive values indicate that the two synergies have similar task preference, whereas a zero value indicates that the two synergies have a radically different task tuning.

Correlations manifested as covariations of the trial-by-trial fluctuation around the mean response to the task are called "noise correlations" (Gawne and Richmond, 1993; Panzeri et al., 1999a; Averbeck et al., 2006). Since these noise covariations are measured at fixed task, they ignore all effects attributable to common task-to-task variations. To quantify the strength of noise correlations, we computed the Pearson correlation coefficient (across trials at fixed task) of the trial-average-subtracted synergy coefficients. This quantifies the correlations of the variations around the mean at each trial and task. Positive values of noise correlation mean that when the activation of one synergy fluctuates over its mean values, the activation of the other synergy is also more likely to do so.

The division in signal and noise correlation is important because, as we shall see below, they have a different impact on information about tasks.

MEASURING HOW CORRELATIONS BETWEEN SYNERGY ACTIVATIONS AFFECT TASK-DISCRIMINATING INFORMATION

After having defined correlations, we proceed to present a methodology for characterizing how they affect the total task information carried by the set of synergies. In other words, we aim at comparing the information available in the set of synergies including correlations between them [denoted$I$, and defined in Equation (3)] with the information that would be available if correlations were absent (Hatsopoulos et al., 1998; Nirenberg and Latham, 1998; Panzeri et al., 1999a, 2010; Golledge et al., 2003; Schneidman et al., 2003; Ince et al., 2010). The former is simply computed as described above on the original data, which are made of a combination of synergy coefficients simultaneously acquired in each trial and thus contain trial-to-trial correlation between synergy activation coefficients. The information in absence of correlations can be denoted as $I_{\text{ind}}(T; T^P)$, the "ind" subscript indicating that it is built from data that are made to be distributed independently at fixed task. $I_{\text{ind}}(T; T^P)$ can be computed again with the procedure described above, but applying it to combinations of synergy coefficients obtained after "shuffling" the data at fixed task, i.e., combining synergy values into non-simultaneous arrays each taken (randomly and without replacement) from different trials in which task $t$was performed (Ince et al., 2010; Panzeri et al., 2010). This shuffling preserves the marginal distributions of the activation of each synergy, and only changes the distribution of their joint observations. All subsequent decoding and information analysis were performed on the shuffled data, and then information results were averaged over the outcome of 50 independent random shufflings. Note that shuffling is done both on the test and training data for the decoder, thus in this way the effect of correlations is removed from both the decision boundaries determined by the decoder (using the training data) and the actual data to be decoded (test data). In the following, for brevity we will denote $I_{\text{ind}}(T; T^P)$ simply as I_{ind}.

From the theoretical point of view, correlations between synergy coefficients can either increase (i.e., $I > I_{\text{ind}}$) or decrease (i.e., $I < I_{\text{ind}}$) information with respect to the case in which their marginal distributions are the same but there is no correlation (Pola et al., 2003). If noise correlations increase the information carried by the muscle synergies, one may speculate that correlations between synergy activations may be useful in describing the salient task-to-task variations of muscle activation patterns. Whether or not correlations increase or decrease the information depends on several factors (Oram et al., 1998; Panzeri et al., 1999a; Averbeck et al., 2006). The first is the stimulus modulation of the strength of noise correlation: strongly task modulated correlation tend to increase the information, because their task-to-task modulation tends to further pull apart task-conditional distributions of joint synergy activations (Panzeri et al., 1999a; Pola et al., 2003). The second

is the interplay between the sign of signal and noise correlations. If signal and noise correlation have opposite signs, noise correlations increase task discriminability compared to what it would be if noise correlations were zero because in such case they tend to pull apart task-specific joint distributions (Oram et al., 1998; Abbott and Dayan, 1999). If, instead, noise and signal correlations have the same sign, then noise correlations decrease information, and task are less discriminable than the zero noise correlation case. For intuitive illustration of these effects, see **Figure 2**.

GENERATION OF SIMULATED EMG DATA

To investigate whether the synergy extraction algorithm used (NMF) affects the correlational structure of the identified synergies, we tested it on EMG data generated from muscle synergies with known task-dependent correlations. To this end, we simulated EMG data from synchronous synergies using the model introduced in Delis et al. (2013). Briefly, the data simulated the activation of 10 muscles used for executing 50 repetitions of each one of 2 motor tasks (T1 and T2). To execute each motor task, the first synergy was activated by a scalar coefficient drawn from a uniform distribution in the [0,1] interval. The activation coefficients of the second synergy were correlated with the ones of the first synergy with a correlation coefficients r_1 for task T1 and r_2 for task T2 respectively. We varied the levels and signs of r_1 and r_2 as shown in **Table 1** to generate four different datasets and ran the synergy extraction 50 times for each dataset.

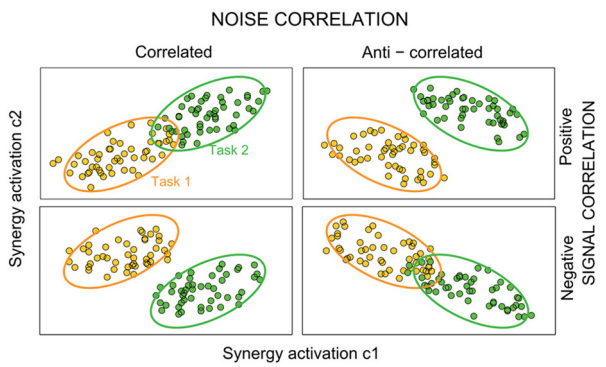

FIGURE 2 | The effect of interplay of signal and noise correlations between synergies on task information. Each panelsketches joint distributions of activations of two hypothetical synergiesduring two different tasks (data for task one and two are plotted in orange and green color, respectively). The dots represent a hypothetical scatterplot from single-trial activations to the given task, and each ellipse denotes 95% confidence limits. In the upper panel, there is positive signal correlation (i.e., individual synergy activations to each task are positive correlated), whereas in the lower panels there is negative signal correlation. Positive noise correlations correspond to ellipses aligned along the diagonal. The more the ellipses are elongated, the stronger the noise correlation. The sign of noise correlations between the joint responses differs across columns of this figure (noise correlation is positive in the left column and negative in the right column). In this figure, noise correlations are task independent—equally strong across stimuli (all the ellipses within a panel have the same elongation). In general, if noise and signal correlation have opposite signs, the effect of correlations increases the information about tasks, because the joint response probabilities to each task become more separated. If instead noise and signal correlation have the same sign, tasks are less discriminable.

EXPERIMENTAL PROCEDURES

To test the methodology presented above and gain more insights about its potential usefulness, we applied it to physiological EMG data recorded in an experiment that has been presented before (Delis et al., 2013). In brief, the experimental dataset that will be used throughout the Results Section was composed of the EMG activity recorded from nine upper body and arm muscles during execution of arm pointing movements in the horizontal plane (see for a detailed description). Four participants were asked to perform center-out (forward, denoted by fwd) and out-center (backward, denoted by bwd) one-shot point-to-point movements between a central location (P0) and four peripheral locations (P1-P2-P3-P4) evenly spaced along a circle. In total, the experimental protocol specified 4 targets × 2 directions = 8 distinct motor tasks denoted by T1, T2, …, T8. Each task was composed of 40 trials. Such a relatively high number of repetitions of each task was useful for evaluating the impact of trial-to-trial variability on the combination of muscle activation patterns.

Body kinematics was recorded by means of a Vicon (Oxford, UK) motion capture system with a sampling rate of 100 Hz. The kinematics data were low-pass filtered (Butterworth filter, cut-off frequency of 20 Hz) and numerically differentiated to compute tangential velocity and acceleration. For each movement, we measured movement onset time, movement end time, maximum speed, maximum acceleration and their times of occurrence. Movement onset and movement end were identified as the times in which the velocity profile of the fingertip superseded 5% of its maximum. Subjects performed all motor tasks at a variety of speeds ranging from normal to very fast. For example, movement durations for subject AK ranged from 182 ms to 651 ms. Across subjects, the mean movement duration varied from 370 ms to 560 ms.

To identify muscle synergies from these data, we used the time course of EMG activity of all recorded muscles in all individual trials for each task.

RESULTS

In this section, we illustrate the application of our method to muscle synergies identified from the EMG data recorded during the performance of point-to-point reaching movements in

Table 1 | Correlation coefficients of the original (left columns) and the reconstructed (right columns) activations of the two simulated synergies for tasks T1 (r_1) and T2 (r_2).

Original		Reconstructed	
r_1	r_2	r_1	r_2
0.77	0.64	0.62 ± 0.06	0.42 ± 0.08
−0.82	−0.43	-0.78 ± 0.01	-0.42 ± 0.02
0.70	−0.74	0.68 ± 0.01	-0.73 ± 0.01
0.79	0.10	0.69 ± 0.05	-0.08 ± 0.08

different directions in the horizontal plane. We first present extensive results of our analysis applied to the synchronous synergies of all subjects and then refer briefly to its application to the time-varying synergies.

IMPACT OF THE SYNERGY EXTRACTION ALGORITHM ON CORRELATIONS

Before applying our methodology to experimental data, we tested the ability of the NMF algorithm to identify correctly the correlational structure in the synergy space. Thus, we simulated EMG data from synergies with known correlations (see Materials and Methods) and checked whether the output of the NMF algorithm represented reliably the correlations that were present in the underlying synergies. An illustration of the impact of synergy extraction on the correlations between synergy activations is shown in **Figure 3**. In this case, the original activations of the two synergies are highly positively correlated for both tasks considered (**Figure 3A**). The NMF algorithm identified correctly the two synergies as well as the positive noise correlations between their activation coefficients (**Figure 3B**). However, the strength of noise correlations was slightly underestimated by NMF.

We then investigated what happened when simulating data with different levels of either positive or negative correlations between the synergy activations. The results are summarized in **Table 1**. In all cases, the NMF algorithm recovered the original synergies and the sign and strength of the signal and noise correlations between the activation coefficients. The signal correlations were reconstructed accurately in all cases ($p > 0.05$, t-test), whereas the reconstructed noise correlations were in general slightly but significantly ($p < 0.05$, t-test) lower compared to the original activations (see **Table 1**). In sum, the application of NMF to our simulated data estimated correctly signal correlation and underestimated slightly noise correlation among the activation coefficients of the extracted synergies.

MUSCLE SYNERGY IDENTIFICATION AND TASK MODULATION

We extracted synchronous muscle synergies from the recorded and pre-processed EMG data and used our information-based methodology to identify the smallest synergy sets that explain, for each subject, all task-discriminating information in the synergy space. In brief, the method first computes the information about task carried by each synergy; then computes the information from a set of synergies starting with the most informative ones and then including other synergies until they stop providing additional information. Since this selection is done using simultaneous (non-shuffled data), this set of synergies contains all information about task that can be extracted from the EMG data, including the information that is transmitted by correlations among synergy activations. Considering synergies belonging to this set (rather than for example including other synergies that explain some variance in the data but do not add any additional task discriminability) ensures that we can work on a compact set that yet contains all relevant variables for task discrimination.

Results of this synergy selection using this information criterion were very similar to the synergy selection that we obtained in a recent study (Delis et al., 2013) on the dataset using a slightly different and slightly less powerful criterion (we considered only percentage of correct decoding—rather than Shannon information—as the task discriminability metric in the above procedure). We will therefore present the selected synergy sets briefly and we refer to Delis et al. (2013) for more details. We found (**Figure 1**) that our method selected four synergies for two subjects (AK, ES) and three for the other two (AM, AB)- **Figure 1C**. These synergies not only carried all information about differences across tasks but also explained a high percentage of the variance of the recorded EMG data (see VAF curves in **Figure 1C**). Most of the extracted synergies were highly similar across subjects and each one had a distinct functional role in movement execution (**Figure 1A**). S1 activated mainly muscles flexing the shoulder, S2 consisted mainly of muscles extending the elbow, S3 had high activations for elbow flexors and S4 activated

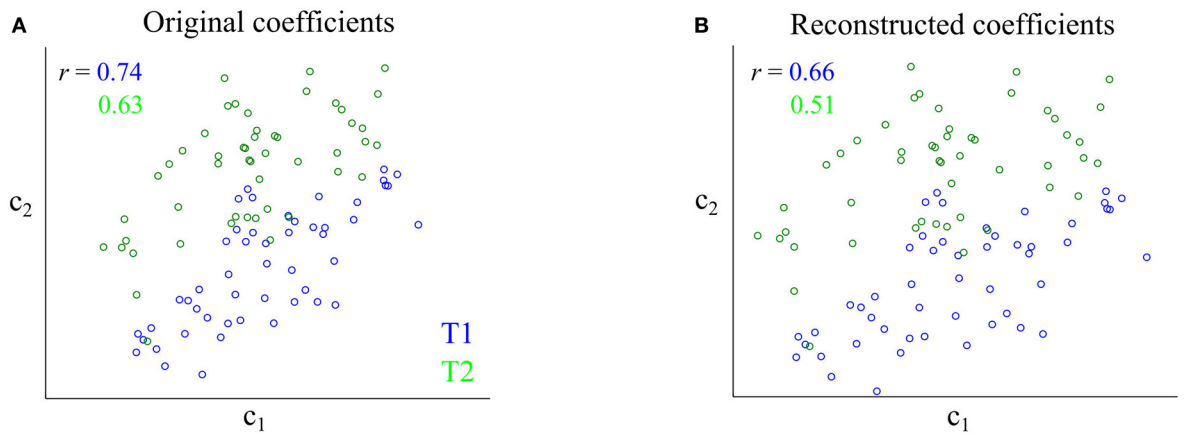

FIGURE 3 | Impact of synergy extraction using NMF on the correlations between synergy activations. (A) Scatterplot of the original activations of the two simulated synergies for two tasks (T1 and T2). **(B)** Scatterplot of the activations of the two synergies as identified by the NMF algorithm. The r values report correlation coefficients at fixed task. Noise correlations are slightly weaker after application of NMF to the data.

highly the shoulder extensors. The results were relatively robust across subjects: three of the four synergies (S1, S2, S3) were identified in all subjects and the fourth (S2) was present in two of them (AK, ES). In the other two subjects, the elbow extensors were activated by other synergies. By examining the trial-averaged synergy activations (**Figure 1B**), we observe that all synergies were shared across the eight motor tasks but their activation levels differed, which led to a high task-discrimination power in the muscle synergy space. Task modulations of individual synergies were robust across subjects, indicating a consistent mapping between synergy activations and task identification.

THE INTERPLAY OF SIGNAL AND NOISE CORRELATIONS AND ITS EFFECT ON TASK-DISCRIMINATING INFORMATION

The previous section considered the tuning of individual synergy coefficients to task. We next wanted to investigate the nature of the joint (rather than the marginal) distributions of synergy coefficients across trials. In other words, we asked if the activation of any given synergy depended only in the task or also on the particular level of activations of other synergies in the same trial. We also asked whether single-trial correlations between synergy activations may affect task discriminability.

To gain more insights into trial-to-trial variations of synergy activations, we first illustrated scatter plots of the integrals of the single-trial activation coefficients for one pair of synchronous synergies (S1–S3). In **Figure 4A**, different tasks are color-coded to show the distribution of synergy activations at fixed task. Colored straight lines indicate the principal axis of dependence and the reported values correspond to the correlation coefficient for each task. Positive noise correlations are reflected in elliptic distributions aligned along the diagonal. The more the ellipses are elongated, the stronger the noise correlation.

The strength of noise correlations between synergy activations varied significantly depending on the task. For example, activations of the S1–S3 synergy pair were strongly positively correlated for the out-center tasks (T5-T6-T7-T8), but they were almost uncorrelated for the center-out tasks T1-T2-T3-T5 (**Figure 4A**).This finding was robust across all four subjects. Thus, these two synergies were differentially coupled across tasks, suggesting that they constitute a functional pair whose single-trial interactions are relevant for the performance of a subset of motor tasks. Theoretical studies demonstrate that the modulation of correlations across different experimental correlates can only increase the information carried about the external

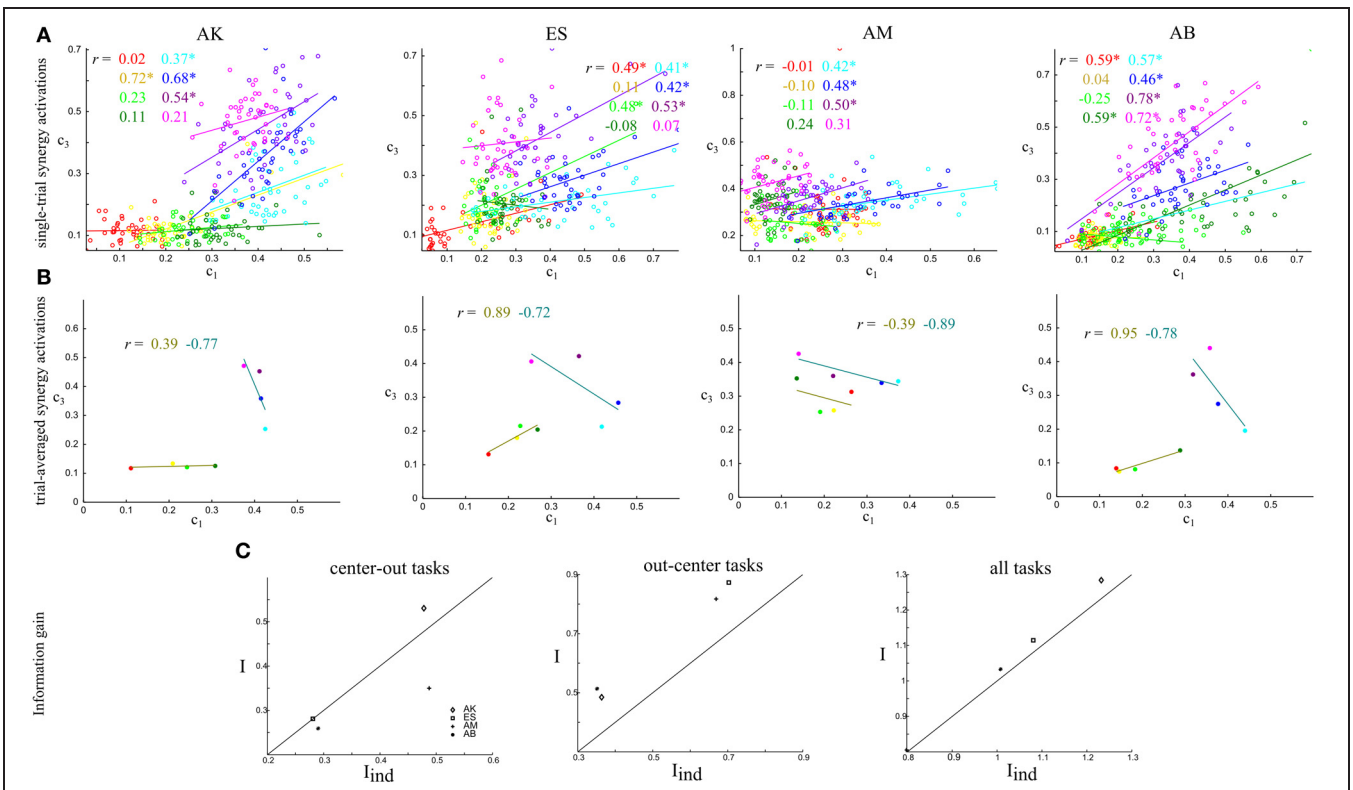

FIGURE 4 | Quantifying noise and signal correlations between the activations of synergies S1–S3, and assessing their impact on information about the task. (A) Scatterplots of the integral of the single-trial activations of synergies S1–S3 across the eight tasks performed. Each one of the four panels corresponds to the data of one subject. Different colors indicate different tasks and the straight lines are the best-fit lines for the distribution of points for each task. The *r* values report correlation coefficients and the * denotes statistical significance at $p < 0.05$. **(B)** Scatterplots of the task-averaged activations of synergies S1–S3. The two straight lines are the best-fit lines for the distribution of points for the center-out and out-center tasks respectively. Conventions are the same as in **(A)**. **(C)** Comparison of the information carried by the activations of synergies S1–S3 when taking into account correlations (I) and when ignoring them (I_{ind}). The scatterplots show I vs. I_{ind} across subjects. We plot the 45°-slope line for comparison purposes. Left: Comparison of information about the center-out tasks. Middle: Comparison of information about the out-center tasks. Right: Comparison of information about all tasks.

correlates, with respect to the case of no correlation or non-modulated correlations (Panzeri et al., 1999a; Pola et al., 2003). These theoretical considerations suggest that the observed task modulation of noise correlations of synergy pairs increase the task discriminability.

To evaluate further the impact that noise correlations may have on the information carried by this pair of synergies, we also examined their signal correlation. As discussed in Materials and Methods, signal correlations of sign opposite to that of noise correlations are best suited to increase task information (**Figure 2**). We considered separately signal correlations between out-center and center-out tasks, as they seemed to give a different pattern of correlations. The joint distribution of the trial-averaged synergy activations across out-center tasks of synergiesS1 and S3 shows that signal correlation was negative robustly across subjects (**Figure 4B**). In other words, out-center tasks that elicited on average a higher activation of synergy S1 for a subgroup of tasks tended to elicit a lower average activation for synergy S3 (**Figure 4B**). Taking into account that noise correlations for center-out tasks were consistently positive, we expected a significant increase of information about center-out tasks due to correlation. We verified this by comparing the amount of information about center-out tasks that can be obtained by observing S1 and S3 simultaneously to the information I_{ind} obtained from data shuffled by pairing S1 and S3 activations from randomly selected trials to the same task. We remind that, while I contains all information carried by synergy coefficients, including the effect of their correlations, I_{ind} is computed from data manipulated to preserve the same marginal distributions of each synergy but without any correlation. Indeed, we found (**Figure 4C** middle) that the information carried by S1 and S3 about out-center tasks was, for each subject, significantly higher ($22.5 \pm 1.5\%$, paired t-test, $p < 0.01$) than the information I_{ind} that neglected the effect of correlations. This suggests that correlations among such synergies enhance the amount of discriminability between out-center tasks.

We then considered signal and noise correlations of S1 and S3 activations among center-out tasks. For the center-out tasks the sign and strength of signal correlations varied across subjects being mostly positive and in general lower in magnitude than the signal correlation among out-center tasks. Hence, we expected the effect of correlations between S1 and S3 on information about center-out tasks to be lower than the effect on out-center tasks. Indeed, by computing the information carried by these two synergies when correlations are taken into account and comparing it with that of the "independent" model (i.e., when we remove noise correlations by shuffling), we found that correlations did not contribute much to the discrimination of the center-out tasks (**Figure 4C** left). This means that noise correlations between S1 and S3 have a positive effect on the identification of the out-center tasks, but essentially no effect for the center-out ones. Over all tasks, there was a significant increase of $4 \pm 0.5\%$ (paired t-test, $p < 0.05$) in the information about all tasks carried by the activation of S1 and S3 due to correlation between S1 and S3 (**Figure 4C** right).

To gain more insights into the impact of correlations on task discrimination, we illustrated graphically the decoding procedure for these two synergies and the four out-center tasks using data from one subject (AB). **Figure 5A** shows the integral of activations of S1 and S3 when correlations were present (**Figure 5A**) and when they were removed by shuffling (**Figure 5B**). In **Figure 5**, the QDA determined the decision boundaries for classifying the trials to the motor task performed, and as a result, separated the 2-dimensional spaces into 4 regions, one for each task. Each point is assigned to the task represented by the colored region on which it lies. The presence of noise correlations resulted in elliptic distributions of the synergy activations at fixed task, which were identified well by the QDA algorithm (**Figure 5A**).

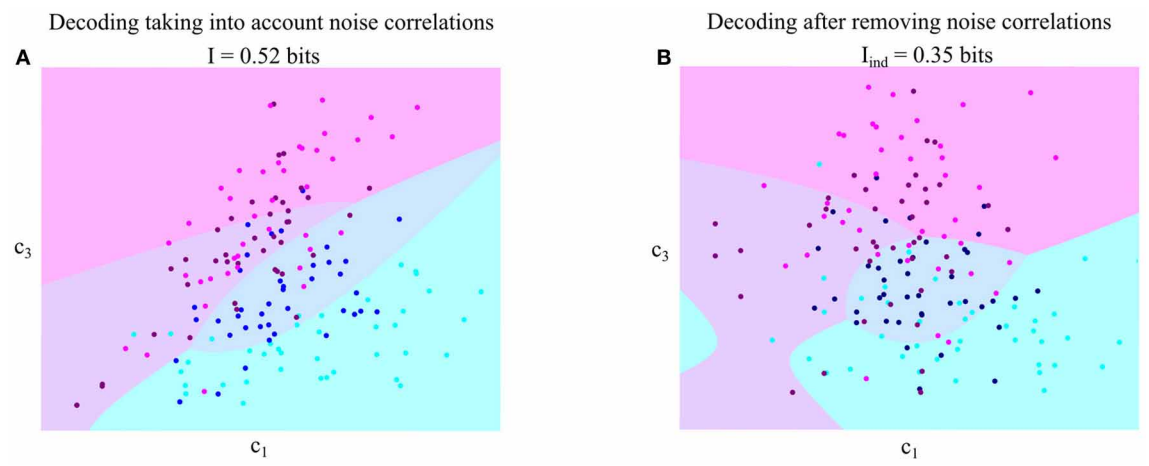

FIGURE 5 | Illustration of the effect upon decision boundaries and joint synergies activation distributions of the removal of noise correlations in task discrimination. Decoding the four out-center motor tasks (T5-T6-T7-T8) using synergies' S1–S3 activation coefficients taking into account correlations **(A)** or after removing them **(B)**. For a given trial to be decoded, the activation coefficients of the synergies are represented as a point in the 2-dimensional space. The color of each point indicates the actual task which this trial corresponds to. The quadratic discriminant algorithm has divided the space into four regions, one for each motor task. The trial is assigned to the task indicated by the color of the region on which the point lies.

Thus, 57% of the trials were correctly decoded and 0.52 bits of information about the task were carried by the co-activation of these two synergies. On the contrary, after eliminating correlations, the distributions of data points were more circular which led to a higher overlap between different tasks and, as a result, to decreased decoding performance (52%) and information (0.35 bits), as shown in **Figure 5B**.

Following this, we investigated how these patterns of signal and noise correlations generalized to other synergy pairs. We found (**Figure 6**) that the synergy pair S2–S4 exhibited a pattern of positive noise and negative signal correlations for the center-out tasks (but not for the out-center tasks). This finding was true for both subjects (AK, ES) for whom we detected four synergies describing all the task related information. We quantified the information gain also in this case and found that information about the task increased by 17% on average when correlations were kept in the analysis.

For all other synergy pairs, noise correlations were mostly weak ($r < 0.35$) and non-significant. The few cases of strong noise correlations were not robustly found across subjects and/or tasks. Regarding signal correlations, activations of synergies S3–S4 were robustly negatively correlated across all eight tasks considered ($r = -0.80$ on average) (as can also be observed by their task-tuning curves in **Figure 2**) but did not show strong noise correlations at fixed task ($r = 0.14$ on average).

Finally, we evaluated quantitatively the contribution of correlations between all synergies explaining task-to-task differences for the four recorded datasets. When considering only the center-out tasks, noise correlations had a slightly detrimental effect on task-discriminating information coding for the two subjects that used three synergies to perform the tasks but contributed positively for the other two subjects (**Figure 7A**). Across subjects, the average information increase when considering correlations was $11 \pm 5.5\%$ but the increase was not significant at the population level (paired t-test, $p > 0.1$). For out-center tasks, there was a significant information gain of $11 \pm 2.5\%$ (paired t-test, $p < 0.1$) when including correlations across all four subjects (**Figure 7B**). We should also note that task discrimination of out-center tasks was poorer than for the center-out for all datasets. Thus, the presence of noise correlations could play a role in improving task discriminability in cases where confusions between tasks are more likely. Overall, the presence of noise correlations resulted in a significant increase of $9 \pm 1.5\%$ (paired t-test, $p < 0.05$) in the total task-discriminating information that was present in the muscle synergy decompositions (**Figure 7C**).

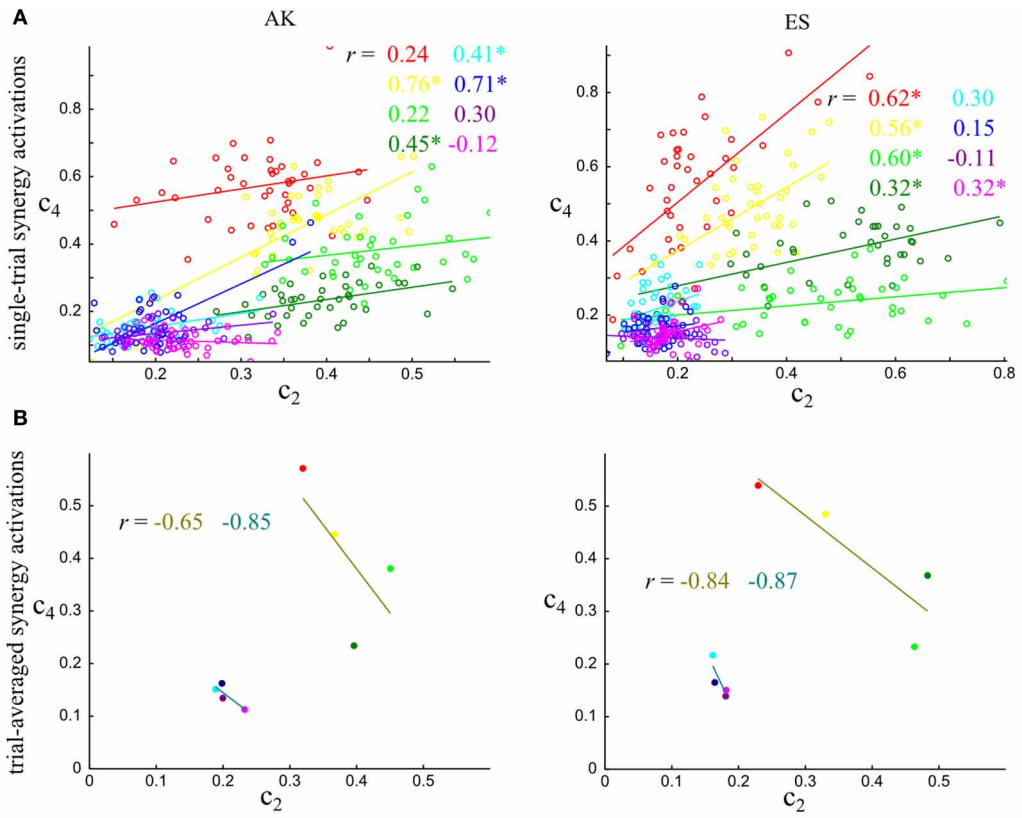

FIGURE 6 | Quantifying noise and signal correlations between the activations of synergies S2–S4, and assessing their impact on information about the task. (A) Scatterplots of the integral of the single-trial activations of synergies S2–S4 across the eight tasks performed. **(B)** Scatterplots of the task-averaged activations of synergies S2–S4. The r values report correlation coefficients and the * denotes statistical significance at $p < 0.05$. Conventions are the same as in **Figure 4**.

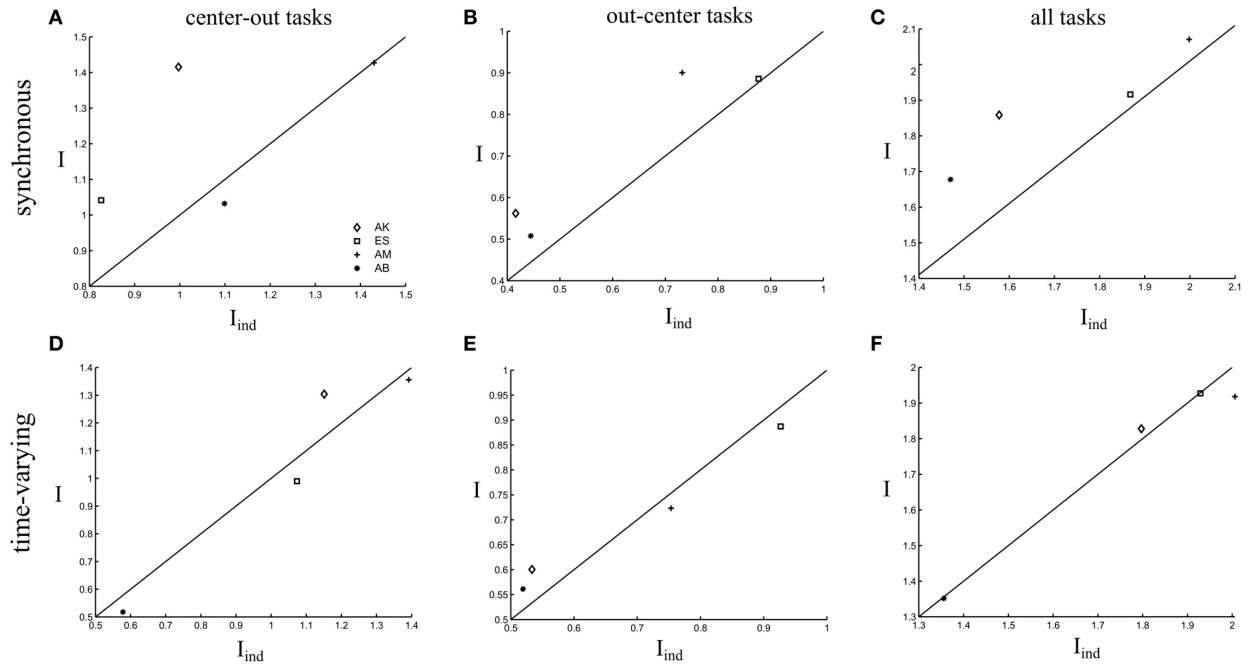

FIGURE 7 | Comparison of the total information carried by the activations of all synergies when taking into account correlations (*I*) and when ignoring them (I_{ind}). The scatterplots show the information values in the $I - I_{ind}$ space for all subjects. We plot the 45°-slope line for comparison purposes. **(A,D)** Comparison of information about the center-out tasks. **(B,E)** Comparison of information about the out-center tasks. **(C,F)** Comparison of information about all tasks.

These findings suggest that single-trial correlations between muscle synergy activations increase task-related differences in muscle activation patterns.

DEPENDENCE OF SYNERGY CO-ACTIVATIONS ON MOVEMENT SPEED

We next asked whether noise correlations among synergy activations may in part reflect the effect of the trial-to-trial covariations of a movement parameter. To answer this, we analyzed the relationship of synergy activations with single-trial kinematic parameters of the movements, such as movement duration, maximum speed and acceleration. Interestingly, our correlation analysis revealed a significant dependence of the activations of synergies S1–S3 on the speed with which the movement was performed for all out-center tasks. **Figure 8** reports scatterplots of the activations of each one of the two synergies at fixed task with respect to maximum movement speed for one subject. These results generalize across all subjects: significant activation-speed correlations were found in 10 out of 16 cases (4 center-out tasks times 4 subjects) for synergy S1 and 11 out of 16 for synergy S3 ($p < 0.05$). Accordingly, activations of synergies S2–S4 were correlated with movement speed for the four out-center tasks for both subjects that used S2 (5/8 and 6/8with significant correlations, $p < 0.05$). Therefore, the positive synergy correlations at fixed task explain a big part of the variability in the speed with which the task was executed.

EXTENSION OF RESULTS TO TIME-VARYING SYNERGIES

Although we illustrated our methodology and discussed our findings only within the synchronous synergy framework so far, the method's applicability can be readily extended to the time-varying synergies. Here we illustrate this extension by decomposing the same dataset in time-varying rather than synchronous synergies.

We found that our synergy selection method identified the same number of time-varying synergies as the number of synchronous synergies for all the four datasets tested. **Figure 9A** shows the four time-varying synergies identified from one subject's dataset. Similar task modulations of average synergy activations were present also for this model (**Figure 9B**). Also in this case, all synergies participated in the execution of the eight motor tasks varying their activation levels in a task-dependent manner. However, when examining the impact of trial-to-trial correlations between synergies, we found weak noise correlations among the scaling coefficients activating the time-varying synergies. An illustrative example of the strength of noise correlations between time-varying synergy activations is shown in **Figures 9C,D**. To compare with the synchronous synergy case presented above, we depict scatterplots for the synergy pairs S1–S3 and S2–S4. In this case, noise correlations are non-significant for almost all tasks. Therefore, these correlations had no impact on task discrimination (they did not increase task-discriminating information, **Figure 7F**). In particular, correlations increased information about the task only in one of the four datasets for both center-out and out-center tasks, whereas they reduced or did not affect information for the other three datasets (see **Figures 7D–F**). This finding indicates that correlated activations of time-varying synergies contribute less to task identification with respect to the modulations of individual synergies.

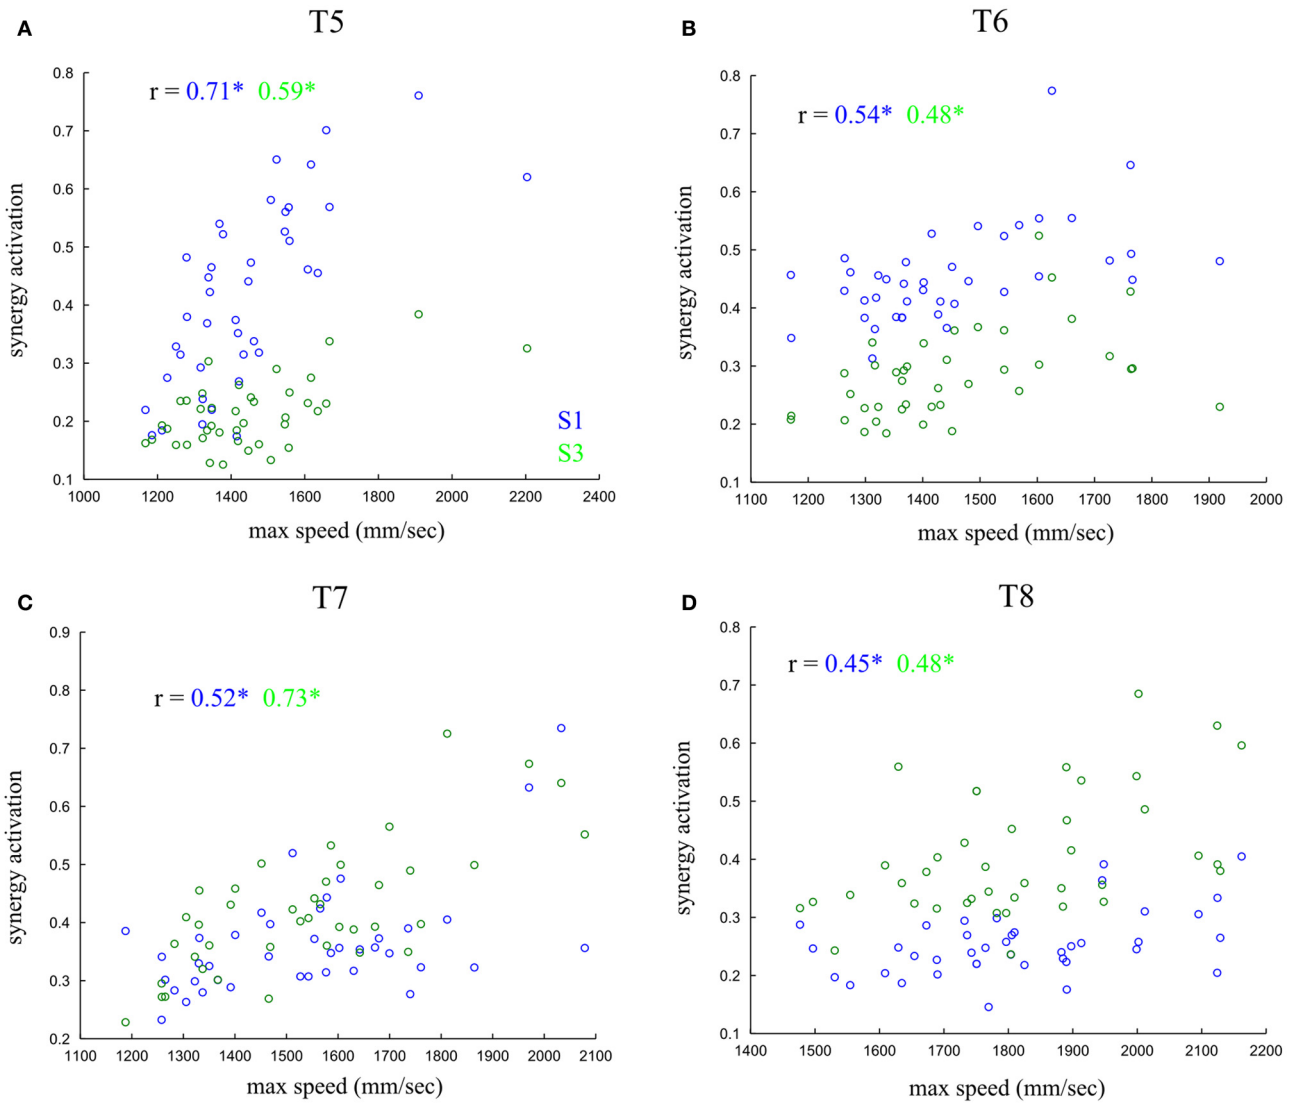

FIGURE 8 | Dependence of synergy activations on movement speed. Scatterplots of the single-trial activations of synergy S1 (blue) and S3 (green) with respect to the max movement speed in each trial at fixed task. The four panels **(A–D)** correspond to the four out-center tasks. The r values report correlation coefficients and the * denotes statistical significance at $p < 0.05$.

DISCUSSION

In this article, we extended a previously-developed single-trial task decoding formalism (Delis et al., 2013) to derive a novel methodology that evaluates quantitatively the impact of trial-to-trial correlations among muscle synergy co-activations on the task-to-task differences in patterns of muscle activation. Our aim was to suggest and test methodological ideas to answer an important question concerning task information coding in the CNS, and more precisely in the context of neuromuscular synergies: Do correlations between synergy activations play a role indiscriminating motor tasks?

METHODOLOGICAL DEVELOPMENTS

The methodological approach that we suggested is derived from the literature in neural population coding, in which the problem of the role of trial-to-trial correlations among groups of simultaneously active neurons have been hotly investigated (Averbeck and Lee, 2006; Averbeck et al., 2006; Ecker et al., 2011). The approaches have been useful both to clarify the conditions in which correlation may increase or decrease information (Oram et al., 1998; Panzeri et al., 1999a; Schneidman et al., 2003; Latham and Nirenberg, 2005; Averbeck et al., 2006; Oizumi et al., 2010) and to indicate the potentially large impact of correlation on the accuracy of population codes especially when considering large number of cells (Zohary et al., 1994; Salinas and Sejnowski, 2001; Averbeck et al., 2006; Schneidman et al., 2006; Pillow et al., 2008; Ince et al., 2010; Oizumi et al., 2011). This has led several authors to propose that the ability of cortical circuits to modify, regulate or tune their correlations is an important feature of cortical functional organization (Salinas and Sejnowski, 2001; Ecker et al., 2010; Kumar et al., 2010; Renart et al., 2010).

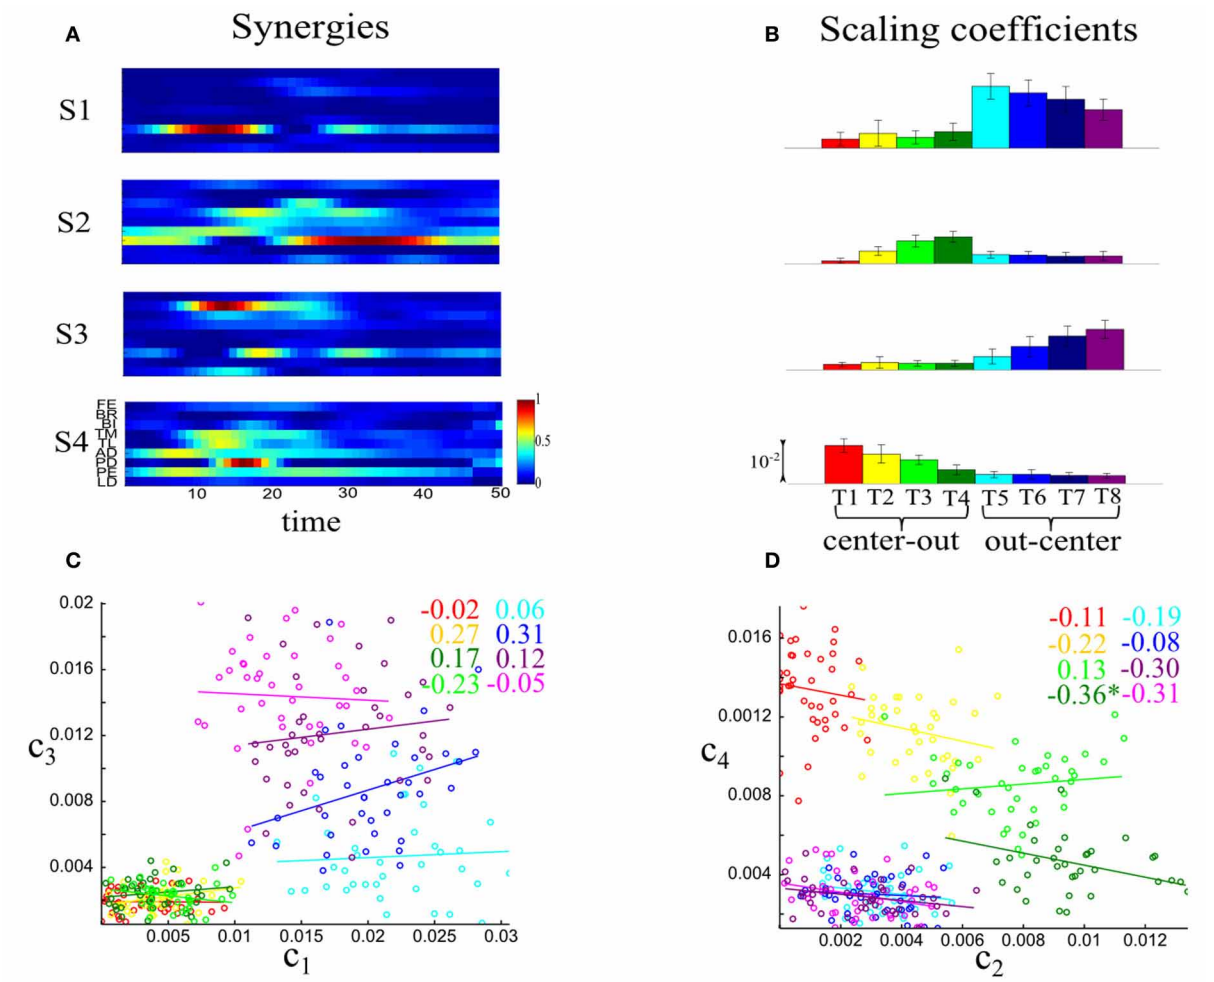

FIGURE 9 | Quantifying noise correlations between time-varying synergy activations. (A) The four time-varying synergies obtained from the experimental data of one subject (AK) as four matrices each representing the activity of nine shoulder and elbow muscles over 50 time steps. **(B)** Histograms of the coefficients activating the four synergies across the eight motor tasks performed. Histograms are plotted as means ± SDs across all trials to the given task. **(C)** Scatterplot of the activation coefficients of synergies S1–S3 across the eight tasks performed. **(D)** Scatterplot of the activation coefficients of synergies S2–S4 across the eight tasks performed. The reported values are correlation coefficients and the * denotes statistical significance at $p < 0.05$. Overall, noise correlations are much weaker than for the synchronous synergy activations.

In this article we discussed how to adapt this approach to EMG recordings. From the methodological point of view, we needed to make some progress before being able to adapt previous neural approaches to EMG recordings. First, we needed a method to select correctly the number of synergies to be used, which is one of the free parameters of the analysis. Here, we took the approach of selecting this number as to give the smallest possible set of variables that carries all task-discriminating information. Second, the sampling issues in computing information are more severe in EMG experiments than in most experiments used to study neural coding in peripheral system or anaesthetized animals, and synergy activations are analog variables rather than yes/no variables (like for spiking neurons). Here we addressed these problems by using an intermediate "decoding" step to project the relatively high-dimensional space of all synergy activations into the task space, and we computed the effect of correlations using data manipulations to destroy them rather than computing their effect with analytical techniques (Panzeri et al., 1999a; Pola et al., 2003). The approach was overall robust and allowed to study, with realistic datasets, the effect of correlation on the task information on decompositions of arrays of up to nine muscles. We feel that the coupling of NMF procedures with information algorithms presented here could be a valuable tool not only for evaluation of muscle synergies, but also for the analysis of large scale simultaneous recordings of neural activity, as it combines two powerful data compression procedures to describe compactly the information content of large datasets. As such, it could be fruitful to further the progress of our understanding of the functional role of correlations among groups of neurons. Here, we used this approach to quantify, using EMGs recorded in a simple reaching task, the amount of task-discriminating information carried by trial-to-trial correlations among synergy activations. We found

that, overall, the presence of correlations between the integrated activation of synchronous synergies enhanced information significantly. Correlations among activations of synchronous synergies increased information about all tasks by 9%, and increased information about out-center reaching tasks by approximately 15%. While they may seem relatively small amounts, we must take into account that the effect of correlation might have been negative, and that this was a simple task that involved only a small set of synergies. Previously documented scaling properties of the impact of correlation of information with the number of elements in the array suggests that more complex tasks involving larger number of synergies may have larger increases of information due to correlation. All in all, these preliminary results suggest that the study of impact of correlations among synergies may be helpful in future experiments to better understand how neural drives need to interact with each other to optimize motor strategies.

ROBUSTNESS OF SYNERGY ACTIVATION CORRELATIONS TO FACTORIZATION ERRORS

The applicability of the proposed methodology to evaluate the role of correlations in synergy activations relies on the ability of the synergy extraction algorithms (NMF here) to correctly estimate the correlational structure of the underlying muscle synergy activations. We evaluated this issue using simulated data with known correlations between synergy activations and found that the output of the NMF algorithm recovers correctly the sign and strength of signal correlations and underestimates only slightly the strength of noise correlations. It is interesting to consider the effect of these small errors in correlation estimation introduced by the NMF on estimating the impact of correlation activation in task discriminating information. In the EMG dataset that we analyzed, the increase in task-discriminating information because of correlation was due to the combination of negative signal plus positive noise correlation. Hence, the effect of the algorithm's artifact (slight reduction in noise correlations only) would go in the direction of slightly reducing the effect of correlation on task-discriminating information with respect to the true value. Thus, the conclusion that correlations between synergy activation coefficients increase task discriminating information seems a genuine property of the data that cannot be attributed to artifacts in correlation estimation due to the NMF decomposition.

POTENTIAL ORIGINS OF NOISE CORRELATIONS

It is tempting to speculate that noise correlations may emerge as a result of the mechanisms implemented by the CNS to guarantee reliable movement reproducibility. For example, correlations among synergies coordinate their relative activation levels in order to stabilize limb movement against the detrimental effect of motor noise which leads to trial-by-trial variability in the neural motor commands. A possible way to achieve this is by using positive noise correlations to regulate the level of muscle co-contraction during movement execution. Put simply, by increasing activation of two muscle groups simultaneously, many muscles are highly activated leading to an increase of the stiffness of the moving limb which enhances movement stability. An example of such case is given in **Figure 4A**. Synergies S1 and S3 are comprised of shoulder flexors and elbow flexors respectively. Their positive noise correlations during performance of tasks T5-T6-T7-T8 (combined with the negative signal similarity) result in the co-contraction of these muscles which enhances task discrimination. As these two groups of muscles act on different joints, their positive noise correlations may suggest a cross-joint coupling of synergy activations to achieve specific task goals. In other words, such anatomical muscle groups may be coupled together to form new functional muscle synergies for some subsets of tasks. Alternatively, because of the vicinity of these muscle groups, we could think that these positive correlations may result from crosstalk artifacts. However, presence of crosstalk would imply strongly positive correlations for all tasks performed, which is not the case here. Instead, the different levels of muscle co-contraction may serve as a "tag" for the target reached in each trial. These differences might be explained by the inertial properties of the arm, for which some movement directions require less muscle effort than others (Gordon et al., 1994).

We also showed that a large part of the synergy co-variations at fixed task explained the variability in the speed with which different trials were performed. Since the task (pointing to a target) did not impose movement speed, the variability in the muscle synergy activations that captures trial-to trial speed variations can be considered as irrelevant for the set of tasks considered (Scholz and Schoner, 1999). Hence, a large part of the variability in the muscle synergy space may correspond to these redundant (task-irrelevant) dimensions in task space (Todorov and Jordan, 2002; Todorov et al., 2005). This interpretation relates closely to the "uncontrolled manifold" (UCM) concept (Scholz and Schoner, 1999) and its application to muscle synergies (Krishnamoorthy et al., 2003). In broad agreement with the UCM hypothesis, our results show that the noise correlation between synergy activations accounts in part for the trial-to-trial variability of a task-irrelevant parameter, as is movement speed in our experiment. As such, our methodology may contribute to answer questions related to the identification of hypothesized task performance variable. Whereas applying the UCM concept to EMG data is not straightforward because partitioning the synergy space variance into components that affect and do not affect the task variable is tricky [in Krishnamoorthy et al. (2003), the method relies on the computation of the Jacobean of the mapping from synergy activations to task variable and its null-space], our method provides a principled and robust information-theoretic approach to address the problem. Extending our method to actually handle the case of task-execution variables such as the reach endpoint coordinates is a future and promising line of research.

Other neurophysiological evidence suggests that noise correlations between synergy activations may arise during execution of correcting movements. Corrections in reaching movements driven by feedback mechanisms have been shown to be described by the superposition of the muscle synergies that are used for unperturbed reaching (D'Avella et al., 2011). Although trial-to-trial variability was not considered in this study, synergy superposition may reflect robust muscle synergy correlations in single trials that are identified by the synergy extraction algorithm as invariant patterns. Thus, the open-loop muscle synergies may be coupled to form new muscle patterns that are appropriate for the accomplishment of the corrected motor task. Further support to

this consideration comes from a study showing that sensory feedback can couple two independently-organized synergies (or uncouple two centrally-coupled synergies) by modulating activation of each synergy independently (Cheung et al., 2005). These findings suggest that synergy activations may be coordinated in single trials by central mechanisms.

CORRELATIONS IN SYNCHRONOUS vs. TIME-VARYING SYNERGY ACTIVATIONS

Our results indicate a more important role of noise correlations in the synchronous synergy model compared to the time-varying synergies. Intuitively, this can be explained if we take into account the functionality of each type of synergies. On the one hand, synchronous synergies consist in functional groups of muscles whose activities co-vary across all tasks (Tresch et al., 2006). In our data, each one of the four synchronous synergies includes muscles that have the same functional role (either flexion or extension of the limb) and act on the same joint. As such, these groups have to be recruited simultaneously in many flexible combinations to perform a variety of motor tasks. Furthermore, recruitment of each synergy in every single trial depends crucially on the recruitment of other synergies, as muscle groups counteract or complement the activation of other muscle groups (e.g., an agonist-antagonist pair of synergies). This explains the existence of large trial-by-trial interactions between synchronous synergy activations and points out the importance of their function. On the other hand, time-varying synergies consist in spatiotemporal patterns of muscle activities that are invariant across tasks (D'Avella and Tresch, 2002; D'Avella and Bizzi, 2005). Although this formulation constitutes a very compact representation of muscle activities in single trials (2 single-trial parameters per synergy), it does not allow much flexibility in reusing muscle synergies across tasks because of the merging of spatial and temporal properties in one unique pattern. This results in the identification of more "task-specific" synergies that participate in the execution of only a subset of tasks. More importantly, activation of only one time-varying synergy can be sufficient for the execution of a task without rendering necessary the simultaneous and interactive activation of other synergies. This is because every time-varying synergy specifies an entire muscle activity waveform for each muscle. As a result, in this framework, task differences are mainly described by the activation of different time-varying synergies and thus, task-discriminating information is carried mainly by the modulations of individual time-varying synergies. Nevertheless, these conclusions are drawn on a somewhat simple dataset, and further investigations should be performed on more complex data involving more motor tasks (also more muscles, more targets, more speeds etc.). The present study mainly aimed at establishing a systematic and principled methodology to address such questions.

A long standing hypothesis in the neuroscience community is that the central nervous system (CNS) generates the muscle activities to accomplish movements by combining a relatively small number of stereotyped patterns of muscle activations, often referred to as "muscle synergies." Different definitions of synergies have been given in the literature. The most well-known are those of synchronous, time-varying and temporal muscle synergies. Each one of them is based on a different mathematical model used to factor some EMG array recordings collected during the execution of variety of motor tasks into a well-determined spatial, temporal or spatio-temporal organization. This plurality of definitions and their separate application to complex tasks have so far complicated the comparison and interpretation of the results obtained across studies, and it has always remained unclear why and when one synergistic decomposition should be preferred to another one. By using well-understood motor tasks such as elbow flexions and extensions, we aimed in this study to clarify better what are the motor features characterized by each kind of decomposition and to assess whether, when and why one of them should be preferred to the others. We found that three temporal synergies, each one of them accounting for specific temporal phases of the movements could account for the majority of the data variation. Similar performances could be achieved by two synchronous synergies, encoding the agonist-antagonist nature of the two muscles considered, and by two time-varying muscle synergies, encoding each one a task-related feature of the elbow movements, specifically their direction. Our findings support the notion that each EMG decomposition provides a set of well-interpretable muscle synergies, identifying reduction of dimensionality in different aspects of the movements. Taken together, our findings suggest that all decompositions are not equivalent and may imply different neurophysiological substrates to be implemented.

Keywords: muscle synergies, non-negative matrix factorization, EMG, elbow rotations, dimensionality reduction, triphasic pattern

INTRODUCTION

A large amount of studies have provided in the last two decades evidence according to which the central nervous system (CNS) generates the muscle patterns necessary to achieve a desired motor behavior by combining a relatively small number of stereotyped spatial and/or temporal patterns of muscle activation, often referred to as "muscle synergies" (Bizzi et al., 2008). An appeal of this framework is that it suggests that the CNS may control movement execution through a relatively small number of degrees of freedom (dof).

Different conceptual definitions of muscle synergies have been given in the literature. These in practice translate into different mathematical models used to factor electromyographic (EMG) array recordings collected during the execution of variety of motor tasks into different kinds of temporal, spatial, or spatio-temporal organizations. Invariant temporal components (or "temporal synergies," see Ivanenko et al., 2004, 2005; Chiovetto et al., 2010, 2012; Dominici et al., 2011) are defined as temporal muscle activation profiles that can be simply scaled and summed together to reconstruct the actual activity of each

muscle. "Synchronous synergies" (Cheung et al., 2005, 2009, 2012; Ting and Macpherson, 2005; Torres-Oviedo and Ting, 2007, 2010) are stereotyped co-varying groups of muscle activations, with the EMG output specified by a temporal profile defining the timing of each synergy during the task execution. "Time-varying synergies" (d'Avella et al., 2003, 2006, 2008, 2011) are genuine spatiotemporal patterns of muscle activation, with the EMG output specified by the amplitude and time lag of the recruitment of each synergy.

Typically, previous studies about muscle synergies focused on a given decomposition that was then used to investigate potential functions of muscle synergies in complex motor tasks involving a large number of dof. Each of these decompositions has been used successfully to identify common physiologically important factors of muscle activity (Cheung et al., 2005; Ivanenko et al., 2005; d'Avella et al., 2006). The existence in the literature of multiple definitions of muscle synergies and their separate application to complex tasks complicates however the comparison and interpretation of the results obtained across studies, and it is not always clear why and when one synergistic decomposition should be preferred to another one. We propose instead here that the systematic study of the application of all these decompositions to the same and simple data set for which the mechanical action of each muscle contraction is well-known would greatly help to build intuition about the merit and functional interpretation of each synergistic decomposition. This would moreover be beneficial to the interpretation and comparison of different studies. We thus considered the extreme case of single-joint elbow movements, characterized by one kinematic dof, two antagonist muscles (biceps and triceps) and four experimental tasks (flexions and extensions along both the horizontal and vertical directions). We applied systematically decompositions into synchronous, time varying and temporal synergies of EMG data recorded during this elementary and well documented motor task (see Berardelli et al., 1996 for a review), whose biomechanical and neurophysiological bases were studied intensively (Gottlieb et al., 1995; Shapiro et al., 2005).

Our findings support the notion that each EMG decomposition provides a set of well-interpretable muscle synergies, identifying reduction of dimensionality in different aspects of the movements. Each temporal synergy indeed conveys information about a specific temporal phase of the movement (acceleration, deceleration, and stabilization). Synchronous and time-varying synergies instead encode respectively the simultaneous and coordinated actions of specific groups of muscles aiming to achieve a specific action goal and a task-related feature of the elbow movements (specifically the direction of motion). Taken together, our findings suggest that all decompositions are not equivalent and may imply different neurophysiological substrates to be implemented.

MATERIALS AND METHODS

SUBJECTS

Eight healthy right-handed subjects (7 males, 1 female, ages 29 ± 4 years, mass 74 ± 9 kg, height 1.77 ± 0.07 m), participated voluntarily to the experiments that were all performed at the Robotics, Brain and Cognitive Sciences Department at Italian Institute of Technology (IIT) in Genoa (Italy). All subjects were in good health condition and had no previous history of neuromuscular disease. The experiment conformed to the declaration of Helsinki and informed consent was obtained from all the participants according to the protocol of the ethical committee of IIT.

PROTOCOL

Subjects sat on a chair with their back straight and perpendicular to the ground. They were asked to perform one-shot 90° elbow rotations between two reference points along either a vertical and a horizontal plane (**Figure 1**). A total of four experimental conditions were thus studied (vertical flexion, VF; vertical extension, VE; horizontal flexion, HF; and horizontal extension, HE). For movements along the vertical direction, the two reference points were located in a vertical plane, placed laterally at approximately 10 cm from the subject's movement plane. To this aim, we used a wooden hollow frame containing 1.5 cm-spaced thin vertical fishing wires to which fishing leads indicating the requested fingertip initial position were attached. One reference point coincided with the subject's fingertip position in the vertical plane when the arm was completely relaxed and extended vertically with the index fingertip pointing at the ground (vertical position number 1, or VP1). The second point coincided with the subject's fingertip position in the vertical plane when, starting from VP1, the elbow was rotated of about 90° so that at the end the forearm was parallel to the ground (vertical position number 2, or VP2). The positions of the fishing leads were adjusted for each subject before the initiation of the experiment, based on the subject's upper arm and forearm lengths. For vertical elbow flexion subjects rotated the elbow so as to move their index finger from VP1 to VP2. On the contrary, during vertical elbow extension they had to move the fingertip from VP2 back to VP1. For rotation along the horizontal plane subjects sat in front of a table. One reference point on the table coincided with the horizontal location of the index fingertip when the upper-arm was kept horizontal with respect to the ground and perpendicular to the coronal plane and the forearm flexed of about 90° with respect to the upper-arm (horizontal position 1, or HP1). The second reference point coincided with the fingertip location when the whole arm was completely extended horizontally in front of the subjects and perpendicular to the coronal plane (horizontal position 2, or HP2). After that

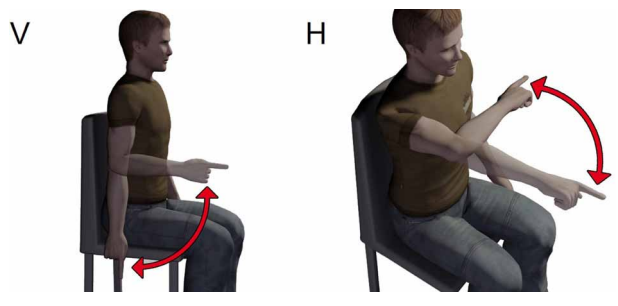

FIGURE 1 | Sketch of the experimental paradigm. Subjects sat on a chair and had to accomplish flexions or extensions of the elbow along both the vertical (V) and horizontal (H) planes.

(for each subject) HP1 and HP2 were identified, their location was marked on the table by means of two small squared pieces of colored tape. The table plane laid 10 cm below the plane of rotation of the arm, avoiding thus to disturb the accomplishment of the movement. For horizontal elbow flexion subjects had to rotate the elbow so as to move their index finger from HP1 to HP2. On the contrary, during horizontal elbow extension they had to move the fingertip from HP2 back to HP1. Subjects were always asked to perform fast movements (mean velocities and average peak velocities are reported in **Table 1** for each subject and condition). They performed 20 elbow flexion and 20 extensions for each plane orientation. During the experiment the wrist joint was frozen by means of two light and small sticks attached to the distal part of the forearm and the proximal part of the hand. At any trial repetition subjects put their index finger on the starting position. The experimenter started data acquisition and gave the "go" signal. The subjects performed the movement after the "go" signal and stopped on the target for about a second. Data acquisition stopped automatically after 2 s. At the end of the trial the subject assumed with his arm a relaxing position until the beginning of the next trial. After 20 trials subjects took a pause of about 3 min to avoid fatigue.

APPARATUS

During trials' execution kinematic data were recorded by means of a Vicon (Oxford, UK) motion capture system. Six passive markers were attached on subjects' right arm (the acromion process, lateral epicondyle of the humerus, the styloid process and the tip of the index finger) and head (external canthus of the eye and auditory meatus). EMG activity of biceps brachii (Bic) and triceps longus (Tri) was monitored by means of an Aurion (Milan, Italy) wireless EMG system. Impedance between the surface electrodes was always checked not to exceed 5 KΩ: in the case of higher values, skin was rubbed by means of an abrasive sponge in order to decrease it. EMG data were amplified (gain of 1000), band-pass filtered (10 Hz high-pass and 1 KHz low-pass) and digitized at 1000 Hz.

For each movement and subject the average velocities (± standard deviations) are reported. Averages and standard deviations were computed over all trial repetitions. The first entry of each row of the table indicates the initials of first and last name of a subject.

DATA PRE-PROCESSING

Data were analyzed off-line using customized software written in Matlab (Mathworks, Natick, MA). Kinematic data were low-pass filtered (Butterworth filter, cut-off frequency of 20 Hz). The angular displacement of the elbow was computed starting from the markers' spatial positions. Elbow angular velocity of rotation was obtained by numerical differentiation of the angular position. Mean and peak angular velocities were computed for each trial. The mean velocity was computed as the mean value of the angular velocity over the movement duration. The time instants of movement initiation (t_0) and end (t_f) were defined respectively as the instants at which the bell-shaped angular velocity profile of the elbow exceeded and dropped below 5% of its peak value. For the EMG analysis, muscle signals were full-wave rectified, normalized in amplitude with respect to their maximum value recorded across all trials and conditions and low-pass filtered once more with a zero-lag Butterworth filter (cut-off frequency 5 Hz). The filtered EMG signals relative to each trial and comprised between 100 ms before t_0 and t_f were normalized to a standard time window of 200 samples. By considering 100 ms before movement initiation we wanted to include in the analysis any kind of anticipatory activity associated with the movement. To identify specific invariant patterns characterizing the EMG activities of the different subjects, two versions of non-negative matrix factorization were applied to the low-pass filtered EMGs. The standard NMF algorithm (Lee and Seung, 1999) was used to identify both temporal components and synchronous synergies.

Temporal synergies (or temporal components)

NMF was applied to the matrix **M** of the EMG signals (size m by T, where m is the number of muscles signals and T the number of time samples), providing two matrices **U** and **C** (of dimension respectively m by Nc and Nc by T, where Nc is the number of temporal components) such that, at the time intant t, it results

$$\mathbf{M}(t) = \sum_{i=1}^{Nc} \mathbf{U}_i C_i(t) + \text{residuals} \quad (1)$$

were $\mathbf{U}_i$ indicates the *i-th* column of the matrix **U** and $C_i(t)$ the *i-th* element of the column vector $\mathbf{C}(t)$. Note the number of muscles m indicates the number of muscles recorded during one single experimental trial. When considering multiple trials the matrix **M** was obtained by concatenating vertically the matrices of the single trials.

Synchronous synergies

NMF was applied to the transpose matrix $\mathbf{M}'$ of **M**, providing thus two matrices **V** and **W** (this time of dimension respectively

T by Ns and Ns by m, where Ns is the number of synchronous synergies) such that

$$\mathbf{M}'(t) = \sum_{i=1}^{Ns} \mathrm{V}_i(t)\mathbf{W}_i + \text{residuals} \quad (2)$$

were $\mathrm{V}_i(t)$ indicates the *i-th* element of the row vector $\mathbf{V}(t)$ and $\mathbf{W}_i$ the *i-th* row of the matrix $\mathbf{W}$. Note that in (1) the *j-th* row of the matrix $\mathbf{M}$ results from the linear combination of the rows of the matrix $\mathbf{C}$ scaled by the scalar coefficients of the *j-th* row of the matrix $\mathbf{U}$. Each row of $\mathbf{C}$ therefore contains one temporal component. In (2), conversely, the *j-th* row of $\mathbf{M}'$ is obtained by combining linearly the rows of $\mathbf{W}$ scaled by the coefficients of the *j-th* row of $\mathbf{V}$. Each row of $\mathbf{W}$ therefore, of dimension 1 by Ns, represents a vector of muscle activations, i.e., a synchronous synergy. Note also that, because of the constraints imposed by NMF on parameters, all the entries of the matrices $\mathbf{U}$, $\mathbf{V}$, $\mathbf{C}$, and $\mathbf{W}$ are non-negative. Even in this case, when considering multiple trials before applying NMF the transposed of the matrixes of the single trials were concatenated vertically.

Time-varying synergies

We applied a customized version of standard NMF and that was developed by d'Avella et al. (2003) and d'Avella and Bizzi (2005). Similarly to standard NMF all the identified parameters are non-negative, but temporal shifts of the synergies are also allowed so that each column vector of $\mathbf{M}$ at the instant t is the following relationship is such that

$$\mathbf{M}(t) = \sum_{i=1}^{Nt} c_i \boldsymbol{w}_i(t - \tau_i) + \text{residuals} \quad (3)$$

where Nt is the number of time-varying synergies and the c_i and τ_i are respectively the scaling coefficient and the time delay associated the synergy $\boldsymbol{w}_i$. The algorithm by d'Avella et al. requires specifying the temporal duration of each time-varying synergy. In this study the time duration of each synergy was set, for each subject, as long as the time duration of the whole trial after time standardization (200 samples). Note that the residuals in (1), (2), and (3) decrease as the number of synergies increase. In case of multiple trials, the matrixes of the single trials were concatenated horizontally.

Selection of the number of synergies to be included in the EMG decomposition and their significance

In (1), (2), and (3) the numbers of muscle synergies (Nc, Ns, and Nt) are free parameters of the analysis that can be set arbitrarily by the experimenter. Here, it was decided to set in all the three cases the number of synergies according to a criterion based on the computation of the variance accounted for (VAF) as a function of Nc, Ns, and Nt. The VAF was defined as it follows

$$\mathrm{VAF} = 100 \cdot \left(1 - \left(\|\mathbf{M} - \mathbf{D}\|^2 / \|\mathbf{M} - \mathrm{mean}(\mathbf{M})\|^2\right)\right) \quad (4)$$

where $\mathbf{D}$ is the matrix of the reconstructed EMG obtained by using a certain number of synergies and mean() is an operator that compute a matrix of the same size of the matrix $\mathbf{M}$ and whose rows are equal point by point to the mean values of the corresponding rows of $\mathbf{M}$. The number of synergies was determined as the number of components at which the graph of the cumulative VAF presented a considerable change of slope (an "elbow") and after which the slope of the graph became constant (Ferré, 1995). The exact point of change was quantitatively determined by using a linear regression procedure already used in literature (Cheung et al., 2005, 2009; d'Avella et al., 2006; Chiovetto et al., 2010, 2012). We computed a series of linear regressions, starting from a regression on the entire cumulative VAF curve and progressively removing the smallest value of number of component from the regression interval. We then compute the mean square residual error of the different regressions and selected the number of optimal synergies the first number whose corresponding error was smaller than 10^{-3}. To minimize the probability to find local minima, we always ran NMF 25 different times on the same data set and consider as valid solution that provided the lowest reconstruction error between original and reconstructed error. To test the robustness and generality of the synergies extracted from each data set we exploited the two following cross-correlation procedures. We divided each data set in 5 parts of the same size. Since every data set consisted of the EMG activities of the Bic and Tri muscles collected during 20 repetitions of the same movement accomplished by one subject, each part consisted of the EMG activities of four trials. We then chose randomly 4 parts to use as training data set and one part as test data set. We extracted the synergies from the training data set and used them to reconstruct the activations of the test data set. We used the original and reconstructed test data sets to compute the VAF to draw the graph of the cumulative VAF. We also used the synergies extracted from each subject to reconstruct the EMG data sets of all the other subjects and assessed the level of reconstruction goodness by computing the VAF. For all cases, we verified that the extracted synergies did not result from a bias associated with the extraction methods by running a simulation. For each subject and decomposition, we compared the VAF values for the reconstruction of the experimental data obtained by combining the identified synergies with the VAF values of the reconstruction of random, structureless data reconstructed by combination of the synergies identified from those artificial data. Such data sets were generated by reshuffling the samples of each muscle independently in each trials of each subject. Reshuffled data were then low-pass filtered (5 Hz cutoff). For each one of the actual data set we simulated 50 artificial data sets and extracted the synergies by using the same procedure used for the observed data. We estimated the significance by computing the 95th percentile of the VAF distribution for simulated data.

Similarity of synergies across subjects

The similarity between synergies of different subjects was quantified by computing their scalar products. For synchronous synergies and temporal components we proceeded as follows. For all possible pairs of normalized synergies of two different subjects the corresponding scalar products were computed. Note that, by definition, such a product can only adopt values ranging between 0 and 1. The pair with highest similarity was selected and the corresponding synergies were removed from the two groups of

synergies. The similarities between the remaining synergies were then computed, and the best matching pair of synergies was selected and removed from the original and reconstructed model. This procedure was iterated until all synergies were matched. To compute the similarity between time-varying synergies the procedure was very similar to the one just described above with the only difference that in the last case, before computing the scalar product, the matrices of the synergies were first rearranged by disposing the entries of the matrices in form of vectors. The similarity between synergies was then quantified by computing the maximum of the scalar products over all possible time delays of the second synergy with respect to the first. To access however the significance of the values of similarity provided by the scalar products we defined a similarity index (S) between two synergies. This index, ranging from 0 (similarity at chance level) to 1 (perfect matching of the synergies) was defined as follows

$$S = (s_{\text{data}} - s_{\text{chance}})/(1 - s_{\text{chance}}) \quad (5)$$

where s_{data} is the scalar product between two synergies extracted from the actual data and s_{chance} is the mean scalar product between 200 pairs of random synergies. We generated the artificial synergies by resampling randomly from the distribution of the activation amplitude of each muscle in the data set from which the synergies were extracted and constructed sequences of random data with the same length of the extracted synergies. Artificial data were then low-pass filtered to match the smoothness of the actual data.

RESULTS

To compare systematically the results provided by different synergistic decompositions when characterizing the same EMG data set, we recorded EMGs during a series of elbow rotations and then we extracted and compared synchronous, time-varying and temporal muscle synergies.

To illustrate the data, we begin by showing in **Figure 2A** the EMGs recorded during a typical trial accomplished by one subject and relative to an elbow flexion in the horizontal plane. Consistent with previous literature (Berardelli et al., 1996), such a movement is characterized by a sequence of three EMG bursts: an initial burst of the agonist muscle having the goal of providing the propulsive force to accelerate the movement, followed by a second burst of the antagonist to decelerate the movement and a third burst of the agonist to dampen the oscillation that other appears at the end of the movement. The latter final corrective action is also reflected in the final overshoot of the finger velocity profile. This sequence of bursts of activity was found also for elbow extension in the horizontal plane and flexion and extension in the vertical one (**Figure 2B**).

We then considered the extraction of synergies from these data. The first interesting question is how many synergies of each type are needed to describe the data. The number of synergies to consider was determined, for each subject and type of decomposition, from the dependence of the percentage of VAF (see "Materials and Methods") upon the number of synergies. The latter curves are plotted in **Figure 3** for each type of synergy factorization and for each subject. The VAF curves in each decomposition were very similar across subjects. While for the temporal and time-varying decomposition we could extract up to 6 synergies (**Figures 2A**,**C**) we found that, when referring to a synchronous synergistic decomposition, two synergies were enough to account for 100% of the variance associated with the original data. We thus did not extract a number of synergies higher than two. In **Figure 3B**, however, we reported an amount of variance equal to 100% even for $N = 3$, 4, 5, and 6, to make **Figure 3B** graphically coherent with the other two panels, i.e., **Figures 3A**,**B**.

Figure 3A reports the VAF dependence upon the number of extracted temporal synergies. For all subject, the VAF reached a high value when including 3 synergies, and the linear interpolation algorithm that we used (see "Materials and Methods") indicated that in all subjects 3 temporal synergies were sufficient to explain the vast majority of the variance (with additional temporal synergies generated by the NMF algorithm adding only a very small fraction of the total variance). The VAF curves for synchronous (**Figure 3B**) and time-varying (**Figure 3C**) synergies show that, for each individual subject, only two synergies were instead required to account for the variance of the EMG data.

After having individuated their number, we next considered the shapes of the synergies extracted by each decomposition. **Figure 4A** reports the shapes of the three temporal synergies extracted from the EMGs of a typical subject (LA). The three temporal components clearly remind of the triphasic organization presented in **Figure 2**. Each temporal component is characterized by one major bump. The first temporal synergy can be interpreted as the component contributing the most to the modulation of the first burst of the agonist muscle during movement accomplishment: the second as the first burst of the antagonist; and the third as the second burst of the agonist. Note that the third temporal synergy shows an initial deactivation before the occurrence of the main peak. This initial part of the synergy can be associated to the antagonist deactivation, prior to movement initiation, of the anti-gravitational muscles during rotation along the vertical plane. The combination coefficients in **Figure 4B** (averaged across the repetitions of each kind of movement) show the contribution of each component to the activity of each muscle. Consistently with a triphasic pattern, it is evident that the first component is contributing more to the activity of the biceps during VF and HF; conversely, it contributes more to the activation of the triceps in VE and HE. Similarly the second temporal synergy is more active for the muscles opposing the actions exerted by the muscles activated by the first components. Thus for HF and VF movements the coefficients of the triceps are higher than those of the biceps. Whereas for VE the coefficient of the biceps is higher than that of the biceps, for HE movements however the level of the coefficients of the two antagonist muscles is approximately the same. The coefficients show then that, in all movements, the third component is contributing to the activations of both muscles in approximately equivalent proportion, in order to compensate for overshoots or to increase the joint stiffness by co-activating opposing muscles.

There are two points that need to be remarked. First of all in the pre-processing step all the EMG signals of each muscle were normalized with respect to the maximum value that

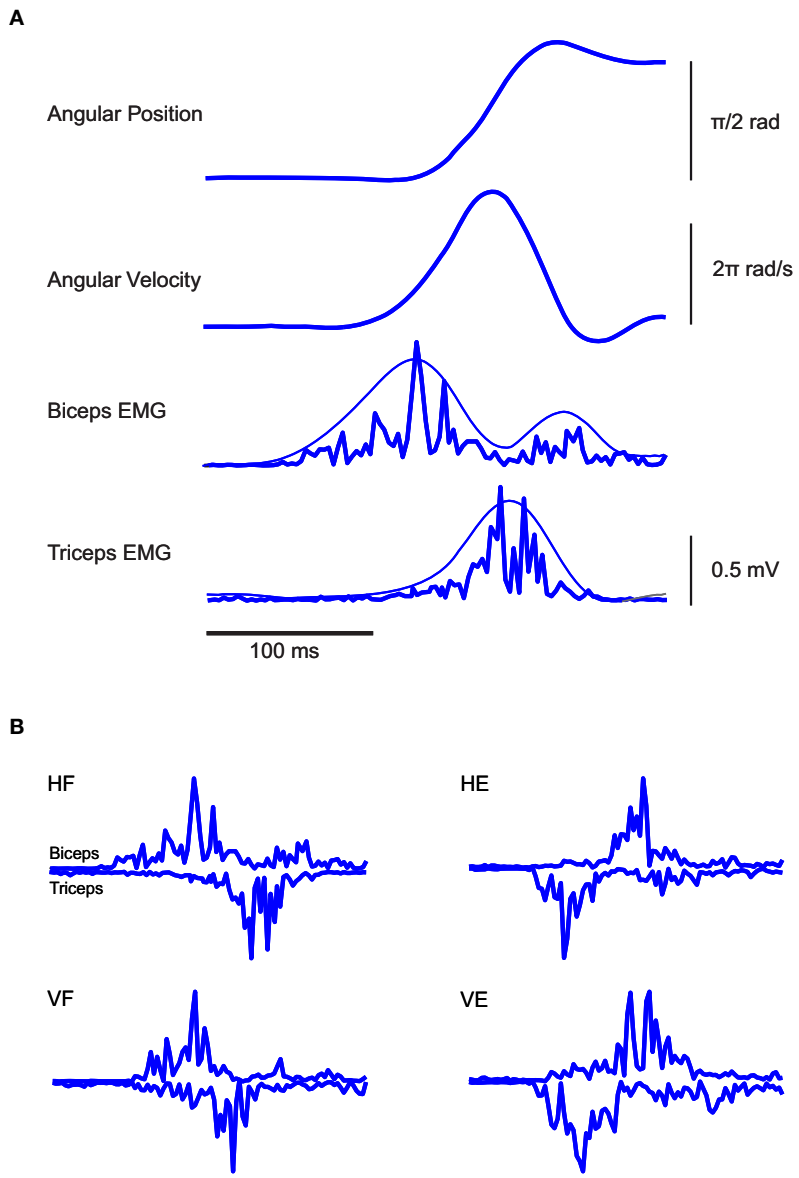

FIGURE 2 | Typical EMG and kinematic data associated with the experimental paradigm. (A) From the top, angular elbow displacement and velocity associated with one typical elbow flexion in the horizontal plane are respectively depicted, along with the EMG activities of Bic and Tric muscles. In the two panels at the bottom, the smoothest lines represent the envelopes of the rectified EMGs and were obtained by low-pass filtering the rectified EMG at 5 Hz, the spikiest ones at 20 Hz. Clearly, different filtering frequencies do not modify the main temporal features of the signals. **(B)** EMG traces of individual rapid flexion and extension movements of the elbow in a normal subject. In all conditions the triphasic pattern results clearly present.

was recorded for that muscle across all trials. Such a procedure may consequently lead to a partial loss of information about the relationship among the EMG amplitudes of different muscles monitored within the same trial. Moreover, trials were normalized in duration, which may introduce some supplementary temporal variability when merging all trials together to extract synergies. These can explain why the average coefficients of biceps and triceps relative to temporal synergy 2 in **Figure 4B** had approximately the same value for condition HE, differently from the expectation according to which the coefficient of the biceps should have appeared much larger than that of the triceps. According to the triphasic strategy, indeed, it should have been expected the second component to contribute mainly to the activation of biceps muscle which, in HE, is devoted to exert the antagonist role.

In addition, it is important to note that the number of identified temporal synergies is three, which is higher than the number of degrees-of-freedom to control (one joint angle, two muscles). This may look at first as a useless increase of complexity. However, the strength of a triphasic strategy in a single-joint motor task lies likely in its flexibility and power of generalization. Indeed, similar triphasic muscle organizations were found

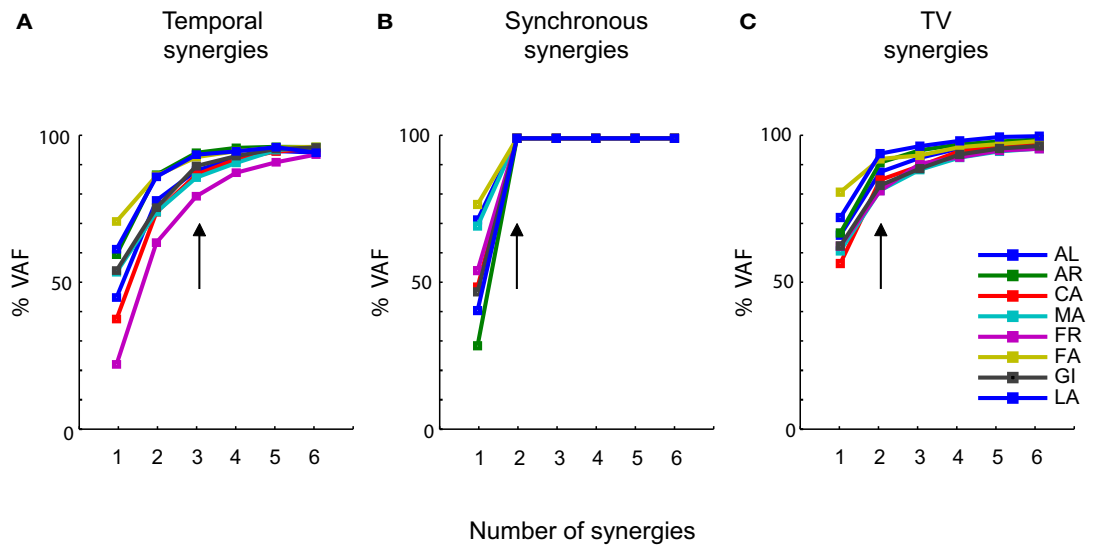

FIGURE 3 | Levels of approximation as a function of the number of synergies. (A) Percentage of VAF as a function of the number of temporal synergies. **(B)** Percentage of VAF as a function of the number of synchronous synergies. **(C)** Percentage of VAF as a function of the number of time-varying synergies. Each colored line is associated to a specific subject (see most right panel), which in the figure is identified by the initials of his first and last name. In all the three panels the vertical arrows indicate the number of primitives at which the curves satisfy the linear regression criterion to choose the number of primitives (see "Materials and Methods"). These points are invariant across subjects and coincide, in most of the cases, with the points at which the curves present an "elbow" and start becoming straight.

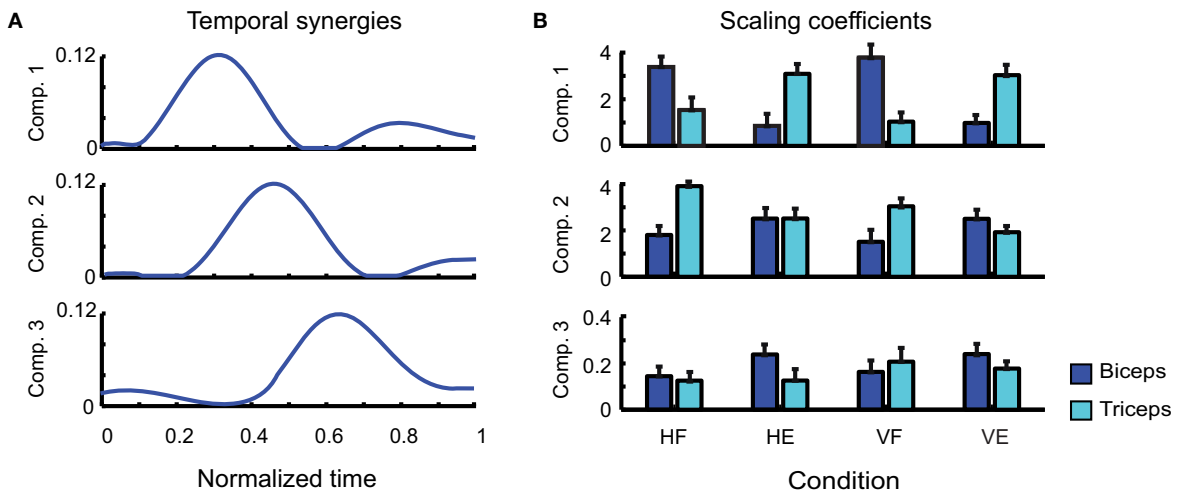

FIGURE 4 | Identified temporal synergies. (A) Temporal components extracted from one typical subject (LA), ordered according to the time of the occurrence of their main peaks. **(B)** Corresponding scaling coefficients.

characterizing also arm raising (Friedli et al., 1984), rapid voluntary body sway (Hayashi, 1998) and whole-body reaching (Chiovetto et al., 2010, 2012) motor tasks. In accordance with this premise, one can note that the four tasks were all executed through a triphasic motor pattern. While previous studies mainly demonstrated the powerfulness of the synergy idea to reduce the dimensionality of motor control and execution, our results show in addition that temporal synergies present marked functional features.

Figure 5A depicts the two synchronous synergies extracted from the EMGs of a typical subject (LA). Each synergy is characterized by the activation of one single muscle. Due to their antagonist nature, biceps and triceps therefore were found to share no common level of activation. Note that, although such a result may seem trivial in a two dimensional space, we might have obtained a pair of linearly independent vectors characterized by noticeable activity of both muscles. In **Figure 5B** the temporal evolution of the scaling coefficients averaged across movement repetition are

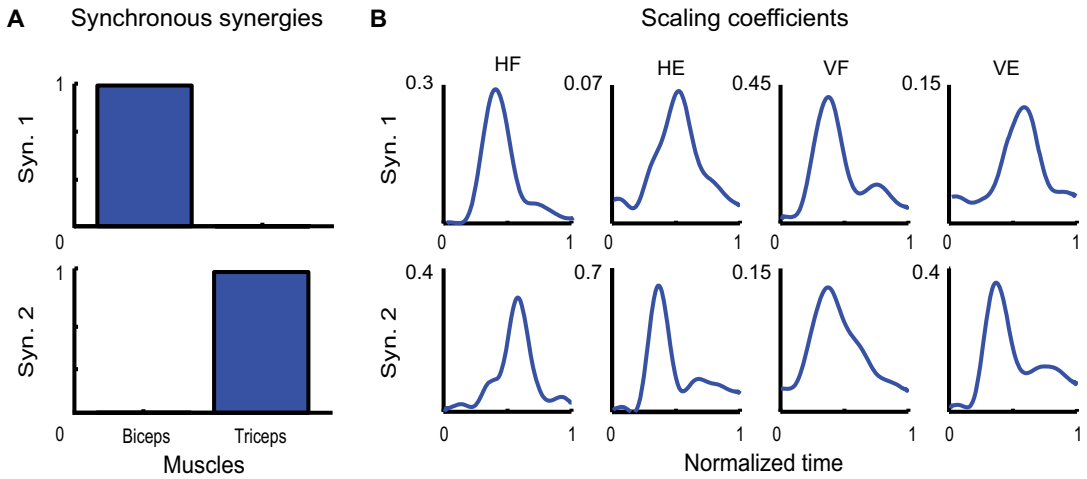

FIGURE 5 | Identified synchronous synergies. (A) Synchronous synergies identified from one typical subject (LA). **(B)** Temporal evolution of the corresponding scaling coefficients.

shown for each muscle and each movement. Note how, within each movement condition, the activities of the agonist and antagonist muscles are always characterized by one main burst in agreement with a classic triphasic pattern. Only for the first coefficient relative to HF movements the second burst is not clearly visible, this being very likely due to the averaging procedure.

Finally, the two time-varying synergies are shown in **Figure 6A**. They were characterized by one single burst for each muscle, one for the biceps and one of the triceps. The two synergies differed however for the temporal order in which the two burst occurred: whereas the burst of the biceps anticipated the burst of the triceps in the first time-varying synergy, the order of the peaks was reversed in the second one. The average scaling coefficients and temporal delays corresponding to each synergy are shown in **Figures 6B**,**C**. Note that also in this case, the contribution of each synergy to the EMG activity of each movement is consistent with the biomechanical feature of the movement itself. Thus time-varying synergy 1, in which the biceps is activated first, contributes more to HF and VF movements, while time-varying synergy 2, in which the triceps is activated first, contributes more to HE and VE movements.

In sum, we found that each kind of muscle decomposition provided a set of interpretable synergies. Each temporal component described a temporal phase of the movement. Each synchronous synergy described the simultaneous and coordinated action of a group of muscles (only one in our case) aiming to achieve a specific action goal. Each time-varying synergy related instead to a specific task-related variable (specifically a direction of motion).

We used the synergies extracted from each subject to reconstruct the EMG data of each one of the others and assessed the percentage of VAF. The results are reported in forms of confusion matrices (**Figure 7**). The average percentage of VAF computed across subjects was 90 ± 7% when temporal synergies were extracted and used for reconstruction, and 87 ± 4 for the data sets reconstructed by using the time varying synergies. These values were found to be significant and did not result from a bias built in the extraction methods. The average 95th percentile of the distribution of VAF values obtained from the reconstructions of the simulated data were indeed much lower of the ones obtained from the reconstruction of the actual data, respectively 17.6 and 39.3% when data where decomposed according to the temporal and time-varying synergistic decompositions. The synchronous case was not considered given the features of the extracted sources and the fact that with such synergies a perfect match of the actual data could always be achieved.

We quantified how much the synergies illustrated in **Figures 4, 5,** and **6** for one single subject were representative also of the synergies extracted from the EMG activity of the other subjects. To this purpose we computed the average scalar products and similarity indices between groups of synergies belonging to different participants. For the temporal components, the average scalar product was $s = 0.93 \pm 0.01$, $s = 1 \pm 0$ for the synchronous synergies and $s = 0.91 \pm 0.05$ for the time-varying ones. The scalar products across subjects of synchronous synergies were always equal to 1 because for all the subjects the same set of synchronous synergies was always identified, in which only one single muscle was recruited at a time. Note that in this case also the similarity index $\boldsymbol{S}$ is always automatically equal to 1. The mean $\boldsymbol{S}$ values computed between groups of synergies extracted from different subjects are plotted in **Figure 8**. On average $\boldsymbol{S} = 0.86 \pm 0.06$ for the groups of temporal synergies and $\boldsymbol{S} = 0.85 \pm 0.11$ for the time-varying synergies. Note that in both cases the average similarity index was much higher than 0 (chance level). In sum, all synergies decompositions show a very high degree of robustness across subjects.

DISCUSSION

We used NMF-based methods to extract three different kinds of muscle synergies from the EMG activity of two antagonist muscles during the accomplishment of single-joint elbow rotations along both the horizontal and vertical planes. By using a well-understood motor task, we aimed to clarify better what are the

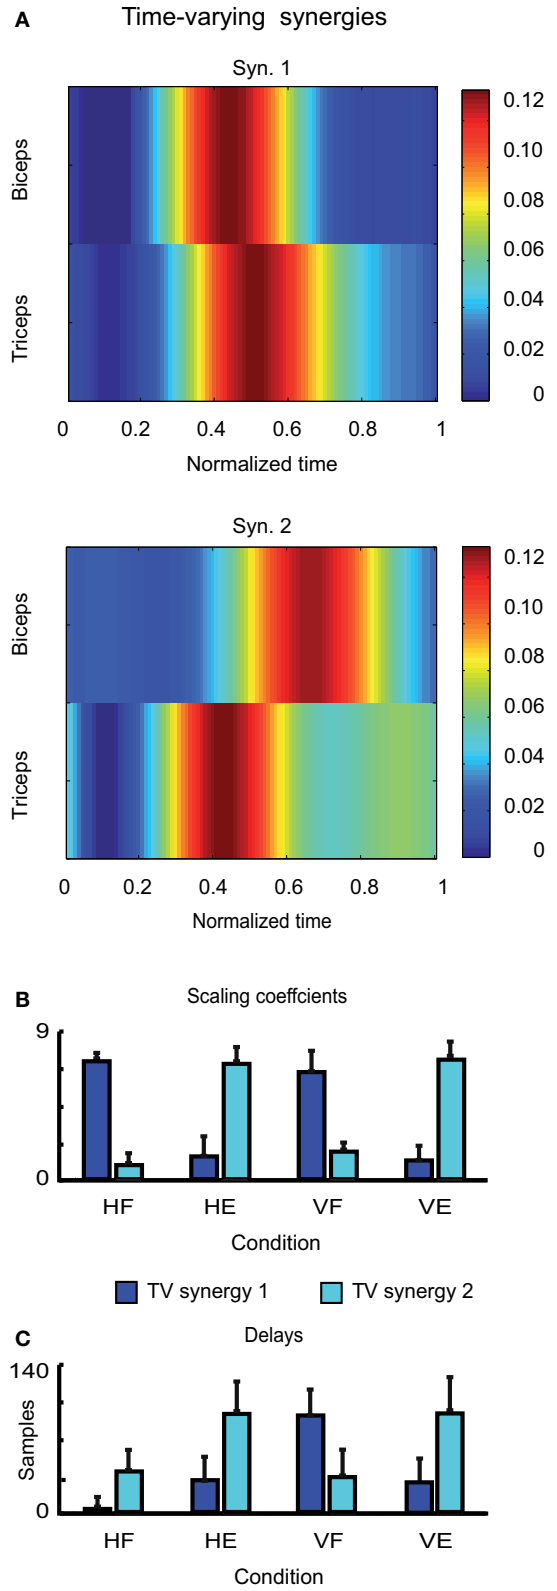

FIGURE 6 | Identified time-varying synergies. (A) Time-varying synergies extracted from the EMG activity of one typical subject (LA). **(B)** Corresponding scaling coefficients. **(C)** Corresponding temporal delays.

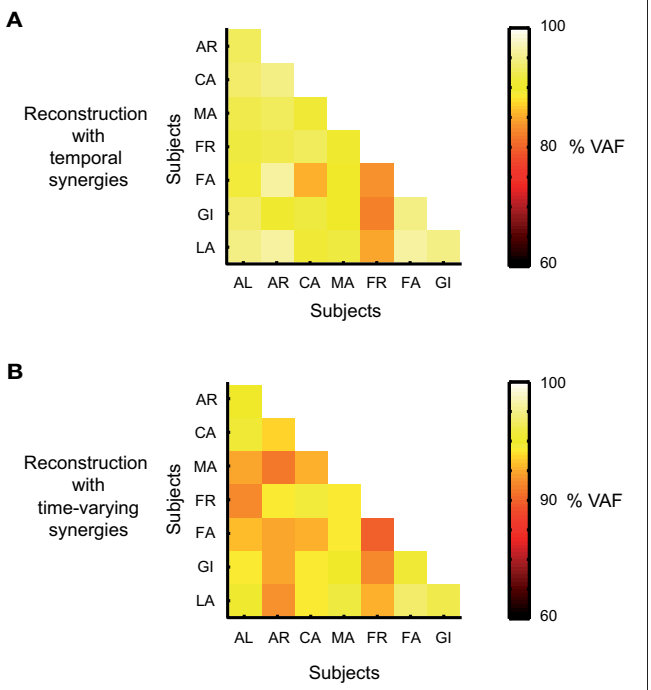

FIGURE 7 | Cross-validation results. (A) Percentage of VAF for the reconstruction of the actual EMG data set of one subject by using the temporal synergies identified from the data sets of the other subjects. VAF values along each row are associated with the reconstruction of the data of one single subject. **(B)** Percentage of VAF for the reconstruction of the actual EMG data set of one subject by using the time-varying synergies identified from the data sets of the other subjects.

motor features characterized by each kind of decomposition and to assess whether, when and why one of them should be preferred to another. We found well-defined interpretable results for each of the EMG signals decomposition considered. This allow us to discuss more in detail about what motor features each kind of muscle synergy decomposition encodes and, consequently, to explain why sometimes the extraction of one type of synergy may be more meaningful than another one.

In some previous studies (Ivanenko et al., 2005; Tresch et al., 2006) different unsupervised learning algorithms were applied to the same data set to verify the independence of the synergies from the particular technique used for their identification, or to test the superiority of an algorithm with respect to another one. In such studies however, all the algorithms used always relied on the same generative model, i.e., on the same definition of synergy. To our knowledge, this is the first study comparing synchronous, time-varying and temporal muscle synergies extracted from the same data set. Hence it offers the possibility to gain novel insights into the benefits provided by the different modular decompositions. Our choice of an elementary motor task for which most of the neuromuscular functions are well-understood, made the interpretations of various synergies as transparent as possible.

The results that we presented revealed that in all the cases NMF led to the identification of interpretable muscle synergies.

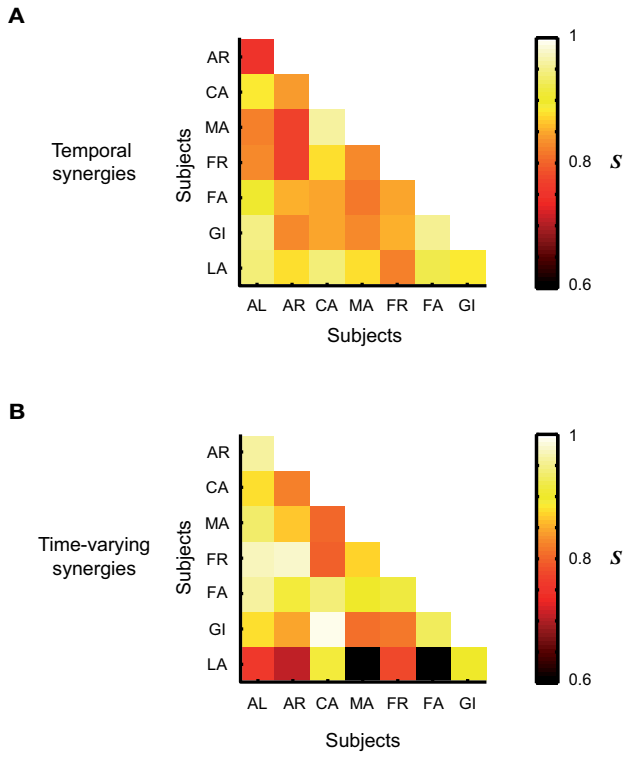

FIGURE 8 | Average level of similarity between groups of synergies identified from the EMG data of the 8 subjects that participated to the experiment. (A) Similarity between groups of temporal synergies. **(B)** Similarity between groups of time-varying synergies. The average level of similarity between synchronous synergies is not shown as the identified set of synchronous synergies was the same across all subjects.

The extraction of synchronous synergies yielded two primitives, each one characterized by the activation of only one of the two muscles, indicating that biceps and triceps (respectively flexor and extensor of the elbow joint) assumed independent levels of activation; in other words their activation waveforms did not, in general, co-vary in time. This might look like a trivial result given the small number of muscles considered and in view of antagonist nature of the two muscles during elbow rotations. However, following the generic definition of a muscle synergy as a group of muscles working together to achieve a common goal, it may appear surprising to find that the two main muscles controlling the task performance are not synergistic. However, the definition of synergies can be restated as groups of muscles acting at one or multiple joints to achieve a specific motor function (in our case the motor function could be simply flexing or extending the arm; in other terms, accelerate or decelerate the arm). From this point of view, our interpretation is in agreement with other previous studies considering more complex movements and a larger number of muscles. Similarly to us, for instance, the synergies extracted by Cheung et al. (2009) from the EMG activations of sixteen elbow and shoulder muscles of subjects performing a set of arm movements in space can be easily split in two groups: one encompassing synergies in which the most active muscles are flexor and another one in which extensor muscles are instead dominating (see Cheung et al., 2009, their **Figure 3A**). Also in this case, therefore, the goal associated with each synergy was to flex or extend the arm. By extension, this may suggest that muscles belonging to the same synchronous synergy share similarities with respect to their biomechanical function for the movement to be performed. Synchronous synergies were shown however encoding also other kinds of functional goals, or "strategies". Torres-Oviedo and Ting (2007) extracted synchronous synergies from a set of leg and trunk muscles during a postural task and found synergies characterized mainly by activation of either ankle or knee muscle. These synergies resulted therefore in producing muscle activation patterns associated with two well-known postural strategies, usually referred to as "hip" and "ankle" strategies, which were previously deeply described in human postural control (Horak and Macpherson, 1996).

When extracting temporal muscle components the application of NMF provided a decomposition based on three temporal synergies. Each one of them was found playing a well-determined functional role during movement accomplishment, in agreement with the three movement phases present in the classical triphasic pattern (see Berardelli et al., 1996, for a review relative to elbow and wrist movements). The three phases can be resumed as follows: a first phase (coinciding with the first agonist EMG burst) to provide the impulsive force to initiate the movement, a second phase (antagonist burst) dedicated to halt the movement at the desired end-point and a third phase (coinciding with the second agonist burst) to dampen out the oscillations which might occur at the end of the movement. Although in a single-joint motor task such a triphasic strategy may look like a useless increase of complexity due to the fact that the number of synergies is higher than the number of muscles to control, its strength lies likely in its flexibility and power of generalization. Indeed, similar muscle organizations were found characterizing also arm raising (Friedli et al., 1984), rapid voluntary body sway (Hayashi, 1998) and whole-body reaching (Chiovetto et al., 2010, 2012) motor tasks. Along with the need of reducing movement complexity by reducing the number of dof (number of muscles), the decomposition of EMG activations based on the definition of temporal synergies showed that at some extent even the temporal dimension of the movement is a source of complexity that could be controlled and simplified by the CNS. These findings also pose the question of the neural implementation of this kind of temporal synergies. For single-joint rotations, Irlbacher et al. (2006) showed that the bursts composing the triphasic pattern were triggered in cascade with the possibility for the second burst to depend partly on what occurred during the first burst and not as a complete undividable sequence. This is compatible with the extraction of three temporal synergies to account for the control of elbow rotations across several conditions. However, this asks the question whether there are indeed three "spinal" temporal patterns recruited by different premotor drives or if the same temporal pattern is recruited by a delayed sequence of premotor drives. Interestingly, this idea of time shifts is present in the time-varying model of muscle synergies, which might have solved this issue.

We found that two time-varying muscle synergies could account quite well for the EMG activity associated with

elbow movements. Each synergy was characterized by two main bursts of activation for both the biceps and triceps, whereas the time of occurrence of their peaks was inverted in the two synergies. While the burst of the biceps in the first synergy of **Figure 6A** occurs for first and may be thought to contribute therefore to start elbow flexion and the burst of the triceps to brake it, in the second synergies to role of the two muscles is inverted and the synergy is consistent with the pattern associated with an elbow extension. The two synergies seem therefore to intrinsically encode the direction of motion, or in other words, the motor task, and therefore may allow a hierarchical control of movements, in which task goals are only needed to be specified to generate complete muscle patterns. This finding is coherent with the results presented in previous investigations regarding arm movements (d'Avella et al., 2006, 2008, 2011) in which, even when a larger number of muscles was taken into account in the analysis, time-varying synergies where found to be directionally tuned, so that they resulted active only when the movements occurred in well-determined directions. We also stress the subtle difference between the interpretation of time-varying synergies and synchronous synergies: with the first time-varying synergy only flexions can be performed (maybe varying its speed or amplitude depending the way it is recruited). In contrast, the first synchronous synergy can be used for both flexion (to accelerate) and extensions (to decelerate), showing that both representations encode divergent aspects of the movements data set.

The use of very simple motor tasks characterized by well-known triphasic pattern allows us to evaluate some pros and cons of each of the decompositions used in this study. Previous works demonstrated that, in a triphasic pattern, the time of activation of the antagonist muscle is controlled independently by the cerebellum (Manto et al., 1995). Other studies (Cheron and Godaux, 1986) also reported that the timing of the antagonist burst onset increases with the movement amplitude, whereas the one of the agonist does not. Our results showed that neither the temporal synergistic decomposition nor the time-varying one can capture such timing features. In the first case, indeed, each one of the three bumps of **Figure 4** is invariant in time and cannot be shifted temporally. This makes impossible to model the inter-trial variability of the onset of the antagonist muscle. Rather, each bump represents the average temporal evolution of the corresponding bursts across all trials. In the second case, differently, in each of the time-varying synergies that we identified from the experimental data set, the time lag between the activation of the two antagonist muscles is constant. This prevents the possibility, when reconstructing the data, to vary from trial to trial the time interval between the activations of the agonist and antagonist muscles, as observed in human subjects. Different considerations can instead be made for the results associated with the synchronous decomposition. As each synergy that was identified from the data is responsible for the recruitment of one single muscle indeed, the activation profile of each muscle can be set arbitrarily and independently for each trial. This allows therefore not only to model independently the times of activation of each burst in each trial, but also their amplitudes, in agreement with other experimental observations. Hannaford et al. (1985) demonstrated indeed that the first agonist burst is not modified by the vibration of the agonist muscle. In contrast the amplitude of the second agonist burst is increased and the vibration of the antagonist muscle increases the amplitude of the antagonist burst. Similarly to the synchronous one, even the temporal decomposition is suitable to capture such features of the amplitudes in the reconstructed data, as it allows the separate scaling of each one of the three identified bumps. The time-varying decomposition, on the contrary, introduces instead by construction a correlation between the amplitudes of the different muscles.

It was demonstrated that discrete movements regulated by a triphasic pattern may present an oscillatory component in the neural command (see for instance Cheron and Godaux, 1986). Very recently, it was also shown by the analysis of the dynamical structure of reaching movement that non-periodic movement such as the one presented here contains a strong rhythmic structure (Churchland et al., 2012). In this study the authors proved that, although EMG responses do not themselves exhibit state-space rotations, EMG can however be constructed from underlying rhythmic components. It makes thus sense to wonder which one of the decomposition methods that we investigated can be more useful or complementary for the understanding of the oscillatory nature of the control of movement. Each model might indeed provide a set of synergies revealing specific oscillatory features underlying the EMGs. In this framework, synchronous components cannot be of help, as they carry spatial and not temporal information. Interesting results might instead be provided by drawing the phase plots associated with each temporal component or with the activity of each muscle trace in a time-varying synergy. In case the plots presented evident rotations indeed, the hypothesis put forward by Cheron and Godaux and later by Churchland et al. would be strengthened. In the contrary case, however, the results obtained by these authors would not be discredited, as the absence of rhythmic features in the components might instead be due to the incapability of the synergy models to account for such features correctly.

We have in this discussion tried to provide evidence that the simple results that we found for the simple movement and system considered in this study might very likely hold also for more complex behaviors involving the action of large number of muscles. We think therefore that, in general, each kind of muscle synergy may encode a different motor feature. Specifically, temporal components encode different temporal phases of the movement, each one playing a specific functional role. Synchronous synergies encode the simultaneous and coordinated actions of specific groups of muscles aiming to achieve a specific motor function (e.g., accelerate the body toward the target). Finally, time-varying synergies encode high-level task-related functions (in this case the direction of motion). This suggests that the type of factorization to be chosen in each condition depends on which of these aspects the study intents to reveal. Note however that each type of synergies may not always characterize uniquely only one single motor feature, mainly because two or more variables may be correlated. Thus, for instance, the direction of motion can be inferred also from the amplitude of the scaling coefficients relative to temporal components (**Figure 4B**) once the

action exerted by the muscles in known, or the triphasic temporal organization can be also reflected in the temporal evolution of the scaling coefficients in **Figure 5B**.

We conclude by stressing that a unifying synergy extraction method capturing all those aspects at once could simplify the interpretation of future works. If all these representations of synergies are simultaneously valid, then a more general model on the top of them should exist. Used systematically, such a model could allow better comparisons and interpretations of muscle synergy studies in more complex motor tasks.

To generate a force at the hand in a given spatial direction and with a given magnitude the central nervous system (CNS) has to coordinate the recruitment of many muscles. Because of the redundancy in the musculoskeletal system, the CNS can choose one of infinitely many possible muscle activation patterns which generate the same force. What strategies and constraints underlie such selection is an open issue. The CNS might optimize a performance criterion, such as accuracy or effort. Moreover, the CNS might simplify the solution by constraining it to be a combination of a few muscle synergies, coordinated recruitment of groups of muscles. We tested whether the CNS generates forces by minimum effort recruitment of either individual muscles or muscle synergies. We compared the activation of arm muscles observed during the generation of isometric forces at the hand across multiple three-dimensional force targets with the activation predicted by either minimizing the sum of squared muscle activations or the sum of squared synergy activations. Muscle synergies were identified from the recorded muscle pattern using non-negative matrix factorization. To perform both optimizations we assumed a linear relationship between rectified and filtered electromyographic (EMG) signal which we estimated using multiple linear regressions. We found that the minimum effort recruitment of synergies predicted the observed muscle patterns better than the minimum effort recruitment of individual muscles. However, both predictions had errors much larger than the reconstruction error obtained by the synergies, suggesting that the CNS generates three-dimensional forces by sub-optimal recruitment of muscle synergies.

Keywords: muscle synergies, isometric force, directional tuning, effort minimization, non-negative matrix factorization

INTRODUCTION

Object manipulation and tool use require accurate control of the three-dimensional force generated at the hand by the contraction of arm muscles. To generate a force at the hand in a given spatial direction and with a given magnitude, the central nervous system (CNS) has to coordinate the recruitment of many muscles. A desired force vector must results from the sum of the force vectors generated by the contraction of each individual muscle. Thus, the control policy implemented by the CNS must select an appropriate muscle activation pattern for each desired force vector output. Such a mapping from force targets to muscle patterns is the inverse of the biomechanical transformation of muscle contraction into output force. However, because of the redundancy of the muscular apparatus, the solution is not unique and infinitely many muscle patterns can generate the same force output. These patterns only differ with respect to the amount of muscle co-contraction, i.e., the part of the muscle contraction which generates force components that cancel each other (Valero-Cuevas, 2009).

How the CNS coordinates many redundant muscles is a long standing question in motor neuroscience (Bernstein, 1967). One possibility is that CNS selects the muscle pattern for a specific goal by minimizing some cost, such as effort or inaccuracy (Harris and Wolpert, 1998; Fagg et al., 2002; Todorov and Jordan, 2002; Franklin et al., 2008; Kutch et al., 2008). Such minimization may be performed searching among all possible muscle patterns and potentially achieving the global minimum of the cost function. As optimization becomes computationally challenging when it involves a large number of variables, the CNS might search for a solution only within the subset of all possible patterns generated by the combination of a small number of muscle synergies, coordinated recruitment of groups of muscles with specific activation balances or profiles (Tresch et al., 1999; Saltiel et al., 2001; d'Avella et al., 2003; Ting and McKay, 2007; Bizzi et al., 2008; Lacquaniti et al., 2012; d'Avella and Lacquaniti, 2013). However, by reducing the number of variables, i.e., constraining the solution to combinations of muscle synergies, only a value of the cost function generally larger than the global minimum can be achieved. Thus, there is a trade-off between optimality and computational complexity in the solution of the coordination problem.

Whether muscle synergies are a simplifying control strategy actually implemented by the CNS or they represent a parsimonious description of the regularities in the motor output generated by a non-synergistic controller and due to specific task constraints is a debated issue (Kutch et al., 2008; Tresch and Jarc, 2009; Valero-Cuevas et al., 2009; d'Avella and Pai, 2010; Kutch

and Valero-Cuevas, 2012; Berger et al., 2013; Bizzi and Cheung, 2013). Evidence for muscle synergies as neural control strategies has come from the observation of low-dimensionality in the muscle patterns. In many species and behaviors the muscle patterns recorded in a variety of conditions can be reconstructed by a combination of a small number of muscle synergies (Tresch et al., 1999; d'Avella et al., 2003, 2006; Ivanenko et al., 2004; Ting and Macpherson, 2005; Torres-Oviedo and Ting, 2007; Overduin et al., 2008; Dominici et al., 2011; Delis et al., 2013). Moreover, neural recordings and stimulation responses suggest that muscle synergies are encoded in the CNS (Saltiel et al., 2001; Ethier et al., 2006; Gentner and Classen, 2006; Hart and Giszter, 2010; Overduin et al., 2012). However, recent simulation studies have argued that the low-dimensionality that might be observed in the muscle patterns during isometric force generation could derive from biomechanical constraints (Kutch and Valero-Cuevas, 2012) and that the shape of the covariance of the force fluctuations recorded during static isometric force production is not compatible with muscle synergies (Kutch et al., 2008).

The aim of this study is to test whether the control policy employed by the CNS for the generation of force minimize effort by either independent recruitment of individual muscles or by synergistic recruitment. We have performed a comparison between the activation of several muscles acting on the shoulder and elbow joints observed during the generation of static isometric force at the hand across multiple three-dimensional force targets and the muscle activation predicted by minimizing effort either over the set of all possible muscle patterns or within the subset of muscle patterns generated by combinations of muscle synergies. To derive these predictions, we have estimated the isometric force generated by each muscle, assuming a linear relationship between rectified and filtered electromyographic (EMG) signal and force, and we have identified time-invariant muscle synergies by non-negative matrix factorization (NMF) (Lee and Seung, 2001; Tresch et al., 2006). While the observed muscle patterns could be reconstructed accurately by the combination of a small number of muscle synergies, they were not well predicted by either minimum effort recruitment of individual muscles or synergies. However, the synergistic prediction had a significantly lower error than the prediction based on individual muscles.

MATERIALS AND METHODS

PARTICIPANTS

Nine right handed subjects (5 males and 4 females, mean age 29.6 ± 4.4 years, age range 24–39) participated in the experiment after giving written informed consent. All procedures were approved by the Ethical Review Board of the Santa Lucia Foundation.

EXPERIMENTAL APPARATUS AND DATA ACQUISITION

Subjects sat on a racing car seat with their torso immobilized by safety belts anchored behind their shoulders and hips. They inserted their right hand and forearm in a splint that immobilized hand, wrist, and forearm positioned on a desktop in front of them. The splint was attached to a steel bar and mechanically connected via a steel rod to a 6-axis force transducer (Delta F/T Sensor, ATI Industrial Automation, Apex, NC, USA) mounted below the desktop. In this posture the center of the palm was aligned with the body midline at the height of the sternum and the elbow was flexed approximately by 90°. The height of the desktop and the distance of the chair from the desktop could be adjusted according to the subject's size. The subject view of his right hand was occluded by a mirror (29.7 × 21 cm), parallel to the desktop, that reflect the image displayed by a 21-inch LCD monitor (Syncmaster 2233, Samsung Electronics Italia S.p.A., Cernusco sul Naviglio, MI, Italy), also parallel to the desktop (**Figure 1A**). The height of the monitor was adjusted at the height of the subjects' eyes and the mirror was positioned halfway between the subjects' hand and the monitor. During the experiments subjects wore 3D shutter glasses (3D Vision P854, NVIDIA Corporation, Santa Clara, CA, USA) and viewed stereoscopically a virtual desktop matching the real desktop and a spherical cursor positioned, at rest, approximately at the center of the palm. The virtual scene was rendered by a 3D graphics card (Quadro Fx 3800, NVIDIA) on a PC workstation using custom software. Force targets were shown as transparent gray spheres and force feedback was provided by the displacement of the spherical blue cursor (**Figure 1B**). The scene was updated at 60 Hz with the cursor position processed by a second dedicated data-acquisition PC workstation running a real-time operating system and transmitted to the first workstation through an Ethernet link using the UDP protocol. Cursor motion was simulated in real time as a mass accelerated by the force applied by the subject on the splint, a viscous force, and an elastic force proportional to the distance from the rest position. The spring constant was set such that the force applied to maintain the cursor stationary at the target, distant 5 cm from the center of the palm, had a magnitude equal to 20% of the subject's mean maximum voluntary force (MVF) across force directions (see below). To maintain fast responses to changes in force while reducing the effect transducer noise when the force was stationary, the mass was adjusted adaptively in the range 15–140 g as a sigmoidal function of the rate of change in the magnitude of the recorded force. The damping constant was set to make the system critically damped.

Electromyographic activity from 17 muscles acting on the right shoulder and elbow was recorded with active bipolar electrodes (DE 2.1, Delsys Inc., Boston, MA), after band-pass filtering (20–450 Hz) and amplification (gain 1000, Bagnoli-16, Delsys Inc.). The following muscles were recorded: teres major (TeresMaj), infraspinatus (InfraSp), latissimus dorsi (LatDors), inferior trapezius (TrapInf), middle trapezius (TrapMid), superior trapezius (TrapSup), brachioradialis (BracRad), biceps brachii, long head (BicLong), biceps brachii, short head (BicShort), triceps brachii, lateral head (TriLat), triceps brachii, long head (TriLong), triceps brachii, medial head (TriMed), anterior deltoid (DeltA), middle deltoid (DeltM), posterior deltoid (DeltP), pectoralis major clavicular (PectClav), pectoralis major sternal (PectStern). Correct electrode placement was verified by observing the activation of each muscle during specific maneuvers. Force and EMG data were digitalized at 1 kHz using an A/D PCI board (PCI-6229, National Instrument, Austin, TX, USA). Only the forces (F_x lateral direction on the horizontal plane, positive to the right; F_y frontal direction on the horizontal plane,

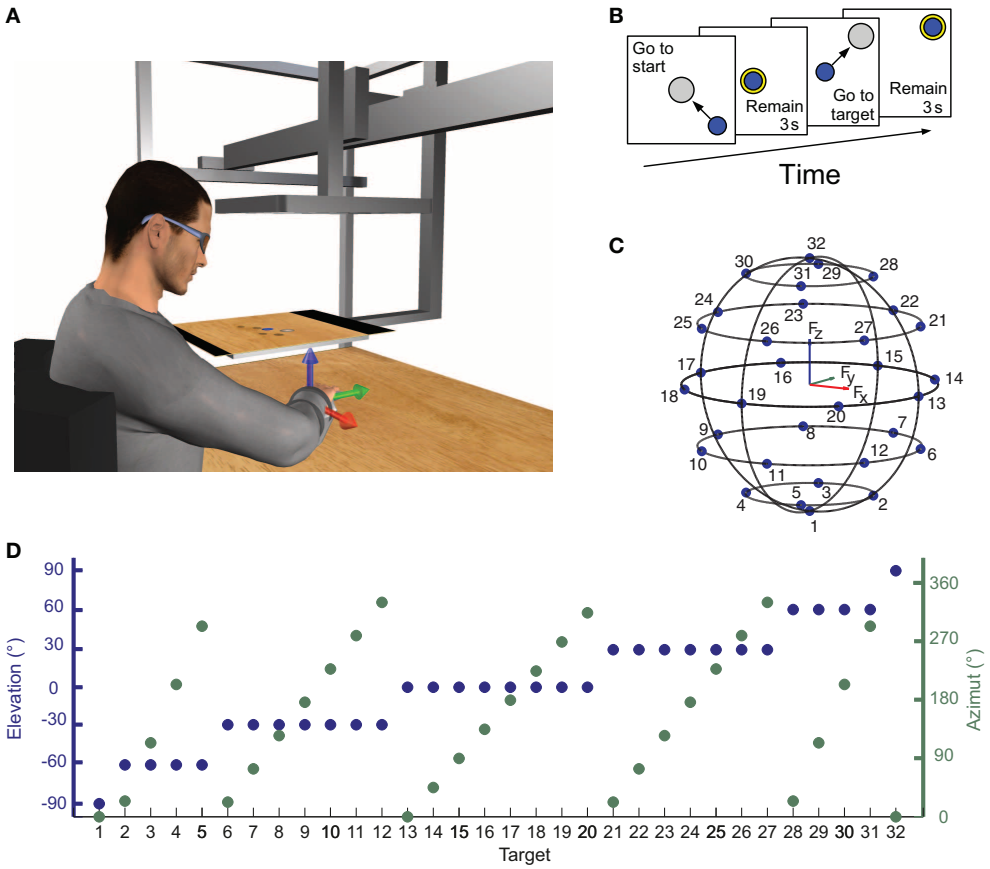

FIGURE 1 | Experimental apparatus and protocol for measuring isometric force and electromyographic signal. (A) Subjects sat in front of a desktop with their right arm, wrist, and forearm immobilized in a splint rigidly coupled to a force transducer mounted below the desktop. A mirror occluded subjects' view of their hand and reflected a virtual scene displayed by a flat horizontal monitor placed at subjects' eyes height and matching the real desktop view. A spherical cursor was displayed at the center of the palm when no forces were applied on the splint. Cursor motion was simulated in real time as a mass accelerated by the force applied by the subject on the splint, a viscous force, and an elastic force proportional to the distance for the rest position. **(B)** Subjects were instructed to perform center-out reaching trials in which they had to maintain the cursor in a central start location for 3 s, reach a target, and maintain the cursor at the target location for 3 s. After this time the subject relaxes to return to the starting position and be ready to start a new trial. **(C,D)** Force targets were distributed on the surface of a sphere of radius of 20% MVF, arranged on horizontal planes at different heights. The elevation and the azimuth angles of each one of the 32 targets were chosen to distribute the targets approximately uniformly on the sphere surface.

positive away from the chest; F_z vertical direction, positive up) were used during the experiment.

EXPERIMENTAL PROTOCOL

For each subject, the MVF along the direction of the 20 vertices of a dodecahedron was estimated at the beginning of the experiment and used to scale the magnitude of the force targets. For each direction the maximum force magnitude was recorded in two trials in which subjects were instructed to generate maximum force in a spatial direction indicated by an arrow. Subjects then performed a series of 160 trials generating forces in 32 directions (5 series of trials in all directions). The target directions were chosen to be approximately uniformly distributed on the surface of a sphere with radius of 0.2 MVF. Targets were arranged on horizontal planes at different heights. On the $F_z = 0$ plane, 8 targets were equally distributed on a circumference. The height of the other horizontal force planes was calculated such that the difference in elevation angle ($\varphi = \tan^{-1}(F_z/(F_x^2 + F_y^2)^{1/2})$) of two adjacent planes was approximately equal to the angle between two adjacent targets of the $F_z = 0$ plane. The number of targets on each plane was chosen such that the azimuth angle ($\vartheta = \tan^{-1}(F_y/F_x)$) difference between two adjacent targets on the plane was as close as possible to the angle between two targets on the $F_z = 0$ plane (45° for 8 targets, see **Figures 1C,D**). At the beginning of each trial subjects were instructed not to apply any force and to maintain the cursor for 3 s (rest phase) within a transparent yellow sphere with a radius larger than the cursor sphere radius by 2% MVF and aligned with the center of the palm. A target, indicated by a gray transparent sphere with a radius larger than the cursor sphere radius by 2% MVF was then displayed in one of the 32 locations and subjects were instructed to move the cursor to the target by applying force (**Figure 1B**). The target sphere turned yellow when the cursor was inside it. Finally, subjects were required to maintain the cursor within the target for 3 s (hold phase) to successfully end the trial.

DATA ANALYSIS

EMG data were used to characterize the directional tuning of muscle activations, to identify time-invariant muscle synergies, and, together with force data, to estimate an EMG-to-force matrix. One subject was excluded from the analysis after realizing that during the experiment the position of the cursor when the subject was not applying any force to the splint (at the beginning of each trial) had drifted, likely due to a lack of proper immobilization of the hand and forearm in the splint. A few trials in which the remaining eight subjects were not able to reach or remain in the target (3.4 ± 4.5 over 160 total trials, mean $\pm$ *SD*, range 0–13) as well as a few additional trials with EMG artifacts (6.0 ± 4.2, range 1–13) were excluded from the analysis. Finally, a few trials of the MVF block with EMG artifacts were also excluded from the analysis. The total number of excluded trials was 15.7 ± 12.3, range 1–33.

Directional tuning of muscle activations

EMG data were rectified and digitally low-pass filtered (2nd order Butterworth, 5 Hz cutoff) and re-sampled at 100 Hz to reduce data size. In each trial, mean EMG activity of each muscle during the last 0.6 s of the rest phase was used to estimate the baseline noise level of each muscle which was then subtracted from the rest of the data. Filtered EMG waveforms for each muscle were aligned to the beginning of the hold phase and then averaged across repetitions of the same target to construct directional tuning curves. Averaged EMG for each muscle were normalized to the maximum voluntary contraction across direction (MVC) recorded during MVF.

The directional tuning of each muscle activation was also fitted by a spatial cosine function:

$$m(f; f_{PD}) = f^T f_{PD} + m_{offset} = f_{PD}[\cos\varphi\cos\varphi_{PD} + \sin\varphi\sin\varphi_{PD}\sin(\vartheta - \vartheta_{PD})] + m_{\text{offset}},$$

where $\boldsymbol{f}$ in the unit vector pointing in the direction of the force target, $\boldsymbol{f}_{PD}$ is a preferred direction vector with length f_{PD}, azimuth angle ϑ_{PD}, and elevation angle φ_{PD}, and m_{offset} is an offset level. The parameters of the preferred direction vector and offset were estimated by multiple linear regressions (Matlab function regress) and the significance of the tuning assessed by an *F*-test.

Muscle synergies

Muscle synergies were identified by a NMF algorithm (Lee and Seung, 1999, 2001). Muscle activation vectors ($\mathbf{m}^k$) constructed with the rectified, filtered, and averaged EMG waveforms of each muscle during the hold phase of *k*-th trial, normalized to MVF after baseline noise level subtraction. Each vector (matrix column) was reconstructed as the combination of a unique set of *N* time-invariant synergies ($\mathbf{w}_i$) scaled by time-varying synergy activation coefficients (c_i^k)

$$\mathbf{m}^k = \sum_{i=1}^{N} c_i^k \mathbf{w}_i$$

or, equivalently, in matrix notation, $\mathbf{M} = \mathbf{W}\,\mathbf{C}$. For each *N* from 1 to the number of muscles, the extraction algorithm was repeated 10 times and the repetition with highest reconstruction R^2 was retained. R^2, the fraction of total variation explained by the synergy model, was defined as 1 - SSE/SST, where SSE is the sum of the squared residuals and SST is the sum of the squared differences between the recorded muscle patterns and their mean.

The number of synergies *N* is a free parameter that we chose as the smallest number that reconstructed accurately the data variation taking noise and the directional tuning of synergy activation coefficient into account. In previous studies using decomposition algorithms to identify muscle synergies, *N* was selected to capture the structured data variation not due to noise either according to a threshold in R^2 (Tresch et al., 1999; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006) or by identifying a change in slope in the R^2 curve (Cheung et al., 2005; d'Avella et al., 2006; Tresch et al., 2006). We considered both criteria, and we computed (i) the smallest *N* for which the R^2 was larger than 0.9 and (ii) as the point at which the R^2 vs. *N* curve had a change in slope (MSE error of linear fit from *N* to 17, the number of muscles, below 10^{-4}). In case of mismatch between the number of synergies selected according to the two criteria, we chose the one set of synergies with a more uniform directional distribution of preferred directions of the synergy activation coefficients (the direction of the maximum of the cosine function best fitting the directional tuning). To do so, for each one of the two synergy sets, we arranged their preferred direction vectors on a unit sphere, we considered all pairs, and we selected the set of synergies with the smallest number of pairs with an angular difference below 20°. Finally, the elements of each synergy vector ($\mathbf{w}_i$) in the selected set were normalized to their maximum value.

Directional tuning curves for the synergy activation coefficients, as for the muscle activations, were constructed by averaging their values in the hold phase and across trials to the same target.

EMG-to-force matrix

The isometric end-point force ($\mathbf{f}$) generated at the hand with the arm in a fixed posture (as both the trunk and the forearm were immobilized) by a muscle activation pattern ($\mathbf{m}$) was modeled as linear combination of the end-point force associated to each muscle, $\mathbf{f} = \mathbf{H}\,\mathbf{m}$, where $\mathbf{H}$ is a matrix with dimensions $[3 \times N_m]$ (N_m number of muscles). For each subject we estimated such matrix using multiple linear regressions of each force component, low-pass filtered (2nd order Butterworth, 5 Hz cutoff) with the rectified, filtered, re-sampled, baseline subtracted, MVC normalized EMG data recorded during the hold phase in all conditions. While the relationship between muscle activation and end-point force is generally not linear, for low muscle activation required for the force magnitude of the targets used in the experiment (0.2 MVF) linearity provided an adequate approximation (Lawrence and De Luca, 1983).

Minimum effort predictions

We predicted the observed muscle activation pattern ($\mathbf{m}^{\text{obs}}$) for each force target either by minimizing the sum of squared muscle activation ($\mathbf{m}^{\text{musc}}$) (Buchanan and Shreeve, 1996; van Bolhuis and Gielen, 1999; Todorov and Jordan, 2002) or by minimizing the sum of squared synergy activations ($\mathbf{m}^{\text{syn}}$), under the

constraint that the predicted pattern generates the desired force target according to the linear EMG-to-force mapping (**H**):

$$\mathbf{m}^{\text{musc}} = \arg\min(\|\mathbf{m}\|^2) \quad \text{such that } \mathbf{f} = \mathbf{Hm}$$

$$\begin{cases} \mathbf{m}^{\text{syn}} = \mathbf{Wc}^{\text{syn}} \\ \mathbf{c}^{\text{syn}} = \arg\min(\|\mathbf{c}\|^2) \quad \text{such that } \mathbf{f} = \mathbf{HWc} \end{cases}$$

We used the MATLAB function quadprog to find these minima.

Minimum effort prediction with random muscle synergies

We performed a Monte Carlo simulation to assess the significance of the prediction obtained by minimizing synergy effort. We compared the mean squared residual of the minimum synergy effort prediction with the distribution of the mean squared residuals obtained with 200 sets of random synergies. For each subject, after randomly shuffling over the columns (trials) each row (muscle) of the muscle activation data matrix (**M**), random synergies were generated either selecting a number of columns equal to the number of synergies identified from the data or by extracting the same number of synergies from the shuffled data matrix.

Statistical analysis

A Wilcoxon rank-sum test was performed for each subject to evaluate if the mean over force targets of the squared error of the prediction obtained minimizing muscle effort ($\mathbf{m}^{\text{musc}}$), $(\varepsilon^{\text{musc}})^2 = ||\mathbf{m}^{\text{musc}} - \mathbf{m}^{\text{obs}}||^2$, was statistically different from the squared error of the prediction obtained minimizing synergy effort ($\mathbf{m}^{\text{syn}}$), $(\varepsilon^{\text{syn}})^2 = ||\mathbf{m}^{\text{syn}} - \mathbf{m}^{\text{obs}}||^2$.

RESULTS

All subjects were able to reach the force targets and to maintain the force within the required 2% MVF tolerance for 3 s. Examples of the raw EMG and force data recorded for three trials to targets are shown along the positive F_x, F_y, and F_z axes in **Figure 2**.

DIRECTIONAL TUNING OF MUSCLE ACTIVATIONS

As in previous studies (Flanders and Soechting, 1990; Roh et al., 2012), we found that the activation of most muscles was modulated by force direction. **Figure 3** illustrates the modulation of the activity of 17 arm muscles recorded in subject 8 as a function of the azimuth of the force target on three different horizontal planes (elevation angles: −29, 0, 29°). For each muscle and target elevation, the directional tuning of the mean activity during the hold phase is illustrated by a polar plot in which the muscle activity is indicated by the radial distance of a marker in the direction of the target azimuth. Most muscles showed a directional tuning resembling the tuning expected by a spatial cosine function. For muscles with a preferred direction vector of the best fitting spatial cosine function lying close to the horizontal plane (e.g., TrapMid and PectStern), their azimuth directional tuning resembles a circle tangent to the origin. For muscles with a large vertical component in their preferred direction (e.g., BicLong, BicShort, TriLong, TriLong, and TriMed), the dependence of their activation on elevation is evident in the different radii of the circles. One muscles (BracRad) had a very narrow and non-significant spatial cosine tuning ($p = 0.14$). Other muscles had a significant ($p < 0.05$) but poor (R^2 value of the cosine fit less than 0.5) spatial cosine tuning (TeresMaj, LatDors, TrapInf, and TrapSup). Across subjects, 0.9 ± 0.3 (mean $\pm$ *SD*) muscles had a non-significant ($p > 0.05$) spatial cosine tuning and 3.2 ± 1.8 a poor fit ($R^2 < 0.5$).

MUSCLE SYNERGIES

We decomposed the muscle patterns recorded during the hold phase as combinations of muscle synergies identified by the NMF algorithm. Across subjects (**Figure 4**) the number of synergies selected according to a threshold either in the fraction of the

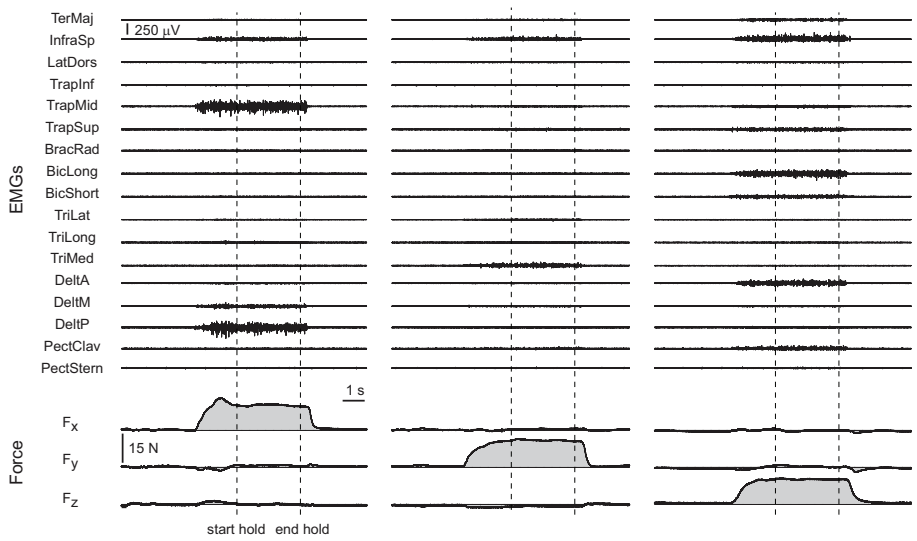

FIGURE 2 | Examples of raw EMG and force data. Data were recorded during three trials of subject 8 with targets at 20% MVF along the positive F_x axis (*first column*, target 16 in **Figure 1**), the positive F_y axis (*second column*, target 18 in **Figure 1**), and the positive F_z axis (*third column*, target 32 in **Figure 1**). The vertical dashed lines indicate the beginning and the end of the hold phase.

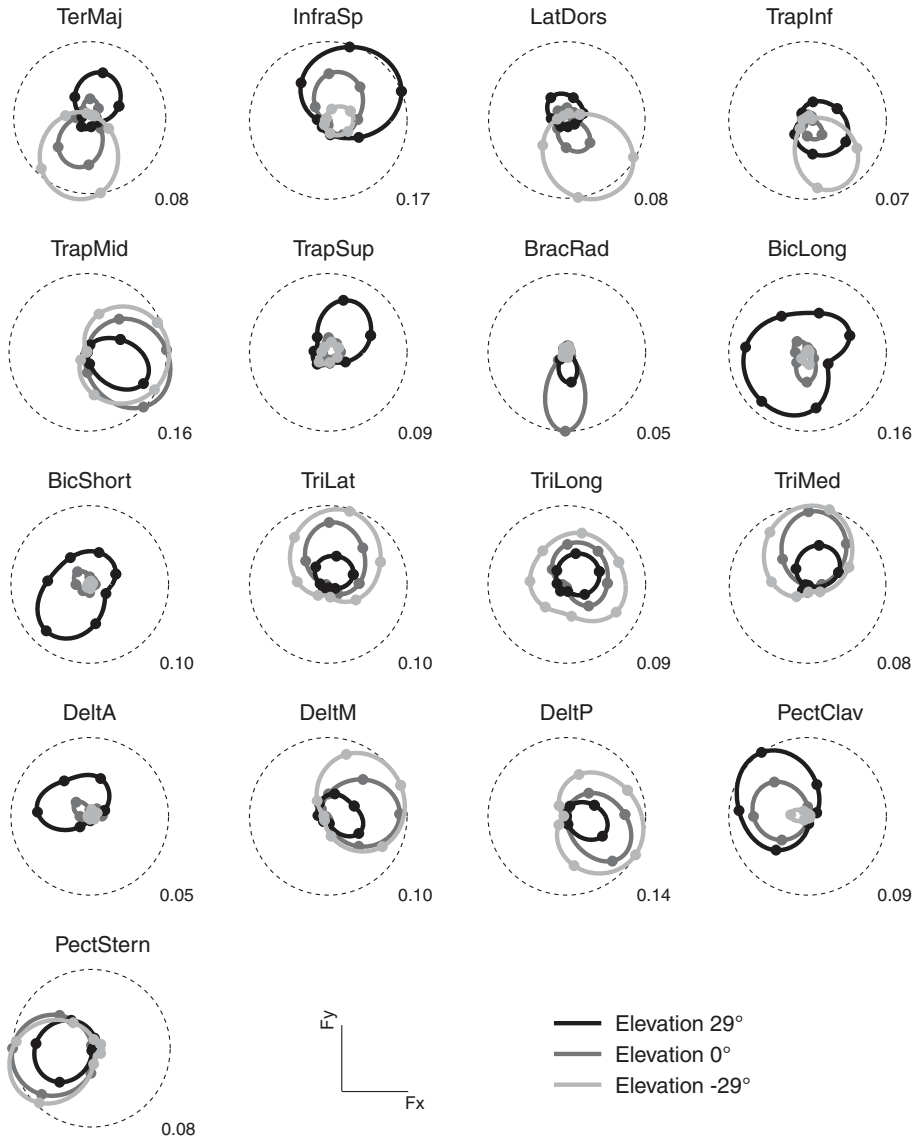

FIGURE 3 | Example of directional tuning of muscle activations. Polar plots representing the average EMG activity (hold phase, normalized to MVC) for targets on three horizontal planes at different elevations (*light gray*: −29°, targets 6–12, *medium gray*: 0°, targets 13–20, *dark gray*: 29°, targets 21–27) recorded in subject 8. Numerical value at the bottom right of each plot represents the fraction of mean MVC across all directions for each muscle and corresponds to the radius of the dashed circle. The direction of each marker represents the direction of the horizontal force components, its radius the average EMG activity when holding the target in that direction. Markers are interpolated by splines in polar coordinates.

total data variation explained by the synergies (R^2) or in the mean squared error of a linear fit of the final portion of the R^2 curve (see Materials and Methods) ranged from 6 to 7 (6.4 ± 0.5, mean $\pm$ *SD*). The corresponding R^2 values ranged from 0.90 to 0.95 (0.93 ± 0.01). Thus, a small number of synergies captured the modulation of activity in many arm muscles across directions and magnitudes of isometric force generated at the hand. **Figure 5A** shows the six synergies identified in the muscle patterns of subject 8. Each synergy has a different balance of activation across muscles, with some muscles more strongly active than others (TrapMid, DeltM, and DeltP in W_1, TerMaj, LatDors, TrapInf, TrapMid, TriLong, DeltP, and PectMajStern in W_2, TriLat, TriLong, TriMed, DeltM and DeltP in W_3, InfraSp and TrapSup in W_4, BicLong and BicShort in W_5, TerMaj, PectStern, and PectClav in W_6) and with many muscles recruited in multiple synergies.

Synergy activation coefficients were in most cases also well captured by a spatial cosine function. The directional tuning of the activation coefficients of the six synergies of subject 8 (**Figure 5B**) was always significant ($p < 0.0001$) and well reconstructed by a cosine fit ($R^2 > 0.5$). Across subjects, only subject 6 had 4 out of 7 synergy activation coefficients not well fitted by a cosine functions ($p = 0.40, 0.22, 0.05, 0.05$) while all other subjects had a significant ($p < 0.05$) spatial cosine tuning. Across all

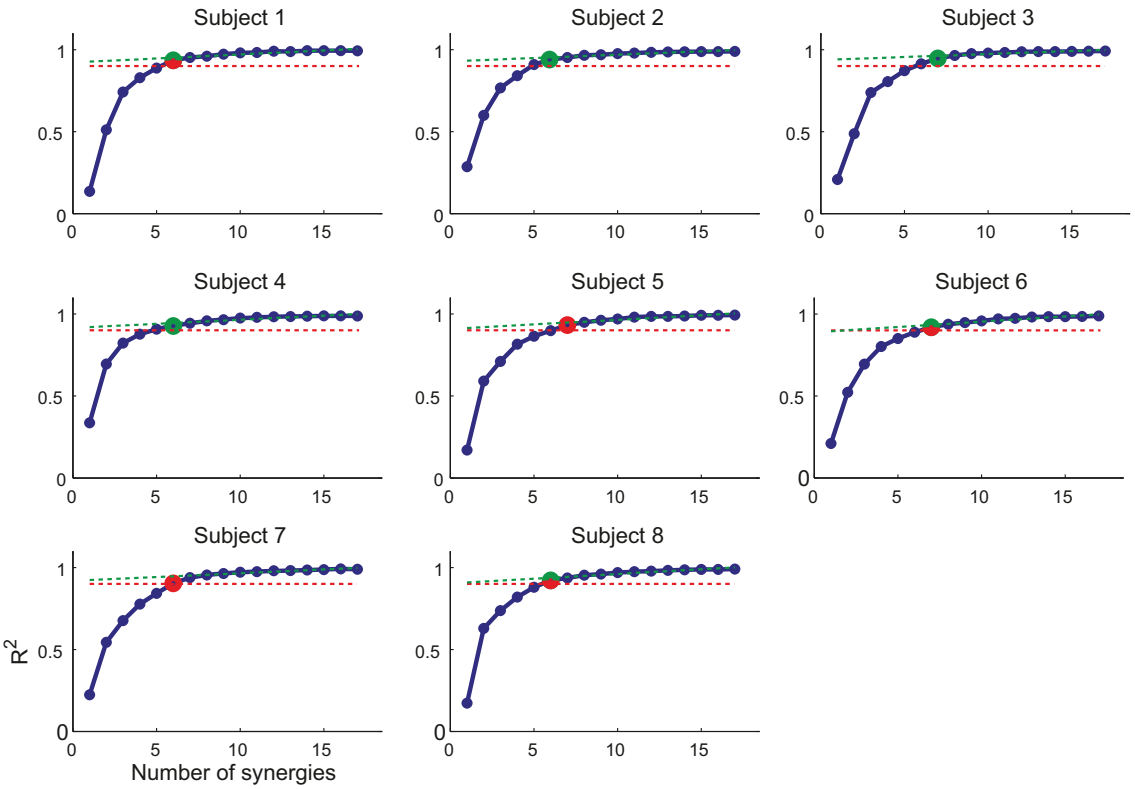

FIGURE 4 | Selection of number of synergies. The number of synergies (N) is chosen for each subject as (i) the smallest N for which the R^2 value (*blue markers and line*) was larger than 0.9 (*red dashed line*) or (ii) the point at which the R^2 vs. N curve had a change in slope [MSE of linear fit from N to max(N) below 10^{-4}, *green dashed line*]. In case of mismatch between the two criteria, the set of synergies with smallest number of similar preferred directions was selected (*red/green marker,* smallest number of synergy pairs with an angular difference between preferred direction below 20°).

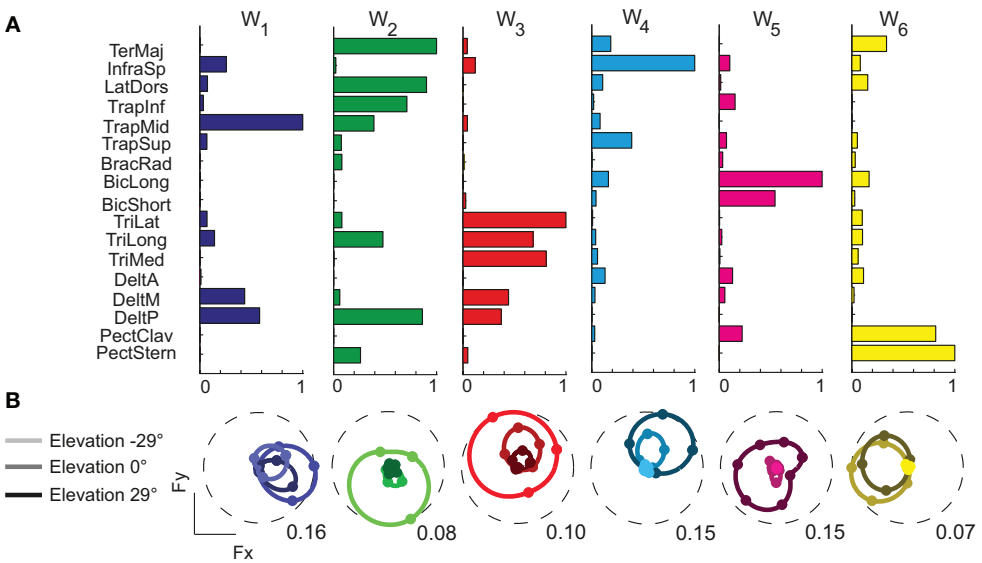

FIGURE 5 | Example of muscle synergies and directional tuning of activation coefficients. (A) Six synergies (W_1–W_6) identified by NMF from the filtered and time-averaged EMGs of subject 8 recorded during the hold phase of all trials. The bar plot in each column (color coded) shows the components of one synergy vector, normalized to its maximum. **(B)** Directional tuning (polar plot as in **Figure 3**) of the synergy activation coefficients for force targets on three horizontal planes.

subjects, only 1.2 ± 1.7 synergy activation coefficients had a poor fit ($R^2 < 0.5$).

EMG-TO-FORCE MATRIX AND SYNERGY DIRECTIONAL TUNING

As in previous studies of muscle activation during isometric force production (Osu and Gomi, 1999; Valero-Cuevas et al., 2009), we modeled the mapping between EMGs and sub-maximal magnitude (20% MVF) end-point force linearly. An EMG-to-force matrix (**H**) was estimated with multiple linear regressions of the mean EMG and forces recorded in the hold phase for each subject. **Figure 6A** illustrates force vectors associated to the activation of each muscle (columns of **H**) for subject 8. These force vectors in most cases matched the pulling directions of the muscles expected from their anatomical configuration. For example, on the horizontal plane (*left*), BracRad (elbow flexors) and TeresMaj (shoulder internal rotator and adductor) were associated to dorsally directed (negative F_y) forces, TriMed (elbow extensors) to a ventrally directed (positive F_y) force, PectClav and PectStern (shoulder flexors) to medially directed (negative F_x) forces, and DeltM (shoulder abductor) to a laterally directed (positive F_x) force. On the sagittal plane (*middle*), DeltA (shoulder adductor), InfraSp (shoulder external rotator), and PectClav showed a large rostral (positive F_z) and ventral force, BracRad a large rostral and dorsal force, TeresMaj a large caudal (negative F_z) and dorsal force, and TriMed a large caudal and frontal force. In the frontal plane (*right*) the two portions of pectoralis major showed distinct rostro-caudal (F_z) components. Across subjects, the forces recorded during the hold phase were reconstructed accurately by the product of the EMG-to-force matrix times the recorded EMGs ($R^2 = 0.89 \pm 0.02$, mean $\pm$ *SD*, $n = 8$, for the reconstruction of the individual force samples in all trials; $R^2 = 0.97 \pm 0.01$ for the reconstruction of the force averaged across time and trials to the same target by averaged EMGs).

We also estimated the force associated to the activation of individual muscle synergies by multiplying the EMG-to-force matrix with the synergy matrix (columns of the **HW** matrix, **Figure 6B**). Each synergy had a distinct force direction in space. W_1 was associated to a lateral force, W_2 to a dorso-caudal force, W_3 to a ventro-caudal force, W_4 to a ventro-rostral-lateral force, W_5 to dorso-rostral force, and W_6 to a medial force. However, with respect to individual muscle forces, there were larger angular differences between individual synergy force directions.

MUSCLE ACTIVATIONS PREDICTED BY MINIMUM EFFORT CRITERIA

We compared the muscle activation observed in all force directions with those predicted by minimizing either muscle effort or synergy effort. Examples of the directional tuning curves on the horizontal force plane (polar plot, *left*) and for all directions

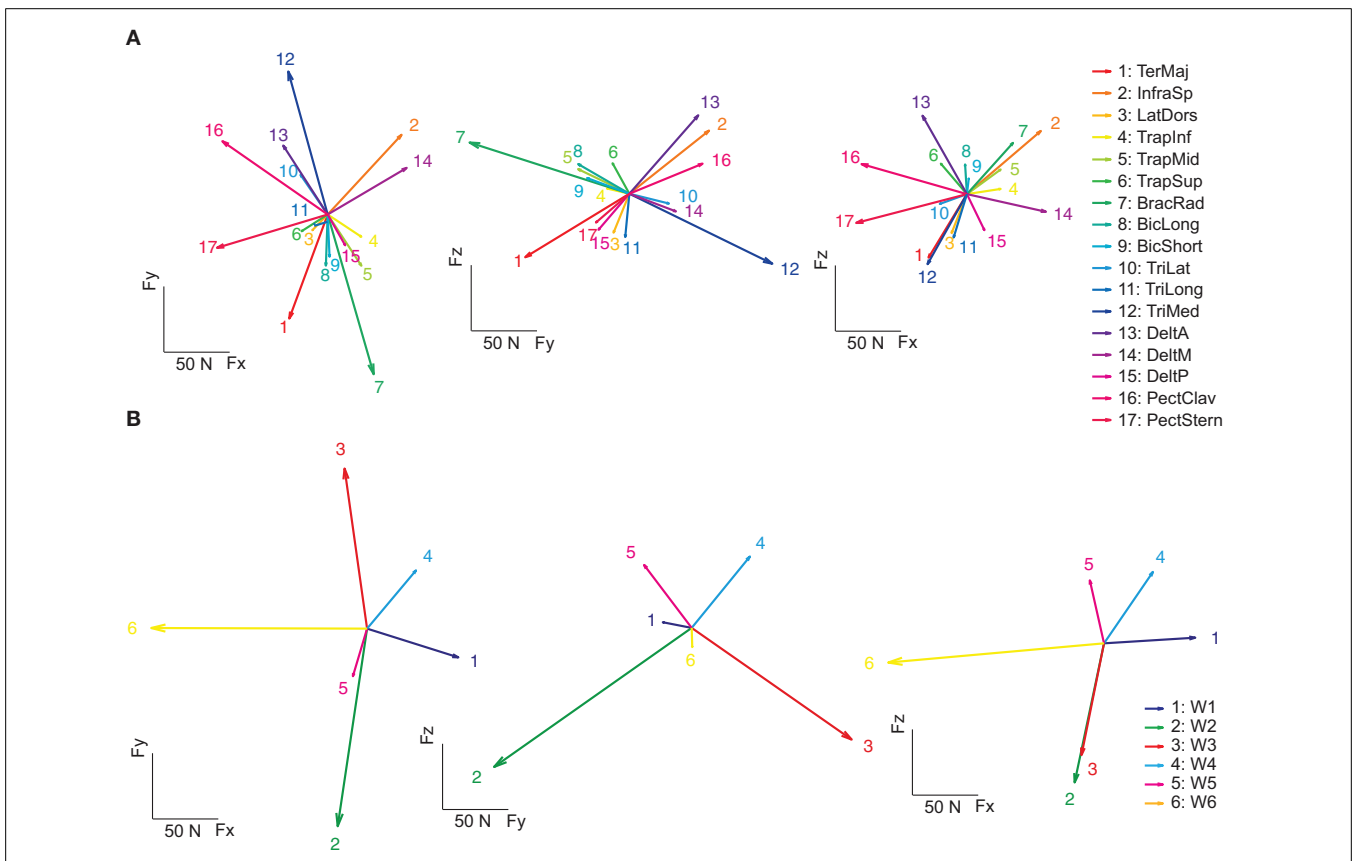

FIGURE 6 | Example of spatial forces associated to muscle and synergies. **(A)** The EMG-to-force matrix ***H*** (*left*: projections of the columns of ***H*** on the $F_z = 0$ plane, *middle*: projection on the $F_x = 0$ plane, *right*: projection on the $F_y = 0$ plane) estimated by linear regression of EMG and force data for subject 8. **(B)** Forces associated to the synergies (columns of the matrix obtained by multiplying the EMG-to-force matrix ***H*** by the synergy matrix ***W***) of subject 8.

(*right*) of three muscles (InfraSp, TrapMid, and DeltM) of subject 8 are illustrated in **Figure 7**. In all three cases the predicted tuning curves peak in same directions as the observed curves but in some cases they do not fit well the whole curve. For InfraSp (*first row*), the minimum muscle effort curve underestimates the observed curve and the minimum synergy effort curve overestimates it. For TrapMid (*second row*), muscle effort minimization predicts a very weak activation while the minimum synergy effort prediction closely matches the observed data. For DeltM (*third row*), the minimum synergy effort prediction again matches the observed data while the minimum muscle effort prediction overestimates them. These differences between the two

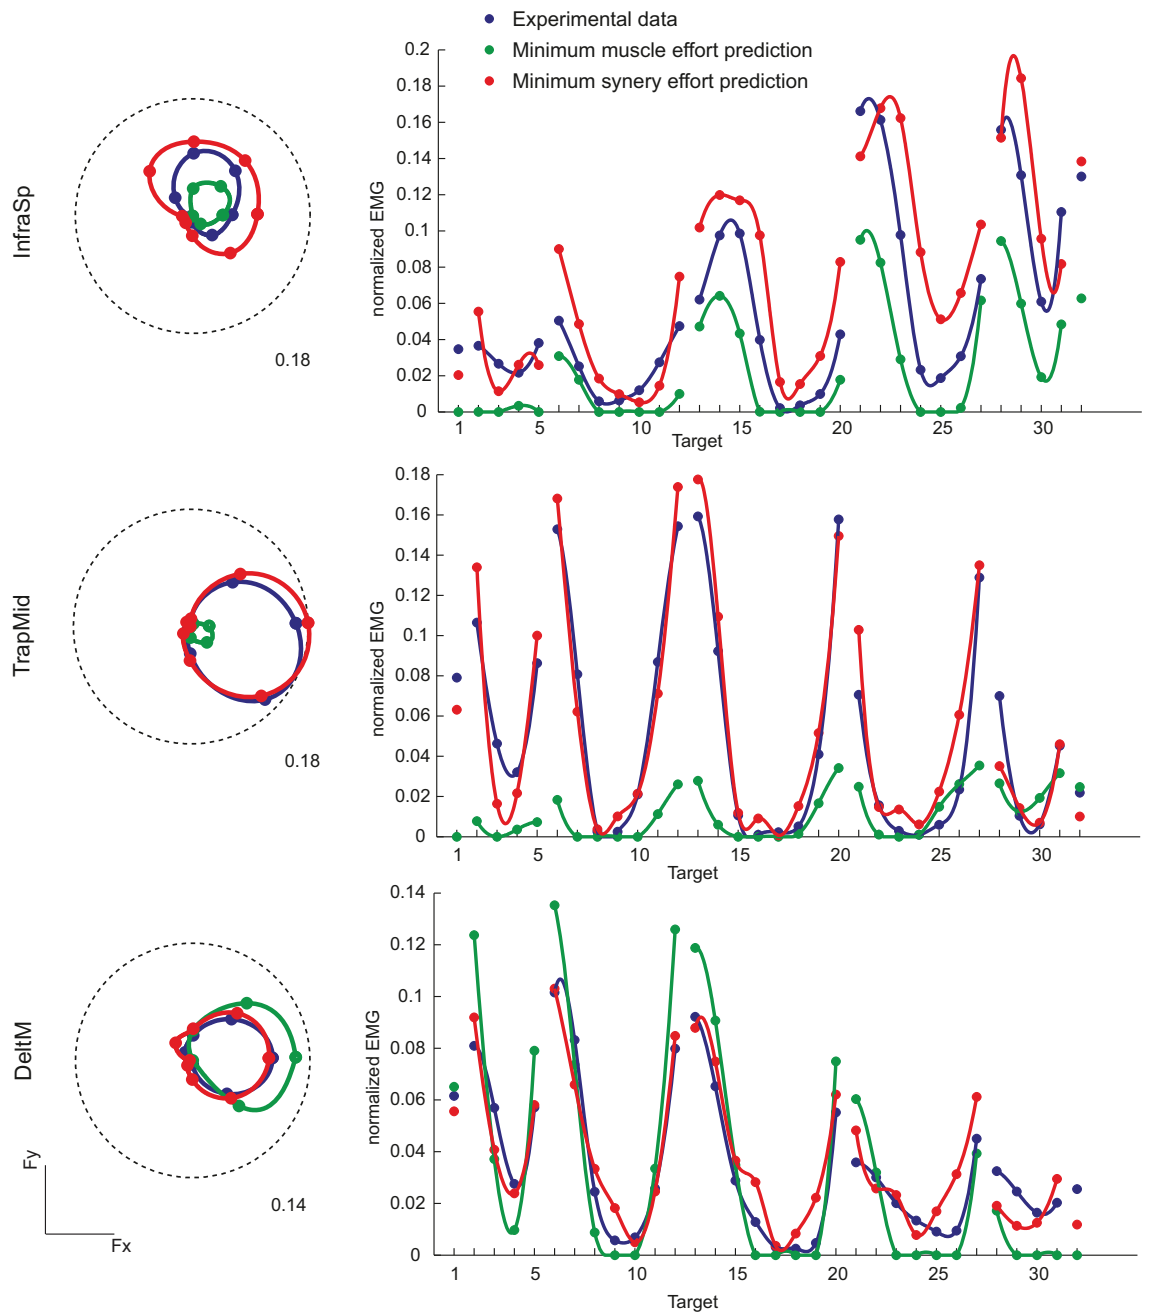

FIGURE 7 | Examples of directional tuning of muscle activation observed and predicted by minimum effort criteria. Muscle activations for three muscles of subject 8 are illustrated. **Left:** Polar plots of the directional tuning on the horizontal force plane ($F_z = 0$, targets 13–20). EMG activity, normalized to the MVC value of each muscle, is averaged during the hold phase. Dashed circles represent the normalized activity indicated by the label. **Right:** Average EMG activity for all 32 targets. *Blue* markers and lines (interpolating the markers with spline curves in polar coordinates) represent experimental data, *green* markers and lines (interpolating the markers with spline curves with negative values set to zero) represent predictions according to the linear EMG-to-force model with the minimum muscle effort criterion, *red* markers and lines with the minimum synergy effort criterion.

predictions depend on how the forces associated to the muscles (the columns of the H matrix, **Figure 6A**) and the synergies (**Figure 6B**) can be combined to minimize effort. For example, the minimum muscle effort criterion predicts an activation of TrapMid much weaker than the minimum synergy effort criterion because the minimum muscle norm solution is achieved by recruiting more strongly other muscles with a pulling direction close to that of TrapMid but with a larger forcer magnitude (in particular BracRad, see **Figure 6A**). In contrast, TrapMid has a stronger activation with the minimum synergy norm solution because it is recruited within W_1 (see **Figure 5**) and no other synergies can generate forces in the medial-dorsal direction with small activations.

Across subjects, we noticed that the mean residual of the minimum muscle effort prediction over all muscles and targets was always negative (sign test, $p < 0.0001$ for all subjects, see *green bars* in **Figure 8A**) and that the mean residual of the minimum synergy effort prediction was always positive ($p < 0.01$ for all subjects except subject 6, *red bars* in **Figure 8A**). Thus, the minimum muscle effort criterion underestimated the observed muscle activations and the minimum synergy effort criterion overestimated them. The minimum muscle effort underestimation corresponds to a larger than minimal amount of co-contraction in the observed muscle patterns. Indeed, the amount of co-contraction, quantified by the mean Euclidian norm of the projection of the muscle patterns onto the null space of the EMG-to-force matrix, was significantly higher for the observed data than for the minimum muscle effort prediction (sign test, $p < 0.0001$ for all subjects; mean $\pm$ *SD* across subjects: 0.16 ± 0.04 for the data and 0.09 ± 0.02 for the prediction). The mean null space norm for the minimum synergy effort criterion (mean $\pm$ *SD* across subjects: 0.19 ± 0.04) was higher than the mean norm for the minimum muscle effort criterion but also slightly higher than the mean norm for observed data (sign test, $p < 0.05$ for subjects 2, 4, 5, 7, and 8) possibly due to inaccuracies in the estimation of the EMG-to-force matrix. Finally, we found that the residuals for many muscles were not normally distributed. Across subjects, the residuals of the minimum muscle effort prediction of the activation of individual muscles had a distribution over different targets significantly different from the normal distribution (Lilliefors test, $p < 0.05$) in 62% of cases (84 cases over 17 muscles in 8 subjects) for the minimum muscle effort model and in 31% of cases for the minimum synergy effort model. However, we could not discern any clear pattern in the residuals.

We then compared the prediction error magnitudes. We found that the mean squared residual of the minimum synergy effort prediction was lower than the mean squared residual of the minimum muscle effort prediction (**Figure 8B**). The difference of the squared residual, averaged across muscles and targets, between the two criteria was significant (Wilcoxon rank-sum test, $p < 0.0001$, $n = 8$). To assess the significance of these results we compared, for each subject, the mean squared residual of the minimum synergy effort prediction with the distribution of the mean squared residual obtained applying the minimum effort criterion on random synergies. We performed a Monte Carlo simulation, generating, for each subject, random synergies either randomly shuffling the EMG data or performing NMF on

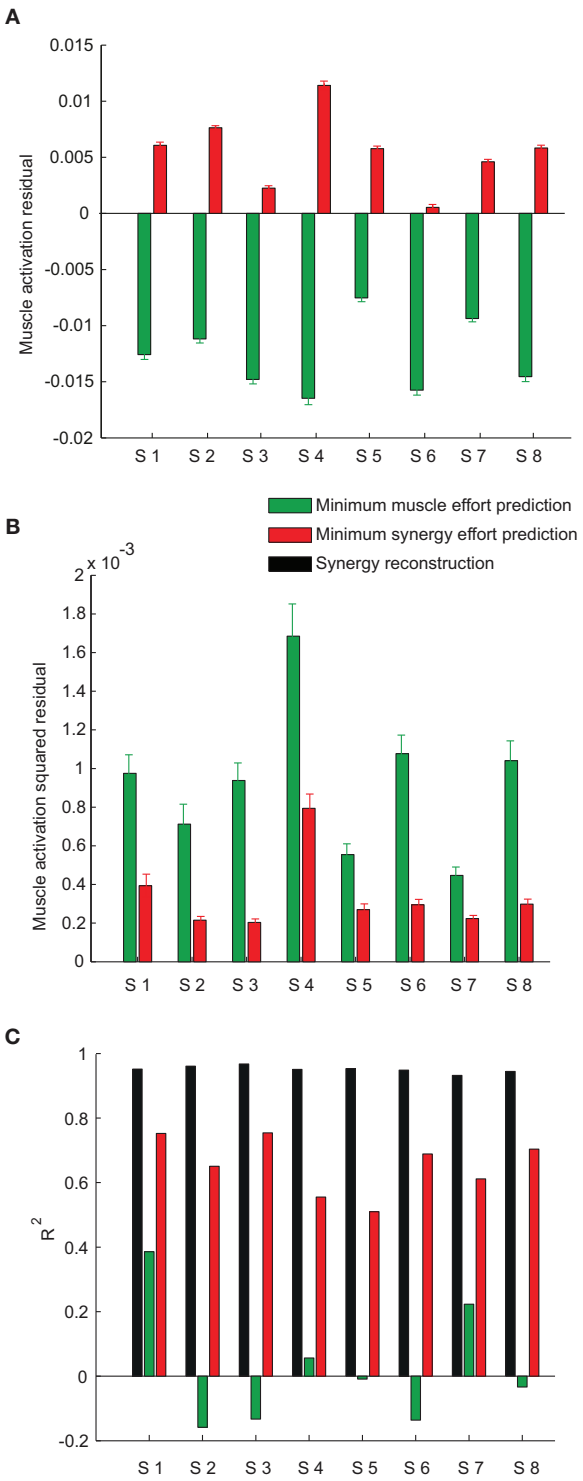

FIGURE 8 | Model prediction error. (A) Mean $\pm$ SE of the residual, over muscles and force targets, of the minimum muscle effort prediction (green bars) and the minimum synergy effort prediction (red bars) for all subjects. **(B)** Mean $\pm$ SE of the squared residual, over muscles and force targets, of the minimum muscle effort prediction (green bars) and the minimum synergy effort prediction (red bars) for all subjects. **(C)** Comparison of the R^2 values for the synergy reconstruction (black bars) and the model predictions.

randomly shuffled EMG data. We found that the mean squared residual obtained with the synergies extracted from the data was much smaller than the residuals obtained with both types of random synergies in all subjects (empirical $p < 0.005$), indicating that the value of the mean squared residual of the minimum synergy effort prediction was not simply due to the small number of synergies but depended on the actual structure of the synergies.

Finally, we compared the squared prediction error of the two models with the reconstruction error of the synergies. For all subjects, the fraction of the variation of the muscle patterns across force targets, averaged over repetitions to the same target, explained by the combinations of the synergies (**Figure 8B**, *black bars*, $R^2 = 0.95 \pm 0.01$, mean $\pm$ *SD*) was much higher than the fraction explained by both models. However, the minimum muscle effort model had a smaller R^2 value (*green bars*, 0.02 ± 0.20) than the minimum synergy effort model (*red bars*, 0.65 ± 0.10).

DISCUSSION

We investigated muscle patterns underlying the generation of isometric force at the hand along 32 uniformly distributed directions in tri-dimensional space. Across subjects, the directional tuning of most muscles was well captured by a spatial cosine function and muscle patterns for all force targets could be reconstructed by the combinations of 6 or 7 muscle synergies identified by NMF. We then estimated the force associated to muscle activation by multiple linear regressions and we used such linear mapping to predict the minimum muscle effort and the minimum synergy effort muscle patterns for each force target. We found that the prediction error with both minimum effort criteria was larger than the synergy reconstruction error but the error obtained minimizing the synergy effort was significantly smaller than the error obtained minimizing muscular effort. These results suggest that the CNS recruits suboptimal combinations of muscle synergies to generate isometric forces.

The estimation of the mapping between muscle activity and isometric force at the hand was necessary to predict the minimum effort muscle patterns for a given force target. We approximated such mapping during the generation of a static isometric force (hold phase) as a linear transformation between rectified, low-pass filtered, MVC-normalized EMGs and low-pass filtered forces. We could then estimate an EMG-to-force matrix by linear regression of the force components as a function of the activity of all recorded muscles. The assumption of linearity is reasonable when the posture does not change and generated forces are much smaller than the MVF (Lawrence and De Luca, 1983), as in our case. Linear models have been used before to predict isometric forces from EMG recordings (Valero-Cuevas et al., 2009) and minimum effort muscle patterns (Fagg et al., 2002). However, our linear approximation of the mapping between muscle activity and force may have contributed to the model prediction error. Qualitatively the muscle pulling directions estimated by multiple linear regressions appeared compatible with the directions expected from the known anatomical arrangement and mechanical action of the muscles. A quantitative evaluation of the EMG-to-force matrix obtained with our simple procedure might be possible by comparing such matrix with one derived using a detailed musculoskeletal model of the arm (Holzbaur et al., 2005) but such comparison is challenging because of the many subject-specific anatomical and physiological parameters that need to be determined in order to generate reliable predictions with a musculoskeletal model. Thus, we believe that our simplifying assumptions are adequate for the purpose of comparing the two minimum effort criteria, since both minimizations rely on the same EMG-to-force matrix.

A second concern with our approach is the selection of the number of synergies. We used two criteria frequently used in the muscle synergy literature (Tresch et al., 2006; Delis et al., 2013): the total variation accounted by the synergies (synergy reconstruction R^2) (Tresch et al., 1999; Torres-Oviedo et al., 2006) and the detection of a change in slope in the R^2curve (d'Avella et al., 2003; Cheung et al., 2005). In case of discrepancy between the two criteria we selected the number of synergies with a more uniform distribution of the preferred directions of the synergy activation coefficients. Both criteria depend, however, on *ad-hoc* thresholds and thus, while they ensure a meaningful comparison across subjects, they cannot guarantee that the correct number of synergies is selected. In a recent study of the muscle synergies underlying force production in a task similar to ours (Roh et al., 2012), a smaller number of synergies has been reported (3–5). Such difference may be due to the smaller number of muscles recorded in that study (8 vs. 17 in ours) and to the different definition of variance accounted for (VAF). As muscle patterns are multidimensional observations, we referred the synergy reconstruction error to the total variation (Mardia et al., 1979) of the muscle patterns, i.e., the multidimensional generalization of the variance of a scalar observation, and we defined $R^2 = 1-$ SSE/SST, with SSE the sum of the squared residual and SST as the sum of the squared residual with respect to the mean muscle pattern, proportional to the total variation (d'Avella et al., 2006; Delis et al., 2013). Roh and colleagues, in contrast, defined VAF $= 100 \times (1 -$ SSE/SST), with SST sum of the squared data, i.e., without subtracting the mean muscle pattern. As a consequence such VAF value is higher than the R^2 value for the same number of synergies and a smaller number of synergies are selected with the same threshold (90%). When we performed the same analysis of Roh and collaborators on our data, using the same 8 muscles, we found a comparable number of synergies (3–5). Notably, a minimum number of 4 synergies is required to generate forces in all spatial directions by non-negative combinations (Davis, 1954).

A number of previous studies have investigated whether the observed muscle patterns can be the result of effort minimization. Buchanan and Shreeve (1996) used models of the muscles about the elbow (11 muscles) and wrist (5 muscles) to compare the observed directional dependence of muscle activation with the prediction from the minimization of several cost functions, including sum of muscle force, stress, and normalized force (Buchanan and Shreeve, 1996). The choice of cost function had little influence on the results and all cost functions were not able to reliably estimate muscle activation as a

function of force direction, even if predictions at the wrist were more favorable than those at the elbow due to the smaller number of muscles and degrees-of-freedom. A sensitivity analysis indicated that the discrepancies between predicted and observed values could not be explained by errors in the physiological parameters of the models, calling into question the applicability of optimization analysis to study such tasks. Our results are in accordance with those observations and extend them to the generation of hand forces by a larger number of muscles acting at the elbow and the shoulder. Moreover, the larger prediction errors that we obtained minimizing muscle effort with respect to synergy effort suggest that the synergistic recruitment of muscles contributes to the sub-optimal co-activation of muscles.

Investigating wrist movements, Fagg and colleagues showed that minimizing effort, defined as we did as the sum of squared muscle activations, yields muscle activation patterns qualitatively similar to those observed experimentally, in particular, reproducing the observed cosine-like recruitment of the muscles as a function of movement direction and also appropriately predicting that certain muscles will be recruited more strongly in movement directions that differs significantly from their direction of action (Fagg et al., 2002). While our model predictions also reproduced cosine-like recruitments and qualitatively similar directional tuning curves in several muscles, in many cases we did observed qualitative and substantial discrepancies between predicted and observed muscle activations. Such poorer model performance may be due, as observed by Buchanan and Shreeve, by the larger number of muscles and degrees-of-freedom considered in our study.

A recent study used a static quadrupedal musculoskeletal model of the cat to predict limb forces and muscle activity in response to multidirectional postural perturbations while minimizing different formulations of control effort, including muscle and synergy effort (McKay and Ting, 2012). Patterns of muscle activity producing forces and moments at the center of mass necessary to maintain balance and the resulting ground reaction forces predicted by the models were compared to experimental data. Limb forces at different stance distances were well predicted by both minimum-effort solutions. Muscle tuning directions were found to be invariant across postural configurations, similar to experimental data, but the quality of the muscle pattern predictions were not quantified and there also appeared to be discrepancies (see their **Figure 8**), especially for the minimum muscle effort solution (e.g., no activity predicted in biceps femoris and gracilis), matching our observations in the human arm. McKay and Ting concluded that reduced-dimension neural control mechanisms, such as muscle synergies, can achieve similar kinetics to optimal solutions, demonstrating the feasibility of muscle synergies as physiological mechanisms for the implementation of near-optimal motor solutions. In our study we could not assess kinetics predictions, as the generation of a specific force target was a constraint in the optimization. However, our analysis of muscle pattern predictions also supports the conclusion that three-dimensional forces are generated as near- or sub-optimal motor solutions by muscle synergy combinations.

The fact that the observed muscle activation patterns did not minimize muscle or synergy effort does not rule out the possibility that they minimized some other cost. The additional co-contraction inherent in the non-minimal effort solutions might be related to an increase in stiffness during the hold phase possibly due to endpoint stability maximization (Franklin and Milner, 2003). Since the task was isometric, in principle there was no need to increase endpoint stiffness to generate a target output force precisely. On the contrary, because of signal-dependent noise in force production by muscle activation, the precision would decrease with an increase in co-contraction. However, subjects had to control a moving cursor in a realistic virtual environment and they might have adopted a control strategy usually employed when required to generate a force while maintaining a freely moving endpoint, typically a tool, close to a fixed position. In those conditions an increase in stiffness associated to an increase in co-contraction would be an appropriate control strategy to achieve higher positional stability at the cost of an additional muscular effort. Thus, as suggested in recent studies, the CNS might adopt habitual rather than optimal (de Rugy et al., 2012) or locally rather globally optimal (Ganesh et al., 2010) muscle coordination strategies.

Whether muscle synergies are organized by the CNS to simplify motor control and motor learning (Giszter et al., 2007; Bizzi et al., 2008; d'Avella and Pai, 2010; Bizzi and Cheung, 2013; d'Avella and Lacquaniti, 2013) or they are results from biomechanical and task constraints (Todorov and Jordan, 2002; Kutch et al., 2008; Kutch and Valero-Cuevas, 2012) is a controversial issue (Tresch and Jarc, 2009). Evidence for muscle synergies as neural control strategies has come mainly from the low-dimensionality in the muscle patterns recorded during a variety of behaviors and task conditions and across different species (Tresch et al., 1999; d'Avella et al., 2003, 2006, 2008, 2011; Krishnamoorthy et al., 2003; Hart and Giszter, 2004; Ivanenko et al., 2004, 2005; Cheung et al., 2005; Ting and Macpherson, 2005; Overduin et al., 2008; Muceli et al., 2010; Dominici et al., 2011; Chvatal and Ting, 2013; D'Andola et al., 2013; Gentner et al., 2013), from neural recordings and stimulation (Saltiel et al., 2001; Ethier et al., 2006; Gentner and Classen, 2006; Gentner et al., 2010; Hart and Giszter, 2010; Overduin et al., 2012), and, recently, from the observation that adaptation to a perturbation of the normal mapping between muscle activity and force, simulated in a virtual environment using myoelectric control, is slower when the perturbation is not compatible with the synergies than when it is (Berger et al., 2013).

Two recent studies (Kutch et al., 2008; Kutch and Valero-Cuevas, 2012) have argued against the neural origin of the muscle synergies involved in the generation of isometric forces. In a first study, Kutch and colleagues compared the directional dependence of the covariance of the force fluctuations observed experimentally during the generation of planar isometric forces with the index finger with the directional dependence predicted by either a minimum synergy effort model of a minimum muscle effort model (Kutch et al., 2008). They argued that, if individual muscles are activated flexibly and the force they generate is affected by signal-dependent noise (Harris and Wolpert, 1998), the force generated in the direction of action of an individual muscle must

show a covariance ellipse elongated in the direction of the force. In contrast, if muscles are recruited within fixed synergies, multiple muscles are always activated simultaneously and the force covariance must be on average less elongated in the direction of the target force. For isometric forces generated by the index finger on a plane, the observed force covariance directness was found to be more in agreement with the directedness predicted by minimum muscle effort than the directedness predicted by minimum synergy effort. However, we wonder whether the results of Kutch and colleagues depended on the fact that the synergies used in their calculation were not extracted from the data but generated randomly, while the directedness of the synergy model was evaluated only in three fixed directions corresponding to the peak values of the directedness of the data. We plan to test the directedness of the force covariance of three-dimensional forces generated at the hand by several arm muscles in a future study.

In a more recent study, Kutch and Valero-Cuevas studied the generation of isometric forces by actuation of the tendons of a cadaveric index finger and with a model of the human leg (Kutch and Valero-Cuevas, 2012). They argued that, if the set of all possible muscle coordination patterns that produce any single endpoint force vector are themselves a low-dimensional subset, the observed low-dimensionality of the muscle patterns could be misinterpreted as neurally-generated muscle synergies. Principal component analysis was performed on the set of all vertices of the solution set in muscle activation space for 16 planar force directions, identified with computational geometry techniques using the linear muscle-to-force mapping derived experimentally or from the model. The dimensionality of all possible coordination patterns resulted indeed lower than the number of muscles, thus, providing an assessment of the upper limit imposed by biomechanics, but, at least for the leg model, higher than the dimensionality typically observed in the data. Thus, such biomechanical limit to dimensionality should be directly compared to the dimensionality extracted from experimentally observed muscle patterns, as we also plan to do, to draw any conclusion on the neural origin of muscle synergies.

In conclusion, we have demonstrated that muscle patterns underlying the generation of three-dimensional forces can be reconstructed accurately by the combination of a small number of muscle synergies but they could not be predicted accurately by either minimization of muscle effort or synergy effort. However, the minimum synergy effort model fitted the experimental data much better than the minimum muscle effort model, suggesting that the CNS generates three-dimensional forces by sub-optimal recruitment of muscle synergies.

Muscle activities underlying many motor behaviors can be generated by a small number of basic activation patterns with specific features shared across movement conditions. Such low-dimensionality suggests that the central nervous system (CNS) relies on a modular organization to simplify control. However, the relationship between the dimensionality of muscle patterns and that of joint torques is not fixed, because of redundancy and non-linearity in mapping the former into the latter, and needs to be investigated. We compared the torques acting at four arm joints during fast reaching movements in different directions in the frontal and sagittal planes and the underlying muscle patterns. The dimensionality of the non-gravitational components of torques and muscle patterns in the spatial, temporal, and spatiotemporal domains was estimated by multidimensional decomposition techniques. The spatial organization of torques was captured by two or three generators, indicating that not all the available coordination patterns are employed by the CNS. A single temporal generator with a biphasic profile was identified, generalizing previous observations on a single plane. The number of spatiotemporal generators was equal to the product of the spatial and temporal dimensionalities and their organization was essentially synchronous. Muscle pattern dimensionalities were higher than torques dimensionalities but also higher than the minimum imposed by the inherent non-negativity of muscle activations. The spatiotemporal dimensionality of the muscle patterns was lower than the product of their spatial and temporal dimensionality, indicating the existence of specific asynchronous coordination patterns. Thus, the larger dimensionalities of the muscle patterns may be required for CNS to overcome the non-linearities of the musculoskeletal system and to flexibly generate endpoint trajectories with simple kinematic features using a limited number of building blocks.

Keywords: modularity, reaching movements, human subjects, inverse dynamics, EMGs, muscle synergies, temporal components, joint torques

INTRODUCTION

How the central nervous system (CNS) coordinates a large number of muscles to generate complex motor behaviors is an open question. The dynamic complexity of the skeletal system with its many degrees of freedom (DoF), the versatility of the motor system, capable of accomplishing many different tasks, and the redundancy and non-linearity of the muscular apparatus all pose challenging control problems. A modular architecture has been proposed as a way for the CNS to tackle the complexity of motor control. In a modular architecture control is subdivided among basic building blocks, allowing for an efficient yet flexible task decomposition. In particular, a modular generation of the muscle patterns might allow for a low-dimensional representation of the motor output incorporating knowledge on the dynamic behavior of the musculoskeletal system into a small set of basic functions shared across tasks and conditions. Recently, the modular control hypothesis has been supported by observations of low-dimensionality in the muscle patterns underlying a variety of motor behaviors in different species. Using multidimensional decomposition techniques such as principal component analysis (PCA), factor analysis (FA), independent component analysis (ICA), and non-negative matrix factorization (NMF) it has been possible to reconstruct the muscle activation patterns as the combination of a small number of components (Tresch et al., 2006; Giszter et al., 2007; Ting and McKay, 2007; Bizzi et al., 2008; Tresch and Jarc, 2009; Lacquaniti et al., 2012; d'Avella and Lacquaniti, 2013). These components may capture different features of the muscle patterns shared across task conditions, such as specific relationships in the strength of activation of groups of muscles, i.e., muscle synergies (Tresch et al., 1999; Ting and Macpherson, 2005) or M-modes (Krishnamoorthy et al., 2003), specific time-courses of the activation waveforms for all muscles, i.e., temporal components (Ivanenko et al., 2004; Dominici et al., 2011), and specific collections of muscle activation waveforms, i.e., time-varying muscle synergies (d'Avella et al., 2003, 2006) but they all construct muscle patterns by linear combinations of a

small number of generators. However, even if muscle patterns can be accurately described by such generators, task accomplishment depends on the actual joint torques and the consequent joint motions produced by muscle contractions. Thus, to better understand how motor tasks may be accomplished by the combination of a few muscle pattern generators it is necessary to assess the relationship between the organization of muscle patterns and that of joint torques.

While joint torques underlying many different motor behaviors have been investigated extensively, a characterization of their dimensionality with multidimensional decomposition approaches such as those recently used to analyze muscle patterns is missing. Joint torque generators for a two-joint arm have been identified before using NMF from simulated data (Chhabra and Jacobs, 2006) but not from experimental data. Focusing on reaching movements in vertical planes, as in many previous studies (Soechting and Lacquaniti, 1981; Lacquaniti et al., 1982; Flanders et al., 1994, 1996; d'Avella et al., 2006, 2008, 2011), our aim was to investigate the dimensionality of joint torques and to compare it with the dimensionality of the muscle patterns. Moreover, we wanted to explore systematically the dimensionality of different types of generators, i.e., generators capturing shared structure in the spatial–across joints or muscles–, temporal, and spatiotemporal dimensions. Planar point-to-point reaching movements, for which joint torques can be estimated using a simplified dynamical model of the arm with two joints, are normally associated with bell-shaped velocity profiles and biphasic torque profiles (Morasso, 1981; Soechting and Lacquaniti, 1981). The shape of such profiles is invariant with respect to movement speed (Soechting and Lacquaniti, 1981) or load (Lacquaniti et al., 1982) and the relationship between shoulder and elbow dynamic torques is almost linear (Soechting and Lacquaniti, 1981; Lacquaniti et al., 1986; Gottlieb et al., 1997). Similar observation were made for reaching movements in three-dimensional space (Lacquaniti et al., 1986). These observations indicate that joint torques for reaching have remarkable regularities suggesting that their dimensionality is also low. One might hypothesize that there is a one-to-one relationship between muscle pattern generators and torque generators. However, biomechanical characteristics and constraints must be taken into account.

To generate the joint torques $\boldsymbol{\tau}(t)$ required to move the arm along a given joint trajectory $\mathbf{q}(t)$, i.e., torques for which the trajectory is a solution of the arm motion equations [see Equation (3) in Material and Methods], the CNS, according to the modular control hypothesis, combines a set of N_m (spatial, temporal, or spatiotemporal) muscle pattern generators:

$$\mathbf{m}(t) = \sum_{n=1}^{N_m} a_n \, \mathbf{v}_n(t)$$

where $\mathbf{v}_n(t)$ is the n-th spatiotemporal generator or the product of the n-th temporal component times the n-th spatial weighting vector for spatial and temporal generators (see "Dimensionality of motor commands" in Materials and Methods). The tension generated by the activation of the each muscle is determined by the dynamics of the musculotendon unit, which depends non-linearly on muscle length, velocity, and muscle activation. Muscle length and velocity depend on joint angles and joint velocities via a matrix of moment arms. Then, muscle torque depends on joint angles, joint velocities, and muscle activations

$$\boldsymbol{\tau} = \boldsymbol{\tau}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{m}).$$

Thus, the required torque profile can be generated by appropriate combination of the muscle pattern generators, i.e., it can be expressed as a function of the combination coefficients **a**:

$$\boldsymbol{\tau} = \boldsymbol{\tau}(\mathbf{q}, \dot{\mathbf{q}}, \sum_n a_n \, \mathbf{v}_n).$$

The torque does not depend in general linearly on the muscle activations and, consequently, on the combination coefficients **a**. When linearity is an adequate approximation, muscle torque can be expressed as a linear combination of the "force fields" associated to each generator, $\boldsymbol{\varphi}_n = \boldsymbol{\varphi}_n(\mathbf{q}, \dot{\mathbf{q}}) = \boldsymbol{\tau}(\mathbf{q}, \dot{\mathbf{q}}, \mathbf{e}_n)$, where $\mathbf{e}_n$ is the unit vector along the n-th dimension in coefficient space:

$$\boldsymbol{\tau} = \sum_n a_n \, \boldsymbol{\varphi}_n(\mathbf{q}, \dot{\mathbf{q}}),$$

i.e., limb control can be achieved by combination of force-field primitives (Bizzi et al., 1991; Giszter et al., 1993, 2007; Mussa-Ivaldi et al., 1994; Kargo and Giszter, 2000a,b; Kargo et al., 2010; Giszter and Hart, 2013). However, torques profiles observed across different task conditions can also be expressed as (or approximated by) a linear combination of N_τ torque generators:

$$\boldsymbol{\tau}(t) = \sum_{n=1}^{N_\tau} b_n \, \mathbf{u}_n(t) \, .$$

Even if there is a one-to-one relationship between muscle pattern generators and force-field primitives, the number of muscle pattern generators must be larger than the number of torque generators because of the non-negativity constraint on muscle activations. As muscles can only pull, muscle pattern generators are combined with non-negative combination coefficients and, even considering a linear muscle-to-torque mapping, to generate torques spanning a N_τ-dimensional space at least $N_\tau + 1$ non-negative generators are required (Davis, 1954; Valero-Cuevas, 2009). Moreover, because of the redundancy of the muscular system, different muscle patterns can generate the same torques and thus the muscle pattern dimensionality can be larger than the minimum imposed by non-negativity, i.e., $N_m \geq N_\tau + 1$. Thus, the minimum number of muscle pattern generators depends on the actual dimensionality of the joint torque required to perform all conditions of a specific task and the actual number of muscle pattern generators can be larger than the minimum and must be determined experimentally. Importantly, we consider here tasks whose conditions can be described by a set of parameters, such as, for example, the position of a target of a point-to-point reaching movement. Then, since the skeletal system is also redundant for the performance of many tasks, e.g., a specific position of the wrist in space can be achieved with many different joint angle

configurations, the actual dimensionality of the joint torques may be lower than the number of joints (i.e., DoF) involved and it must also be determined experimentally. Finally, while the minimal number of muscle pattern generators might guarantee an optimal solution in terms of computational complexity, it might be suboptimal in terms of other costs such as muscular effort. Thus, comparing the torque and muscle pattern dimensionality can provide new information on the control strategy employed to perform a specific task.

We analyzed EMGs data recorded from 19 muscles and kinematic data collected from markers positioned on the arm of subjects performing fast reaching movements from one starting position to 8 targets on the sagittal plane and eight targets on the frontal plane. We used a dynamic model of the arm with four rotational joints (three at the shoulder and one at the elbow) and three translational DoF (the position in space of the shoulder) to estimate joint torques from joint angles with an inverse dynamics computation (Corke, 1996). We then considered the dynamic component of the torques, i.e., the total torques with the gravitational components removed (Gottlieb et al., 1997), and the phasic component of the muscle activity waveforms, i.e., the total rectified and filtered EMG waveforms with the tonic, anti-gravity components removed (Flanders and Herrmann, 1992; d'Avella et al., 2006). Spatial, temporal, and spatiotemporal torque generators were identified by performing PCA on different arrangements of the data matrix. Similarly, spatial, temporal, and spatiotemporal muscle pattern generators were identified with NMF. We first determined the dimensionality of generators according either to a threshold on the fraction of data variation explained (Tresch et al., 1999; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006; Roh et al., 2012) or to the detection of a "knee" in the curve of the variation explained as a function of the number of generators (d'Avella et al., 2003; Cheung et al., 2005; d'Avella et al., 2006; Tresch et al., 2006). We used the former criterion for the torque data and the latter for the EMG data. However, to directly compare the dimensionality of torques and muscle patterns, we then also used a single criterion which took into account the different intrinsic variability of the two datasets when determining their dimensionality (Cheung et al., 2009).

MATERIALS AND METHODS

PARTICIPANTS, EXPERIMENTAL APPARATUS, AND TASK

Four right handed subjects (aged between 27 and 40) gave their written informed consent to participate in the study, which conformed with the Declaration of Helsinki and had been approved by the Ethical Review Board of the Santa Lucia Foundation. The experimental apparatus and reaching task has been described in details in a previous report (d'Avella et al., 2006). Briefly, standing subjects gripped with their right hand an handle (weight 180 g) which had a sphere (diameter 4 cm) attached to one extremity. The center of sphere was aligned with the axis of the forearm at a distance of 12 cm from center of the palm. Participants were instructed to move the sphere between a central position and 8 targets uniformly arranged on a circle at 15 cm of distance on either the frontal or sagittal plane while minimizing shoulder and wrist movements. The central position was adjusted for each subject so that it required maintaining the upper arm vertical and aligned to the trunk and the elbow flexed at 90°. The targets were indicated by transparent spheres lighted from inside by an LED. In each trial, after holding the sphere at the start position for at least 1 s, subjects were instructed to move after a go signal, to reach the target with a movement of a duration (defined as the interval in which the speed of the sphere was above 10% of its maximum) shorter than 400 ms, and to hold there for at least 1 s. Unsuccessful trials were repeated. Each subject performed each movement successfully five times in different blocks of trials for a total of 160 point-to-point movements (2 planes × 8 targets × 2 directions -from the center to the target and from the target back to the center- × 5 repetitions).

DATA ACQUISITION

The motion of the arm was recorded using an optic motion-tracking system (Optotrack 3020, Nothern Digital, Waterloo, Ontario, Canada) with a sampling frequency of 120 Hz and spatial resolution below 0.1 mm. Active optical markers were positioned on the shoulder (acromion), the upper arm (at the proximal end close to the head of the humerus), the elbow (epicondylus lateralis), the wrist (one over the styloid process the radius and one on the styloid process of the ulna). The motion of the sphere on the handle (end-point) was recorded with an electromagnetic motion-tracking system (Fastrak, Polhemus, Calchester, VT) with sampling frequency of 120 Hz and spatial resolution below 4 mm, as estimated by a calibration process performed within the workspace used in the experiment.

EMG activity was recorded with active bipolar surface electrodes (DE 2.1; Delsys, Boston,MA) from the following muscles: biceps brachii, short head (BicShort), biceps brachii, long head (BicLong), brachialis (Brac), pronator teres (PronTer), brachioradialis (BrRad), triceps brachii, lateral head (TrLat), triceps brachii, long head (TrLong), triceps brachii, medial head (TrMed) deltoid, anterior (DeltA), deltoid, middle (DeltM), deltoid, posterior (DeltP), pectoralis major, clavicular portion (PectClav), pectoralis major, lower portion (PectLow), trapezius superior (TrapSup), trapezius middle (TrapMid), trapezius inferior (TrapInf), latissimus dorsi (LatDors), teres major (TeresMaj), infraspinatus (InfraSp). EMG signal was band-pass filtered (20–450 Hz) and amplified (total gain 1000, Bagnoli-16, Delsys Inc.). EMG data were digitized at 1 KHz (PCI-6035E, National Instruments, Austin, TX).

Data acquisition and experiment control were performed on a workstation with custom software written in LabView (National Instruments, Austin, TX). Fastrak data were processed on-line to compute the movement time and target accuracy and to provide auditory feedback about unsuccessful trials. The experiment control program logged the time of all relevant behavioral events.

DATA ANALYSIS

End point kinematics

All analyses were performed with custom software written in Matlab (Mathworks, Natick, MA). Position and orientation of the handle and the measured geometric parameters of the handle were used to compute the position of the end-point. The data were low-pass filtered (FIR filter; 15 Hz cutoff; zero-phase

distortion; Matlab *fir1* and *filtfilt* functions) and differentiated to compute tangential velocity and speed. For each movement we computed the *onset time* and the *end time*, defined respectively as the time in which the speed profile crossed 10% of its maximum value, and the *movement duration* (MT), defined as the interval between the movement onset and the movement end.

Arm model

A kinematic and kinetic model of the arm, incorporating geometrical and inertial parameters of the upper arm and forearm segments, was used to estimate joint angles and joint torques from the recorded spatial position of the shoulder, the elbow, and the wrist markers. The kinematic model was developed using the Denavit-Hartenberg (D-H) notation (Hartenberg and Denavit, 1955), i.e., as chain of articulated links with four parameters for each link (a: length, α : twist, d: offset, ϑ : joint angle) describing the position and orientation of a Cartesian reference frame fixed on each link with respect to the reference frame fixed on the preceding link of the chain according to the 4×4 homogeneous transformation matrix T:

$$T = \begin{bmatrix} \cos\vartheta & -\sin\vartheta\cos\alpha & \sin\vartheta\sin\alpha & a\cos\vartheta \\ \sin\vartheta & \cos\theta\cos\alpha & -\cos\theta\sin\alpha & a\sin\theta \\ 0 & \sin\alpha & \cos\alpha & d \\ 0 & 0 & 0 & 1 \end{bmatrix}. \quad (1)$$

The rotation axis of each joint coincides with the z axis of the preceding link in the chain. The x axis in each frame is directed as the normal between the z axis of that frame and the z axis of the next frame. In this way the joint angle is the angle between the x axes of the frames of the two links connected by the joint. We modeled four rotational degrees-of-freedom (DOFs) of the arm—three rotations at the shoulder, i.e., adduction, flexion and external rotation, and one rotation at the elbow, i.e., elbow flexion (see **Figure 1**)—and three translational DOFs of the shoulder. We assumed that shoulder was a spherical joint (i.e., the rotation axes of the three joints intersect at a single point). Lengths of upper arm, forearm, and hand of each subject were estimated as a function of the subject's weight and height according to regression equations (Winter, 1990). Forearm, hand, and handle were considered a single link (7th) of length equal to the sum of the forearm length and the length of the opened hand, thus approximating the total length of the closed hand and the handle along the direction of the forearm axis with the length of the opened hand.

The kinetic model of the arm was developed adding to each link its inertial parameters (mass, center of mass, inertia tensor) also estimated as a function of the subject's weight and height according to regression equations (Zatsiorsky and Seluyanov, 1983). No mass was associated to the first three links required to represent the spatial position of the shoulder. However, these translational DOFs were introduced to take into account shoulder movements when estimating the joint torques. The mass of the upper arm was assigned to the 6th link, which had an offset equal to the length of the upper arm segment. The mass of the forearm, hand, and handle was assigned to the 7th link, associated with the elbow flexion. The inertial parameters for this link were computed from the inertial parameters estimated separately from the regression equations for the forearm and hand. As the estimated position of the center of mass of the hand and of the handle coincided, the mass of the handle (180 g) was summed to the mass of the hand. The moments of inertia were computed with respect to its center of mass. The model was implemented in Matlab using the Robotic Toolbox (Corke, 1996, 2011). The D-H parameters of the generic arm model are reported in **Table 1** and the specific geometric and inertial parameters estimated for each subject are reported in **Table 2**.

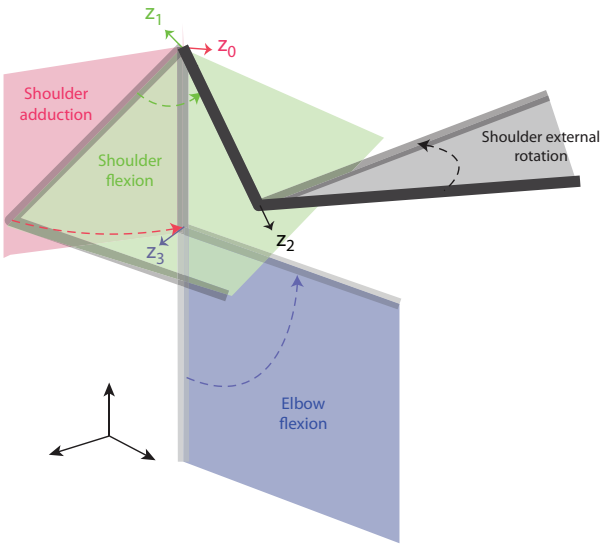

FIGURE 1 | Joint angle definition for the arm model. The four joint angles included in the model (shoulder adduction, shoulder flexion, shoulder external rotation, and elbow flexion) are illustrated by a sequence of postures in space of a two-link arm. The four rotation axes are indicated by colored arrows and correspond to the z-axes of the four reference frames defined according to the D-H notation (see text) and labeled z_0–z_3.

Joints kinematics

The arm model was used to estimate at each time sample the shoulder adduction angle, the shoulder flexion angle, the shoulder external rotation angle, the elbow flexion angle using the positions of the shoulder and elbow markers and the mean position between the two wrist markers. For each time sample and each joint angle, a vector between two markers aligned with the axis of the limb segment defining the rotation of that joint (i.e., shoulder and elbow markers for shoulder adduction and shoulder flexion, elbow and wrist markers for shoulder external rotation and elbow flexion) was computed first. Then, the segment vector was transformed into the reference frame associated to the joint according to the matrices defined by Equation (1) and the angle computed as

$$\vartheta_i = \tan^{-1}(y/x) \quad (2)$$

where x and y are the coordinate of the vector in the reference frame associated with the joint rotation axis (z axis). To compensate for potential misalignment between the tracker z axis and the vertical axis, the coordinates of the markers were first rotated into a Cartesian reference frame with the gravitational acceleration along the z axis. The direction of the gravitational acceleration

Table 1 | D-H parameters for the 7 DOFs arm model.

Link	DOF	α_i	a_i	θ_i	d_i	Type	Offset
1	Sh X	$\pi/2$	0	$\pi/2$	0	P	0
2	Sh Y	$\pi/2$	0	$\pi/2$	0	P	0
3	Sh Z	$\pi/2$	0	$\pi/2$	0	P	0
4	Sh adduction	$\pi/2$	0	0	0	R	$-\pi/2$
5	Sh flexion	$\pi/2$	0	0	0	R	$\pi/2$
6	Sh external rotation	$\pi/2$	0	0	L_U	R	π
7	El flexion	0	L_F	0	0	R	$\pi/2$

Sh, shoulder; El, elbow; L_F, forearm link length; L_U, upper arm link length; P is for prismatic joints and R is for revolute joints.

L_U, upper arm length; L_F, forearm length (including hand and handle); rU, position of the upper arm center-of-mass along the link-6 x axis; rF, position of the upper arm center-of-mass along the link-7 x axis; I(lo) U, inertia along the longitudinal axis of the upper arm; I(ap) U, inertia along the antero-posterior axis of the upper arm; I(tr) U, inertia along the trasversal axis of the upper arm; I(lo) F, inertia along the longitudinal axis of the forearm + hand + handle system; I(ap) F, inertia along the antero-posterior axis of the forearm + hand + handle system; I(tr) F, inertia along the trasversal axis of the forearm + hand + handle system.

was estimated by means of a calibration of based on tracking two markers attached to the fulcrum and the extremity of a pendulum.

Angular velocity and acceleration were computed by numerical differentiation. To validate the kinematic model, forward kinematics was used to compare estimated and measured end-point trajectories.

Inverse dynamics

Joint angles, joint velocities and joint accelerations were used to estimate the torque profiles via recursive Newton-Euler calculation (*rne* function of Matlab Robotics Toolbox). We computed the total torques $\boldsymbol{\tau}$

$$\boldsymbol{\tau} = \mathbf{M}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} + \mathbf{G}(\mathbf{q}) \tag{3}$$

where $\mathbf{M}$ is the manipulator inertia matrix, $\mathbf{C}$ is the Coriolis and centripetal torque, and $\mathbf{G}$ is the gravitational torques. To estimate non-gravitational (dynamic) torques we subtracted gravitational torques from the total torques.

To validate the inverse dynamics calculation we also performed a forward dynamics simulation (*fdyn* function of Matlab Robotics Toolbox) using the arm model and the estimated torque profiles to reproduce the original joint angle trajectories.

Data preprocessing

The EMGs for each trial were digitally full-wave rectified, low-pass filtered (FIR filter, 20 Hz cut-off, zero-phase distortion, Matlab *fir1*, and *filtfilt* functions), and integrated over 10 ms intervals. In a few cases muscle waveforms showed some artifacts, possibly due to a partial detachment of the electrode from the skin, or to an high correlation between two or more muscles, and those muscles were removed from further analysis (subject 1: PectLow; subject 2: TrapInf, PectLow).

EMGs and torques for all the trials in each experimental condition (2 planes × 8 targets × 2 directions) were aligned on the time of movement onset and averaged.

Finally, both torques and muscle waveforms were normalized in time to equal MT and resampled with 50 samples per MT. Samples from 0.5 MT before movement onset to 0.5 MT after movement end (total 100 samples) were considered for further analysis.

Dimensionality of motor commands

We consider a set of D command signals (joint torques or muscle patterns) delivered by a controller in a given time interval (sampled T times) to accomplish a task in one of K distinct task conditions (e.g., different reaching targets). We hypothesize that a modular controller generates these command signals by modulating and combining a small set of generators whose structure is invariant across all task conditions. The structure of such generators may be defined in the spatial (across signals, i.e., muscles or joints), temporal, and spatiotemporal domains. The dimensionality of the ensemble of command signals is then simply the number of generators necessary to accomplish all K tasks conditions.

Spatial dimensionality is the number of generators necessary to capture time-invariant relationships between the signals. For N generators:

$$\mathbf{x}^k(t) = \sum_{n=1}^{N} c_n^k(t)\, \mathbf{w}_n \tag{4}$$

where $\mathbf{x}^k(t)$ are the set of signals for condition k, i.e., a vector-valued (D-dimensional) function time (or a $D \times T$ matrix for discrete time samples), $c_n^k(t)$ is a condition-dependent, time-varying combination coefficient for the n-th generator, $\mathbf{w}_n$ is the condition-independent, time-invariant n-th spatial generator, i.e., a D-dimensional vector capturing the relative activation weight of different signals.

Temporal dimensionality is the number of generators necessary to capture temporal components shared across all signals (i.e., space-invariant). For N generators:

$$\mathbf{x}^k(t) = \sum_{n=1}^{N} c_n(t)\, \mathbf{w}_n^k \tag{5}$$

where $\mathbf{x}^k(t)$ are again the set of signals for condition k, $c_n(t)$ is the condition-independent, time-varying n-th generator (or temporal component), $\mathbf{w}_n^k$ is the condition-dependent, time-invariant n-th D-dimensional weight vector for the n-th component. Notice how the critical difference in the definition of spatial and temporal generators and dimensionality is in the dependence on the task condition (k). Indeed, generators are useful concepts only if they can be used for a variety of conditions thus allowing an effective reduction of the number of parameters to select for each condition.

Spatiotemporal dimensionality is the number of generators capturing simultaneously invariant spatial and temporal features in the signals. Thus, each generator includes a set of signal components that can be expressed as a time-varying vector. For N generators

$$\mathbf{x}^k(t) = \sum_{n=1}^{N} a_n^k \mathbf{v}_n(t) \tag{6}$$

where a^k is a condition-dependent combination coefficient for the n-th generator, $\mathbf{v}_n(t)$ is the n-th spatiotemporal generator, i.e., a condition-independent, time-varying D-dimensional vector (or a $D \times T$ matrix for discrete time samples). However, as different signals may be related synchronously or asynchronously, we can distinguish the case of *synchronous* spatiotemporal generators:

$$\mathbf{v}_n(t) = c_n(t)\mathbf{w}_n \tag{7}$$

in which each generator $\mathbf{v}_n(t)$ can be expressed as the product of a scalar function of time $c_n(t)$times a time-invariant weight vector $\mathbf{w}_n$. In contrast, asynchronous spatiotemporal generators cannot in general be factorized into separate spatial and temporal generators.

In addition to being scaled in amplitude, spatiotemporal generators may also be recruited at different times across task conditions, i.e., they may also show invariance for time shifts (d'Avella et al., 2003, 2006). If we assume that the duration of each spatiotemporal generator is smaller than the duration of the signals, we can incorporate condition-dependent onset times t_n^k into Equation (6):

$$\mathbf{x}^k(t) = \sum_{n=1}^{N} a_n^k \mathbf{v}_n(t - t_n^k) \tag{8}$$

Identification of generators and their dimensionality

To investigate the spatial, temporal, and spatiotemporal dimensionality of joint torques and muscle patterns we used multidimensional decomposition techniques to identify the different types of generators. We considered the dynamic component of the torques and the phasic component of the muscle activity waveforms. We then used PCA to identify torque generators and, because of the inherent non-negativity of muscle activity, we used NMF to identify muscle pattern generators. Finally, as discussed below, we selected the number of generators with three different criteria, two specific for each dataset and one for both datasets.

Dynamic torques and phasic muscle patterns. Reaching movements in vertical planes require torques and muscle activities to accelerate and decelerate the limb and to balance gravitational forces. In this work we focused on the former components, i.e., dynamic torques and phasic muscle patterns. Dynamic torques were computed as the total torques with the gravitational components [the last term of the right hand side of Equation (3)] removed (Gottlieb et al., 1997). Flanders and collaborators (Flanders and Herrmann, 1992) found that it is possible to distinguish the phasic component (related to the movement) from the tonic one (related to maintain a specific posture of the arm) of an EMG signal. As in d'Avella et al. (2006) we used a subtraction procedure to remove the tonic component, i.e., we subtracted a constant muscle activation level before and after the movement and a linear ramp between the two constant values during the movement. After the subtraction a small fraction of EMG samples assumed negative values, indicating that the phasic EMG activity was lower than the tonic activity. However, in order to use the NMF algorithm, we set to zero all negative values (ratio of negative area over total area of all muscles, 0.15 ± 0.04, mean $\pm SD$ over subjects). To assess the effect of this procedure on the number of generators and on their structure, we also identified generators from the original phasic muscle patterns without imposing a non-negativity constraint and using an iterative factorization algorithm based on gradient descent in place of NMF (see below).

Data matrices. To identify spatial, temporal, and spatiotemporal generators, joint torque and muscle patterns data, after preprocessing, were organized into three different data matrices that were factorized by either PCA (torques) or NMF (muscle patterns). For each subjects we identified generators from K task conditions ($K = 32$, except for subject 3 for which we had to exclude 2 conditions on the frontal plane and 2 on the sagittal plane because of missing data from the arm markers used to compute joint angles). To identify spatial generators, the data for each condition (D signals, EMG or torque, times T samples, with $T = 100$ after time normalization and resampling, see **Figure 2**) were arranged into a data matrix $\mathbf{X}$ with D row and $T \times K$ columns which was factorized, according to Equation (4) in matrix notation, as $\mathbf{X} = \mathbf{W}\ \mathbf{C}$, where $\mathbf{W}$ is the condition-independent synergy matrix with D rows and N columns, N number of generators, and $\mathbf{C}$ is the matrix of condition- and time-dependent combination coefficients with N rows and $T \times K$ columns. For temporal generators, in contrast, the data matrix was constructed by arranging the waveforms from all signals in all conditions as columns, i.e., $\mathbf{X}$ had T rows and $D \times K$ columns, and it was factorized, according to Equation 5 in matrix notation, as $\mathbf{X} = \mathbf{C}\,\mathbf{W}$, with $\mathbf{C}$ is the condition-independent matrix of temporal components, with T rows and N columns, and $\mathbf{W}$ is the condition- and signal-dependent matrix of weights, with N rows and $D \times K$ columns. Finally, for spatiotemporal generators, the data samples for all signals of each conditions were arranged in a column and the data matrix $\mathbf{X}$, with $D \times T$ rows and K columns, was factorized, according to Equation 6 in matrix form, as $\mathbf{X} = \mathbf{V}\ \mathbf{A}$, with $\mathbf{V}$ condition-independent matrix of time-varying synergies with $D \times T$ rows and N columns and $\mathbf{A}$ condition-dependent

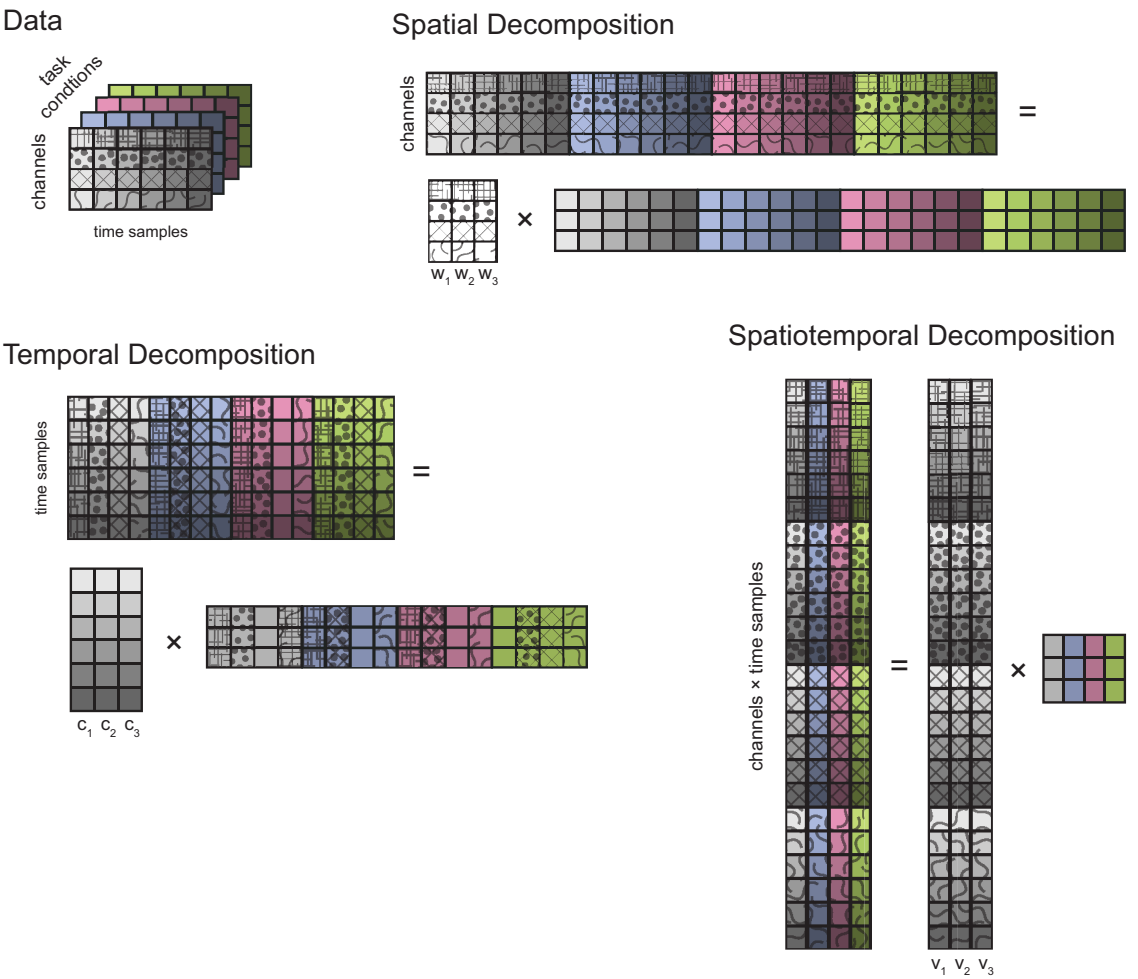

FIGURE 2 | Types of multidimensional decomposition of data from different task conditions. Data collected from *D* channels (4 in this schematic illustration, represented by different patterns) over *T* time samples (6, represented by different color saturations) in a single task condition are represented by a grid of squares. Different task conditions are represented with different background colors. A spatial decomposition is obtained by factorizing the data matrix obtained by stacking the data from individual conditions horizontally (i.e., matching their spatial—channels—dimension) into a matrix of *N* (3) spatial generators (*D* rows and *N* columns) times a matrix of time-and condition-dependent coefficients. A temporal decomposition is obtained by factorizing the transpose of data matrix obtained by stacking the data from individual conditions vertically (i.e., matching their temporal dimension) into a matrix of *N* (3) temporal generators (*T* rows and *N* columns) times a matrix of channel- and condition-dependent coefficients. Finally, a spatiotemporal decomposition is obtained by arranging all the data samples of each condition into a column and factorizing the resulting matrix into a matrix of *N* (3) spatiotemporal generators (*D* × *T* rows and N columns) times a matrix of condition-dependent coefficients.

matrix of combination coefficients with *N* rows and *K* columns. For joint torque generators, the covariance of the data matrix was computed and, for each *N*, the first *N* principal components (extracted using MATLAB *pcacov* function) were considered. For muscle pattern generators, for each *N*, **C** and **W** matrices were initialized randomly and the best solution out of 20 runs of the NMF algorithm was selected. Each run of the iterative algorithm was terminated when the reconstruction R^2 increased in one iteration by less than 10^{-4} for five consecutive iterations. To assess the effect of clipping to zero the negative values of the phasic muscle patterns, we also identified generators without non-negativity constraints using an iterative gradient descent algorithm. We minimized the data reconstruction error by combination of spatial, temporal, and spatiotemporal generators iterating a step in which combination coefficients (**C** and **A**), in the spatial and spatiotemporal cases, and weights (**W**), in the temporal case, were updated and a step in which synergies (**W** and **V**), in the spatial and spatiotemporal cases, and temporal components (**C**), in the temporal case, were updated. Both updates were performed along the direction opposite to the error gradient with step size of 0.05 for the combination coefficients (spatial and spatiotemporal cases), 0.0018 for the weights (temporal case), 0.0005 for the synergies (spatial and spatiotemporal cases), 0.0019 for the temporal components. These gradient step sizes were selected within a range of values in order to achieve the highest reconstruction R^2. As in d'Avella et al. (2006), in the spatial and spatiotemporal cases, we added a term to the error function to penalize large negative values in the identified synergies. The same number of

runs and termination conditions as for the NMF algorithm were used.

Selection of the number of generators. For torque generators, we selected their number as the minimum number which explained at least 90% of the data variation (VAF or R^2, defined as 1—SSE/SST, with SSE sum of square residuals of the data reconstruction by the generators, and SST sum of the squared residuals of the data with respect to the mean over the rows of the data matrix). Such criterion ("R^2 threshold") has been frequently used in the muscle synergy literature (Tresch et al., 1999; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006; Roh et al., 2012), even if sometimes with a different definition (i.e., with SST defined as the sum of the squared data, see Delis et al., 2013). Such criterion is based on the assumption that the fraction of data variation unexplained is due to noise and the threshold is supposed to separate structured variation due to the combination of generators and noise. However, if an independent estimation of the noise level is not available the choice of such threshold is necessarily *ad-hoc*. An alternative approach, also used in previous studies (d'Avella et al., 2003; Cheung et al., 2005; Tresch et al., 2006), that we used for selecting the number of muscle pattern generators is the detection of a "knee" in the curve of R^2 as a function of the number of generators. Such criterion ("R^2 knee") relies on the assumption that the noise is isotropic, i.e., contributes equally to all dimensions, and does not depend on a specific assumption of the relative level of noise. To detect a change in slope in the R^2 curve, for each N, we performed a linear fit of the portion of the curve from N to the end (i.e., D) and we selected N for which the mean square error of the fit was $< 10^{-4}$, indicating that the "tail" of the curve after the "knee" was essentially straight. We could not use this second criterion for the torques as their maximum spatial dimension (4) was too low and it was impossible to identify a "knee" with such procedure. However, to compare torque and muscle pattern with the same criterion, we also determined their dimensionality with a criterion ("R^2 shuffle") that took into account the different intrinsic noise levels of the two datasets. We then used a threshold on the slope of the R^2 curve according to slope of the curve obtained after a random shuffling the rows of the data matrix (Cheung et al., 2009). Data samples after shuffling were low-pass filtered to match the smoothness in the original data. By shuffling the data the multidimensional structure of the original data was lost but each dimension maintained the original variability. Thus, we selected the number of generators as the point on the original R^2 curve at which any further increase in the number of extracted generators yielded an R^2 increase smaller than 75% of that for the generators extracted from the shuffled data (mean over 50 extractions from reshuffled data).

Comparison of generators across subjects. To compare generators across subjects, we tested how well a set of generators identified in one subject could reconstruct the data of a different subject. We then computed a R^2-value to assess the similarity of the subspaces spanned by the generators of different subjects. To assess the significance of these R^2-values we performed a Monte Carlo simulation identifying generators from random data obtained by randomly shuffling the original data (50 runs for each subject and type of generator). We then computed the 95% percentile of the distribution of R^2-values for the reconstruction of the original data with generators identified from random data.

Effect of potential contamination of EMG recordings by cross-talk. As surface EMG recordings can be affected by cross-talk due to volume conduction of the EMG signal from neighboring muscles, we performed a Monte Carlo simulation to assess the effect of such potential contamination on the dimensionality of the spatial muscle pattern generators. For each muscle, i.e., the i-th row of the normalized data matrix $\mathbf{X}$, we simulated a cross-talk contamination from a second muscle (j-th row), randomly chosen from all other muscles and not limited to the neighboring ones, according to a cross-talk weight (α) randomly drawn from an exponential distribution with mean 0.1, i.e., $X'_{ik} = X_{ik} + \alpha X_{jk}$. We then identified the generators from the contaminated data matrix $\mathbf{X}'$ with NMF and we estimated their dimensionality. For each subject, we performed a total of 100 simulation runs, and, across all subjects, we found that the dimensionality estimated using the contaminated data matrix was different from the dimensionality estimated using the original matrix only in 6.7% of runs (0 runs for subjects 1, 2, 4; 27 runs for subject 3, mean dimensionality difference 0.27). Thus, while we cannot exclude that our EMG recordings were not affected by cross-talk, we are confident that such potential contamination did not significantly alter muscle pattern dimensionality estimation.

RESULTS

DYNAMIC TORQUES

Joint torques were estimated by inverse dynamics from joint angle trajectories using a kinetic model of the arm parametrized by the height and weight of each subject. To validate the arm model and the results of the inverse dynamics computation we performed a forward dynamic simulation. The joint angle trajectories simulated using the torques estimated by inverse dynamics matched well the original joint angle trajectories of all subjects and conditions ($R^2 = 0.99 \pm 0.02$, mean across subjects $\pm SD$). **Figure 3** shows an example of end point trajectories, end point speed profiles, joint angle trajectories, angular velocities, and gravitational and dynamic joint torque profiles for eight center-out movements on the frontal plane. As expected, end point trajectories were straight and velocity profiles bell-shaped. Joint angle trajectories and the corresponding angular velocities were modulated by movement direction. Dynamic torques, i.e., total torque with the gravitational torques removed, were bi-phasic, as observed before (Gottlieb et al., 1997). The time courses of the joint angle trajectories and angular velocities were different across joints and conditions but, because of the dynamic interaction between the different DOFs and they were generated by a synchronous biphasic pulse of torque distributed across joints with different balances depending on the movement direction. Such coordination patterns in the dynamic torque profiles is clearly visible in a scatter plot of a pair of joint torques. **Figure 4** shows the six scatter plots of all pairs of joint torque profiles, during an interval of 250 ms around movement onset, approximately capturing the

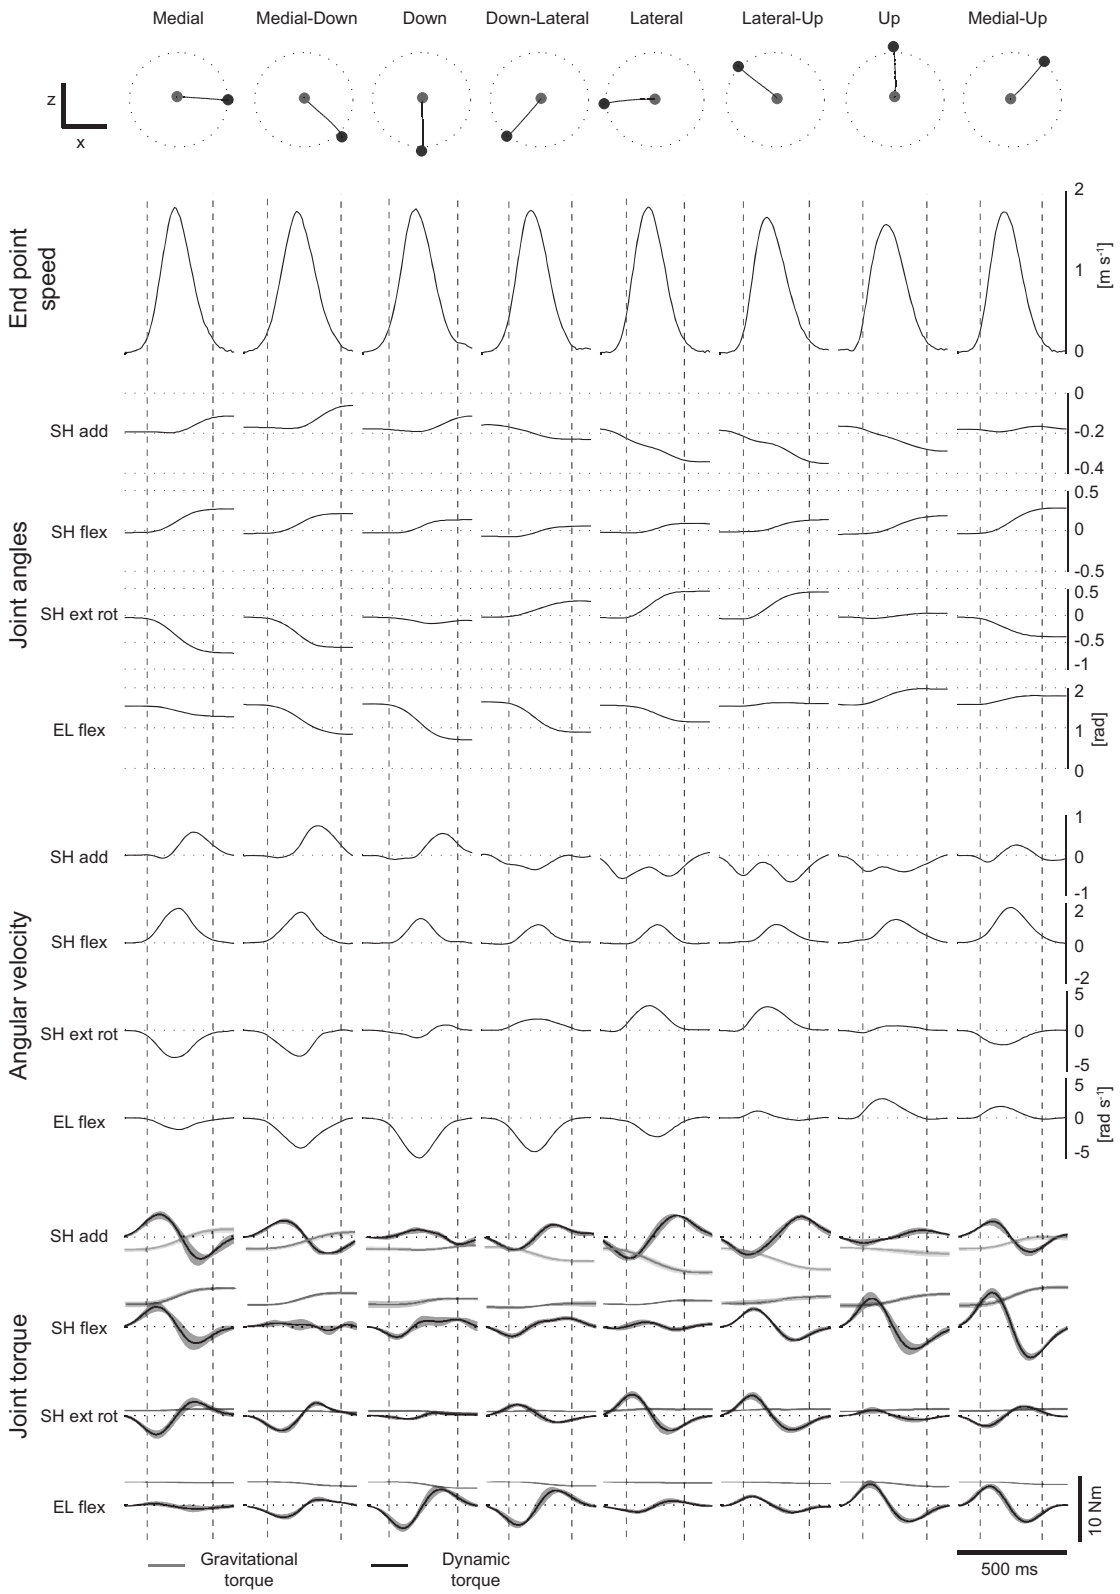

FIGURE 3 | Example of endpoint speed, velocity, joint angles and torques. Example of endpoint trajectories, end-point speed profiles, joint angles, joint angular velocities, gravitational (*light gray*) and dynamic (*dark gray*) torques for eight center-out movements in the frontal plane of subject 1 (mean across repetitions of each movement). Vertical dashed lines represent the times of movement onset and movement end. Shaded areas around gravitational and dynamic torque profiles represent ±1 *SD* around the mean.

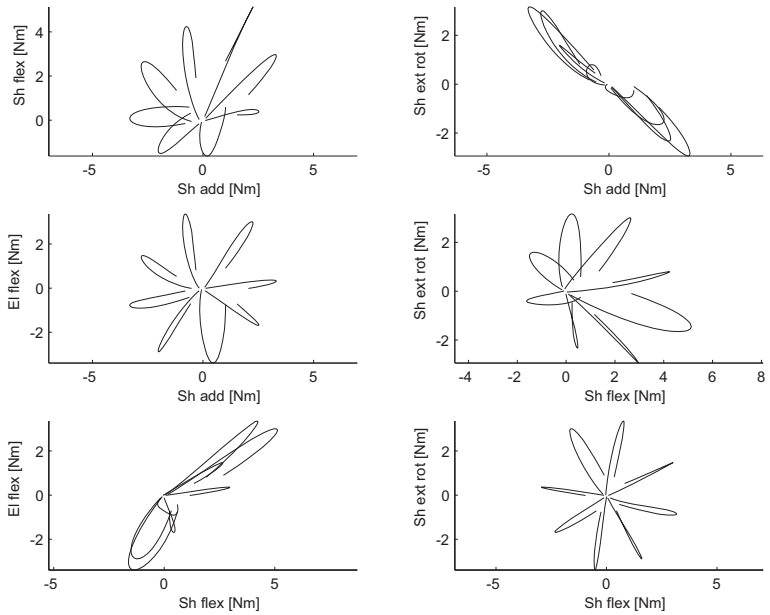

FIGURE 4 | Example of coordination between pairs of dynamic torques. Each scatter plot illustrated the dynamic torques for a pair of joints recorded in an interval of 250 ms around the time of movement onset for 8 center-out movements in the frontal plane of subject 1.

first phase of the profile, for the same 8 movements of **Figure 3**. If a pairs of torques were modulated synchronously, the corresponding trajectory in the scatter plot would appear as a straight line segment with a direction depending on the relative amplitude. Indeed, for most pairs and movement directions dynamic torques appeared to be modulated close to synchronously, especially in the initial (raising) portion of the profile. Finally, for two pairs of dynamic torques, shoulder external rotation-shoulder adduction and elbow flexion-shoulder flexion, the direction of the line segment in the scatter plot depended only weakly on the movement direction, suggesting that the dynamic torques were spanning a subspace of the four dimensional torque space orthogonal to those two directions. We then generalized these observations by identifying dynamic torque generators and estimating their dimensionality.

Spatial dimensionality

We first assessed the spatial dimensionality of the dynamic torques by identifying spatial generators, i.e., vectors in the torque space capturing specific balances of torque magnitude which could reconstruct the data once multiplied by time- and condition-dependent coefficients (see Materials and Methods and **Figure 2**), using PCA. For each subject, the number of generators was selected as the minimum number for which the fraction of data variation explained exceeded 0.9 ("R^2 threshold" criterion) and as the number of generators for which adding an additional generator increased the R^2-value less than 75% of the mean R^2-values obtained identifying generators from shuffled data ("R^2 shuffle" criterion). The mean dimensionality across subjects was 2.25 according to the R^2threshold criterion and 2.75 according to the R^2 shuffle criterion (see **Table 3** for individual values). The maximum potential spatial dimensionality of the torques was 4, corresponding to the number of joints, i.e., the number of rows of the data matrix used for spatial decomposition (**Figure 2**).

Figure 5A shows the R^2-value as a function of the number of generators for subject 1 and **Figure 5B** the three spatial generators of the same subject selected according to the R^2 shuffle criterion. The first generator ($\mathbf{w_1}$) is dominated by shoulder flexion torque. The second generator ($\mathbf{w_2}$) combines a large shoulder adduction torque with a smaller shoulder internal rotation (i.e., negative external rotation) and elbow extension (i.e., negative elbow flexion). Finally, the third generator ($\mathbf{w_3}$) represents a large elbow flexion torque and a smaller shoulder adduction torque. Notably, none of the generators or their combinations can generate coordinated shoulder adduction and shoulder external rotation torques, i.e., the direction orthogonal to the torques direction observed in the corresponding scatter plot of **Figure 4**. Thus, the structure of the spatial generators indicated that such torque coordination pattern was never used to perform reaching movements in the frontal and sagittal planes.

Figure 5C illustrates an example of the reconstruction of the dynamic torque profiles of subject 1 in six different conditions by the combination of the three spatial generators of **Figure 5B**. The dynamic torques for the first two conditions, medial and lateral movements in the frontal plane, are generated by a comparable level of activation of all three generators with a bi-phasic activation of shoulder adduction and internal rotation followed by shoulder abduction and external rotation for the medial movement and the opposite order for the lateral movement captured mainly by the activation of the second generation with similar bi-phasic profiles but opposite signs of its combination coefficient

Table 3 | Comparison of different types of dimensionality of dynamic torques and phasic muscle patterns estimated according to three criteria for the selection of the number of generators.

Subject	Criterion	Torques			Muscle patterns		
		Spatial	Temporal	Spatiotemporal	Spatial	Temporal	Spatiotemporal
S 1	R^2 threshold	2	1	3	–	–	–
	R^2 knee	–	–	–	4	5	5
	R^2 shuffle	3	1	3	4	4	7
S 2	R^2 threshold	3	1	3	–	–	–
	R^2 knee	–	–	–	5	5	6
	R^2 shuffle	3	1	3	5	4	7
S 3	R^2 threshold	2	1	3	–	–	–
	R^2 knee	–	–	–	6	4	6
	R^2 shuffle	3	1	3	6	3	7
S 4	R^2 threshold	2	1	2	–	–	–
	R^2 knee	–	–	–	5	4	5
	R^2 shuffle	2	1	2	5	4	8

(c_2). The last two conditions, backward and forward movements in the sagittal plane, require large shoulder flexion/extension torques that are generated by a bi-phasic activation of the first generator, captured by the first time-varying coefficient (c_1).

To assess the similarity between the subspaces spanned by the generators identified in each subject we reconstructed all dynamic torques of each subject with the generators of all subjects. **Table 4** shows the R^2-values obtained using the number of generators determined according to the R^2 shuffle criterion (see **Table 3**). The R^2-values for the reconstruction of the data of each subject by the generators extracted from the other subjects (0.96 ± 0.04, mean $\pm SD$, $n = 12$) were close to the R^2-values of the reconstruction of the data of each subject by the generators extracted from the same data (0.98 ± 0.02, $n = 4$) and were significantly higher than the R^2-values obtained with generators identified from randomly shuffled data, indicating that the dynamic torques of the different subjects shared a similar spatial organization.

Temporal dimensionality

To identify generators of the temporal organization of dynamic torques we performed PCA on the collection of the torque profiles of all joints and conditions. The resulting temporal components were then waveforms with the same duration as the torque profiles and each profile was reconstructed by multiplying the component matrix by a weight specific for that joint and condition. The dimensionality was 1 for all subjects and for both criteria (see **Table 3**). In contrast, the maximum potential temporal dimensionality of the torques was 100, corresponding to the number of time samples after time-normalization and resampling from −0.5 MT before movement onset and 0.5 MT after movement end, i.e., the number of rows of the data matrix used for temporal decomposition (**Figure 2**).

Figure 6A illustrates the R^2 curve for the temporal decomposition up to 12 generators for subject 1 and **Figure 6B** the single temporal component identified in this subject and representative of all subjects, clearly showing a bi-phasic profile. **Figure 6C** illustrates the reconstruction of the joint torques for the same six conditions of **Figure 5C** by the temporal generator. The torque profiles for each condition are reconstructed multiplying the single temporal component (c_1) by a single condition-dependent weight vector ($\mathbf{w_1}$). With respect to the reconstruction with spatial generators, the weight vector, which has the same dimensions of a spatial generator, is now modulated by the movement. For example the opposite signs in the bi-phasic profiles of shoulder adduction and external rotation for medial and lateral movements and for shoulder flexion for backward and forward movements are obtained by opposite signs of the components of the weight vector.

Finally, the temporal generators were also similar across all subjects. As for spatial generators, the reconstruction of the data of each subject by the generators of all other subjects had R^2-values (0.93 ± 0.01, mean $\pm SD$) which were comparable with the R^2-values for the reconstruction of the data of each subject by the generator extracted from the same data (0.94 ± 0.01) and significantly higher than the R^2-values obtained with generators identified from randomly shuffled data.

Spatiotemporal dimensionality

Spatiotemporal generators, which can be viewed as either time-varying vectors capturing a different spatial coordination among torques at each time or as collections of different waveforms for each torque, were identified by PCA on a data matrix obtained arranging all time samples from all joints in a single column for each movement condition. Thus, torque samples from different joints and times represented different dimensions and the possibility of generating the data with a number of generators smaller than the maximum potential dimension (400, corresponding to the number of joints times the number of samples) revealed a coordination in the activation of different joints at different times. Once a set of spatiotemporal generators are identified, the data are reconstructed by multiplying each generator by a single condition-dependent coefficient (see

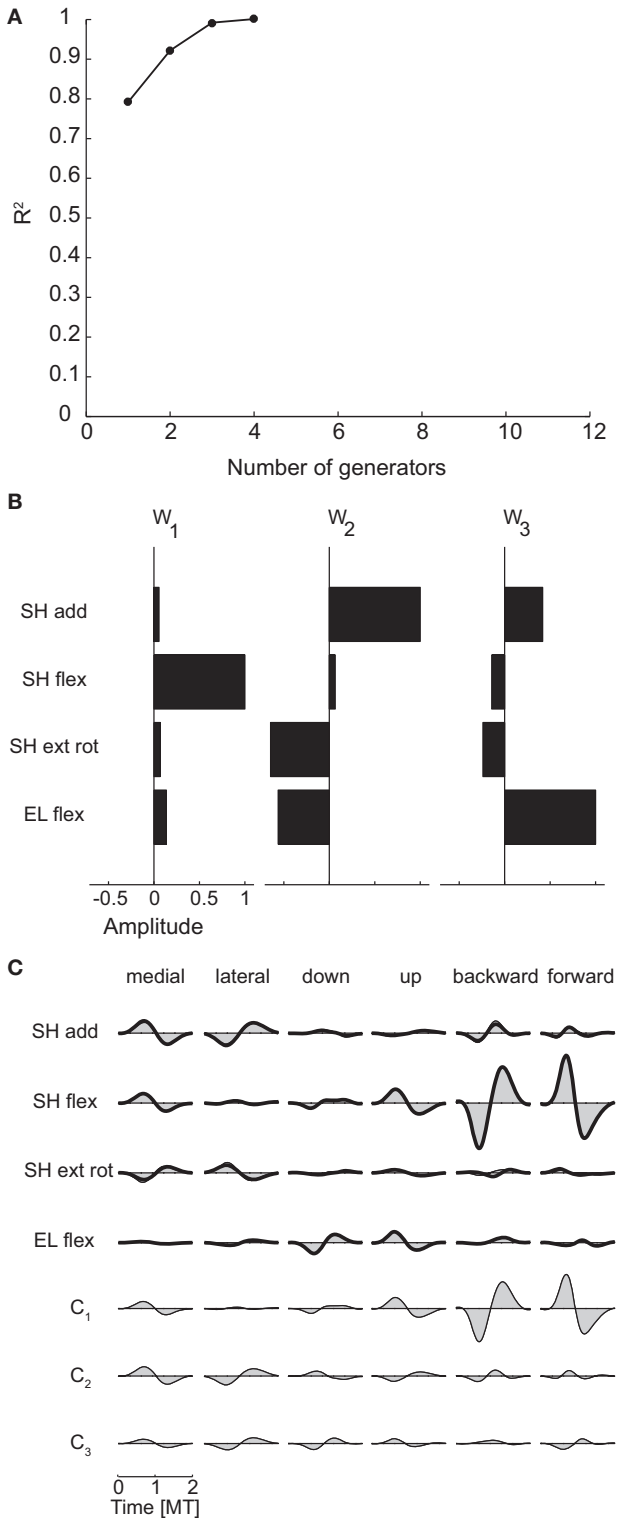

FIGURE 5 | Spatial decomposition of dynamic torques. (A) R^2 curve for subject 1 obtained by spatial decomposition using PCA. **(B)** Three spatial generators selected for subject 1. **(C)** Example of the reconstructions of the dynamic torques for six movement conditions of subject 1 obtained with the generators illustrated in panel **(B)** (*shaded area*: original data, *thick line*: reconstructed data, *bottom*: time-varying combination coefficients).

Table 4 | R^2 for the reconstruction of the data of each subject with the torque generators identified in all subjects.

	Generators/data	S 1	S 2	S 3	S 4
Spatial	S 1	0.99	0.99	0.98	0.99
	S 2	0.99	0.99	0.97	0.99
	S 3	0.99	0.98	0.99	0.99
	S 4	0.92	0.90	0.88	0.95
Temporal	S 1	0.95	0.92	0.92	0.93
	S 2	0.94	0.93	0.94	0.93
	S 3	0.91	0.92	0.94	0.92
	S 4	0.94	0.92	0.93	0.93
Spatiotemporal	S 1	0.97	0.92	0.90	0.94
	S 2	0.94	0.95	0.92	0.93
	S 3	0.90	0.89	0.96	0.92
	S 4	0.88	0.84	0.82	0.91

Figure 2). Thus the spatiotemporal decomposition provides a potentially very compact representation of the structure inherent in the data. The mean spatiotemporal dimensionality across subjects was 2.75 according to both criteria (see **Table 3** for individual values). Notably, mean spatial and spatiotemporal dimensionalities were very close and even equal for each subject when considering the R^2 shuffle criterion. Moreover, as the temporal dimensionality was 1, the spatiotemporal dimensionality was essentially the product of the spatial and the temporal dimensionalities.

pt **Figure 7A** illustrates the R^2 curve for the spatiotemporal decomposition up to 12 generators and **Figure 7B** the three spatiotemporal component for subject 1. Comparing the structure of these generators with that of the spatial (**Figure 5B**) and temporal (**Figure 6B**) generators of the same subject, it is apparent how each spatiotemporal generator appears as the product of a spatial generator by a temporal one. Indeed, the activation waveforms of all spatiotemporal generators are approximately synchronous and similar to the waveform of the single temporal generator. **Figure 7C** illustrates the reconstruction of the joint torques for the same six conditions of **Figures 5C**, **6C**. The torque profiles for each condition are reconstructed multiplying each spatiotemporal component by a single condition-dependent coefficient ($\mathbf{c_i}$), represented by the height of the rectangle below the torque profiles. With respect to the reconstruction with spatial and temporal generators, movements requiring torque profiles with opposite signs are generated simply by changing the sign in a single combination coefficient, e.g., c_2 for medial and lateral movements and c_1 for backward and forward movements.

As in previous cases, spatiotemporal generators were similar across subjects. The R^2-values for the reconstruction of the data of each subject by the generators of all other subjects (0.90 ± 0.04, mean $\pm SD$) were close to the R^2-values for the reconstruction of the data of each subject by the generator extracted from the same data (0.95 ± 0.02) and significantly higher than the R^2-values obtained with generators identified from randomly shuffled data.

Potential misestimation of subject mass and height

The estimation of the joint torques from the recorded joint kinematics through the inverse dynamic calculation depends on geometric and inertial parameters which are estimated as a function of the subject mass and height according to anthropometric tables (see Arm Model section in Materials and Methods). We assessed the effect of a potential misestimation of such parameters on the estimated torque dimensionality by identifying joint torque generators after varying the mass and the height of each subject by ±5, ±10, ±15, ±20%. We recomputed joint torques for individual trials of all subjects and re-processed the torque data as with the original parameters. Across all subjects and types of generators, the dimensionality was affected by a change in mass in 8 out of 96 cases (4 subjects × 3 types of generators × 8 mass change levels) and by a change in height in nine cases. Thus, the estimation of torque dimensionality is robust to small errors in the estimation of anthropometric parameters.

MUSCLE PATTERNS

Phasic muscle patterns, obtained by subtracting the anti-gravity (tonic) components from the rectified, filtered, averaged, time-normalized, and resampled EMG waveforms, were decomposed with NMF to assess their dimensionality. Phasic muscle patterns for fast reaching movements in vertical planes have been described before (d'Avella et al., 2006). In contrast to our previous study, here we identified spatial generators, temporal generators, and spatiotemporal generators without onset delays and we compared their dimensionality with the dimensionality of the corresponding generators of dynamic torques.

Spatial dimensionality

The mean spatial dimensionality of the phasic muscle patterns across subjects was five according to the position of change in slope of the R^2 curve as a function of the number of generators (R^2 knee criterion) and five according to the R^2 shuffle criterion (see **Table 3** for individual values). Thus, as expected, the dimensionality of the muscle pattern generator was larger than the number of spatial torque generators (2.75 according R^2 shuffle criterion) as muscle pattern generators could only be combined with non-negative time- and condition-dependent combination coefficients. However, the number of muscle pattern generators was larger than the minimum required for generating a space of the same number of linear dimensions as the torque generators (2.75) by non-negative combinations ($3.75 = 2.75 + 1$).

Figure 8A shows the R^2 curve for the spatial decomposition of the phasic muscle patterns of subject 1, in which a knee at four generators is clearly visible. The lower R^2-value at the selected number of muscle patterns generators (0.80) with respect to the corresponding value for the torque generators (0.99) indicated that a much larger fraction of the muscle data variation was due to noise. The four spatial generators (or time-invariant muscle synergies) for the same subject illustrated in **Figure 8B** ($\mathbf{w_1}$–$\mathbf{w_4}$) show specific groupings of muscles spanning multiple joints and with the same muscle recruited by multiple generators. Finally, in **Figure 8C** the examples of the reconstruction of the phasic muscle patterns for six movement conditions by the combination of the spatial generators are presented. The temporal structure of muscle

Table 5 | R^2 for the reconstruction of the data of each subject with the muscle pattern generators identified in all subjects.

	Generators/data	S 1	S 2	S 3	S 4
Spatial	S 1	0.80	0.60	0.54	0.62
	S 2	0.64	0.74	0.61	0.70
	S 3	0.67	0.71	0.80	0.69
	S 4	0.73	0.75	0.60	0.85
Temporal	S 1	0.88	0.83	0.88	0.83
	S 2	0.85	0.86	0.88	0.85
	S 3	0.81	0.79	0.86	0.79
	S 4	0.77	0.78	0.83	0.81
Spatiotemporal	S 1	0.84	0.30	0.27	0.32
	S 2	0.37	0.77	0.41	0.51
	S 3	0.25	0.41	0.79	0.36
	S 4	0.38	0.49	0.39	0.80

patterns and of combination coefficients is clearly more complex than that of the spatial generators with the tri-phasic organization of the muscle patterns generated by both the temporal structure of the combination coefficients and by the superposition of different generators.

Finally the spatial generators for the muscle patterns were less similar across subjects than the spatial generators for the torques (see **Table 5**). The reconstruction of the data of each subject by the generators of all other subjects had a R^2-values (0.66 ± 0.06, mean $\pm SD$) much lower than the mean R^2 for the reconstruction by the generators extracted from the same data (0.80 ± 0.04) but still significantly higher than the R^2-values obtained with generators identified from randomly shuffled data.

Temporal dimensionality

The mean number of temporal generators of the phasic muscle patterns was 4.5 according to the R^2 knee criterion and 3.75 according to the R^2 shuffle criterion (see **Table 3** for individual values). As for the spatial generators, the temporal dimensionality of the muscle pattern generators was larger than the minimum number required to generate a space with the same linear dimensions as the number of temporal torque generators (1) by non-negative combinations ($2 = 1 + 1$).

Figure 9A shows the R^2 curve for the temporal decomposition of the phasic muscle patterns of subject 1 and **Figure 9B** the four temporal generators (or components) selected in that subject according to both criteria. The first three generators capture a single burst of muscle activity and the fourth component a small burst followed by a larger burst. The four components peak at different times and thus they appear to capture four distinct phases of the muscle patterns observed in different directions. However, the examples of muscle pattern reconstructions and combination weights for six movement directions (**Figure 9C**) show that in many cases the weight vectors loading the different components were similar within each movement condition (e.g., for the first two components of the medial movement and the last two components of downward movement), suggesting that such temporal decomposition was necessary to capture not only the major changes in the muscle patterns over the duration of the movement but also small asynchronous adjustments.

In contrast to the spatial generators but similarly to the temporal generators for torques, muscle pattern temporal generators were similar across all subjects. The R^2-values for the reconstruction of the data of each subject by generators of all other subjects (0.82 ± 0.04, mean $\pm SD$) were close to the values for the reconstruction by the generators extracted from the same data (0.85 ± 0.03) and higher than the R^2-values obtained with generators identified from randomly shuffled data.

Spatiotemporal dimensionality

The mean number of spatiotemporal generators of the phasic muscle patterns was 5.5 according to the R^2 knee criterion and 7.25 according to the R^2 shuffle criterion (see **Table 3** for individual values). Both dimensionality estimates were larger than the minimum number of generators required for generating a space with the same linear dimensions as the number of torque spatiotemporal generators (2.75) by non-negative combinations ($3.75 = 2.75 + 1$). Moreover, differently from torques, the product of the spatial and temporal muscle pattern dimensionalities (22.5 according to the R^2 knee criterion and 18.7 according to the R^2 shuffle criterion) was much higher than the spatiotemporal dimensionality. Thus the spatiotemporal generators captured asynchronous muscle coordination patterns that were not simply the result of the synchronous combination of all possible spatial and temporal generators.

Figure 10A shows the R^2 curve for the spatiotemporal decomposition of the phasic muscle patterns of subject 1 and **Figure 10B** the seven spatiotemporal generators selected in that subject according to the R^2 shuffle criterion. The asynchronous nature of the muscle activation waveforms can be noticed in most of these spatiotemporal generators. For example, in TrLat and TrLong in $\mathbf{w}_1$ show two clearly delayed peaks. Finally, the examples of muscle pattern reconstructions and combination coefficients for six movement conditions illustrate how the organization of the muscle patterns is captured parsimoniously by the spatiotemporal generators as each movement is reconstructed specifying only 7 scalar combination coefficients (represented by the height of the rectangles depicting the mean generator waveform over all muscles).

Finally, muscle patterns of different subjects did not have similar spatiotemporal generators. The reconstruction of the data by generators of all other subjects had a much lower R^2-values (0.37 ± 0.08, mean $\pm SD$) than the R^2-values for the reconstruction of the data by generators extracted from the same dataset (0.80 ± 0.03) but still higher than the R^2-values obtained with generators identified from randomly shuffled data.

Effect of setting to zero negative values in the phasic muscle patterns

To identify muscle pattern generators from phasic muscle patterns using NMF we set to zero all negative values resulting from the subtraction of the tonic muscle activity from the filtered EMG waveforms. However, to assess the effect of such procedure we also extracted muscle pattern generators from the unclipped phasic

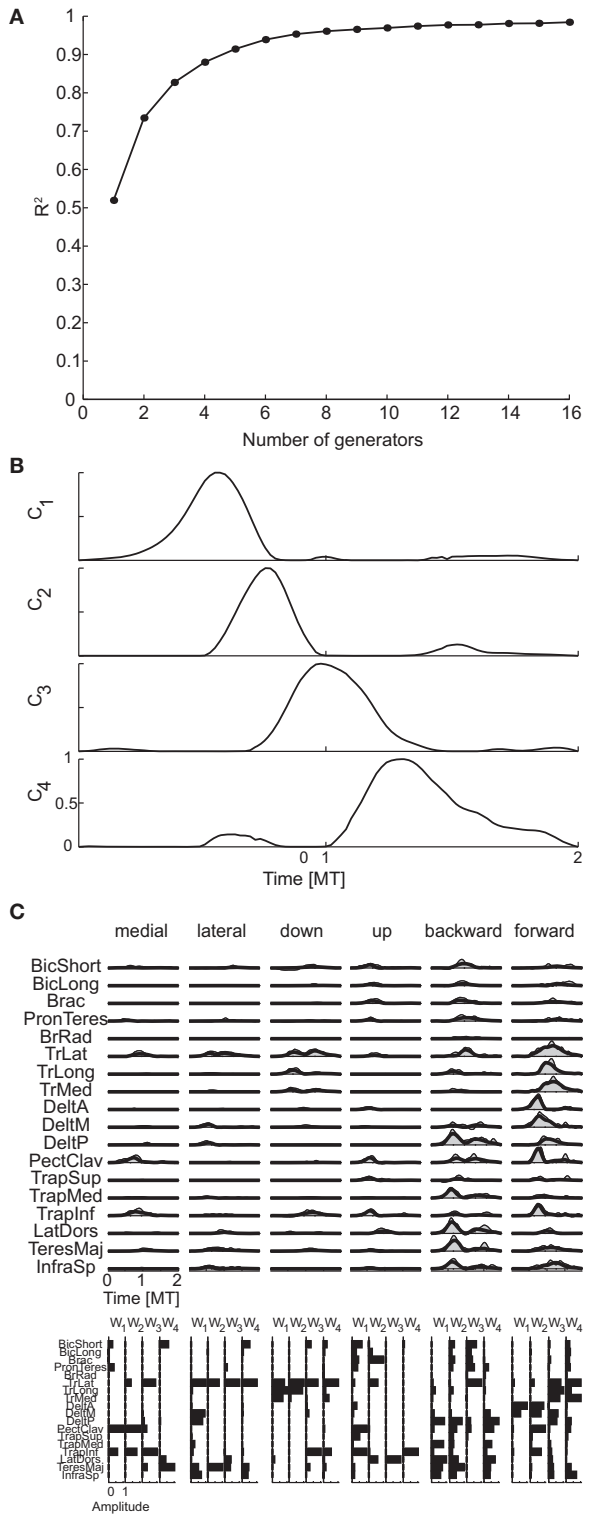

FIGURE 9 | Temporal decomposition of phasic muscle patterns. FIGURE 10 | Spatiotemporal decomposition of phasic muscle patterns. (A) R^2 curve for subject 1 obtained by spatiotemporal decomposition using NMF. **(B)** Seven spatiotemporal generators selected for subject 1. **(C)** Example of the reconstructions of the muscle patters for six movement conditions of subject 1 obtained with the generator illustrated in panel **(B)** (*shaded area*: original data, *thick line*: reconstructed data, *bottom*: combination coefficients represented by the height of the rectangle containing the temporal profile of each generators averaged over muscles).

muscle patterns using a gradient descent iterative algorithm (see Materials and Methods). In all cases the dimensionality of the generators identified with the gradient descent algorithm from the unclipped data was close to the dimensionality of the generators identified by NMF from the clipped data and the generators extracted in the two cases were very similar. The dimensionality of the spatial generators identified from the unclipped data was, on average across subjects, 4.75 (according to both R^2 knee and R^2 shuffle criteria) and thus differed only by 0.25 from the dimensionality of the generators identified from the clipped data. For the temporal generators the difference in dimensionality was 0.5 according to the R^2 knee criterion and 0.25 according to the R^2 shuffle criterion. Finally, for the spatiotemporal generators the difference was 0.25 according to both criteria. The similarity between the spatial generators identified from the clipped data and the same number of generators identified from the unclipped data, quantified by the mean normalized scalar product between matched pairs of generators, was 0.91 ± 0.09 (mean across subjects $\pm$ *SD*). For all subjects the similarity value was significantly higher that the value expected by chance, i.e., it was above the 95% percentile of the distribution of the similarity values between generators identified from the unclipped data and generators identified from the shuffled clipped data. The similarity between the temporal generators identified from the clipped data and the same number of generators identified from the unclipped data was 0.91 ± 0.05, also significantly higher than chance for all subjects. Finally, for spatiotemporal generators the similarity was 0.90 ± 0.02 and also significantly higher than chance for all subjects. We can thus conclude that clipping to zero the negative values of the phasic muscle patterns affected the dimensionality and the structure of the identified muscle pattern generators only minimally.

DISCUSSION

We assessed the dimensionality of the dynamic joint torques responsible for accelerating and decelerating the arm during point-to-point reaching movements in different directions in the frontal and sagittal planes and the dimensionality of phasic muscle patterns underlying the production of those torques. We used multidimensional factorization techniques, PCA for the torques and NMF for the muscle patterns, to identify generators capturing the spatial, temporal, and spatiotemporal organization of the motor commands. The number of generators selected according to either a threshold in the total data variation explained, or a change in slope in the curve of the variance explained, or the increase in data variation explained adding an additional generator with respect to the increase obtained extracting generators from randomly shuffled data was taken as an estimate of the dimensionality. The spatial dimensionality of the dynamic torques was lower than the number of joints considered, indicating that some of the available spatial coordination patterns were never employed by the CNS when generating the joint torques for this task. A single temporal generator with a biphasic activation profile was identified in all subjects, in accordance and generalizing previous observations on the temporal organization of dynamic torques on a single vertical plane (Gottlieb et al., 1997). However, a higher number of temporal generators may be required to account for more complex changes in joint torques in other types of reaching movements (e.g., slow, egocentric etc., see Lacquaniti et al., 1986). The number of spatiotemporal generators was in most subjects equal to the product of the spatial and temporal dimensionality and their structure indicated that the spatiotemporal organization of the dynamic torques was essentially synchronous, obtained by the temporal modulation of the spatial generators by the biphasic profile of the single temporal generator. In contrast, the spatial, temporal, and spatiotemporal dimensionalities of the phasic muscle patterns were higher than the corresponding torque dimensionality, as expected because of the non-negativity constraints in the combination of muscle pattern generators, but also higher than the minimum number required according to this biomechanical constraint. Moreover, the spatiotemporal dimensionality of the muscle patterns was much lower than the product of their spatial and temporal dimensionality, suggesting that specific asynchronous coordination patterns were used in the generation of muscle patterns. In fact, most of the identified spatiotemporal generators showed peaks of activity in different muscles at different times, i.e., coordination patterns that cannot be captured by the synchronous modulation of one of the spatial generators by one of the temporal generators.

The CNS might generate motor commands by organizing a few generators, basic elements in a modular architecture capturing shared knowledge across tasks and conditions, to reduce the number of parameters required for control (Alessandro et al., 2013; Ruckert and d'Avella, 2013). Evidence for a modular organization of the motor commands has recently come from the observation of low-dimensionality in the muscle patterns recorded in many species, behaviors, and tasks (Tresch et al., 1999; d'Avella et al., 2003, 2006; Hart and Giszter, 2004; Ivanenko et al., 2004; Ting and Macpherson, 2005; Overduin et al., 2008; Muceli et al., 2010; Dominici et al., 2011; Berger et al., 2013) and from neural recordings and stimulation (Saltiel et al., 2001; Ethier et al., 2006; Gentner and Classen, 2006; Hart and Giszter, 2010; Overduin et al., 2012). Intramuscular recordings during isometric contractions have also revealed that the number of basic muscle activation patterns in complex movements is very limited (ter Haar Romeny et al., 1984; van Zuylen et al., 1988). However, motor task and behaviors are accomplished by the joint torques generated by the simultaneous and coordinated activation of many muscles and to understand how a small set of muscle pattern generators may accomplish a task it is necessary to understand the relationship between muscle patterns and joint torques. The transformation between muscle patterns and torques depends on several biomechanical characteristics and constraints. There are more muscles than joints, making motor commands at the level of muscle patterns redundant, i.e., the same torque pattern can be generated by different muscle patterns. Muscles can only pull and their activation can be expressed by non-negative values, thus introducing a fundamental non-negativity constraint in the generation of muscle patterns. These characteristics and constraints affect the potential dimensionality of the joint torques associated to the dimensionality of the underlying muscle patterns. For a linear mapping

of muscle activity into force, an assumption that may be true only in specific conditions such as submaximal isometric contractions (Borzelli et al., 2013) but useful for illustrative purposes, because of the non-negativity constraint, at least $D+1$ generators are required to span a D dimensional torque space (Davis, 1954; Valero-Cuevas, 2009). In fact, by linearity, the image of the pseudo-inverse transformation of the D dimensional torque space is a D dimensional subspace of muscle space but such subspace is not contained in the positive orthant of the muscle space, i.e., cannot be generated by non-negative activations and an additional dimension in the null space of the linear transformation needs to be used to achieve a non-negative muscle pattern for each torque. In the general non-linear case, the manifold in muscle space containing all the minimum patterns associated to a D dimensional torque space may be already higher than D even before considering the non-negativity constraint. Thus, the dimensionality of the muscle space must be at least $D+1$ to generate a D dimensional torque space for the non-negativity constraint and possibly larger. However, because of redundancy, the CNS might use a number of muscle pattern generator larger than the minimum to optimize some other cost in addition to the number of control parameters, such as effort. Since the generation of muscle patterns with a smaller number of generation requires in general more effort, the dimensionality of the muscle pattern generators might result from a trade-off between computational complexity and effort. We found that the muscle pattern dimensionality is indeed larger than the minimum prescribed by non-negativity, likely an effect of non-linearity but possibly also due to a choice of generators capable of achieving the same motions with less effort. Future investigations comparing tasks with similar kinematics but different effort might help clarify this point.

As mentioned in the Introduction, muscle pattern generators can be associated to force-field primitives (Bizzi et al., 1991; Giszter et al., 1993; Kargo and Giszter, 2000a,b; Giszter and Hart, 2013), endpoint force or joint torque generators that depend on joint angles and velocities and are linearly combined using the activation coefficients of the muscle pattern generators. Competence of force-field primitives to generate observed force and kinematic behaviors has been demonstrated in the frog through forward biomechanical simulation (Kargo et al., 2010). Similarly, a forward dynamics simulation of a musculoskeletal model of the human leg has shown that the combination of a small number of muscle pattern generators is sufficient to perform the basic sub-tasks of walking (Neptune et al., 2009). Moreover, a recent simulation study using a musculoskeletal model of the human arm has indicated that spatiotemporal generators adequate to perform reaching movements can be learned through reinforcement (Ruckert and d'Avella, 2013). Here, in contrast, we did not perform forward dynamics simulation to assess the competence of muscle pattern generators and associated force-field primitive to control reaching movements. We focused, instead, onto the dimensionality of recorded muscle patterns and the dimensionality of joint torques estimated from recorded kinematics by inverse dynamics. Force-field primitives are associated one-to-one with muscle pattern generators, i.e., they have the same dimensionality. Because of the non-negativity of muscle pattern generator activation coefficients and the non-linearity in the muscle-to-force mapping, such dimensionality is necessarily higher than the dimensionality of the joint torques, i.e., the number of torque generators necessary to adequately reconstruct the observed torques by linear combinations. As different numbers of muscle pattern generators and force-field primitives can potentially generate the same set of observed torques and thus being equally competent to perform a given behavior, comparing the dimensionality of muscle patterns and joint torque provides additional information on the strategy that the CNS employs to organize a modular control architecture.

We assessed the dimensionality of joint torques and muscle patterns according to three different definitions of generators (spatial, temporal, and spatiotemporal) and we could then also compare, within each dataset, the different types of dimensionality. For the torques we found that the dimensionality of the spatiotemporal generators was equal to the product of the dimensionalities of the spatial and temporal generators, suggesting that such generators can be obtained as the product of spatial and temporal generators (Delis et al., 2014). The spatial dimensionality was two or three, i.e., less than the number of angular DoF involved in the task, indicating that the CNS selected specific coordination strategies already at the kinematic level. The temporal dimensionality was one, indicating, in accordance with previous observations (Gottlieb et al., 1997), that the temporal organization of the dynamic torques is very simple: a bi-phasic profile shared by all joints and movement conditions (but see Lacquaniti et al., 1986 for more complex torque profiles). The dimensionality of the spatiotemporal generators was in all subjects equal to the spatial dimensionality because, given a single temporal generator, each spatiotemporal generator was obtained by the temporal modulation of each spatial generator by the temporal generator. Consequently, the spatiotemporal organization of the torques was essentially synchronous. In contrast, the number of spatiotemporal generators for the muscle patterns was much less than the product of spatial and temporal dimensionalities. Indeed, spatiotemporal generators captured asynchronous activations across muscles that could not be obtained by the modulation of a single spatial generator by a single temporal generator, which necessarily produces a synchronous pattern. Thus, spatiotemporal generators appear to provide a very compact representation of the organization of the muscle patterns (Delis et al., 2014). However, differently from our previous analyses of muscle patterns during reaching (d'Avella et al., 2006, 2008, 2011; d'Avella and Lacquaniti, 2013), in the present spatiotemporal decomposition we did not take into account the possibility of shifting in time the onset of different generators (Equation 8) because in this way we could use the same NMF algorithm used for spatial and temporal decomposition. We found a larger number of generators without time-shifts than the number of time-varying muscle synergies (with time-shifts) reported before. Thus, additional structure in the muscle patterns can be captured by allowing the independent modulation of the time of recruitment of the generators thus allowing for an even more compact representation of the muscle pattern organization.

The validity of our observations depends on a number of assumptions made in the analysis of the torque and muscle activity data. Concerning the estimation of the joint torques from the recorded motions of markers positioned on the subjects' arm, we relied on a simplified model of the human arm. We assumed that the shoulder was a spherical joint, i.e., all three rotation axes intersect at a single point, we estimated the length (Winter, 1990) and inertial parameters (Zatsiorsky and Seluyanov, 1983) of each segment as a function of the height and weight of each subject. To assess the effect of potential inaccuracies in the parameters of our model, we performed inverse dynamics varying the mass and height of each subject up to ±20% and we found that the estimated joint torque dimensionality changed only in a small fraction of cases. Thus, we believe that the estimation of torque dimensionality is robust to small inaccuracies in the anthropometric parameters. Concerning the identification of the muscle pattern generators with NMF, in order to be able to run such algorithm, we set to zero all samples with a negative value after subtracting the tonic components. We assessed the effect of such procedure by identifying muscle pattern generators from unclipped data using a gradient descent algorithm and we found that both the dimensionality changed only minimally (less than 0.5 in all cases) and did not significantly affect the structure of the generators. Concerning the criteria for the selection of the number of generators, we used a threshold based criterion for torques, a criterion based on the detection of a change in slope (i.e., a "knee") in the R^2 curve for muscle patterns, and a criterion based on the comparison of the slope of the R^2 curve for the generators extracted from the original data and those extracted after randomly shuffling the data (along the rows of the data matrix). All these criteria rely on the assumption that the data are generated by a number of generators smaller than the maximum dimensionality and that a fraction of the variation observed in the data is due to noise. Such assumption is shared by all previous studies using multidimensional decomposition to identify muscle synergies or temporal components but it is clear that it is not possible a-priori to exclude that, once a specific number of generators has been selected, the additional dimensions attributed to noise might be also necessary to capture the structure in the motor commands or, vice-versa, a generator might actually describe noise instead of structure in the motor commands. Moreover, unless an independent estimation of the level of noise in the data is available, the selection of the number of generators depends on *ad-hoc* choices of thresholds and parameters. However, as the determination of threshold on the MSE of the linear fit of the terminal portion of the R^2 curve, used for the R^2 knee criterion, is less dependent on the amount noise in the data than the threshold on the R^2-value, used in the R^2 threshold criterion, we prefer, whenever possible, to use the former criterion, as we have done previously (d'Avella et al., 2003, 2006; Cheung et al., 2005), to the latter, also used in previous studies (Tresch et al., 1999; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006; Roh et al., 2012). Unfortunately it was impossible to use the R^2 knee criterion for the spatial torque dimensionality, as the maximum dimension was 4 in that case, and we could only estimate the residual of a linear fit of the R^2 curve from 1 or 2 to 4 generators, i.e., evaluating the presence of a knee only at 1 or 2 generators. We then used the third criterion to compare more directly both datasets. The R^2 shuffle criterion (Cheung et al., 2009) is based on the assumption that the multidimensional structure but not the noise is affected by randomly shuffling the data. Thus, the selection of the number of generators in datasets with different amount of noise is based on the comparison of the slope of the R^2 curve for each data set with the slope of the R^2 curve of a random dataset with comparable level of noise. In most cases the number of generators selected by the two criteria either matched exactly or different by one.

In conclusion, whether spatial (time-invariant muscle synergies), temporal (temporal components or patterns), or spatiotemporal (time-varying muscle synergies) generators are fundamental building blocks in a modular control architecture and how are they implemented in the CNS remain open and debated questions. Our comparison of the dimensionality of muscle patterns and joint torques suggests that the larger dimensionalities and spatiotemporal complexity of the muscle patterns with respect to the joint torques may be required for the CNS to overcome the non-linearities of the musculoskeletal system and, exploiting its redundancy, to flexibly generate endpoint trajectories with simple kinematic features using a limited number of building blocks.

During visuomotor adaptation a novel mapping between visual targets and motor commands is gradually acquired. How muscle activation patterns are affected by this process is an open question. We tested whether the structure of muscle synergies is preserved during adaptation to a visuomotor rotation. Eight subjects applied targeted isometric forces on a handle instrumented with a force transducer while electromyographic (EMG) activity was recorded from 13 shoulder and elbow muscles. The recorded forces were mapped into horizontal displacements of a virtual sphere with simulated mass, elasticity, and damping. The task consisted of moving the sphere to a target at one of eight equally spaced directions. Subjects performed three baseline blocks of 32 trials, followed by six blocks with a 45° CW rotation applied to the planar force, and finally three wash-out blocks without the perturbation. The sphere position at 100 ms after movement onset revealed significant directional error at the beginning of the rotation, a gradual learning in subsequent blocks, and aftereffects at the beginning of the wash-out. The change in initial force direction was closely related to the change in directional tuning of the initial EMG activity of most muscles. Throughout the experiment muscle synergies extracted using a non-negative matrix factorization algorithm from the muscle patterns recorded during the baseline blocks could reconstruct the muscle patterns of all other blocks with an accuracy significantly higher than chance indicating structural robustness. In addition, the synergies extracted from individual blocks remained similar to the baseline synergies throughout the experiment. Thus synergy structure is robust during visuomotor adaptation suggesting that changes in muscle patterns are obtained by rotating the directional tuning of the synergy recruitment.

Keywords: muscle synergies, visuomotor rotation, motor adaptation, isometric force, EMG, directional tuning

INTRODUCTION

Human subjects can learn to move in novel environments and they can adapt to visuomotor (Ghilardi et al., 1995; Imamizu et al., 1995; Ghahramani et al., 1996; Krakauer et al., 1999, 2000) or dynamic (Lackner and Dizio, 1994; Shadmehr and Mussa-Ivaldi, 1994) perturbations. Generally, when subjects are exposed to a perturbation of the mapping between motor commands and end-effector motion or force, they initially produce large errors and they then gradually adapt, compensating for the perturbation and re-establishing baseline performance. When the perturbation is removed subjects make large errors in the opposite direction (after-effects) before gradually re-adapting. If the perturbation is unexpectedly and occasionally removed in a single trial (Thoroughman and Shadmehr, 2000) or if it changes continuously and randomly (Scheidt et al., 2001; Baddeley et al., 2003; Cheng and Sabes, 2007) the error experienced in one trial affects the motor command generated in the following trial. These observations suggest that the central nervous system (CNS) relies on internal models of the body and of the environment to predict the sensory consequences of motor commands and that adaptive processes adjust the internal models to reduce sensory prediction errors (Shadmehr et al., 2010; Krakauer and Mazzoni, 2011; Wolpert et al., 2011). Such adaptive processes can be modeled as error-based learning that reduces sensory prediction error by adjusting an internal state according to a linear time-invariant dynamics (Thoroughman and Shadmehr, 2000; Donchin et al., 2003; Cheng and Sabes, 2007; Tanaka et al., 2012). Multiple learning processes operating at different timescales (Smith et al., 2006) and learning at different hierarchical levels in the internal model (Braun et al., 2009) explain the time-course of performance errors under a variety of experimental manipulations. However, albeit behavioral observations, such as error time-course and generalization properties, made in numerous motor adaptation studies are well captured by current models, how the motor commands change during motor adaptation has been investigated only in a few cases (Wise et al., 1998; Thoroughman and Shadmehr, 1999; Li et al., 2001; Paz et al., 2003; de Rugy et al., 2009). Muscle pattern generation and its relationship to force generation during motor adaptation still needs to be fully understood.

Because of the redundancy in the musculoskeletal system, the change in motor commands underlying the change in motion or force necessary to compensate for a visuomotor or dynamic perturbation is not unique. For example, the rotation of the direction of force required to adapt to a rotation imposed onto

the mapping between the force applied on an isometric joystick and the motion of a cursor on a computer screen (visuomotor rotation) may be accomplished by infinitely many different combinations of changes in individual muscle activations. In principle, during motor adaptation the performance error may be gradually reduced by changing the force output associated to each visual target using the same muscle pattern used for that force output before the perturbation. Alternatively error may be reduced by changing the activity of individual muscles independently of the muscle patterns used before the perturbation. For wrist muscles it has been shown that the rotation of the muscle directional tuning curve closely follows the rotation imposed onto the force-to-cursor mapping (de Rugy and Carroll, 2010), suggesting that adaptation occurs at the level of the planned force output. The first aim of our study was to investigate if this is also true for shoulder and elbow muscles during visuomotor rotation of the mapping between isometric forces generated by the arm at the hand, i.e., with a musculoskeletal system involving a larger number of muscles and joints.

The changes of the motor commands underlying adaptation to a visuomotor rotation may occur at the target force or at the muscle level, but in both cases the question of how a specific muscle pattern is selected to generate a desired force remains open. One hypothesis which has recently received considerable attention is that muscle patterns are generated as combinations of a few muscle synergies, coordinated recruitment of groups of muscles with specific activation balances, thus requiring the selection of only a small number of synergy combination parameters to generate a desired force. While muscle synergies have been studied intensively in human reaching movements (d'Avella et al., 2006, 2008, 2011; Muceli et al., 2010), isometric force generation (Borzelli et al., 2012; Roh et al., 2012), locomotion (Ivanenko et al., 2004; Dominici et al., 2011), cycling (Hug et al., 2010, 2011), responses to postural perturbations (Krishnamoorthy et al., 2003; Torres-Oviedo and Ting, 2007; Chvatal and Ting, 2012), complex motor skills (Frere and Hug, 2012), and in several different animal behaviors (Tresch et al., 1999; Saltiel et al., 2001; d'Avella et al., 2003; Hart and Giszter, 2004; Cheung et al., 2005, 2009; d'Avella and Bizzi, 2005; Ting and Macpherson, 2005; Torres-Oviedo and Ting, 2007; Overduin et al., 2008, 2012; Hart and Giszter, 2010), muscle synergies have not been directly investigated during adaptation to visuomotor rotations. Thus, our second aim was to investigate whether the synergies capturing the muscle patterns underlying the generation of multidirectional isometric forces are robust during motor adaptation. Thus, we hypothesized that the change in the tuning of muscles during adaptation to visuomotor rotation closely follows the rotation of the force and that the underlying changes in the muscle patterns can be explained by changes in the recruitment of synergies whose structure remains fixed.

MATERIALS AND METHODS

PARTICIPANTS

All procedures were approved by the Ethical Review Board of Santa Lucia Foundation. Eight right-handed naïve subjects (mean age 28.6 ± 6.0 year, age range 24–43, 5 females and 3 males, see **Table 1**) participated in the experiments after giving written informed consent.

EXPERIMENTAL SETUP

Subjects sat in front of a desktop with their torso immobilized by safety belts. Their right forearm was inserted into a splint immobilizing the hand, wrist, and forearm. The center of the palm was aligned with the body midline at the height of the sternum and the elbow was flexed approximately by 90°. The subjects' view of the hand was occluded by a 21-inch LCD monitor inclined with its

surface approximately perpendicular to the subjects' line of sight when looking at their hand (**Figure 1A**). After a calibration procedure, the monitor could display a virtual desktop matching the real desktop, a spherical cursor matching, at rest, the position of the center of the palm and moving on a horizontal plane, and spherical targets on the same plane (**Figure 1B**). A steel bar at the base of the splint was attached to a 6-axis force transducer (Delta F/T Sensor, ATI Industrial Automation, Apex, NC, USA) positioned below the desktop to record isometric forces. Surface electromyographic (EMG) activity from 13 muscles acting on the shoulder and elbow muscles was recorded with active bipolar electrodes (DE 2.1, Delsys Inc., Boston, MA), after band-pass filtering (20–450 Hz) and amplification (gain 1000, Bagnoli-16, Delsys Inc.). Force and EMG data were digitized at 1 kHz using an A/D PCI board (PCI-6229, National Instruments, Austin, TX, USA). The virtual scene was rendered by a PC workstation with a refresh rate of 60 Hz using custom software. Cursor position information was processed by a second PC workstation running a real-time operating system and transmitted to the first workstation through an Ethernet link. Cursor motion was simulated in real time as a mass accelerated by the horizontal force (parallel to the desktop) applied by the subject on the splint, a viscous force, and an elastic force proportional to the distance for the rest position. The spring constant was set such that a constant force with a magnitude equal to 20% of the mean maximum voluntary force (MVF) magnitude across force directions (see below) would maintain the cursor stationary at 5 cm from the origin. The damping constant was set to make the system critically damped.

EXPERIMENTAL PROTOCOL

The experiment was subdivided into blocks, each consisting of a set of trials (**Figures 1C,D**). The first maximum voluntary contraction (MVC) block served to establish a mean MVF over horizontal force directions of each subject. At each trial subjects moved the sphere along a virtual line in one of 8 directions (equally spaced by 45°) by applying horizontal forces until they reached their maximum force production capability. After remaining 1 s at the position of maximum force, subjects were instructed to relax and to bring back the sphere to the rest position. When the trial stopped after 15 s, a new trial with a different target direction was initiated. In the following blocks, subjects performed center out forces to 8 equally spaced targets with force levels of 20 and 30% of MVF (corresponding to displacements of 5 and 7.5 cm of the sphere, respectively). Each target was repeated two times in a pseudo-random order (i.e., 32 trials per block). A trial was initiated

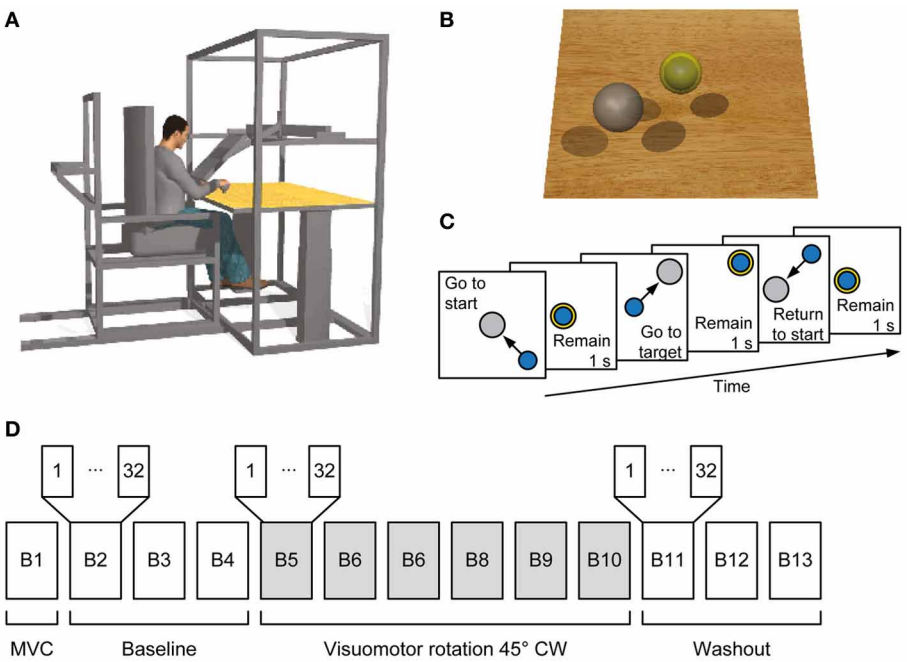

FIGURE 1 | Experimental setup and procedures. (A) Subjects sat in a moveable chair with their forearm pronated and fixed in a splint rigidly coupled to a force transducer. A flat monitor occluded the subject's hand and displayed a virtual scene co-located with the real desktop. **(B)** Screenshot of the virtual scene. Subjects controlled the position of the blue sphere by applying forces to the force transducer. The sphere is illustrated inside the yellow semi-opaque sphere indicating the start position. The target is shown as a gray sphere. **(C)** Sequence of events in a trial. Subjects had to maintain the blue sphere inside the start sphere for 1 s. Afterwards the target appeared and the start sphere disappeared instructing the subject to reach it and to hold the blue sphere inside the target sphere for 1 s. The target sphere changed its color from gray to yellow when the target was reached. Finally, the subject was instructed to return to the start position and remain there for 1 s. **(D)** Organization of an experimental session. In the first block the maximum voluntary contraction (MVC) during generation of maximum voluntary force across directions was established followed by three baseline blocks, each consisting of 32 trials. From the fifth block to the tenth block a clockwise (CW) visuomotor rotation was introduced followed by three washout blocks without visuomotor rotation.

by keeping the sphere at the start position (tolerance ±2% of MVF, i.e., 0.5 cm) for 1 s. Afterwards, a target appeared and the sphere indicating the start position disappeared. Subjects were instructed to move to the target as fast as possible, and to remain for 1 s at the target (tolerance ±2% of MVF). The trial was finished successfully 0.5 s after returning to the start position (**Figure 1C**).

Subjects performed three blocks of 32 trials (baseline), followed by six blocks with a 45° clockwise (CW) visuomotor rotation applied to the planar force used to compute the cursor displacement (rotation), and another three blocks without the rotation (washout) as shown in **Figure 1D**.

DATA ANALYSIS

Initial directional error

To evaluate the adaptation to the visuomotor rotation at the kinematics level we computed the initial directional error at 100 ms after movement onset. Movement onset was defined when the cursor speed exceeded 0.5 cm s^{-1}. The initial directional error was defined as the angle of the vector pointing from movement onset to the cursor position at 100 ms after movement onset with respect to a straight line to the target (**Figure 2B**).

Synergy extraction

Muscle synergies from each block were identified by non-negative matrix factorization (NMF) from EMG patterns recorded from the go signal to the end of successful target acquisition. Recorded EMG data were rectified and digitally low-pass filtered (2nd order Butterworth, 5 Hz cutoff) and re-sampled at 100 Hz to reduce data size. In each trial, mean EMG activity of each muscle during the initial rest phase was used as an estimate of baseline noise level and subtracted from the rest of the data. The EMGs were normalized to the maximum activation across direction recorded during the MVC block. Finally, the rectified and normalized EMGs of each trial from a given block (or from several blocks) were pooled together into a single data matrix **M**. The concatenated EMG patterns **m** (columns of the matrix **M**) were described by a combination of synergy coefficient by $\mathbf{m} = \mathbf{W}\,\mathbf{c}$, with **W** the $M \times N$ synergy matrix whose columns are vectors specifying relative muscle activation levels (invariant across time and trials), and **c** a N-dimensional synergy activation vector (time- and trial-dependent), N the number of synergies and M the number of muscles. The number of data points (columns) in the matrix **M** slightly varied between blocks and subjects because the time to successfully complete the target acquisition was not constant for each trial. For each possible N from 1 to M, the iterative optimization algorithm (Lee and Seung, 1999, 2001) was repeated 10 times and the solution with the highest fraction of data variation explained (R^2) was retained. We selected the smallest number of synergies which explained more than 90% of the data variation. Synergies were extracted from the following 13 muscles: Brachioradialis (BracRad), Biceps brachii, short head (BicShort), Biceps brachii, long head (BicLong), Triceps brachii, lateral head (TrLat), Triceps brachii, long head (TrLong), anterior Deltoid (DeltA), medial Deltoid (DeltM), posterior Deltoid, posterior (DeltP), clavicular part of the Pectoralis major (PectMajClav), medial Trapezius (TrapMed), Latissimus dorsi (LatDorsi), Teres Major (TerMaj) and Infraspinatus (InfraSp).

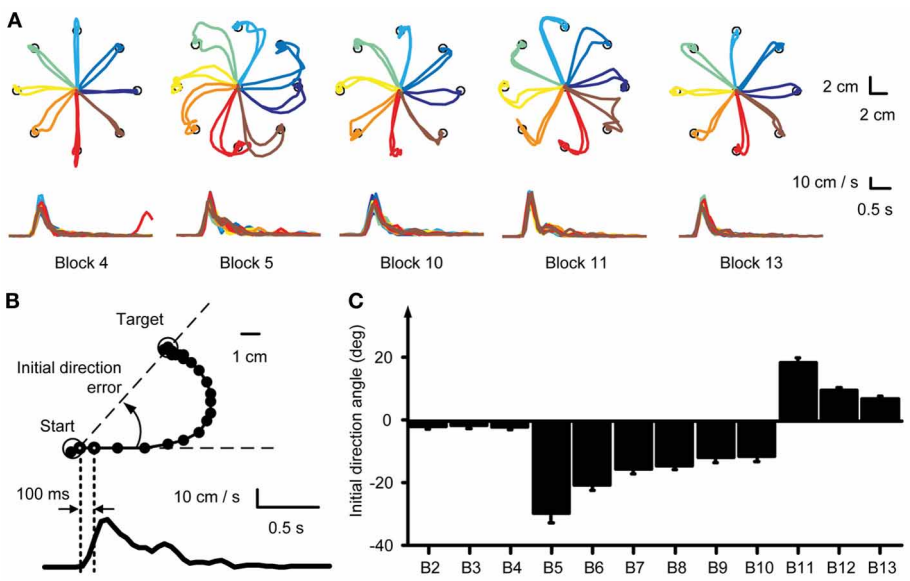

FIGURE 2 | Kinematic analysis. (A) Example force traces to targets located at a distance 30% of MVF. Trajectories to the targets were straight in the baseline block (Block 4) and curved at the beginning of the visuomotor perturbation (Block 5). With practice subjects adapted to the rotation and trajectories were again straight at the end of the exposure to the perturbation (Block 10). Aftereffects were present at the beginning of the washout (Block 11). At the end of the washout (Block 13) subjects re-adapted and were again able to produce straight trajectories to the target. **(B)** The initial movement direction angle with respect to a straight line to the target established at 100 ms after movement onset was used as a measure to quantify the adaptation process. **(C)** Mean initial direction error across subjects for each block.

Tuning curves

Muscle and synergy tuning curves and preferred directions (PDs) were calculated for each block by a cosine fit (d'Avella et al., 2006) between the activation of each muscle or the coefficients of each synergy (averaged across target distances and repetitions in a block) and the corresponding target position. We fitted the muscle (or synergy) activity with a linear regression $m(\theta) = \beta_0 + \beta_x \cos(\theta) + \beta_y \sin(\theta)$, where $m(\vartheta)$ is the muscle (synergy) activity for a target in direction ϑ and $\theta^{PD} = \tan^{-1}(\beta_y/\beta_x)$ is the PD of the cosine tuning. Tuning curves were computed for the time interval between movement onset and the following 100 ms, equivalent to the computation of the initial movement angle error. For visualization, the tuning curves were smoothed by a 2-dimensional spline interpolation and plotted in a polar coordinate system. Muscles or synergy coefficients which were not significantly cosine tuned were excluded from analysis (see **Table 1**). Significant cosine tuning was assumed when the *p*-value of the regression between the data and the optimal cosine tuning was smaller than 0.05 (see **Table 1** for R^2 values of the regression for each subject). After applying a CW visuomotor rotation, the cursor movement was initially directed CW with respect to the target, i.e., with the same directional error that would have been obtained with a rotation of the target in a counter-clockwise (CCW) direction instead of the CW cursor rotation. Thus, the PDs of muscles and synergies were computed according to the CCW-rotated visual targets, i.e., the actual force targets. Then the initial change of PD is directed CCW as displayed for individual muscles in **Figure 3A**. To better compare the changes of muscle- and synergy-PDs with the cursor initial direction error, we changed the sign of those PDs in block 5–10.

Data reconstruction by synergies

To quantify how well the structure of the muscle patterns of one block were captured by the synergies extracted from different blocks we reconstructed the EMG traces by finding the synergy coefficients that reconstructed those traces with the highest R^2 value. To find the optimal synergy coefficients we ran the same iterative optimization algorithm used for the extraction of the synergies without updating the synergies. We calculated the R^2 value of the reconstruction of EMG traces from blocks 2–13 using the synergies extracted from the pooled data from blocks 2–4. Monte-Carlo simulations were used to ensure that the reconstruction quality was higher than chance level. For the Monte-Carlo simulation we selected 30 sets of EMG signals at randomly chosen time points which reflected sets of $M \times N$ "random" synergies. The number of random synergies for each set and subject was chosen equal to the number of selected synergies. For each set of random synergies the EMG traces were reconstructed and the R^2 value computed.

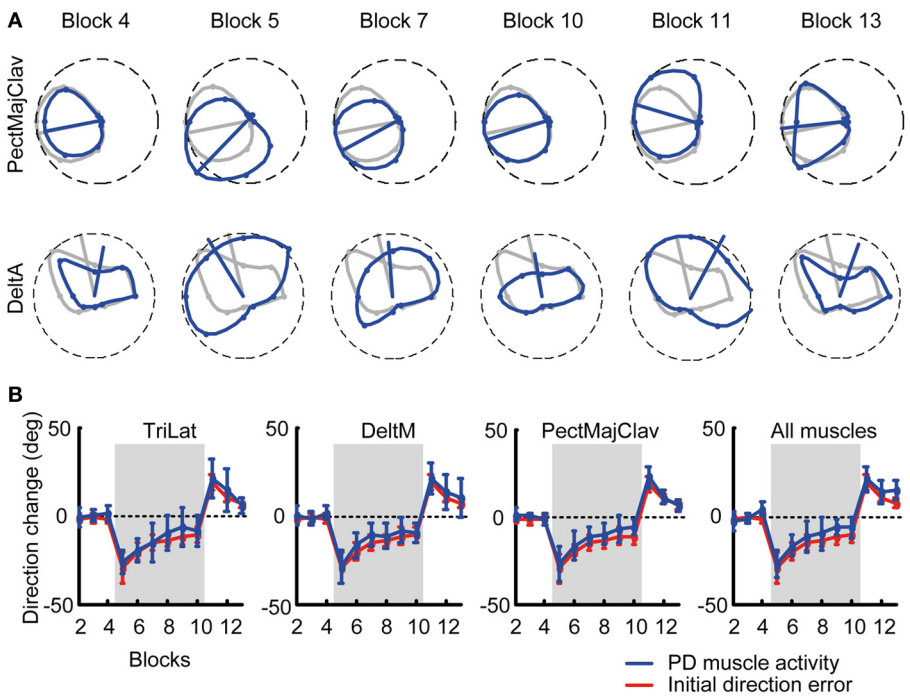

FIGURE 3 | Tuning curves and preferred directions of individual muscles. (A) Example of tuning curves for two muscles (*first row*: PectMajClav, *second row*: DeltA) of subject 3 estimated from different blocks (*blue* markers and lines) compared to the tuning curve of the muscles calculated from the pooled data of all baseline blocks (reference blocks, *gray* markers and lines). As for PectMajClav, the changes in preferred direction (PD, *blue* radial segment) of many muscles with respect to the PD in the reference blocks were similar to the initial direction angle errors. However, the activation of some muscles such as DeltA was not cosine tuned and those muscles were excluded from analysis. **(B)** Examples of the mean PD-change of three muscles across subjects and grand mean of the PD-change across muscles and subjects (*rightmost panel*). The PD changes of the muscles (*blue*) was not statistically different from the initial direction angle error (*red*).

Synergy similarity

We measured the similarity between two synergies by normalizing the synergy vectors (Euclidean norm) and computing their scalar product. Similarity between two sets of synergies was assessed by first matching pairs of synergies according to their normalized scalar product (starting from the pair with the highest value and continuing with the pairs from the remaining synergies until all pairs were matched) and then computing the mean scalar product over all matched pairs. We selected the number of synergies from the reference synergies for all comparisons of different sets of synergies for each subject. As for the reconstruction R^2, Monte-Carlo simulations were used to ensure that the similarity was higher than chance level.

Statistical analysis

Two-Way repeated measures ANOVAs (2 adaptation measures × 6 perturbation blocks) were conducted to detect significant differences between the time course of initial direction error and that of change of muscle PDs. Paired *t*-tests with Bonferroni correction were applied where appropriate.

RESULTS

INITIAL DIRECTION ERROR CHANGES DURING VISUOMOTOR ROTATION

In the baseline blocks subjects produced relatively straight trajectories (**Figure 2A**, Block 4) with bell shaped velocity profiles (**Figure 2A**, *bottom row*). Change of visuomotor mapping caused distorted trajectories (**Figure 2A**, Block 5) and multi-peaked velocity profiles reflecting corrective movements necessary to reach the target. After exposure of six blocks with visuomotor rotation subjects compensated (**Figure 2A**, Block 7) for the perturbation and were able to produce relatively straight movements to the target (**Figure 2A**, Block 10). Velocity profiles approached a single bell-shaped velocity profile again. When the visuomotor rotation was removed (**Figure 2A**, Block 11), subjects showed aftereffects in the opposite direction of the perturbation, which were extinguished after three washout blocks (**Figure 2A**, Block 13).

We quantified the adaptation of all subjects by analyzing the initial movement direction error with respect to a straight line to the target at 100 ms after movement onset (**Figure 2B**, *right dotted vertical line*). Movement onset was defined as the time when the cursor speed exceeded a threshold of 5 cm/s (**Figure 2B**, *left dotted vertical line*) after the Go-signal had occurred. Across subjects, the initial movement direction showed a large CW deviation when the rotation was introduced (Block 5, **Figure 2C**) that was gradually reduced with practice (Blocks 5–10) and a large CCW deviation (aftereffect) once the perturbation was removed (Block 11). One-Way repeated measures ANOVA confirmed a significant difference of initial direction error (factor: block number, $F = 5.04$, $p < 0.001$). In the baseline blocks the initial direction error was small (Block 2: $-1.86 \pm 2.41°$, mean ± SD, Block 3: $-1.44 \pm 3.05°$; Block 4: $-1.96 \pm 2.64°$). At the beginning of the visuomotor perturbation the initial direction error (Block 5: $-29.59 \pm 8.42°$) was significantly different from the error in the last baseline block ($p < 0.001$, two-tailed, paired *t*-test) but approached baseline level by a gradual adaptation in subsequent blocks (Block 10: $-11.35 \pm 4.53°$, $p = 0.002$ with respect to Block 4). After the perturbation was removed, the initial direction error was significantly (Block 11: $18.62 \pm 4.33°$, $p < 0.001$) higher than in the last baseline block, but approached baseline level at the end of the washout (Block 13: $7.02 \pm 2.71°$, $p < 0.001$ with respect to Block 4). All comparisons remained significant after Bonferroni correction.

PREFERRED DIRECTION CHANGE OF MUSCLES MATCHES INITIAL DIRECTION ERROR CHANGE

We tested if the PD of muscle directional tuning followed the change of initial direction error, as was observed in visuomotor rotation of isometric wrist movements (de Rugy, 2010). We found that not all recorded muscles were cosine-tuned. Some muscles showed peaks of activity in multiple directions and their tuning was not captured by a single cosine function. We therefore excluded all muscles which were not significantly cosine-tuned in the reference baseline blocks (see **Table 1** for R^2 values of the cosine fit) for this analysis as their PDs did not characterize their directional tuning reliably.

Figure 3A shows an example of a typical change of the PD of a cosine-tuned muscle (*blue tuning curves*, PectMajClav) with respect to the PD of the reference blocks (*gray*, Blocks 2–4). Several muscles were found not to be cosine-tuned, for example DeltA shown in **Figure 3A** (*second row*). The time-course of the PD of DeltA across blocks would indicate a larger PD change in the last baseline block (Block 4) than in the first visuomotor rotation block (Block 5) with respect to the reference blocks. Considering only cosine-tuned muscles the PDs closely followed the change in force direction error as shown for three muscles and the overall mean across muscles and subjects, respectively, in **Figure 3B**. A Two-Way repeated measures ANOVA comparing the mean change of the muscle PDs across subjects and muscles with the mean initial direction error did neither reveal a difference (adaptation measure × perturbation block, $F = 0.73$, $p = 0.394$) between the two measures nor a significant interaction ($F = 0.34$, $p = 0.889$).

ROBUSTNESS OF SYNERGY STRUCTURE

Given the close relationship between muscles and forces we tested whether the adaptation process could be explained by fixed muscle synergies being recruited with PDs rotating together with the muscle PDs. We extracted synergies from each block from the EMG signals beginning at movement onset until the time point at which the target was successfully acquired. **Figure 4A** shows the fraction of data variation explained by the extracted synergies for the last baseline block (Block 4, *black*) and the first perturbation block (Block 5, *gray*). The number of synergies selected according to a 90% threshold was not significantly ($p = 0.598$, two-tailed paired *t*-test) different between the two blocks (Block 4: 4.75 ± 0.71 synergies, Block 5: 4.62 ± 0.52 synergies). When considering all blocks, the minimum number of synergies explaining more than 90% of the data variation was not significantly different over time, as revealed by a One-Way repeated measures ANOVA (factor: block number, $F = 1.68$, $p = 0.093$).

The structure of the synergies in most cases was similar across subjects and blocks. **Figure 4B** compares the synergies extracted

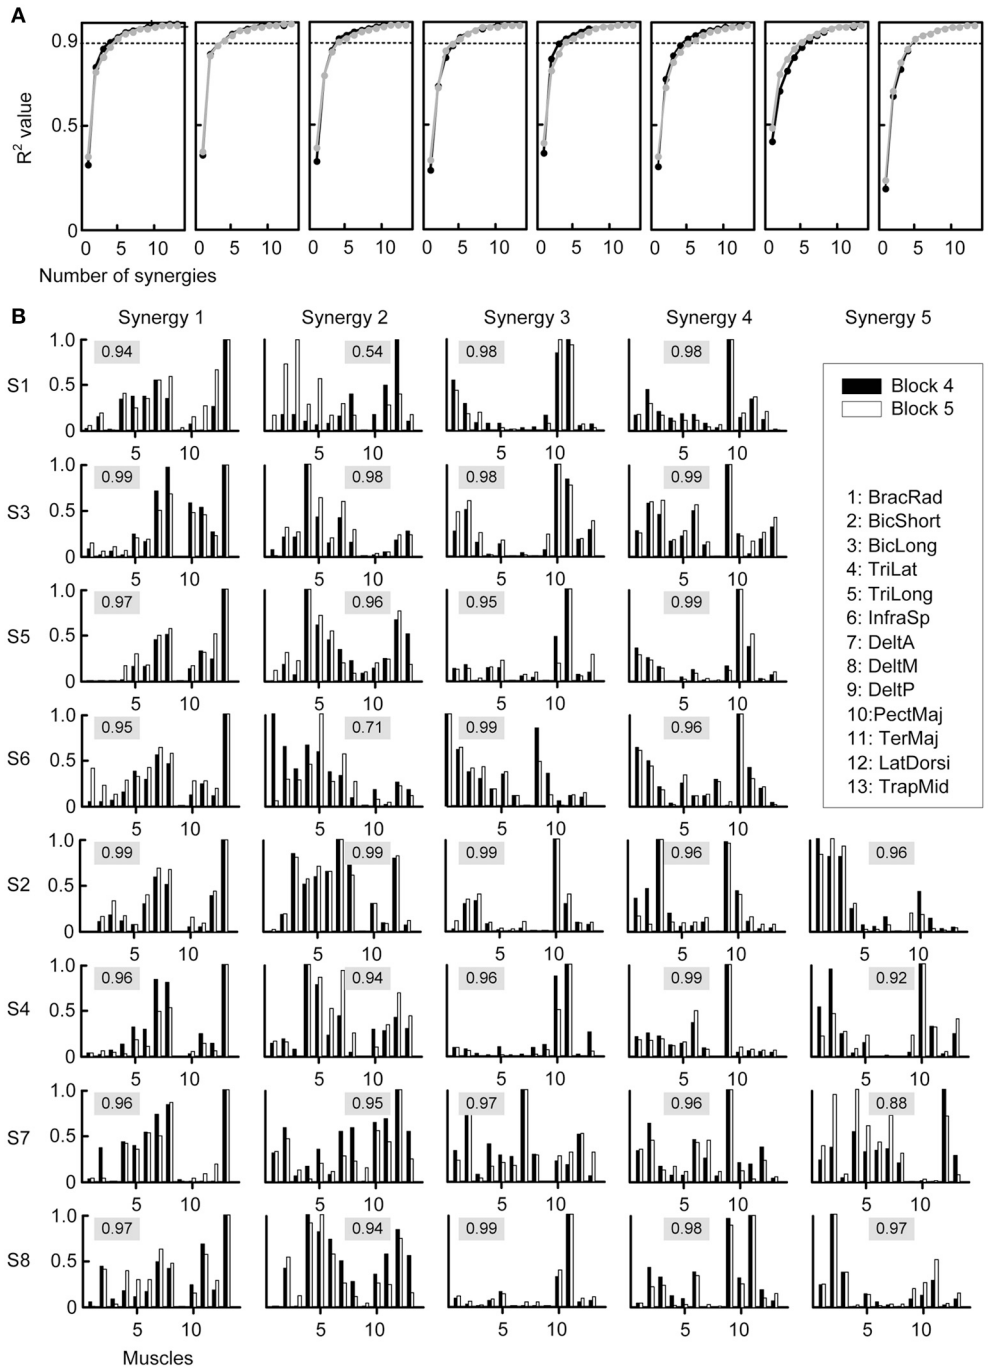

FIGURE 4 | Selection of number of synergies and synergy structure. (A) Fraction of total variation explained (R^2) by the synergies extracted from Block 4 (last baseline block, *black*) and by the synergies extracted from Block 5 (first perturbation block, *gray*) were similar for all subjects (*different plots*). **(B)** Synergies from all subjects (*rows*) extracted from Block 4 (*black bars*) and Block 5 (*gray bars*). The numeric value in each plot represents the similarity between the two synergies, quantified by the scalar product of the normalized synergies (cosine-value).

from Block 4 (black bars) with those extracted from Block 5 (white bars) for each subject. We compared a number of synergies in Block 4 and 5 equal to the number of synergies extracted from the pooled data of Blocks 2, 3, and 4 ("reference synergies," see **Table 1**). We identified the best matching pairs of synergies according to the similarity quantified by the cosine between the synergy vectors and plotted them side-by-side (**Figure 4B**, cosine values are shown with a gray shaded background). In general, the similarity of synergies from Block 4 and 5 across subjects, as indicated by a cosine-value close to one, was high (mean ± SD of

similarity: 0.95 ± 0.06, range: 0.54–0.99). However, 2 out of 36 pairs had a similarity <0.8 (S1: second pair, similarity 0.54; S6: second pair, similarity 0.71) and an additional pair had a similarity <0.9 (S7, fifth pair, similarity 0.88). Additional analysis of the synergies in such pairs indicated that they were similar either to one of the synergies in the reference set with the same number of synergies (S6: similarity 0.93 and 0.90 for the synergies extracted from Block 4 and 5 respectively; S1: similarity 0.98 for the synergy extracted from Block 5; S7: similarity 0.93 for the synergy extracted from Block 5) or to one of the synergies in the reference set with an additional synergy (S1: similarity 0.95 for the synergy extracted from Block 4). In one case (S7), the sets of 4 synergies extracted from Blocks 4 and 5 had a much higher similarity (mean 0.97, minimum 0.94) than the sets with the same number of synergies as the reference synergies (5 for S7). These observations suggest that the identification of the synergies from individual blocks is affected by noise and inter-trial variability more than the identification of synergies from the pulled data of all three baseline blocks. Moreover, even if the data of a specific block were best captured by a synergy that did not match closely any synergies in a different block, such synergy might only have captured a very small amount of variation in the data.

Thus, we quantified the stability of the subspace spanned by the reference synergies by assessing how well they could reconstruct the muscle patterns of all other blocks. The similarity of the reconstructed muscle patterns (obtained by multiplying synergies extracted from reference blocks and synergy coefficients fitted onto the data of each block) with respect to the actual muscle patterns of each block was quantified as a R^2 value. The high R^2 values (range: 0.72-0.94, mean ± SD: 0.88 ± 0.04) indicate that muscle patterns during adaptation to visuomotor rotation are selected from a stable muscle subspace (**Figure 5A**). However, there was a small but constant decrease of R^2 values during the experiment, possibly reflecting small changes in elbow position or fatigue.

To exclude that the high R^2 values were obtained by chance, we attempted to reconstruct the data using random synergies. We repeated the reconstruction with 30 sets of random synergies. In all blocks the R^2 value obtained with random synergies was significantly smaller (all $p < 0.001$, two-tailed paired t-tests, *gray bars* in **Figure 5B**) than the reconstruction using synergies extracted from the reference blocks (**Figure 5B**, *black bars*).

We also assessed the similarity of the synergies extracted from the reference blocks and those extracted from all blocks. In all subjects and blocks, the mean normalized scalar product between the best matched pairs of synergies was close to one (**Figure 5C**), indicating a high similarity. Across subjects, in all block the similarity (**Figure 5D** *black bars*, range: 0.69–0.99, mean ± SD: 0.92 ± 0.07) was significantly higher that between random synergies (*gray bars*, $p < 0.01$).

ADAPTATION BY ROTATION OF SYNERGY PREFERRED DIRECTION

Given the stability of muscle synergies during visuomotor adaptation, we expected the change of PDs of the synergy coefficients to closely match the change of directional error of the initial force and the change of PDs of the muscles. **Figure 6A** shows an example of the directional tuning and the PDs of the synergy coefficients for subject 3 (*blue tuning curves*) with respect to the tuning and PDs in the reference blocks (*gray*, Blocks 2–4). The change of synergy coefficient PDs from subject 3 is shown across all blocks. The PD change was similar across synergies with −1.43 ± 2.51° (mean ± SD) deviation in the last baseline block (Block 4), an initial deviation of −34.91 ± 0.85° at the beginning of the visuomotor rotation (Block 5), a gradual reduction of PD change (−9.67 ± 4.03°, Block 10), aftereffects at the beginning of the washout phase (19.79 ± 11.43°, Block 11) and a gradual return to baseline (7.52 ± 6.49°, Block 13) at the end of the experiment (**Figure 6B**). Across subjects the mean PD change of synergy coefficients (**Figure 6C**, blue traces) was: Block 4: 1.06 ± 4.53, Block 5: −26.95 ± 5.54, Block 10: −9.97 ± 6.02, Block 13: 6.16 ± 7.57, similar to the change of PDs of muscles.

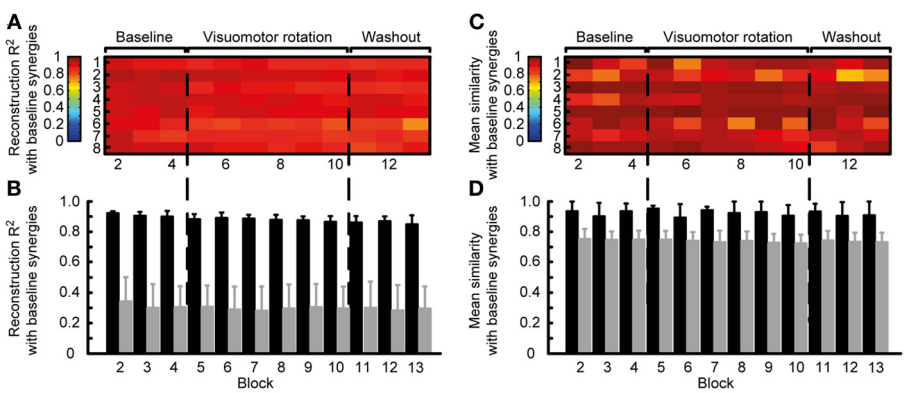

FIGURE 5 | Robustness of synergies during adaptation. (A) Quality of the reconstruction of EMGs recorded from different blocks throughout the experiment (*columns*) for each subject (*rows*) by synergies extracted from the reference blocks. **(B)** Mean reconstruction R^2 for each block over subject (*black bars*) compared with the mean reconstruction R^2 for random synergies (*gray bars*). **(C)** Similarity (mean normalized scalar product over best matching pairs) between the synergies extracted from the reference blocks and those extracted from each individual block. **(D)** Mean similarity for each block over subjects (*black bars*) compared with the mean similarity for random synergies.

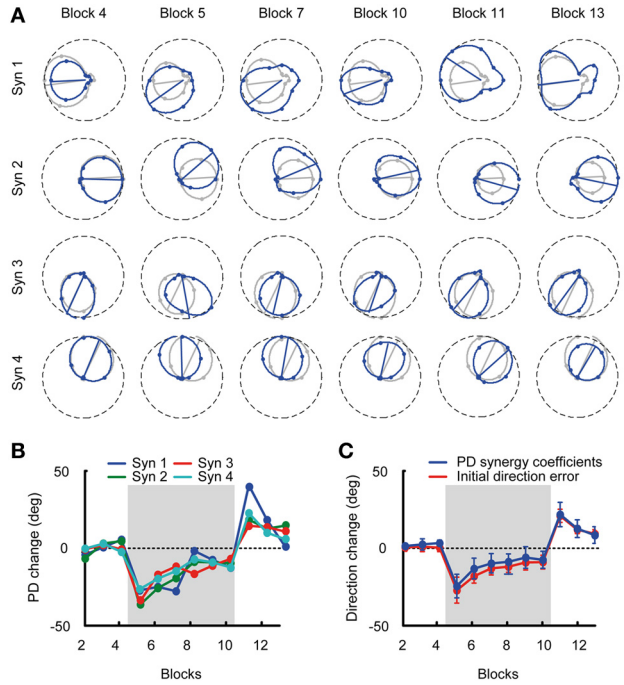

FIGURE 6 | Tuning curves and preferred directions of synergy coefficients. (A) Example of tuning curves for the four synergies of subject 3 estimated from different blocks (*blue* markers and lines) compared to the tuning curves calculated from the pooled data of all baseline blocks (reference blocks, *gray* markers and lines). **(B)** Mean PD-change of synergy coefficients for subject 3 for all blocks. **(C)** Grand mean of the PD-change across synergies and subjects (*blue*) and initial direction angle error (*red*) for all blocks. The PD change of the synergy coefficients was not statistically different from the initial direction angle error.

DISCUSSION

We investigated the changes in the muscle patterns underlying visuomotor adaptation in a virtual reaching task requiring the generation of multidirectional isometric forces with the arm. We found that the changes in the PDs of most of the muscles closely followed the change in force direction required to compensate for the perturbation, suggesting that the adaptive process relies on remapping target directions into new planned force output directions. We then tested whether a given force output is generated, during adaptation to a novel rotation of the force-to-cursor mapping and after re-adaptation to the normal mapping, by the same set of muscle synergies which capture the muscle patterns in the baseline condition. We found that the number and the structure of the synergies was robust throughout adaptation and re-adaptation. In each subject, four or five synergies extracted in the baseline condition could reconstruct with a comparable level of accuracy the muscle patterns recorded before, during, and after the visuomotor rotation and they had a mean similarity with the synergies extracted from individual blocks throughout the experiment significantly higher than the mean similarity between random synergies. We also found that the change in the PDs of the synergy recruitment closely matched the change in the PDs of the individual muscles.

Many studies of motor adaptation after dynamic or visuomotor perturbation have used center-out reaching tasks in which the motion of the hand is either directly perturbed, by viscous force fields generated by a robotic device (Shadmehr and Mussa-Ivaldi, 1994) and by Coriolis forces arising in a rotating room (Lackner and Dizio, 1994), or mapped into a virtual end-effector, as with visuomotor rotation of a cursor on a computer screen (Ghilardi et al., 1995; Imamizu et al., 1995; Krakauer et al., 2000). Only in a few cases isometric force at the hand has been used as motor output instead of hand motion to investigate visuomotor adaptation (Hinder et al., 2007; de Rugy et al., 2009; de Rugy and Carroll, 2010). By using isometric force, as the posture of the arm is fixed, there is no need for visual-proprioceptive recalibration after the perturbation. In contrast, the adaptive response to a visuomotor rotation of the movement of a cursor associated with actual hand movement involves both sensorimotor remapping and sensory recalibration, i.e., alignment of the felt and seen position of the hand at the end of the movement (Simani et al., 2007). Moreover, with isometric force as motor output there is no need for increasing limb impedance by increasing muscle co-contraction to stabilize the hand trajectory immediately after the perturbation, i.e., before it is compensated in the feed-forward motor command. Increase in muscle activation has been reported after dynamic perturbations (Thoroughman and Shadmehr, 1999; Franklin et al., 2003) but also after visuomotor rotation (Paz et al., 2003). In contrast, we did not observe a significant increase in muscle activation, in accordance with a previous study of visuomotor rotation in an isometric reaching task (de Rugy and Carroll, 2010).

Stability of the relationship between directional tuning of the muscles and force has been observed before in macaque monkeys and human subjects after both visuomotor and dynamic perturbations. In monkeys performing a reaching task by moving a joystick that controlled a cursor on a video screen, most muscles recorded in the shoulder, neck and trunk showed clear PDs which were stable in motor coordinates during adaptation to visuomotor rotations (Wise et al., 1998). In humans adapting to viscous force fields, i.e., to velocity dependent forces applied perpendicularly to the hand movement direction, the peak of EMG activity of two pairs of shoulder and elbow muscles counteracting the perturbation gradually shifted earlier in the reaching movement, becoming a feed-forward command, and the EMG tuning curves gradually rotated by an amount specific to the force field (Thoroughman and Shadmehr, 1999). Similarly in monkeys, during adaptation to force fields the PDs of shoulder and elbow muscles rotated in the direction of the external force and returned to baseline when the perturbation was removed (Li et al., 2001), indicating a stable relationship between muscle directional tuning and generated force. In an isometric virtual reaching task in which wrist flexion/extension and radial/ulnar deviation forces generated by human subjects were mapped, respectively, into horizontal and vertical movements of a cursor on a vertically mounted computer screen, the changes in the directional tuning of four wrist muscles closely matched the rotation of the directional error in force after a 45° visuomotor rotation, indicating that the functional contribution of muscles remained consistent during adaptation (de Rugy and

Carroll, 2010). Thus, our observations on the stability of the relationship between muscle directional tuning of cosine tuned muscles and force are in accordance with previous observations but they are reported for the first time for adaptation to visuomotor rotation of the isometric force generated by a large number of arm muscles.

Importantly, subjects were not informed on what kind of perturbation (consistent rotation of the force by a fixed angle) they will experience in the experiment. This kind of adaptation is likely to occur implicitly when the desired hand trajectory and the executed trajectory in visual space do not match (Mazzoni and Krakauer, 2006; Krakauer, 2009), possibly by reducing a prediction error computed by a forward model (Shadmehr et al., 2010). A question that arises in this context is why the nervous system does not exploit the redundancy inherent in the neuro-muscular system to compensate the perturbation by reducing the force error at the level of force components generated by individual muscles. Indeed, it would have been possible to compensate for the perturbation by adapting the activation of each muscle reducing the error between force target and muscle force, possibly ending with a muscle pattern in the adapted state different from the muscle pattern selected to generate the rotated force before the perturbation. Despite the theoretical flexibility of the mapping from muscles to forces, i.e., many different muscle patterns can generate the same forces (Kutch and Valero-Cuevas, 2012), adaptation of individual muscles did not appear to be used for compensating the distorted visuomotor mapping. In contrast, the relationship between muscles and forces remained fixed indicating that subjects tried to adapt to the perturbation by rotating the forces ("aiming in a different direction") from the beginning on. An explanation could be that adaptation to this kind of perturbations occurs early in the sensorimotor transformations mapping visual targets into muscle patterns by adapting a single learning parameter (force direction) resulting in a coordinated rotation of all the muscle PDs. However, adapting only a few high level parameters may be computationally advantageous but it might also be required if the generation of muscle patterns is not as flexible as theoretically possible. The characteristics of the connectivity between different areas in the motor systems might prevent the nervous system from adapting the recruitment of individual muscles to compensate for visuomotor perturbations. Divergence from premotor neurons to many muscles and convergence to a single muscle from many premotor neurons (Graziano, 2006; Rathelot and Strick, 2006) might underlie the organization of muscle synergies in the primary motor cortex (Gentner et al., 2010; Overduin et al., 2012) and in the spinal cord (Hart and Giszter, 2010).

We therefore considered whether the visuomotor adaptation process is compatible with muscle synergies. Muscle synergies has been recently identified during isometric force production (Roh et al., 2012). However, to our knowledge, a direct test of robustness of muscle synergies during visuomotor adaptation has never been conducted. The structure of the synergies and their number appeared to be similar across subjects and blocks. During the adaptation the coefficients of cosine tuned synergies rotated almost identically as the PDs of individual tuned muscles, albeit some synergies contained contributions of non-cosine tuned muscles. Therefore, isometric visuomotor adaptation can be equally well described by rotation of forces, muscle-PD changes, and PD changes of synergy coefficients. Moreover, as adaptation may involve components with different learning rates (Smith et al., 2006) the analysis of muscle synergies may allow to dissociate different components of the adaptive process. A rapidly adapting component may be related to the adjustment of synergy coefficients, e.g., rotating their recruitment to compensate for a visuomotor rotation. A slower component may be involved in the acquisition of new synergies or in changing the structure of existing ones. In isometric visuomotor adaptation we found that only a fast learning component as there is no need for altering the synergies. In contrast, we recently found that adaptation to novel perturbations that cannot be compensated by adapting the recruitment of existing synergies but require new or altered synergies is slower than adaptation to similar perturbations compatible with the synergies (Berger et al., 2013). Testing such perturbations has provided new direct evidence for a synergistic organization (d'Avella and Pai, 2010).

To assess the robustness of the synergies during adaptation we assessed the quality of reconstruction of the muscle patterns recorded throughout the experiment by the synergies extracted from the baseline condition (reference blocks) and their similarity with the same number of synergies extracted from individual blocks. For each subject, the number of synergies was selected as the minimum number sufficient to explain at least 90% of the data variation. While criteria based on a threshold on the variation accounted for (VAF) has been frequently used in the muscle synergy literature (Tresch et al., 1999; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006) other criteria based on the detection of a "knee" in the curve of the VAF as a function of the number of synergies (d'Avella et al., 2003; Cheung et al., 2005; Tresch et al., 2006), on a combination of VAF-threshold and knee (Berger et al., 2013) have been proposed. All these criteria depend on some threshold which must be chosen *ad-hoc*. Recently, a new criterion based on decoding single-trial task parameters from synergy coefficients has been proposed (Delis et al., 2013). Such criterion does not depend on *ad-hoc* parameters but it can be only applied to synergies extracted from a large number of repetitions (>10) of the same experimental condition. Thus, selection criteria for synergies extracted from averaged data or a limited number of repetitions, as in our case, mainly guarantee that the number of synergies can be meaningfully compared across different conditions and subjects rather than ensuring that the "true" number of synergies has been selected. Moreover, to simplify the assessment of synergy similarity we compared the same number of synergies extracted from the reference blocks and extracted from individual blocks. An alternative approach would have been to select a different number of synergies for each block according to the VAF criterion and to assess both the similarity between the pairs formed with the smallest of the two synergy sets and the dimensionality of the set. However, as VAF criterion is affected by noise, we preferred to rely only on the number of synergies selected from three baseline blocks (reference blocks) rather than on the number selected from individual blocks. An incorrect identification of the number of synergies in a single block might in fact significantly

affect the mean similarity, as the set with an additional synergy often contains two synergies resulting from the splitting of one of the synergies in the original set (d'Avella et al., 2003) and both synergies can have low similarity with the original one. In any case, the R^2 measure of synergy subspace robustness does not depend on the number of synergies selected for the individual blocks as it is based on the reconstruction of the actual data of each block.

In summary our results indicate that muscle synergy structure is robust during visuomotor adaptation and that the required changes in the muscle patterns are obtained by rotating the directional tuning of the synergy recruitment. Visuomotor adaptation may occur by remapping desired end effector movement into synergy coefficients. Further experiments are required to identify synergies as a physiological correlate of motor learning.

In this study we employed a dynamic recurrent neural network (DRNN) in a novel fashion to reveal characteristics of control modules underlying the generation of muscle activations when drawing figures with the outstretched arm. We asked healthy human subjects to perform four different figure-eight movements in each of two workspaces (frontal plane and sagittal plane). We then trained a DRNN to predict the movement of the wrist from information in the EMG signals from seven different muscles. We trained different instances of the same network on a single movement direction, on all four movement directions in a single movement plane, or on all eight possible movement patterns and looked at the ability of the DRNN to generalize and predict movements for trials that were not included in the training set. Within a single movement plane, a DRNN trained on one movement direction was not able to predict movements of the hand for trials in the other three directions, but a DRNN trained simultaneously on all four movement directions could generalize across movement directions within the same plane. Similarly, the DRNN was able to reproduce the kinematics of the hand for both movement planes, but only if it was trained on examples performed in each one. As we will discuss, these results indicate that there are important dynamical constraints on the mapping of EMG to hand movement that depend on both the time sequence of the movement and on the anatomical constraints of the musculoskeletal system. In a second step, we injected EMG signals constructed from different synergies derived by the PCA in order to identify the mechanical significance of each of these components. From these results, one can surmise that discrete-rhythmic movements may be constructed from three different fundamental modules, one regulating the co-activation of all muscles over the time span of the movement and two others elliciting patterns of reciprocal activation operating in orthogonal directions.

Keywords: rhythmic movement, muscular synergy, dynamic recurrent neuronal network, principal component analysis, upper limb, figure-eight

INTRODUCTION

The concept of synergy, associated with basic motor modules of activity, refers to two distinct notions. On the one hand, the large variety of movements accomplished by a limb could be explained by the activation of a reduced number of muscular synergies (Saltiel et al., 2001; Ivanenko et al., 2004; d'Avella et al., 2006). On the other hand, for a given movement, the establishment by the central nervous system (CNS) of synchronous muscular synergies could explain how activity is distributed within a muscle group (Weiss and Flanders, 2004; d'Avella and Bizzi, 2005; Klein Breteler et al., 2007). The first notion gives rise to a simplification in the number of degrees of freedom to be controlled by the CNS for motor control while the second one links modules of activity presented by limb muscles and their functional meaning in the context of motor action. Non-invasive recording of the electromyographic (EMG) signals are widely used to extract muscular synergies (d'Avella et al., 2003, 2008; Ivanenko et al., 2004; Klein Breteler et al., 2007; Cheung et al., 2012; Frère and Hug, 2012). These muscular synergies seem to be structured in the brain stem and spinal cord (Cheung et al., 2009; Clark et al., 2010) and even in the motor cortex for highly skilled movements (Gentner and Classen, 2006; Rathelot and Strick, 2006).

Most attempts to define muscular synergies to date have relied on tools such as principal component analysis or other forms of factor analysis that extract stable relationships (structure) between the activation patterns of multiple muscles. These

techniques do not, however, serve to identify structure in the mapping of EMG inputs to the actual motor output (e.g., movement of the hand). In this context, the use of dynamic recurrent neural networks (DRNN) to interpret biological signals coming from the human body could be an interesting complementary approach to extract modules underlying the input-output relationship between muscle activation patterns and movement, where the input signal consist of the EMG signals provided by different muscles implicated in the movement and the output signals of the DRNN would be the movement kinematics. Our proposition is that using a DRNN to map EMGs to kinematics can provide a new, indirect method to better understand motor organization in the CNS, for reasons that we will lay out in following paragraphs.

DRNNs are recognized as universal approximators of dynamical systems (Kuan and Hornik, 1991; Doya, 1996; Yi et al., 2006; Tani et al., 2008; Bicho et al., 2011; Laje and Buonomano, 2013) and the attractor states reached through DRNN learning of EMG-to-kinematic patterns correspond to biologically interpretable solutions (Cheron et al., 1996, 2003, 2006, 2007, 2011; Song and Tong, 2005; Liu and Buonomano, 2009). After the learning phase, the identification performed by the DRNN offers a dynamic memory which has been used, for example, to recognize the physiological preferred direction of action for the studied muscles (Cheron et al., 1996, 2003, 2006, 2007). But the correct recognition by a trained DRNN of EMG patterns not included in the training set may also be related to motor learning, as shown by the following example. When humans learn a specific movement, the initial solutions acquired through self-organized principle are often unstable and become more stable with practice. This feature is apparent in the study by Dominici et al. (2011) where they demonstrated that development of motor patterns from neonatal to toddler consisted of learning new muscle synergies, adding new patterns to the few basic patterns present already at birth. When a DRNN was applied to EMG and kinematic data also acquired from infants and toddlers (Cheron et al., 2001) we showed that it is only when behaviors have been practiced sufficiently by the children and when the task and the context are unchanging that patterns emerged were sufficiently stable to allow the DRNN to generalize (Cheron et al., 2011). Thus, the ability of a DRNN to generalize across movements is a reflection of the stability and maturity of the underlying building blocks. Here we apply a similar concept to analyze a different question, that of how the CNS generalizes the task of programming movements across different kinematic and biomechanical conditions. We hypothesize that the CNS accomplishes this task by exploiting modules to simplify the computation of the motor command. If this hypothesis is valid, then application of the DRNN can be used to characterize which modules are stable across varying situations.

Taking into account Bernstein's theory of motor control (Bongaardt, 2001) where the motor program (also called engram) used to generate a movement is organized at a higher level in the CNS while the details of motor action (also called ecphoria) are selected at a lower level, we can consider that in the EMG command one can find a mixture of the higher (topological) and lower (metrics) aspects of motor action. If we extract the "synchronous synergies" for a given movement, each module could contain different levels of information ranging from the general (what is the form to be reproduced by the hand) to the more specific (what are the joint displacements and muscle activations used to generate the movement of the hand). Applied to the analysis of a drawing movement, such as a figure-eight, we should find in the EMG signals information corresponding to a generalized "figure-eight" motor program mixed with the information corresponding to the specific aspects of motor execution, such as the movement's velocity, amplitude, joint configuration and biomechanical constraints.

We chose to study figure-eight movements. These gestures require the displacement of the end-effector segment through all the directions within the plane of the figure. Note, however, that starting from the central point one can perform this figure with one of four different initial directions. Given the fact that EMG patterns are modulated by movement direction in 3D space (Flanders et al., 1994, 1996; Hoffman and Strick, 1999), forcing the DRNN to converge to any one of these four patterns of movement should create an attractor state that reflects the directional tuning of synergies within the workspace. Given also that a muscle's activation depends on its mechanical action, which in turn depends on joint configuration (Hogan, 1985; Buneo et al., 1997), a DRNN that converges to the four figure eights realized in one part of the joint workspace may or may not recognize muscle activities when the same movements are performed in a different workspace region. Finally, considering that the precise structures of some muscle synergies are subject-specific (Torres-Oviedo and Ting, 2010), a DRNN trained with all the figure-eight movements of one subject may or may not detect the tuning synergies of another, depending on how stable the underlying modules are across subjects. We therefore set out to measure the ability of a DRNN to learn and recognize movements from EMG signals for figure-eight movements performed in different directions and in different parts of the workspace as a mean to assess the invariance of movement modules or primitives across a variety of movement conditions. We also used the DRNN in a novel fashion to identify the physical manifestation, in terms of hand kinematics, of synchronous synergies (d'Avella and Bizzi, 2005; Klein Breteler et al., 2007) identified by principal component analysis in our previous study (see companion paper, this issue).

MATERIAL AND METHODS

Data were collected from five right-handed subjects aged between 21 and 40 years. All were in good health, free from known neurological disorders, and had given informed consent to take part in the study, which was approved by the local ethics committee. They were asked to draw, as fast as possible, two series of figure-eight movements in free space with the right arm fully extended at the elbow (for more details see Bengoetxea et al., 2010). Movements were initiated in the center of the figure with an initial up-right (UR), down-right (DR), up-left (UL) or down-left (DL) direction with respect to external coordinates. Three subjects performed the task in both the frontal and sagittal workspaces (in separate sets of trials) depending on the flexion or abduction posture of the shoulder. Two additional subjects (subjects 4 and 5) performed the movements only in the frontal workspace.

DATA ACQUISITION

Movements of the index finger were recorded and analyzed using the optoelectronic ELITE system (2 CCD-cameras, sampling rate of 100 Hz; BTS, Milan; Ferrigno and Pedotti, 1985). The cameras were placed 4 m apart from each other and 4 m from the subject. Four markers were attached to the arm (on the acromion, the lateral condoyle of the humerus, the radial apophysis of the wrist and the index finger). Velocity signals were obtained by digitally differentiating position signals using a fifth-order polynomial approximation. Reconstruction of the arm movements by the ELITE system using the trajectories of the 4 markers confirmed the visual observation that the upper arm, forearm, hand and index finger acted as a rigid link (Bengoetxea et al., 2010). Thus, we analyzed here only the marker on the index finger that was used to trace the figure-eight.

Surface electromyographic activity (EMG) was recorded with the TELEMG system (BTS, Milan) synchronized with the kinematic data. Silver-silver chloride electrode pairs (inter-electrode distance of 2.5 cm) were placed over the belly of the following 7 muscles: posterior deltoid (PD), anterior deltoid (AD), median deltoid (MD), pectoralis major superior and inferior (PMS and PMI), latissimus dorsi (LD), and teres major (TM). Raw EMG signals (differential detection) were amplified by a portable unit with a gain of 1000 and transmitted to the main unit via a telemetry system (Telemg, BTS). A functional resistance test that isolated specific muscles was made in order to verify the absence of cross talk between adjacent muscles. Thereafter, EMGs were band-pass filtered (10–500 Hz), digitized at 1 kHz, full-wave rectified and smoothed by means of a third-order averaging filter with a time constant of 20 ms (Hof and Van den Berg, 1981).

DYNAMIC RECURRENT NEURAL NETWORK

We used a DRNN, that consisted of 50 fully connected hidden neurons, 7 input neurons and 2 output neurons. The network included a looping mechanism (fully connected structure) that enables this network to learn and store information (memory). This feature allows the network to model complex situations with multiple influences. This particular DRNN structure has varying time constants as well as varying weights for the artificial neurons. The adaptive time constants make the DRNN dynamic and therefore capable of modeling time varying input and outputs.

The DRNN was governed by the following equation:

$$T_i\, dy_i/dt = -y_i + F(x_i) + I_i \tag{1}$$

where $F(\alpha)$ is the squashing function

$$F(\alpha) = (1 + e^{-\alpha})^{-1},$$

Y_i is the state or activation level of unit i, I_i is an external input (or bias), and x_i is given by

$$x_i = \sum\nolimits_j w_{ij}\, y_j, \tag{2}$$

which is the propagation equation of the network (x_i is called the total or effective input of the neuron, and w_{ij} is the synaptic weight between units i and j). The time constant T_i acts like a relaxation process, allowing a more complex dynamical behavior and improving the non-linearity effect of the sigmoid function (Cheron et al., 1996; Draye et al., 1996, 1997). In order to make the temporal behavior of the network explicit, an error function is defined as

$$E = \int_{t_0}^{t_1} q\left(y(t), t\right) dt \tag{3}$$

where t_0 and t_1 give the time interval during which the correction process occurs. The function $q(y(t), t)$ is the cost function at time t which depends on the vector of the neuron activations y and on time t. We then introduce new variables p_i (called adjoint variables) that are determined by the following system of differential equations:

$$\frac{dp_i}{dt} = \frac{1}{T_i}\int_{t_0}^{t_1} p_i - e_i - \sum\nolimits_j \frac{1}{T_j} w_{ij} F'\left(x_j\right) p_j \tag{4}$$

with boundary conditions $p_i(t_1) = 0$. After the introduction of these new variables, we can derive the learning equations:

$$\frac{\partial E}{\partial w_{ij}} = \frac{1}{T_i}\int_{t_0}^{t_1} y_i F'^{(x_j)} p_j dt;\ \frac{\partial E}{\partial T_i} = \frac{1}{T_i}\int_{t_0}^{t_1} p_i \frac{dy_i}{dt} dt \tag{5}$$

The training of the DRNN was supervised, involving learning-rule adaptations of the synaptic weights and time constants of each unit (for more details, see Draye et al., 1997). This algorithm, called "backpropagation through time," aims to minimize the error value defined as the differential area between the experimental and simulated output kinematics signals.

DRNN learning strategy

The DRNN used here was adapted from a previous version originally developed for the reproduction of a figure eight (Cheron et al., 1996; Draye et al., 1997). Although in our previous study we showed that the DRNN could recognize the preferential direction of the muscles based on a single movement, it was not able to generalize from training on one movement to reproduce movements based on EMG signals from trials with different initial directions of the movement. In order to obtain this ability to generalize, we developed a new learning procedure called "multi-pattern learning" (**Figure 1**). In this figure we illustrated a multi-pattern learning for four movements realized in the frontal workspace, each one corresponding to a figure eight initiated in one different direction. This DRNN was alternatively trained in sequential iterations on one of the four patterns, in a random sequence. Three types of multi-pattern training were performed, the first one with the 4 movements realized in the frontal plane, the second one with the 4 figure-eight movements realized in the sagittal plane and the third one with the 8 figure-eight movements taken from both planes. We compared the results of these training processes to the results obtained when trained on a single movement, as reported in our previous publication.

DRNN generalization

After training on data from a given workspace, EMG profiles corresponding to novel movements from either the same workspace

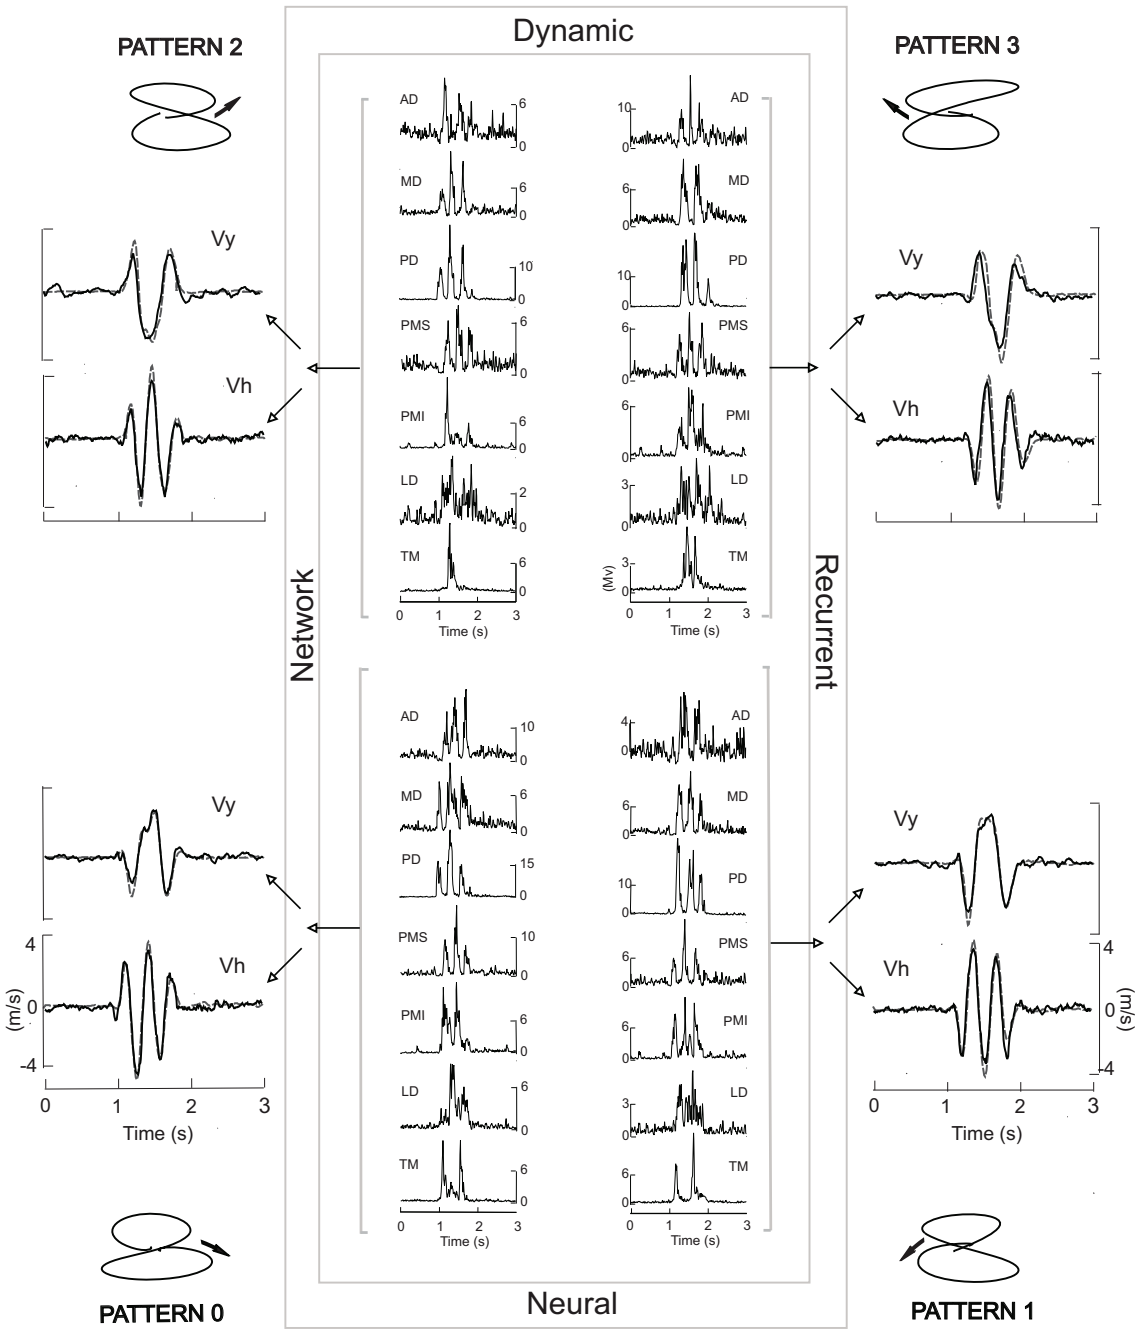

FIGURE 1 | The central box symbolizes the DRNN. Inside each corner of the box the four EMG patterns used to train the network are illustrated, one for each of the four movement patterns shown outside the box. Each EMG signal from a given movement was sent to all 50 artificial neurons (hidden units) which converge on two output units acting merely as summators. One output neuron provides the vertical component of the finger velocity, the other the horizontal component. Each iteration of the training was performed with one pattern at a time in random order. Black velocity profiles represent the learned output. Gray dashed velocity profiles correspond to the experimental data. The corresponding experimental trajectory is illustrated in each corner of the figure.

or from the other workspace were fed into the trained DRNN. A comparison was then made between the velocity profiles predicted by the DRNN and the actual measured movements of the index finger. In order to quantify the resemblance between the measured and simulated velocity profiles, we calculated a similarity index (SI), using the following equation:

$$SI = \frac{\int f_1(t) f_2(t)\, dt}{\left[\left(\int f_1(t)^2 dt\right)\left(\int f_2(t)^2 dt\right)\right]^{\frac{1}{2}}} \quad (6)$$

We looked for the effect of the injection of novel EMG profiles in each of the 3 types of multi-pattern DRNN. For statistical analysis, we first tested for normality in the distributions of SIs, using the Kolgomorov–Smirnov test. We then used a repeated-measures ANOVA followed by Scheffe's test for *post-hoc* analyses (Statistica ©Statsoft).

Synergy action identification via DRNN simulation

In the second part of our study we explored the physiological meaning of purported muscle synergies by reconstructing the EMG signals based on different combinations of components computed by principal component analysis and injecting them into the DRNN. The methods used to compute the principal components as well as an analysis of the resulting synergies are presented in our companion paper published in this issue. We limited this analysis to the first three PCs, which accounted for at least 75.28% of the total variance in each movement (mean across movements: 83.01 ± 2.84% of the total variance). For each muscle we reconstructed the EMG signals from components PC1, PC2, and PC3 individually and compound EMG signals constructed from PC1&2, PC1&3, PC2&3, and PC1&2&3, plus the movements predicted from the full EMG signal (i.e., PC1-7), for a total of 8 different sets of EMG signals. These sets of EMG signals were then injected into the DRNN that has been trained on figure eight movements performed in all four directions in both the frontal and sagittal planes. A comparison was then made between the velocity profiles predicted by the DRNN and the actual measured movements of the index finger, using the SI. We performed a similar procedure for EMG signals reconstructed from the first three factors after a varimax rotation.

RESULTS

We first looked at the ability of the DRNN to predict patterns of movement from EMG signals as a function of the set of movements used to train the network. **Figure 1** illustrates the typical performance of the DRNN trained on the EMG patterns (center) and movement recordings from a set of 4 frontal workspace movements. To each side of the rectangle, representing the DRNN, we have superimposed the learned (black curves) and the measured (gray dashed curves) velocity profiles. After a learning phase involving 15,000 iterations, the DRNN trained on this set of movements in the frontal workspace was able to reproduce the horizontal and vertical velocity profiles of the training set with a mean error value of 0.004 ± 0.001.

Figure 2 shows a comparison of learning performance of the network for different learning strategies. The learning sequence for 1-pattern learning (left column), for 4-pattern learning corresponding to the figure-eight movements realized in the frontal workspace (middle column) and 8-pattern learning trained with the movements realized in the frontal and sagittal plane and with the 4 different initial directions (right column). The first 40 iterations for each training session are plotted in the top row showing the sequence of movements presented to the network on each iteration, thus illustrating the difference between the three training strategies.

The middle row of **Figure 2** shows the RMS error as a function of iteration in the learning procedure. Note the change in scale on the X axis. One can observe that the learning error only reached the value of 0.001 that we observed in our previous studies for the single pattern training, despite the greater number of iterations performed for the multi-pattern trainings. For the multi-pattern training illustrated here, the mean error was 0.004 ± 0.001 and 0.009 ± 0.002 for 4- and 8-pattern training, respectively. In terms of the ability of the network to converge to a stable response, essentially all networks starting from a random set of initial synaptic weights and time constants and trained on a single movement pattern converged to a stable response. In contrast, out of the 90 multi-pattern trainings with 4 movements that were initiated, 32.5% had asymptotic error curves with a mean error of 0.016 ± 0.21. Similarly, out of the 79 sessions initiated for multi-pattern trainings with 8 movements, 21.5% had asymptotic error curves with a mean error of 0.011 ± 0.002.

The bottom row of **Figure 2** shows the actual, measured hand velocities (Vy and Vz) for a single movement pattern (Pattern #3, which started in the upward/leftward direction) compared to the simulated hand velocity produced by each of 3 DRNNs, after 1-pattern (left), 4-pattern (middle) and 8-pattern (right) learning. It is interesting to note that for the three learning conditions shown in **Figure 2**, the temporal relationship was well reproduced in all three cases between the real and the learned velocity profiles. The only differences between the actual and reconstructed hand trajectories appeared in the magnitude of the peak velocities, as can be seen in the example shown here. These qualitative differences were reflected in the similarity index for each of the velocity components for this particular movement. For the example shown, one can see that the SI for the vertical component decreased from 0.99 to 0.97 to 0.95, and for the horizontal component from 0.98 to 0.96 to 0.94, for 1-, 4-, and 8-pattern training, respectively.

The mean SI ± SD for the vertical and the horizontal velocity components were respectively 0.98 ± 0.004 and 0.97 ± 0.001 for the 1-pattern training, 0.97 ± 0.01 and 0.97 ± 0.02 for the 4-pattern training and 0.93 ± 0.02 and 0.95 ± 0.01 for the 8-pattern training. These values are illustrated in **Figure 3A** for the 1-pattern and 4-pattern training and in **Figure 3B** for the 4-pattern and 8-pattern learning (filled circles). A Kolgomorov–Smirnov test showed that the SIs followed normal distribution for the two velocity components and for the three types of training. To test the ability of each training method to reproduce the movements within the respective training sets, we performed repeated-measures ANOVA on the SIs with training type (1-pattern, 4-pattern, 8-pattern) and velocity component (Vy, Vz) as independent factors. The ANOVA showed a significant main effect of training type [$F_{(2,\ 14)} = 36.92$; $p < 0.001$] and Scheffe's *post-hoc* analysis showed that the DRNN trained on 8-patterns reproduced significantly less accurately the velocity curves than either the 4- and 1-pattern trained DRNNs ($p < 0.001$ for both comparisons). There was no main effect of velocity component and although there was a significant cross effect between the two factors [$F_{(2,\ 14)} = 6.04$, $p = 0.0128$], indicating a difference in the way that the SIs changed for the two velocity components across training types, *post-hoc* analysis did not detect a significant difference between SIs for Vy and Vz within any of the three training types.

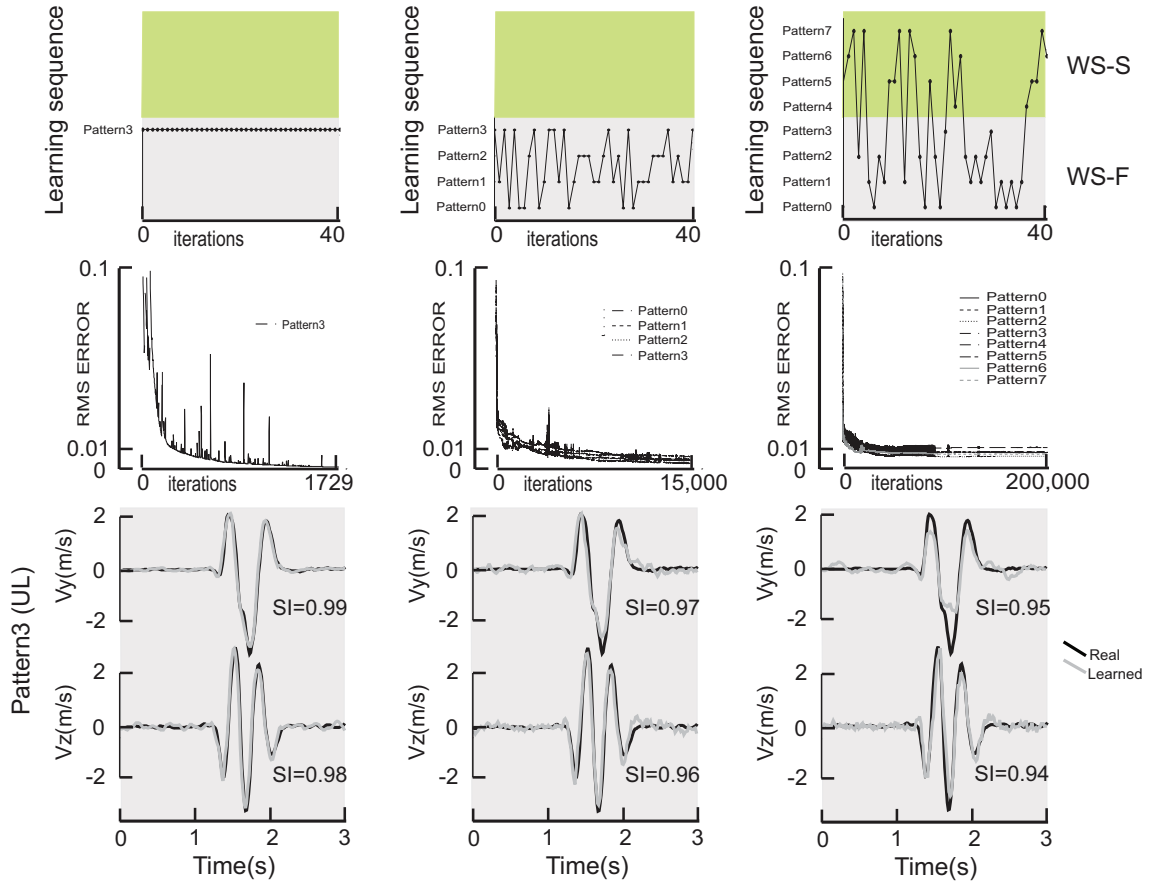

FIGURE 2 | Comparison of learning performance of the network for different learning strategies. The top row illustrates the sequence for a 1-pattern learning (left column), for a 4-pattern learning (middle column) and finally an 8-pattern learning (right column). Green and gray surfaces represent the frontal and sagittal workspaces. The first 40 iterations for each training session are plotted in the top row showing the sequence of movements presented to the network on each iteration. The middle row shows the RMS error as a function of iteration in the learning procedure. The bottom row shows the actual, measured hand velocities (Vy and Vz) for a single movement pattern (pattern #3, which started in the upward/leftward direction) compared to the simulated hand velocity produced by each of 3 DRNNs, after 1-pattern (left), 4-pattern (middle) and 8-pattern (right) learning.

DRNN GENERALIZATION

To test the ability of each DRNN to predict movement patterns from EMG signals that were not in the training set, we injected various EMG patterns, corresponding to figure-eights initiated with different directions and realized in both workspaces, as inputs to the DRNN and compared the output of the network to the corresponding movement. For the generalization phase we used only the DRNN instances with the best mean error for each learning condition. This set of 7 trained DRNNs (4 1-pattern, 2 4-pattern, and 1 8-pattern) was used to test the ability of the networks trained in each fashion to generalize across movements within the same movement plane, to generalize across movement planes and to generalize across subjects, as we will describe in the following paragraphs.

Generalization between movement directions

Consider first the generalization across movement patterns within the same workspace. Four instances of the DRNN were each exposed during the training phase to a single movement and the corresponding EMG recordings in the frontal plane, one for each of the four possible directions of movement. We then injected EMG patterns from four additional movements performed by the same subject in the frontal plane into each of the four instances of the DRNN (for a total of 16 EMG/DRNN pairings) and computed the similarity index between the predicted and actual movement velocities in Y and Z. The resulting similarity indices were then divided into four groups according to the pairing between the test movement and the movement on which the particular instance of the DRNN was trained. Four pairings consisted of test and training movements that started in the same direction in both Y and Z. Four pairings consisted of test and training movements that started in the same direction in Y but opposite directions in Z while conversely, four pairings consisted of test and training movements that started in the same direction in Z but opposite directions in Y. Finally, four pairings consisted of training and test movements that started in opposite directions in both Y and Z. To this we added one additional pairing in which each of the four test movements were injected into an instance of the DRNN that had been exposed to all four movements from the training

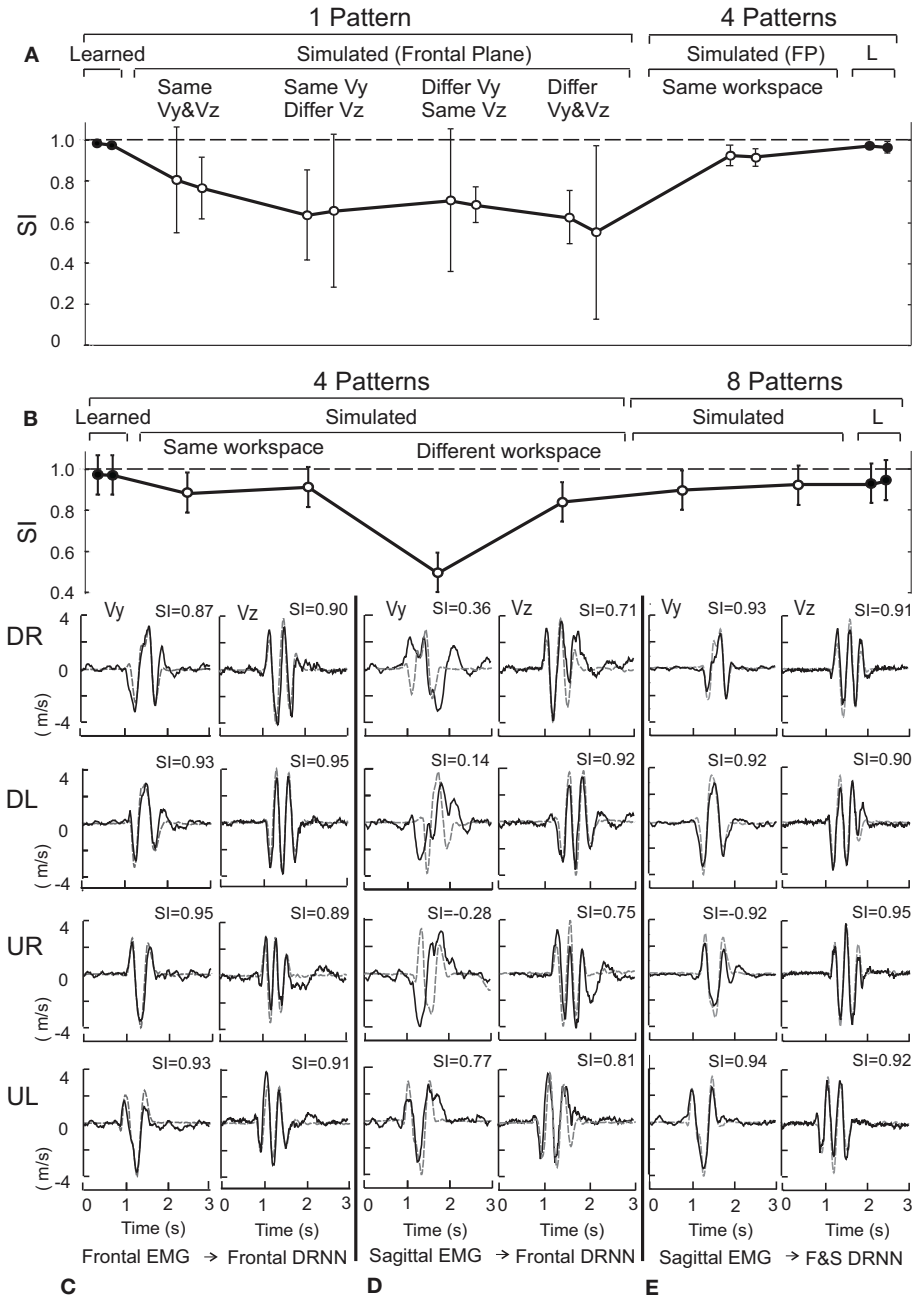

FIGURE 3 | (A) Shows the mean and standard deviation of the similarity index for the same and different movement directions within the frontal plane for 1-pattern DRNN and 4-pattern DRNN trainings. **(B)** Presents similarity indexes for same and crossed workspaces for 4-pattern DRNN and 8-pattern DRNN trainings. SIs for learned and simulated curves correspond to black and open circles, respectively. **(C)** Illustrates the simulated and experimental velocity profiles for the four frontal movements (DR: down-right; DL: down-left; UR: up-right; UL: up-left) injected into the frontal DRNN. **(D)** Shows the simulated velocity profiles from injecting the sagittal EMG patterns into the frontal DRNN. **(E)** Shows the simulated velocity profiles from injecting the sagittal EMG patterns into the dual DRNN. The similarity indexes are indicated above each profile's graph.

set according to the multi-pattern learning scheme depicted in **Figures 1**, **2**.

Although an instance of the DRNN trained on a single movement converged to a very low RMS error for predicting the velocity of the hand from the EMG used to train the DRNN, such 1-pattern trained DRNNs did a poor job, in general, of reproducing from EMG signals figure-eight movements that were not included in the training set (mean SI for the vertical and horizontal velocity components were 0.63 ± 0.22 and 0.68 ± 0.15, respectively, across movements in all four directions). Of greater interest is the effect of movement direction on the ability of a single-pattern DRNN to reproduce the movement. When

the EMG came from a movement not in the training set, but initiated in the same direction as the training movement in both Y and Z, the mean values of SI were 0.80 ± 0.16 and 0.76 ± 0.09 for the vertical and horizontal velocity components, respectively. When the test and training movements shared the same initial vertical component but had opposite initial horizontal component, the mean SIs were 0.63 ± 0.14 and 0.66 ± 0.23 for Vy and Vz, respectively, while when the two movements shared the same initial horizontal component but opposite vertical component, the corresponding SIs were 0.71 ± 0.22 and 0.68 ± 0.05. SIs were lowest when both vertical and horizontal component were different, with values of 0.62 ± 0.08 and 0.55 ± 0.27, respectively. An ANOVA with factors *velocity component* and DRNN/direction *pairing* showed a significant effect of the pairing factor [$F_{(4,\ 12)} = 4.8398$, $p = 0.01477$), with no significant difference between Vy and Vz and no cross effect. The DRNN trained on all 4 patterns from the same workspace was much better able to reproduce the kinematics generated from the EMG recordings for other movements performed within that workspace. Indeed, the 4-pattern DRNN, with average SIs of 0.92 ± 0.03 and 0.91 ± 0.03 for Vy and Vz, respectively across all movement directions (**Figure 3A**), was better able to reproduce the hand velocities than a 1-pattern trained DRNN could for figure eights performed in the same direction as it's own training movement.

Generalization between planes

Next we considered the ability of a DRNN to generalize between different parts of the workspace (i.e., different movement planes). For the frontal and sagittal movements, each simulated by the appropriate frontal and sagittal DRNNs, the mean SIs for the vertical and horizontal velocity components were 0.89 ± 0.06 and 0.91 ± 0.03, respectively (**Figure 3B**, "same workspace"). **Figure 3C** illustrates a typical pair of simulated velocity profiles (Vy and Vz) computed from EMG signals taken during movements in the frontal plane that were not in the training set, overlaid on the actual velocity profile.

DRNNs trained on all four movement patterns within one plane were nevertheless much less able to predict the hand trajectories from EMG signals recorded from movements in the other. **Figure 3D** illustrates the simulated and actual velocity profiles for the injection of the EMG patterns from a sagittal movement into the DRNN trained on the 4 frontal movements. While the predictions of the horizontal velocity profiles (Vz) achieved levels of SI similar to that produced by the 4-pattern DRNN for the same workspace, the DRNN did not successfully reproduce the vertical velocity component (Vy) across workspaces. The mean SI for simulated movements computed by the 4-pattern DRNN trained on the "other" workspace was 0.84 ± 0.06 for the horizontal component and 0.50 ± 0.13 for the vertical component (**Figure 3B**, "different workspace"). On the other hand, an 8-pattern DRNN trained on movements from both workspaces was able to reproduce movements in either workspace just as well as each of the 4-pattern DRNNs were able to reproduce movements within their own workspaces. For the 8-pattern DRNN, the mean similarity index for the vertical and horizontal velocity components was 0.90 ± 0.07 and 0.92 ± 0.02, respectively (**Figure 3B**, "8 patterns").

We used ANOVA to test for statistical significance of the observations described above. From all the movements recorded for the one subject whose data was used to train the networks, we injected the EMG signals from all the other movements that were not in the training sets into each of three instances of the DRNN, the one that had been trained on 4 movements in the frontal plane, the one that had been trained on 4 movements in the sagittal plane and one that had been trained on all 8 movements, resulting in a total of $8 \times 3 = 24$ simulated movements. We then used the pairing between the DRNN and the actual movement's workspace to divide the 24 simulated movements into 3 groups of 8 movements each, those produced by the 4-pattern DRNN trained on movements from the same plane, those produced by the 4-pattern DRNN trained on the other plane and those produced by the 8-pattern DRNN trained on both planes. This resulted in a 3×2 multifactor ANOVA, with *DRNN/EMG pairing* (same-plane, cross-plane, and dual-plane) and *velocity component* (Vy, Vz) as within-group factors (i.e., a repeated measure for the same movement produced by the subject). Note that the normality of our data set was first verified by the Kolgomorov–Smirnov test before the ANOVA was applied.

The ANOVA described above revealed a highly significant main effect for the type of DRNN/EMG pairing [$F_{(2,\ 14)} = 23.61$; $p = 0.0003$]. There was a significant main effect of velocity component [$F_{(1,\ 7)} = 7.58$, $p = 0.0284$] and a significant interaction [$F_{(2,\ 14)} = 6.04$, $p = 0.0129$]. Scheffe's *post-hoc* analysis showed that there was no significant difference between the ability of each of the three DRNN/EMG pairings to reproduce the horizontal velocity component (Vz). On the other hand, the SIs for the vertical velocity component (Vy) were significantly lower (worse) for the cross-plane simulations than for the simulations produced by either the same-plane or the dual-plane DRNN/EMG pairings (illustrated in **Figure 3B**).

As a control, we considered whether the DRNN's inability to predict movements across planes could be attributed to differences in the kinematics of the figure-eight movements performed in each plane. **Figure 4A** shows a comparison of the velocity components for pattern #3 for the reference subject, performed in the frontal (blue) and sagittal (red) planes. One can observe that the movements were very similar both in terms of velocity amplitude and in terms of the temporal characteristics. **Figure 4B** shows a comparison of the mean similarity index (SI) computed between the real test movement in one plane and the corresponding training movement from the other plane (real-trained) and between the real test movement from one plane and the movement predicted from the corresponding EMGs by the DRNN that had been trained on movements from the other plane. One can see that on average the SIs between actual movements in different planes were high for both the vertical and horizontal velocity components (0.93 ± 0.04 and 0.92 ± 0.06, respectively). SIs between actual movements and movements predicted by the DRNN from EMGs were somewhat lower, especially for Vy (0.93 ± 0.04 and 0.6 ± 0.3). Statistical analyses revealed that although there was no difference between the SI for the comparison of real movements and predicted movements for the horizontal velocity component (Vz), there was a significantly lower similarity between predicted and actual movements for the vertical component

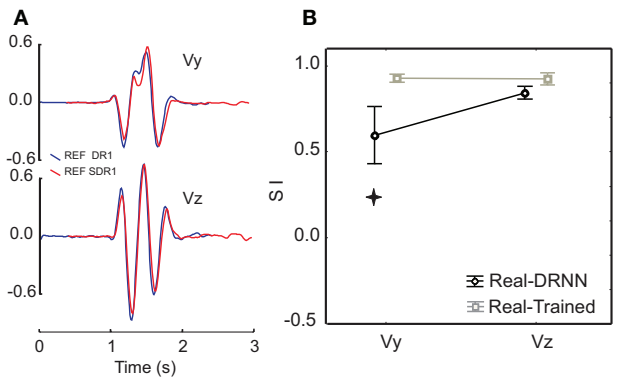

FIGURE 4 | Comparison of similarity between actual and predicted movements between the two planes. (A) An example of velocity profiles for a single movement pattern performed in the frontal (blue) and sagittal (red) planes. **(B)** Similarity indexes for the comparison of actual movements performed in the frontal and sagittal planes, overlaid with the similarity indexes for movements reconstructed from EMG collected in one plane by a DRNN trained on movements performed in the other plane. The star shows SIs that were significantly different ($p < 0.005$).

(Vy) (Scheffe's *post-hoc*: $p < 0.005$), compared to the similarity of actual movements performed in different planes [$F_{(1,\ 14)} = 10.986$, $p = 0.00511$]. In other words, the inability of the DRNN to generalize across movement planes in terms of Vy cannot be attributed to differences in the movement kinematics performed in each plane.

Finally, we asked whether the inability of the DRNN to generalize across movement planes could be related to changes in muscle synergies as identified through principal component analysis of these same movements and EMG. In our companion paper we showed that the loading vectors (synergies) varied, on average across subjects, between figure eights drawn in the frontal and sagittal planes. **Figure 5** shows the average loading for each PC, computed for each of the two movement planes, for the reference subject alone. We performed an ANOVA on the loadings with movement plane (frontal or sagittal) as a grouping factor and muscle (AD, MD, PD, PMS, PMI, LD, TM) as a repeated measure. For each of the 3 PCs, there was a significant main effect of the muscle factor, a significant main effect of movement plane and a significant cross effect between the two. But this ANOVA was not performed with these global contrasts in mind. The pertinent test from this analysis was the *post-hoc* analysis that we applied to determine which muscle loadings, if any, changed between the two movement planes within each PC. For PC1 and PC2, Scheffe's *post-hoc* test detected no significant changes in individual muscle loadings between the frontal and sagittal planes. For PC3, however, there was a significant increase in the loading of LD and a significant decrease in the loading of PMI when passing from the frontal to the sagittal movement plane.

Synergy action identification via DRNN simulation

We then set out to see how the DRNN would interpret the action of EMG signals associated with each of the different components identified by principal component analysis and by varimax

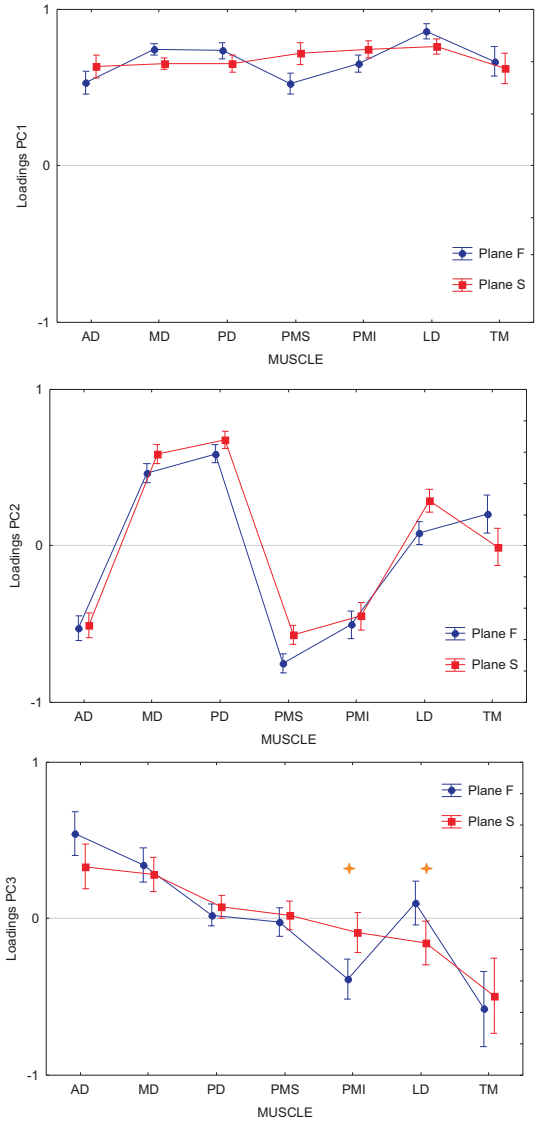

FIGURE 5 | Average loadings for each PC and each muscle, computed for each of the two movement planes. Each graph shows the loading for Anterior Deltoid (AD), Medial Deltoid (MD), Posterior Deltoid (PD), Pectoralis Major Superior (PMS), Pectoralis Major Inferior (PMI), Latissimus Dorsi (LD), and Teres Major (TM). In blue are represented the loadings for movements performed in the frontal workspace, in red the loadings for movements performed in the sagittal workspace. Stars show loading for individual muscles that were significantly different between the frontal and sagittal planes ($p < 0.001$).

factor analysis (see companion paper). The simulation phase consisted of sending to the 8-pattern (dual plane) trained DRNN the EMG signal reconstructed with the first, second and third components and the combinations of components 1&2, 1&3, 2&3, and 1&2&3 for both the principal component (**Figure 6**) and varimax (**Figure 7**) decompositions. In these figures are illustrated the simulations for EMG signals taken from the reference subject for the same figure-eight movement (initiated down and to the right) realized in the frontal and sagittal workspaces.

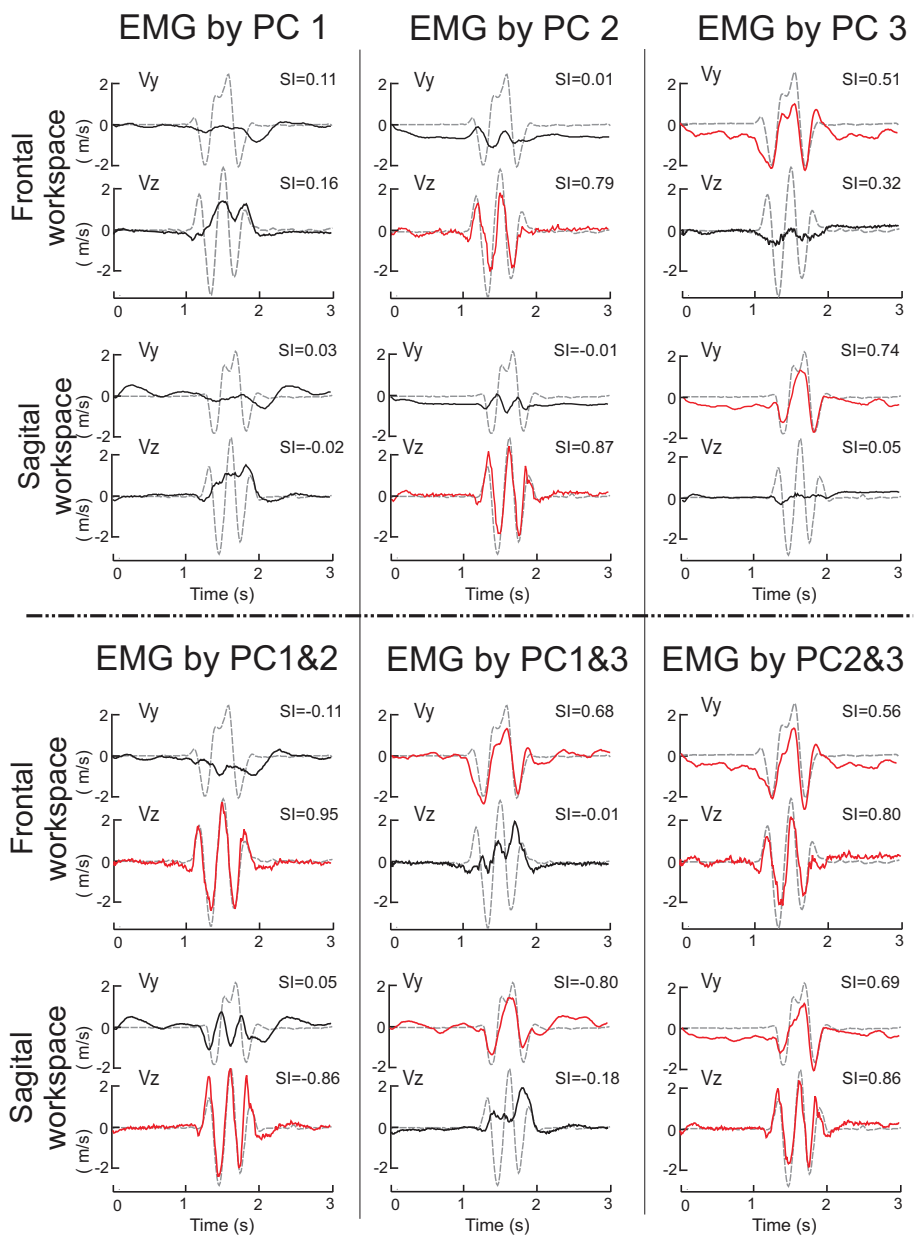

FIGURE 6 | Simulations with the 8-pattern DRNN trained on movements from both planes. In this figure are illustrated the simulations for EMG signals reconstructed by means of PC1, PC2, PC3 (top part of the figure) and PC1&2, PC1&3, and PC2&3 (bottom part) for the same figure-eight movement (initiated down and to the right) realized in the frontal (first row) and sagittal (second row) workspaces. Real curves are represented by gray dashed traces and simulated curves by black and red traces. Traces were drawn in red when the SIs exceeded a threshold arbitrarily set to 0.5. SIs are indicated in the upper right corner of each graph.

Principal components

The superposition of real (gray dashed curves) and simulated (black and red curves) velocity curves in **Figure 6** shows that the EMG signals composed by PC2 and PC3 alone reproduced very nearly the horizontal and vertical velocity component, respectively, while the EMG signal reconstructed from PC1 alone produced simulated movements that did not resemble either of the velocity components. Nevertheless, combining PC1 with either PC2 or PC3 (lower part of **Figure 6**) increased the level of reproduction for the horizontal and vertical component respectively, compared to any one component alone. Indeed, PC1 seems to have an influence for the stability in the static phase existing before and after the movement, as we can see in the simulation velocity curves resulting from EMG reconstructed with the

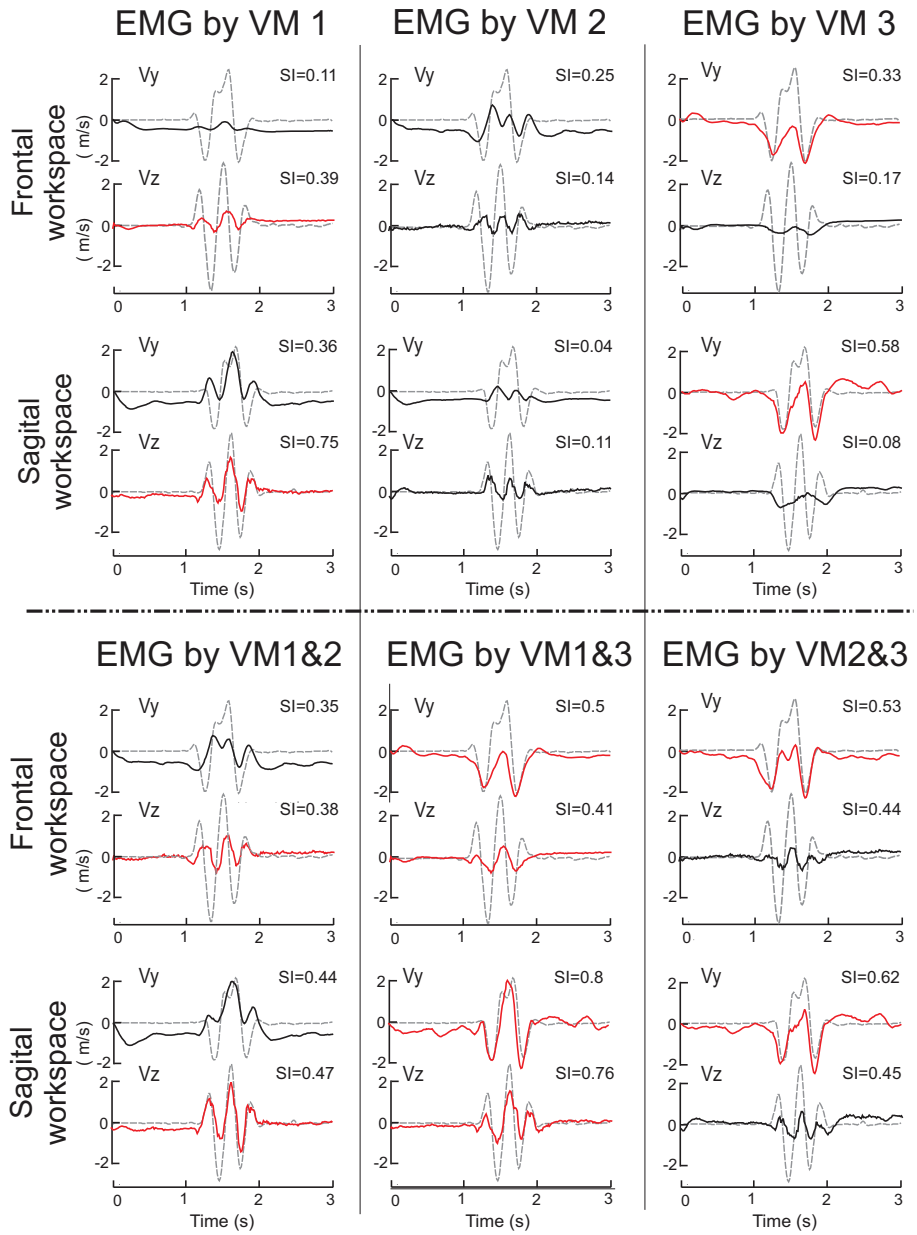

FIGURE 7 | Simulations with the 8-pattern DRNN trained on movements from both planes. In this figure are illustrated the simulations for EMG signals reconstructed by means of VM1, VM2, VM3 (top part of the figure) and VM1&2, VM1&3, and VM2&3 (bottom part) for the same figure-eight movement (initiated down and to the right) realized in the frontal (first row) and sagittal (second row) workspaces. Real curves are represented by gray dashed and simulated curves by black and red lines. SIs are indicated in the upper right corner of each graph.

second and third, but not the first PCs combined. Compared to the simulation from PC1, PC1&2, and PC1&3, the simulated movements that did not contain PC1 (PC2, PC3, PC2&3) exhibited a negative bias in Vy both before and after the figure-eight movement, indicating that without the PC1 component the hand would drift downwards.

We used ANOVA to test statistically the ability of each PC or combination of PCs to reproduce the velocity profiles of the actual movements. We compared the similarity indexes between the 8 measured movement patterns for the reference subject with the simulated movements from the eight different DRNN reconstructions from the corresponding EMG signals (PC1, PC2, PC3, PC1&2, PC1&3, PC2&3, PC1&2&3, PC1-7 = real EMG). Recall that the EMG signals and movement recordings that were used to simulate movements via the DRNN were different from the EMG and movement recordings used to the train the DRNN.

This resulted in an ANOVA with two repeated-measures factors (PC combination, velocity component). The repeated measures ANOVA showed that the SIs were significantly different depending on which combination of PCs were used to reconstruct the EMG signal [main effect: $F_{(7,\ 49)} = 144.36$, $p < 0.0001$]. Sheffe's *post-hoc* analysis showed that SIs obtained with EMG reconstructed from P1&2&3 were not significantly different from the movements simulated with the real EMG (mean SI: 0.80 ± 0.02 and 0.91 ± 0.01, respectively; $p > 0.99$]. SIs for movements simulated with PC2&3 (0.78 ± 0.02) were significantly lower than those simulated from the real EMG ($p = 0.046$), but only slightly worse than those simulated with PC1&2&3 ($p > 0.99$). For all the other simulated movements with PC1, PC2, PC3, PC1&2, PC1&3, or PC2&3 (mean SI 0.05 ± 0.04, 0.42 ± 0.03, 0.37 ± 0.02, 0.45 ± 0.03, 0.36 ± 0.03, respectively), the SIs were significantly lower than the reconstruction from the full EMG signal ($p < 0.001$).

The repeated measures ANOVA did not show a significant main effect of the velocity component factor [$F_{(1,\ 7)} = 4.26$, $p = 0.078$] but there was a highly significant interaction between the velocity component and the PC combination factors [$F_{(7,\ 49)} = 117.95$, $p < 0.0001$]. Scheffe's *post-hoc* analysis confirmed the results illustrated in **Figure 6**:

(1) Simulation of the movements based on the EMG signals in PC2 reproduced the horizontal velocity component of figure-eight movements but not the vertical one ($p < 0.001$). The mean SIs for the horizontal and vertical velocity component were 0.82 ± 0.03 for Vz and 0.03 ± 0.05 for Vy.
(2) The simulated movements corresponding to PC3 reproduced the vertical velocity component but not the horizontal one ($p < 0.001$). The mean SI for the horizontal and vertical velocity component were -0.02 ± 0.04 for Vz and 0.76 ± 0.03 for Vy.
(3) The EMG reconstructed with PC1&2, and with PC1&3 confirmed the preceding results. The mean SI for the horizontal and vertical velocity component were 0.89 ± 0.02 and 0.01 ± 0.06 for PC1&2, and 0.02 ± 0.06 and 0.70 ± 0.04 for PC1&3, respectively.

There were no differences in SIs for the horizontal and vertical velocity components for EMGs composed with PC2&3, with PC1&2&3 or for the real EMG ($p > 0.99$). The mean SI for the horizontal and vertical velocity component were 0.81 ± 0.03, and 0.74 ± 0.02, 0.88 ± 0.02 and 0.72 ± 0.03, 0.92 ± 0.01 and 0.90 ± 0.02, respectively.

Varimax

The simulation of the velocity traces by the DRNN based on EMG signals reconstructed from the varimax decomposition (**Figure 7**) were more difficult to interpret in terms of the actions of each component. We display the velocity signals in this figure in black or red depending on whether the SIs for the varimax-reconstructed EMGs were significantly different from the best scores obtained for the principal component (**Figure 6**). From this one can see that no single varimax component produced very well either of the velocity components. Even the traces shown in red manifest noticeable differences between the actual and predicted velocities. While VM3 produced the same number of peaks in Vy, the predicted velocities were strictly negative while the real velocity had both positive and negative components. For VM1, the predicted and actual Vz showed similarities in the number of peaks, but the DRNN predicted velocities that were not nearly as strong as the actual measured velocities.

We used ANOVA to test statistically the ability of each PCA method (unrotated or varimax) to reproduce the velocity profiles of the actual movements. We compared the similarity indexes between the 8 measured movement patterns for the reference subject with the simulated movements from the 7 different DRNN reconstructions from the corresponding EMG signals from the principal component (PC1, PC2, PC3, PC1&2, PC1&3, PC2&3, PC1&2&3) and varimax (VM1, VM2, VM3, VM1&2, VM1&3, VM2&3, VM1&2&3). This resulted in an ANOVA with two repeated-measures factors (EMG components X velocity component). **Figure 8** illustrates the mean and SD values for SIs obtained for 8 measured figure-eight movements. In this figure we have drawn a "threshold" line that separate the SI values that present a significant difference from the best SIs values obtained with unrotated PCA for EMG composed with PC1&2. One observes that PC3 and VM3 were interpreted similarly as acting on the vertical component of the movement whereas VM1 acted more like PC2, each having a functional link with Vz. VM2 seems to have a more complex combination of information concerning both velocity components. When looking at the DRNN interpretation by combining PCs 2-by-2, one observes that PC2&3 and VM1&3 are interpreted similarly by DRNN as having the same level of action on Vy and Vz (Scheffe's *post-hoc* $p < 0.99$). The same situation is true for unrotated and varimax PC1&2. But the pattern of SIs for VM1&3 did not bear any resemblance to the patterns achieved with the principal components, since it reproduced better Vy than Vz. This observation, added to the fact that the mean SI for VM1&2 was not different from the one obtained for PC1&3, leads us to conclude that VM2 corresponded to a synergy that acts partly on horizontal and partly on vertical velocity component, without the clear demarcation between components that is found for unrotated principal components.

We went further to ask whether the differences between the principal component and varimax decompositions in terms of the mapping of EMG components to hand velocity could be explained simply by differences in the particular instances of the trained DRNN, or whether the pattern is repeatable to any successfully trained instance of the DRNN. In **Figure 9** we compared the behavior of 3 different instances of the DRNNs, all of which were trained with the same 8 movement trials from the reference subject, but each of which converged starting from a different random set of initial weights and time constants. Globally, the observations made for the single DRNN above were valid for all three instances of the DRNN. PC2 was associated with Vz while PC3 was associated with Vy. A Three-Way ANOVA, with PC combination, velocity component and DRNN instance showed no main effect of DRNN instance [$F_{(14,\ 84)} = 1.4213$, $p = 0.16$], nor any cross effects be DRNN instance and either of the other two independent factors.

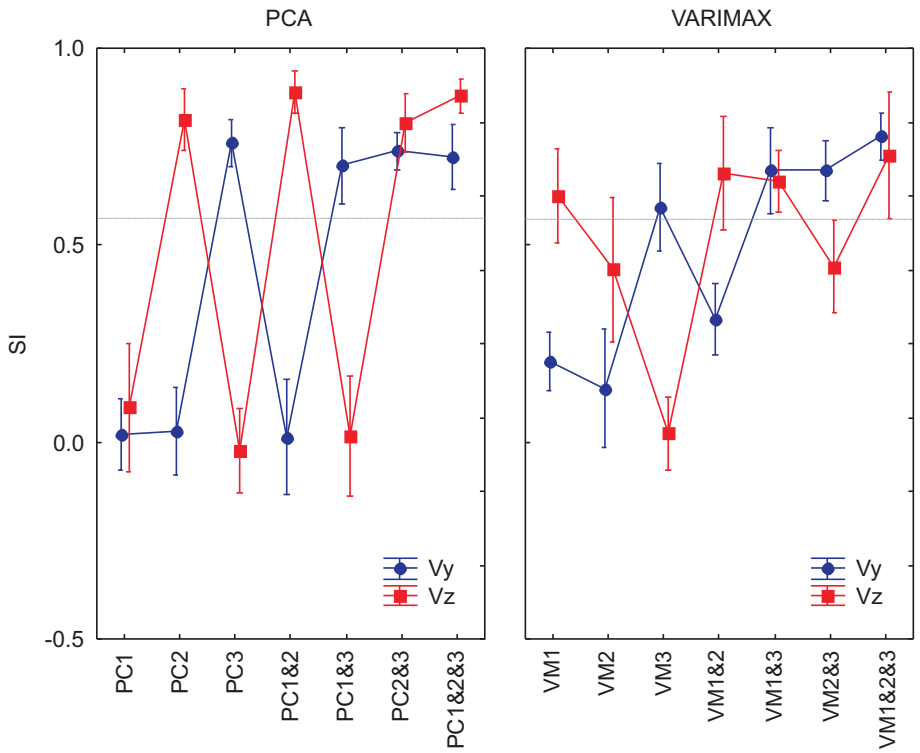

FIGURE 8 | SIs for EMG composed by PCs and VMs for an 8-pattern DRNN trained. In blue, the SIs for the vertical component and in red the SIs for the horizontal component of the index-finger velocity.

DRNN generalization between subjects

We then tested the ability of a DRNN trained on data from one subject to simulate movements based on EMG signals recorded from another. We fed EMG signals from five different subjects to the same 8-pattern DRNN trained on movements from both planes performed by a single subject. The set of five subjects included the one subject whose data were used to train the networks, hereafter referred to as the reference subject, and four other subjects who performed the experiment in the frontal plane. Note that as in the previous analysis, the EMGs used to simulate movements for the reference subjects were different from that subject's EMG recordings used to train the network. The results of this analysis are shown in **Figure 10A**, where we have overlaid the velocity traces of for each subject and we have plotted the similarity indexes for the comparison of the actual movements and the movements predicted by the DRNN from the EMG (dark symbols). For comparison, we have plotted the SIs for the actual movements performed by each subject and the corresponding actual movements from the reference subject used to train the network (gray symbols). ANOVA showed that in general the DRNN predicted less well the velocity profiles of the other four subjects and that in all cases the SIs for Vy (Scheffe's *post-hoc*: $p < 0.05$) were lower than for Vz [cross-effect between subjects, velocities and real-trained movement vs. real-DRNN predictions $F_{(4,\ 49)} = 15.156$, $p < 0.001$]. This is in contrast to the between-subject comparisons of the actual movement profiles, which showed SIs that were greater than those observed for the DRNN-reconstructed movements and which did not differ between Vy and Vz.

We performed a two-factor ANOVA to test the ability of each DRNN to reproduce the measured hand velocities from the recorded EMGs. As before, *velocity component* (Vy and Vz) was treated as a repeated measure, to which was added the grouping factor *subject* to indicate which subject's EMG data was used to simulate each movement. This led to a 2×5 mixed-model ANOVA. The ANOVA also showed a significant difference in SIs between the five subjects [main effect of subject, $F_{(4,\ 49)} = 28.439$, $p < 0.0001$]. *Post-hoc* tests showed that the DRNN did a significantly better job, on average across both velocity components, of reproducing the trajectories for the reference subject (mean SI 0.91 ± 0.02) compared to all four other subjects ($p < 0.00001$). There was no overall difference ($p > 0.3$) for the simulations between three of the other subjects (mean SI was 0.64 ± 0.06, 0.52 ± 0.31 and 0.52 ± 0.37 for subject 2, 3, and 5 respectively). But subject 4 presented significantly lower SIs ($p < 0.05$) than any of the other subjects (mean SI 0.33 ± 0.46). There was, however, a significant cross effect between the subject and velocity-component factors [$F_{(4,\ 49)} = 13.947$, $p < 0.0001$]. Indeed, the main difference for the simulations between the reference subject and the other subjects was found for the vertical velocity component: Scheffe's *post-hoc* analysis showed a significant difference ($p < 0.0001$) for Vy between the reference subject (mean SI 0.9 ± 0.07) and three of the other four subjects (mean SI 0.3 ± 0.25, 0.004 ± 0.05, and 0.26 ± 0.19 for subjects 3, 4, and 5

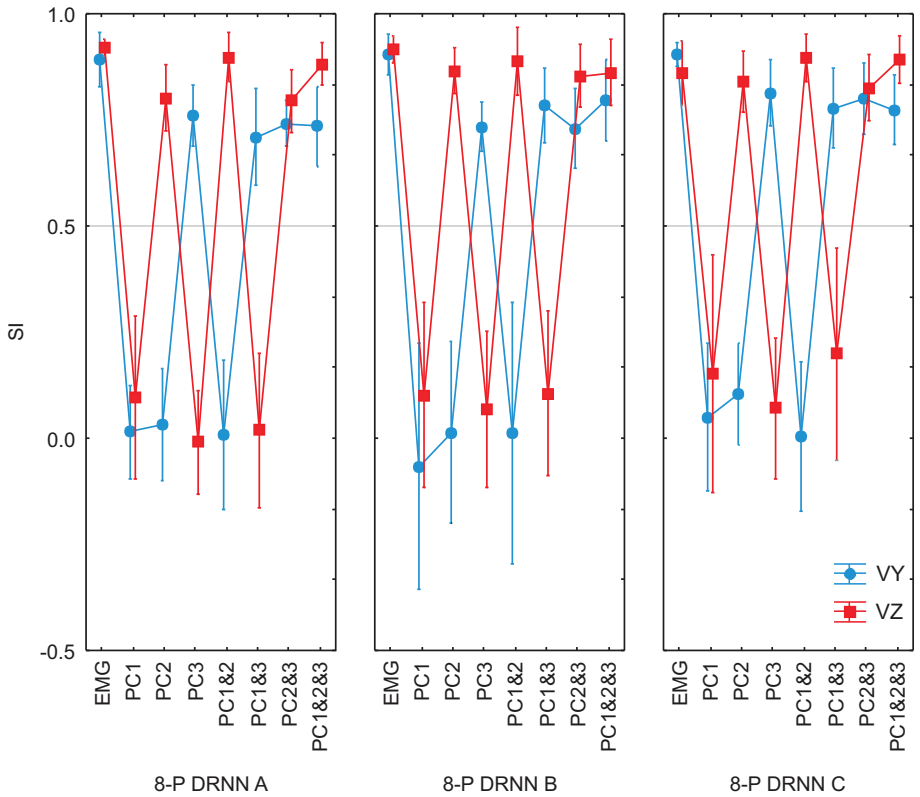

FIGURE 9 | SIs for EMG composed by PCs for 3 different instances of 8-pattern DRNNs trained from a random initial state. Each graph represent the SIs for the simulations with the real EMG and the EMG composed by means of PC1, PC2, PC3, PC1&2, PC1&3, PC2&3, PC1&2&3. In black: the SIs for the vertical component and in gray the SIs for the horizontal component of the index-finger velocity.

respectively) but not for subject 2 ($p < 0.054$) (mean SI 0.60 ± 0.2 for subjects 2). For the horizontal component, Scheffe's *post-hoc* analysis showed no differences between the reference subject and the four others (mean SI were 0.92 ± 0.02, 0.68 ± 0.18, 0.73 ± 0.14, 0.66 ± 0.12, and 0.79 ± 0.03 for subjects 1, 2, 3, 4, and 5 respectively).

We went further to test whether the patterns in the mapping of EMG components to hand velocity was specific to this particular instance of a trained DRNN, or whether the pattern was repeatable to any successfully trained instance of the DRNN. In **Figure 10B** we compared the behavior of three different DRNN instances, all of which were trained with the same eight movement trials from the reference subject, but each of which converged starting from a different random set of initial weights and time constants. We performed an ANOVA on the similarity indices with *DRNN instance* (dual-plane A, dual-plane B, and dual-plane C) and *velocity component* (Vy and Vz) as repeated measures. To this was added the grouping factor *subject* to indicate which subject's EMG data were used to simulate each movement. This led to a $3 \times 2 \times 5$ mixed-model ANOVA. There was no significant effect between the three instances of 8-pattern DRNNs [$F_{(2,\ 98)} = 0.31392$, $p = 0.73131$] nor was there a significant cross-effect between instances of 8-pattern DRNN and the factor subject [$F_{(8,\ 98)} = 1.6801$, $p = 0.11275$]. There was, however, a significant cross effect between the velocity and subject factors [$F_{(4,\ 49)} = 16.861$, $p < 0.00001$]. As we have observed in the other analyses, the main difference for the simulations between the reference subject and the other subjects was found for the vertical velocity component: Scheffe's *post-hoc* analysis showed a significant difference ($p < 0.05$) between the reference subject and each of the other 4 subjects for Vy but not for Vz. We note, finally, that the three-way interaction between subject, velocity component and 3 instances 8-pattern DRNN was not significant [$F_{(8,\ 98)} = 1.0999$, $p = 0.36998$].

We completed our analysis by examining the ability of a DRNN trained on data from one subject to reproduce the hand trajectories of the other subjects on the basis of EMG signals reconstructed from different combinations of principal components. The similarity index was computed between each simulated movement and the corresponding actual movement and the SI's were subjected to a mixed-model ANOVA with *subject* as a grouping factor and *PC combination* (PC1, PC2, PC3, PC1&2, PC1&3, PC2&3, PC1&2&3, PC1–7) and *velocity component* (Vy, Vz) as repeated measures. This analysis showed that SIs depended on which subject's EMGs were fed to the DRNN [subject main effect: $F_{(4,\ 49)} = 13.98$, $p < 0.0001$], on which principal components were used to reconstruct the EMG (PC combination main effect: $F_{(7,\ 343)} = 175.65$, $p < 0.0001$] and on the velocity direction (velocity component main effect: $F_{(1,\ 49)} = 91.757$,

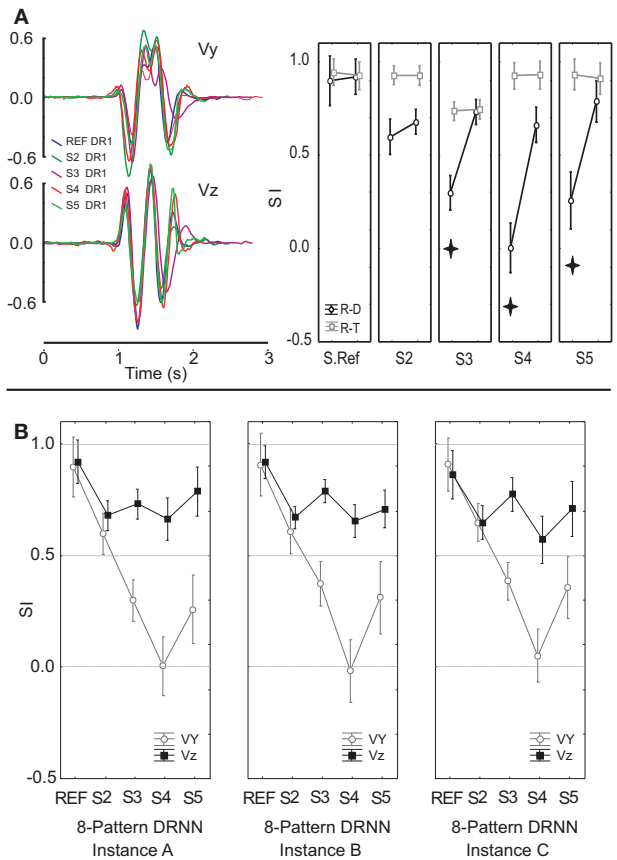

FIGURE 10 | (A) An example of velocity profiles for a single movement pattern performed by 5 subjects. Similarity indexes for movements reconstructed from EMGs collected from each of 5 different subjects by an 8-pattern DRNN trained on data from the reference subject only. **(B)** Similarity indices for movements reconstructed by three different instances of an 8-pattern DRNN trained on data from the reference subject. Each instance converged to the final solution from a different set of random initial weights and time constants. Stars show SIs that were significantly different ($p < 0.005$).

$p < 0.0001$]. All interaction effects were highly significant ($p < 0.0001$). **Figure 11** shows the overall results, from which one can make the following observations:

(1) Reproduction of the horizontal velocity component depended on the presence of PC2 in the reconstructed EMG. For each subject, all SIs for Vz for reconstructions that included PC2 (PC2, PC1&2, PC2&3, PC1&2&3) were as good as the SI for Vz for the full EMG, while all SIs for Vy for EMGs that did not include PC2 (PC1, PC3, PC1&3) were equally bad.

(2) Reproduction of the vertical velocity component depended on the presence of PC3 in the reconstructed EMG. For each subject, all SIs for Vy for reconstructions that included PC3 (PC3, PC1&3, PC2&3, PC1&2&3) were equally good as the SI for Vy for the full EMG and all SIs for Vz for EMGs that did not include PC3 (PC1, PC1&2) were equally bad.

(3) The DRNN decoded the horizontal component of the hand velocity (Vz) just as well across all subjects as it did for the reference subject on whose data the network was trained. Compared to the reference subject, however, the DRNN did a much poorer job of reproducing the vertical component (Vy) for the 4 other subjects.

Finally, we tested whether the ability of the DRNN to predict movements for different subject could be related to differences between subjects in the loading vectors (synergies) identified by principal component analysis. We applied ANOVA to the loading vectors obtained in our companion study for each subject with *subject* as a grouping factor and *muscle* as a repeated measure. We limited this analysis to movements in the frontal plane. **Figure 12** shows the average loadings for subjects 2–5, compared to the average loading for the reference subject (S1). Differences in individual muscle loadings that were significant (as measured by Scheffé's *post-hoc* test) are indicated with a *. As shown in our companion article, the identified principal components were remarkably similar across subjects, with PC1 representing a global activation of all 7 muscles over the course of the movement, PC2 indicating a reciprocal relationship primarily between AD, PMS, and PMI on one side and MD and PD on the other, and PC3 showing a reciprocal relationship primarily between AD and MD on one side and PMI and TM on the other. Differences between the loadings of each subject and the loadings of the reference subject were restricted largely to PC3. This is consistent with the observation that (1) PC2 is linked to Vz and PC3 is linked to Vy and (2) that the DRNN predicted better Vz than Vy across subjects. There is nevertheless an indication of a tradeoff between the participation of TM, with this muscle sometimes participating primarily in PC2 and sometimes in PC3.

DISCUSSION

In this study we looked for modularity in patterns of drawing movements exemplified by the figure eights performed by our subjects. We used the training of a DRNN as a means to identify structure in the mapping from muscle activations to hand movements. While one might quibble over whether the DRNN has learned the dynamics of the arm, it is certain that the DRNN identified structure in the mapping of EMG signals to movements of the hand. Otherwise, it would not be able to predict movements from EMGs not included in the training set. But as we reported, the DRNN was not always able to predict movements from novel EMGs.

A failure of a trained DRNN to generalize to EMG inputs from outside the training set can arise either because the DRNN does not have enough degrees of freedom to learn the actual movement dynamics or because the training set does not contain enough contrasting information to reveal all the underlying structure. In our study, whenever the DRNN failed to generalize from a given, limited set of training movements, it always succeeded when presented with a broader set of examples during training. We concluded that the DRNN structure was sophisticated enough to capture the EMG-to-movement relationship, if presented with a rich enough training set. It is therefore interesting to contrast when the DRNN could and could not generalize from

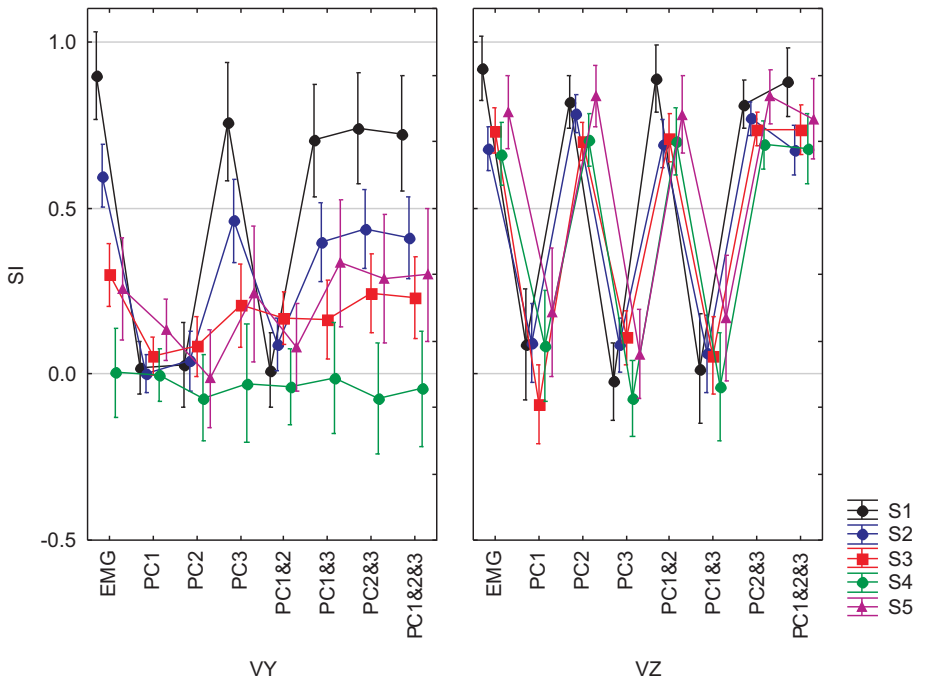

FIGURE 11 | SIs for EMGs composed from PCs for 5 subjects and for the 8-pattern DRNN. The graphs in left and right columns show the SIs for vertical and horizontal velocity components, respectively. Each graph represent the SIs for the simulations with the real EMG and the EMG composed by means of PC1, PC2, PC3, PC1&2, PC1&3, PC2&3, PC1&2&3. Each of the 5 subjects is identified by a different color.

one dataset to another, as this provides an indicator as to what changes in conditions require modifications to the underlying movement-generating modules.

In this article we have also proposed a novel use of the DRNN to reveal properties of the modules that generate movement of the human arm. In the past we fed to the already trained DRNN modified versions of the individual EMG inputs that were scaled in amplitude (Cheron et al., 1996, 2003) or delayed in time (Cheron et al., 2007), in order to identify the action of individual muscles. In the current study we fed the trained DRNN with potential synergies that we identified through principal component analysis. This more global approach addressed the question of the neural organization of muscle activations from a modular point of view, in contrast to our preceding anatomical viewpoint concerning muscle mechanical actions.

SPATIAL vs. TEMPORAL

As shown by de Rugy et al. (2013), variability in synergies could arise from specific behaviors or tasks to be accomplished. For the same motor program (a figure-eight) we should find in the EMG signals information corresponding to a general "figure-eight" motor program mixed with the information corresponding to the specific aspects of motor execution such as the movement's velocity, amplitude, joint configuration and biomechanical constraints. In this context, the cases where the DRNN failed to generalize can be summarized as follows: (1) the DRNN could not generalize from a single movement direction in a given workspace to the other three movements in the same workspace, (2) the DRNN could not generalize from movements performed in the four different directions in one workspace to the same four movement patterns in the other workspace, and (3) the DRNN could not generalize from one subject to another. One might hypothesize that the inability to generalize in any or all of these situations could be due to differences in the kinematics of the movements that were actually performed, i.e., the DRNN might fail to generalize if it has not been exposed to hand-velocity patterns in the training phase that are included in the test dataset. While this would be an interesting observation in itself, this was not the case in the study reported here. All the movements reported here corresponded to the realization of a figure eight. For the movements in different directions in the same plane, we have previously shown that the four movements were very similar in terms of spatial parameters and the temporal aspects of the trajectories (Cheron et al., 1999). Concerning the inter-workspace and inter-subject comparisons, the analysis of similarity indices between movements in the training and test datasets reported here (**Figure 4**) reject the hypothesis that the inability of the DRNN to generalize across these conditions can be attributed to differences in the movement patterns themselves. The differences detected by the DRNN between conditions must necessarily represent contrasts in the mapping between EMG and the movement in each situation.

Consider, then, the inability of the DRNN to generalize between movement directions within the same workspace. The spatial aspects of each of the four movements were the same, with the hand following the same spatial form (the figure eight), and the arm was fully outstretched in all cases. The biomechanical aspects of the different movements were therefore essentially

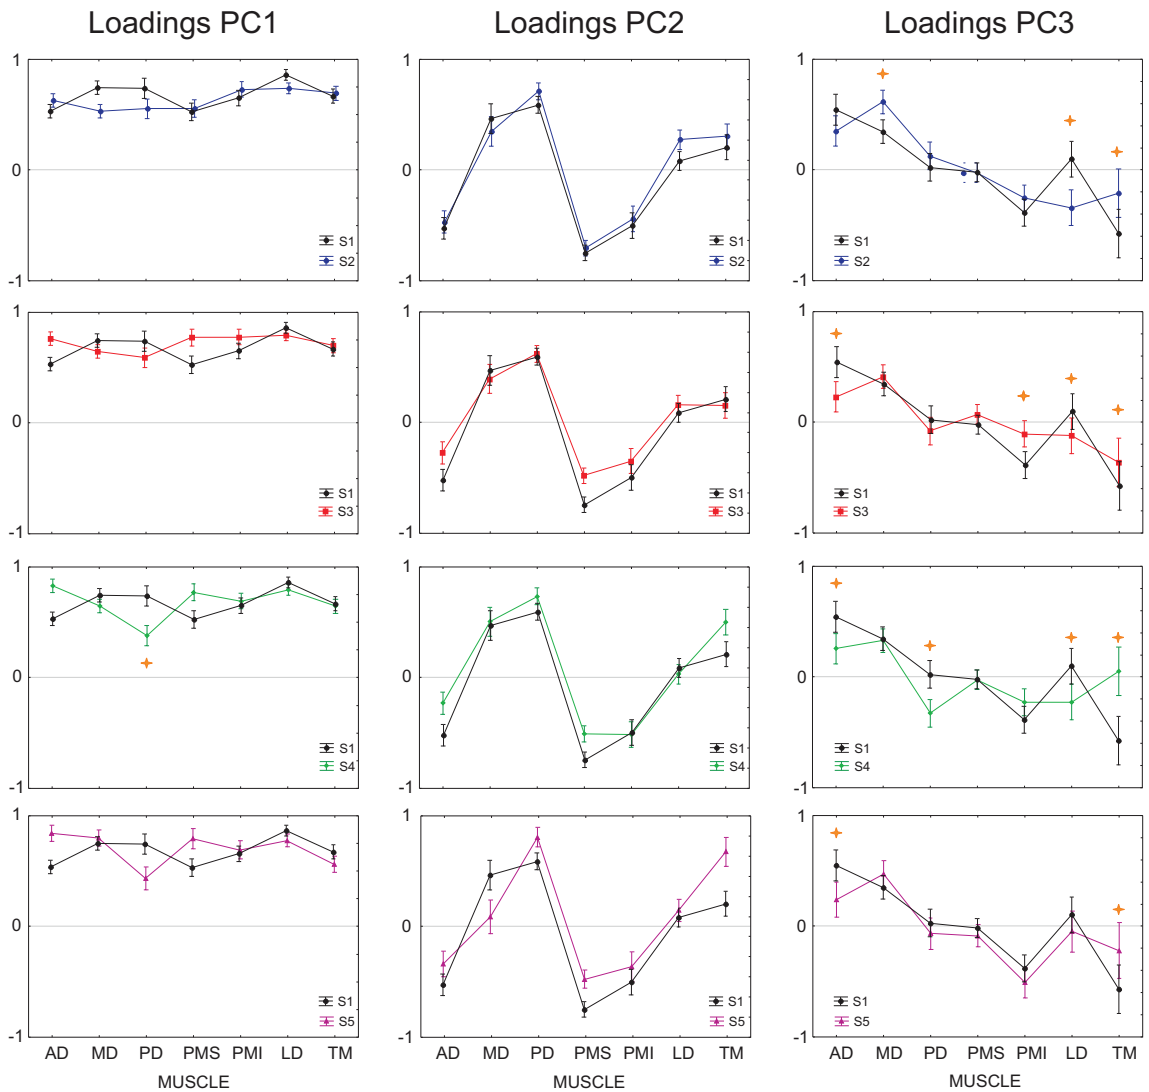

FIGURE 12 | Average loadings for subjects 2–5, compared to the average loading for the reference subject (subject 1). Individual muscle loadings that differed significantly between the reference subject and each of the other subjects are indicated with a •$p < 0.001$.

constant, at least in terms of the moment arms and preferred directions for the muscles involved. The velocities and accelerations of the hand were also similar across the four different movement directions, although they were not presented in the same order within each of the different movements. If the mapping from movement to EMG required to generate that movement consists of a simple mapping of instantaneous position, velocity or acceleration to muscle activations, the DRNN should have been able to capture that simple, time-invariant relationship from any one of the four movements in the same plane. The fact that the DRNN was unable to generalize from one movement direction to another suggests, therefore, that the modules underlying movement generation must take into account the temporal aspects of muscle activation patterns (Ivanenko et al., 2004; d'Avella et al., 2008; Delis et al., 2014). As shown in our companion article concerning the synergy analyses of figure-eights, factor loadings of the first three PCs did not show any systematic differences with respect to different initial direction of movements, but the temporal components for PC2 and PC3 were modulated according to horizontal and vertical movement components, respectively.

The fact that the DRNN trained with 4 figure-eights realized only in the frontal workspace, was unable to generalize for the sagittal workspace (and vice-versa) could indicate that it was able to detect the biomechanical differences between the two workspaces and the related retuning of the modular commands (Hogan, 1985; Buneo et al., 1994; Cheung et al., 2005; Kamper et al., 2006; d'Avella et al., 2008). Similarly, even though the DRNN was able to generalize across all movements for the reference subject, if trained with all eight movement patterns, it was not able to predict movement patterns from EMGs taken from other subjects. In this context we note that across our 5 subjects

the DRNN consistently associated the second principal component with the horizontal component of the finger velocity; and that the analyses of the loadings showed that for all the subjects this second PC revealed the same muscular synergy: a reciprocal activation of muscles according to their line of action in the horizontal plane. In contrast, the DRNN did not correctly predict movements from EMG generated with the third PC for anyone but the reference subject, and the loadings analyses showed significant differences for grouping muscles between them. Studies concerning kinematic and muscular synergies have already proposed that the lower PCs may be responsible for the general aspects of the movement and present less inter-individual variability whereas higher PCs would be responsible for more subtler aspects and by consequence it present more inter-individual variability (Santello et al., 1998; Torres-Oviedo and Ting, 2007; Frère and Hug, 2012). In the case of our vertical figure-eight the invariant aspect necessary to accomplish the trajectory would be expressed by the activation of PC1 and PC2 whereas the personal "signature" would be the consequence of the activation of PC3.

Exactly the same invariant identification was observed for the reference subject when we crossed the EMG/DRNN pairing. A 4-pattern DRNN trained on movements from one plane was able to reproduce the horizontal component of the finger velocity for EMG from movements in the other plane, but was unable to reproduce the vertical component. Factor loadings analyses showed that PC2 maintained the same muscular synergy across planes whereas the third PC loadings analyses showed significant differences for grouping muscles between planes. One can therefore conclude that the DRNN was able to detect directional, biomechanical and subject-dependencies in the mapping from EMG to movement (Muceli et al., 2010; Torres-Oviedo and Ting, 2010; Frère and Hug, 2012; Kristiansen et al., 2013). Indeed it associated directional dependencies to temporal tuning and biomechanical and subject dependencies to spatial tuning of the third PC.

HORIZONTAL vs. VERTICAL

An interesting question emerges from the observation that the DRNN was much more able to reproduce the horizontal component of the hand's velocity than the vertical component. A 4-pattern DRNN trained on movements from one plane was able to reproduce the horizontal component of the finger velocity for EMG from movements in the other plane, but was unable to reproduce the vertical component. Similarly, an 8-pattern DRNN trained on data from one subject was able to reproduce, in most cases, the horizontal component but not the vertical component of movements produced by the other subjects. This observation indicates that the trained DRNN was able to identify an invariant aspect corresponding to the figure-eight, i.e., the control of the horizontal velocity.

Across all the movement conditions the only aspect that remained invariant was the fact that all the movements corresponded to the realization of a figure-eight. Across all the generalizations the only relationship that remained invariant was the identification of the synergy extracted by PC2 with the finger horizontal velocity component. This synergy corresponded to a reciprocal command that groups the shoulder muscles with respect to their horizontal preferred action direction. In a previous work (Bengoetxea et al., 2010) concerning the temporal activation pattern for a figure-eight, cross-correlation analyses showed that the invariant aspect across shoulder position and subjects was the emergence of two groups of muscles acting in a reciprocal mode in relation with the horizontal direction. This invariant synergy suggests the existence of an underlying oscillator module (Hogan and Sternad, 2012), acting in the horizontal direction, and the DRNN seems to have identified this module.

The analyses of the loading corresponding to PC3 across subjects indicates that the muscular synergies associated with the vertical component of the figure-eight were more variable, compared to the synergies defined by PC2 (see companion paper). We can offer several possible explanations of this observation. The first is purely methodological. The third principal component is by definition the one that explains the least amount of variance in the input signals, compared to the first and second. This means that the signal associated with this purported synergy would be smaller and thus more sensitive to noise. But that would seem unlikely to explain the enormous difference in the ability to predict the horizontal or vertical velocity components. The second is behavioral, as it could be that each subject has developed their own idiosyncratic synergies depending, for instance, on their professional activities or sports played. An alternative explanation may be found in the phasic/tonic aspects of a discrete figure-eight movement. For discrete reaching movement it has been shown that synergies are stable across subjects and shoulder positions (d'Avella et al., 2008). Modulations of synergies correspond to a cosine tuning for postural and tonic synergies and more complex pattern for phasic synergies. Tonic synergies are responsible for antigravity and postural control, whereas phasic synergies are responsible for overcoming inertia to accelerate and decelerate the arm (d'Avella et al., 2008). In our case the DRNN had to learn both tonic synergies, before and after movement, and phasic synergies during the movement. The fact that the DRNN was not able to generalize the vertical component of the movement across workspaces or subjects as well as their third PC could be due to the fact that the postural synergy and the phasic synergy for the vertical component of the movement were mixed.

Comparison of the principal component and varimax decompositions via the DRNN provides further fuel for our argument that muscle synergies for discrete-rhythmic movements are best captured by that identified by the principal components; i.e., one module controlling co-activation and two modules producing reciprocal activations, one in the horizontal and one in the vertical direction. When we fed the trained DRNN with EMG reconstructed by the first, second and the third PCs, we obtained a clear identification of each two spatial velocity components of the figure-eight movement. The reciprocal command extracted by PC2, where muscles were partitioned by their horizontal line of action, was clearly associated by the trained DRNN with the horizontal component of the finger velocity. Similarly, the reciprocal grouping by PC3, where muscles were partitioned by their vertical preferred direction, was associated by the trained DRNN with the vertical component of the finger velocity. The DRNN predicted little or no movement from an EMG signal constructed only from PC1, as would be expected from a co-activation module destined

to tune the mechanical state of the system, rather to generate movement *per se*. The hand velocities predicted by the DRNN for the first three varimax components (VM1, VM2, VM3) were not nearly so well demarcated, with each producing a combination of vertical and horizontal velocity.

Using the DRNN to interpret the physiological meaning of the muscle synergies that were previously identified through principal component analysis is therefore an interesting addition to the tools that may be used to study modularity in movement control. One might say that the DRNN has captured to some degree the physiological and mechanical relationship between the muscles and the motor output. Of course, use of the DRNN cannot replace a thorough biomechanical model of muscle, bones and joints if one wishes to fully understand the mapping from EMG to movement. But like principal component analysis and other forms of factor analysis, the analysis by DRNN can be useful to identify structure in the underlying relationship, with the added advantage of linking muscle activation to actual movement and with the possibility of identifying causal relationships resulting from neural connections as well as from biomechanical constraints. The DRNN could potentially be coupled with other exploratory techniques, such as more recent efforts to identify modularity in temporal as well as spatial domains (d'Avella et al., 2003; d'Avella and Bizzi, 2005; Delis et al., 2014). Indeed, the "memory" elements of the DRNN have the potential to identify dynamical constraints that determine not only which muscles to activate for a given movement, but also when.

CONCLUSIONS

A comparison of a DRNN's ability to generalize between movement conditions combined with principal component analysis suggests that tuning of movement-generation modules for movement direction seems to be related primarily to the temporal aspects of the movement whereas tuning to take into account joint biomechanics and inter-subject difference seems to be spatial (in the sense of how activity is spread between muscles). Analysis of the network's interpretation of synergies identified by principal component analysis provides further insight into how movement-generating modules are defined. This tool may therefore be used to motivate future experiments on the question of how human motor behavior may be organized in a modular fashion.

A central question in Neuroscience is that of how the nervous system generates the spatiotemporal commands needed to realize complex gestures, such as handwriting. A key postulate is that the central nervous system (CNS) builds up complex movements from a set of simpler motor primitives or control modules. In this study we examined the control modules underlying the generation of muscle activations when performing different types of movement: discrete, point-to-point movements in eight different directions and continuous figure-eight movements in both the normal, upright orientation and rotated 90°. To test for the effects of biomechanical constraints, movements were performed in the frontal-parallel or sagittal planes, corresponding to two different nominal flexion/abduction postures of the shoulder. In all cases we measured limb kinematics and surface electromyographic activity (EMG) signals for seven different muscles acting around the shoulder. We first performed principal component analysis (PCA) of the EMG signals on a movement-by-movement basis. We found a surprisingly consistent pattern of muscle groupings across movement types and movement planes, although we could detect systematic differences between the PCs derived from movements performed in each shoulder posture and between the principal components associated with the different orientations of the figure. Unexpectedly we found no systematic differences between the figure eights and the point-to-point movements. The first three principal components could be associated with a general co-contraction of all seven muscles plus two patterns of reciprocal activation. From these results, we surmise that both "discrete-rhythmic movements" such as the figure eight, and discrete point-to-point movement may be constructed from three different fundamental modules, one regulating the impedance of the limb over the time span of the movement and two others operating to generate movement, one aligned with the vertical and the other aligned with the horizontal.

Keywords: rhythmic movement, figure-eight, muscular synergy, principal component analysis, varimax factor analysis, upper limb

INTRODUCTION

Following the quantitative definitions for discrete and rhythmic gestures proposed by Hogan and Sternad (2007), handwriting movements, in terms of behavioral and observational features, are special cases of discrete movements because they have rhythmic phases but last a finite duration, with the hand starting and ending at zero velocity. Making the distinction between discrete and rhythmic movements is central because their underlying neural control could be different (Hollerbach, 1981). In fact, one can find in the literature three different proposals concerning the control of discrete vs. rhythmic movements. One view is that rhythmic movements are a concatenation of a series of discrete movements, the latter of which form the basic building blocks for complex movements (Abend et al., 1982; Soechting and Terzuolo, 1987a,b; Kalaska et al., 1997; Sabes, 2000). An opposing view is that rhythmic movements represent the fundamental class and that discrete movements are simply abbreviated rhythmic movements (Sternad and Schaal, 1999; Sternad et al., 2000; Schaal and Sternad, 2001; Sternad and Dean, 2003). Both of these viewpoints would suggest that only a single, common control mechanism is used to achieve both types of movement. A third possibility is that rhythmic and discrete movements represent two distinct movement classes that are mediated by separate neural control circuitry.

Recent behavioral (Ikegami et al., 2010; Howard et al., 2011) and imaging studies (Schaal et al., 2004) support this latter hypothesis.

Numerous studies have examined the invariance of kinematic parameters for drawing movements, looking for the principles used by the central nervous system (CNS) for motor control (Viviani and Terzuolo, 1982; Lacquaniti et al., 1983; Viviani and McCollum, 1983; Soechting et al., 1986; Lacquaniti, 1989). Based on the kinematic invariance of the end-effector obtained, these authors have proposed that for curved movements the CNS respects the so-called "2/3 power law" and that each kinematic segment respects the same kinematic invariance presented by discrete movement, as specified by the "isochrony principle". In light of these kinematic invariances, their conclusions have been used to support the hypothesis that the figure-eight and other "discrete-rhythmic" movements are composed of a series of concatenated discrete movements. Indeed, the observed presence of multiple peaks in the endpoint velocity profile might suggest that a figure-eight is composed of a series of superimposed discrete segments (Richardson and Flash, 2002). But kinematic segmentation doesn't necessarily imply a segmented control of the movement (Sternad and Schaal, 1999). Indeed, evidence that the figure-eight is in fact an abbreviated rhythmic movement is emerging (Bengoetxea et al., 2010).

Within the set of all handwriting movements, the figure-eight is of particular interest from a theoretical and experimental point of view because it can be described as a Lissajous figure for which the vertical and horizontal frequency components are in an exact ratio of 2 (Buchanan et al., 1996). A figure eight can therefore also be described as the result of two coupled oscillators acting in perpendicular directions over a finite number of cycles (two horizontal cycles and one vertical cycle, to be exact). Although we previously demonstrated that for rapid execution of a single figure-eight movement the isochrony principle and the 2/3 power law between angular velocity and curvature are respected, and that the tangential velocity profile is invariant relative to the initial direction of movement (Cheron et al., 1999), electromyographic activity (EMG) analyses have shown that muscular activations present temporal modulation related to the figure as a whole, in contrast to directional pattern of tuning that would point to a segmented control. Moreover, we have shown that the prime movers are partitioned into two sets of synergistic muscles acting in a reciprocal mode and this reciprocal command was highly correlated with the spatial component of the velocity presenting the highest frequency (in the case of a vertical figure-eight the horizontal velocity component) (Bengoetxea et al., 2010). These results pointed to one or more oscillators controlling two muscular synergies.

In the study presented here we set out to determine if the modules underlying the production of discrete-rhythmic movements, in terms of muscle synergies, reflect an organization based on a series of discrete movements or on a combination of abbreviated oscillations. We reasoned that if two orthogonal coupled oscillators underlie the execution of the figure-eight movement, these oscillators should define two muscular synergies, each one dedicated to one of the two spatial components of the kinematics. On the other hand, we know that the synergistic organization is flexible and that a single muscle may be a member of more than one synergy (Tresch et al., 1999; Weiss and Flanders, 2004). We also know that EMG patterns are modulated by movement direction in 3D space (Flanders et al., 1994, 1996; Hoffman and Strick, 1999) and that muscle activation depend on its mechanical action, which depend on joint position (Hogan, 1985; Buneo et al., 1997). Finally, we know that the mapping of required muscle forces and joint torques is most often under constrained, allowing the CNS to exploit additional degrees-of-freedom to tune other properties of the musculoskeletal system, such as limb impedance (Hogan, 1985). We therefore looked at how each of these considerations influences the grouping of muscles into functional modules.

In the present work we asked how movement type (discrete vs. discrete-rhythmic), in addition to directional and biomechanical constraints, affects the organization of modules used to generate movements of the arm. We used principal component analysis (PCA) and varimax factor analysis to extract synchronous synergies (d'Avella and Bizzi, 2005; Klein Breteler et al., 2007) to see the relative involvement of each recorded muscle. We compared the synergies identified by these methods between different orientations, joint configurations and directions of movement for the figure eight and between figure eights and discrete point-to-point movements. In a companion article (see Bengoetxea et al., 2014) we combined this factor analysis with the identification of the relationship between EMG and movement parameters via a dynamic recurrent neuronal network (DRNN), in order to link the muscular synergies extracted with the movement generated. These two studies revealed a high-level of communality between the production of discrete and discrete-rhythmic movements and suggest an organization of motor control constructed from one or more modules controlling limb dynamical properties (e.g., impedance) and multiple modules that elicit reciprocal activation of opposing muscles to generate forces and movement.

MATERIAL AND METHODS

Data were collected from a total of 8 right-handed subjects, 4 males and 4 females, aged between 21 and 40 years. All were in good health, free from known neurological disorders, and had given informed consent to take part in the study, which was approved by the ethics committee at Brugman Hospital in Brussels ("Comité d'éthique hospitalier"—OM26). Data from one subject were unfortunately unusable due to a technical problem, leaving a total subject pool of 7 (3 males, 4 females).

Subjects were asked to draw, as fast as possible, figure-eight movements in free space with the right arm fully extended at the elbow (for more details see Bengoetxea et al., 2010). Movements were initiated in the center of the figure with an initial up-right (UR), down-right (DR), up-left (UL) or down-left (DL) direction with respect to external coordinates and subjects performed each of these movements twice. Two trials for one subject were lost for technical reasons, leaving a total of $7 \times 4 \times 2 - 2 = 56$ figure-eight movements in the frontal plane. All seven subjects also performed eight point-to-point movements starting from a central

target, one in each of eight different directions. In addition, three subjects (subjects 1, 2 and 3) performed figure-eight movements in both the frontal and sagittal workspaces, while the four other subjects (subjects 4, 5, 6 and 7) performed "horizontal" figure-eight movements (figure eights rotated in the frontal plane by 90°, such that the long axis of the figure was horizontal, instead of vertical). A part of the data has been reported in a previous study (data from the four subjects performing figure eights in the frontal and sagittal planes, see Bengoetxea et al., 2010). Data from the discrete movements performed by these subjects, and from the figure-eight and discrete movements from the three other subjects, are reported for the first time here and in our companion article in this issue.

DATA ACQUISITION

Data acquisition methods were the same for both the previously reported data sets (Bengoetxea et al., 2010) and the new data reported here. Movements of the index finger were recorded and analyzed using the optoelectronic ELITE system (2 CCD-cameras, sampling rate of 100 Hz) (BTS, Milan) (Ferrigno and Pedotti, 1985). The cameras were placed 4 m apart from each other and 4 m from the subject. Four markers were attached to the arm (on the acromion, the lateral condoyle of the humerus, the radial apophysis of the wrist and the index finger). Velocity signals were obtained by digitally differentiating position signals using a fifth-order polynomial approximation. Reconstruction of the arm movements by the ELITE system using the trajectories of the 4 markers confirmed the visual observation that the upper arm, forearm, hand and index finger acted as a rigid link (Bengoetxea et al., 2010). Thus, we analyzed here only the index-finger marker that was used to trace the figure-eight.

Surface EMG was recorded with the TELEMG system (BTS, Milan) synchronized with the kinematic data. Silver-silver chloride electrode pairs (interelectrode distance of 2.5 cm) were placed over the belly of the following 7 muscles: posterior deltoid (PD), anterior deltoid (AD), median deltoid (MD), pectoralis major superior and inferior (PMS and PMI), latissimus dorsi (LD) and teres major (TM). Raw EMG signals (differential detection) were amplified by a portable unit 1000 times and transmitted to the main unit with a telemetry system (Telemg, BTS). A functional resistance test that isolated specific muscles was made in order to verify the absence of cross talk between adjacent muscles. Thereafter, EMGs were band-pass filtered (10–500 Hz), digitized at 1 kHz, full-wave rectified and smoothed by means of a third-order averaging filter with a time constant of 20 ms (Hof and Van den Berg, 1981).

COMPONENT ANALYSIS

In the first part of our study we set out to identify synchronous synergies (d'Avella and Bizzi, 2005) using PCA. The input to the PCA was the EMG signal for each muscle and each figure-eight movement. The EMG signals were first normalized on a movement-by-movement basis for the discrete-rhythmic movements. For each EMG recording, the minimum value over the entire signal for each movement was subtracted and the maximum value was used to normalize the peak EMG signal during figure-eight movements. With this normalization, all EMG signals for each movement ranged from 0 and 1. A similar analysis was performed on a set of 8 point-to-point movements concatenated together, one in each of 8 directions, to produce the principal components associated with the production of discrete movements (Klein Breteler et al., 2007). We performed the PCA using the Statistica (© Statsoft) factor analysis module. This analysis resulted in 7 principle component vectors each composed of 7 loading factors ($W1_{muscle}$–$W7_{muscle}$) corresponding to the weights given to the EMG from each of the 7 muscles for each factor.

We focused the subsequent analysis of the principal component decompositions on the first 3 principal components, as these components accounted for 83.01 $\pm$ 2.84 % of the variance in the EMG data (mean across movements). We also computed the varimax rotation (Kaiser, 1958) of the first three principal components for each movement to generate a new set of three orthogonal loading vectors for each movement.

Because we computed the principal components on a movement-by-movement basis, we obtained multiple principal component and varimax decompositions for each direction, plane, figure-eight orientation and movement type. The principal component calculation, by design, assigns loading vectors in decreasing order according to the amount of variance explained by each one. If one adopts the basic premise that principal components reflect an underlying module or synergy, it is possible for a given synergy to be represented by the first, second or third principal component for a given movement trial, if the amount of movement (variance) associated with a given synergy increases or decreases between trials. We therefore used k-means clustering, with the number of clusters set to three, as an objective means to assign each loading vector to the group PC1, PC2 or PC3 based on similarity rather than on the amount of variance explained. The clustering algorithm was applied the set of first three principal component loadings collected across all movements, all mixed together for a total of 351 vectors, without regard for each vector's ranking within the trial from which it was obtained. If the synergies are stable across movement types and subjects, one would expect that one of the three loading vectors from each movement would be assigned to PC1, one to PC2 and one to PC3. In the rare case where the k-means clustering assigned two loading vectors from a single movement trial to the same cluster, the loading vector with the highest distance from the cluster mean was shifted to the cluster that was left unassigned for that trial. A similar process was applied to assign the varimax loading vectors in each trial to groups VM1, VM2 and VM3.

The time courses of the activation of each principle component (PC1–PC3) and varimax loading (VM1–VM3) were then computed by projecting, at each time step, the vector of 7 muscle EMGs onto the loading vector describing each component. Note that the calculation of the covariance used to compute the PCA removes the mean from each of the 7 columns of the input matrix (i.e., removes the average EMG at the input) and also scales each input so that each channel has a variance equal to 1. The reconstructed EMG signals were therefore scaled and offset appropriately to account for this scaling of the inputs to the PCA.

Statistical analyses

We considered that the loading vectors associated to PC1, PC2 and PC3 within a given condition were sufficiently similar to allow the PCs to be compared based on the mean and variance of the loading vectors computed across subjects. This assertion is supported by two statistical arguments. First, we performed the k-means cluster analysis on the ensemble of loading vectors identified by PCA for the figure-eight movements performed in the frontal plane. Out of 54 movements (162 principal-component loading vectors), only one PC1 loading vector was misclassified into the cluster containing PC2s. Thus, the principal components were highly repeatable and unambiguously grouped into three clusters. We further verified that the loading values for each muscle and each PC across subjects did not violate the assumption of a normal distribution, according to the Kolmogorov-Smirnov (K-S) test ($p > 0.20$ in all cases). We therefore used MANOVA to compare the average PC1, PC2 or PC3 vectors across different conditions. Whenever the MANOVA revealed a significant difference ($p < 0.01$) of the loading vectors between conditions we performed a one-way ANOVA muscle-by-muscle to determine which muscle loadings were affected.

Loading vectors based on the varimax rotation (VM1, VM2 and VM3) were somewhat less distinct across trials. Using the same k-means clustering as described for the principal components in the frontal plane, there were more instances (8 out of 54 movements) where the k-means clustering attributed two loading vectors from the same movement to the same group. Furthermore, even after correcting these cases by reclassifying the vector with the largest distance from the cluster mean, the loading values for individual muscles did not always follow the normal distribution across trials (K-S: $p < 0.05$). Nevertheless, based on visual inspection and the central limit theorem, we considered that the within-subject averages could be compared across trials as a means of detecting systematic changes between conditions. Indeed, when we computed the average VM1, VM2 and VM3 for each subject across all 4 figure-eight movement directions (See Section Results for further details), the individual weight for each muscle of these average loading vectors did respect the normal distribution (K-S: $p > 0.2$). We therefore also applied MANOVA to compare VM1, VM2 and VM3 for different types of movement, as we did for the principal components PC1, PC2 and PC3.

To compare which of the two factoring methods (principal component or varimax) produced the least variation in loadings across subjects, we counted the number of times that the cluster analysis assigned two loading vectors from the same movement to the same cluster, with the underlying assumption that the more the loading vectors varied in terms of directions, the higher the chance that such misclassification can occur. We also computed the distance from the cluster mean for each loading vector and applied a one-way ANOVA with component (PC1, PC2, PC3, VM1, VM2, VM3) as the independent factor as a measure of the dispersion of individual vectors within each cluster.

RESULTS

We first looked to see if the PCA, which we applied to each movement one-by-one, was able to identify regular patterns of muscle involvement across the different movement directions and movement planes. Given that subjects may differ in the way that muscles may be organized into modules or synergies, we analyzed first the results from a single representative subject. This is the same subject whose data was used to train the artificial neural network in our companion study (see Bengoetxea et al., 2014). We then analyzed the principal components obtained across all participants to look for systematic, subject-independent changes in potential muscle synergies between conditions.

PCA ANALYSIS

Figure 1 illustrates for the one representative subject the factor loadings for the 3 first principal components (left column) for each initial direction movement, the latter represented by different colors and symbols. From the factor loadings, one can observe that PC1 included a contribution of all 7 muscles in a synergistic pattern (all weights were positive), PC2 identified a reciprocal pattern of activation (positive and negative weights) between MD, PD and TM on one side and AD, PMS and PMI on the other (LD had loadings close to 0), while PC3 identified a different reciprocal relationship with AD and MD clearly on one side and PMI and TM clearly on the other (PD, PMS and LD had loadings close to 0). It is interesting to note that in PC2 and PC3 two groups of muscles appeared according to their mechanical actions. For PC2, the two sets of muscles have opposite actions with respect to horizontal (left-right) movements, while for PC3, the groups of muscles have opposite actions with respect to vertical (up-down) movements.

Figure 1 (right column) also shows the temporal evolution of the principal components for each of the 4 different movement directions (UL, UR, DL, DR). One can see that PC1 showed activation over the duration of the movement, with little or no activity in the stationary phase of the recording (prior to 0.5 s and after 2.0 s in the figure shown). There was little difference between the 4 different movement directions. The time course of the second and third PCs both showed significant modulation over the course of the movement that depended on the direction. PC2 presented 3 positive and 2 negative peaks for the UR and DR directions and 3 negative and 2 positive peaks for the UL and DL directions. PC3 also showed temporal modulation, but differed in terms of the number of peaks compared to PC2. Specifically, PC3 presented 1 negative and 2 positive peaks for the UL and UR directions and 1 positive and 2 negative peaks for the DL and DR directions.

To characterize to what extent the different muscles participated in each principal component, independent of their direction of action, we performed for this subject an ANOVA with muscle and PC as repeated measures on the absolute values of the loadings factors, with principal component (PC1, PC2, PC3) and muscle (AD, MD, PD, PMS, PMI, LD, TM) as independent factors. The cross-effect showed a significant difference between muscles and PC ($F_{(12,84)} = 48.012$, $p < 0.001$). Scheffe's *post-hoc* analyses showed that AD and PMI participated with similar loadings in all three PCs (mean loading $\pm$ SD were 0.53 ± 0.1, 0.52 ± 0.11, 0.54 ± 0.1 for AD for PC1, PC2 and PC3 respectively and 0.65 ± 0.07, 0.50 ± 0.09, 0.39 ± 0.09 for PMI). MD and LD

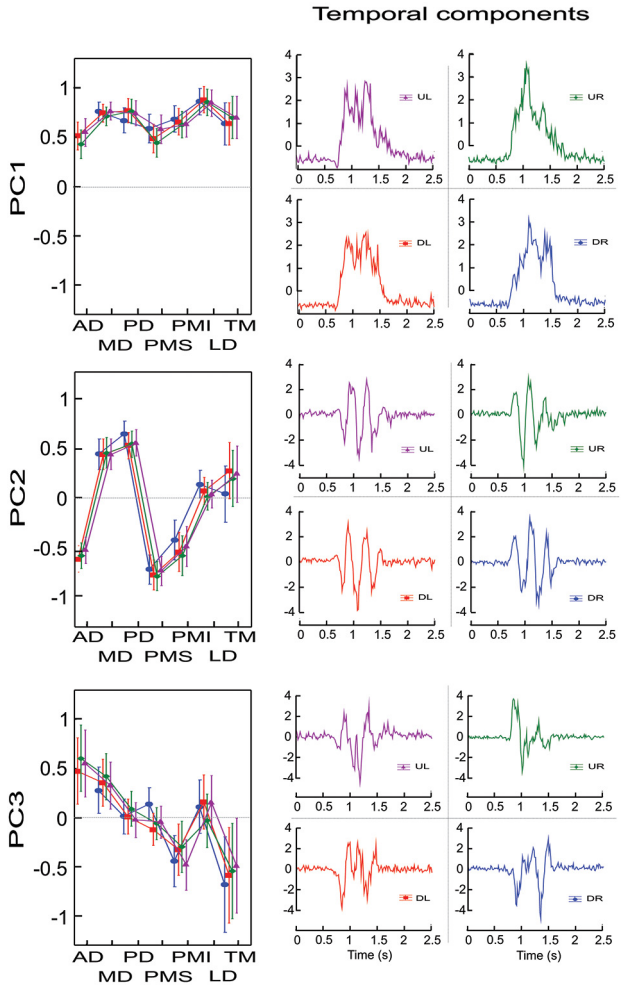

FIGURE 1 | Factor loadings and temporal components for un-rotated principal component analyses for one representative subject and for each initial direction movement. The left column presents the mean factor loadings for PC1, PC2 and PC3 for each of the 7 muscles recorded. AD: anterior deltoid, MD: medial deltoid, PD: posterior deltoid, PMS: pectoralis major superior, PMI: pectoralis major inferior, LD: latissimus dorsi and TM: teres major. The right column present the temporal component for each PC and each direction. Each direction is identified by colors. UR: green, UL: purple, DR: blue and DL: red.

participated significantly more in the first PC compared to PC2 and PC3 ($p < 0.03$), whereas they showed little or no difference between PC2 and PC3. LD had loadings near to 0 for PC2 and PC3 while MD participated in both PC2 and PC3 at the same level as AD and PMI (mean loadings ± SD were 0.75 ± 0.03, 0.46 ± 0.05, 0.35 ± 0.05 for MD for PC1, PC2 and PC3 respectively and 0.86 ± 0.02, 0.1 ± 0.07 and 0.11 ± 0.07 for LD). PD and PMS had the same level of participation for PC1 and PC2 but were not implicate in PC3 (mean loadings ± SD were 0.74 ± 0.05, 0.59 ± 0.05 and 0.04 ± 0.03 for PD for PC1, PC2 and PC3 respectively and 0.53 ± 0.09, 0.75 ± 0.05 and 0.1 ± 0.07 for PMS). TM was the only recorded muscle that had the same level of activity in PC3 as in PC1 (0.58 ± 0.1, 0.67 ± 0.06) and participated lightly in PC2 (0.21 ± 0.12).

Figure 2 illustrates the EMG signals for each muscle corresponding to the time course and loadings of each of the first 3 principal components, shown here for the movement initiated downward and to the right (DR). The reconstructed signals reinforce the interpretation given previously about the role of each principal component (synergy) in the execution of the movement. Specifically, one can observe a co-contraction of all muscles during the movement for EMG reconstructed from PC1, whereas synergies from PC2 and PC3 produced reciprocal activation patterns for which not all muscles participated at the same level. For EMG activations reconstructed from PC2 the figure illustrates that for a movement initiated in the down and right direction, MD and PD were the prime movers (for a right arm their action is to move the arm to the right) and presented a reciprocal command with respect to AD, PMS and PMI. LD and TM are not implicated in this synergy. The synergy extracted by PC3 shows that TM and PMI were agonists and presented the first activity given the fact that they are muscles that move the arm downward and presented a reciprocal activity with respect to AD, MD and PMS. But the reciprocal activity for PC3 was less "pure" than for PC2.

Figure 3 shows the muscle loadings for each of the first three principal components for all subjects, separated as a function of PC and of movement direction. The loading factors were remarkably similar for the 7 different subjects; the average inter-subject standard deviation for each muscle and each factor was 0.133 ± 0.047. This observation, plus the stability in the cluster analysis of PCs (See Section Methods), justified the statistical comparison of loading patterns across subjects.

FACTORS AFFECTING MUSCLE SYNERGIES

Based on the analysis and observations presented above we proceeded to analyze the data based on the means and variances across subjects of the muscle loadings for each of the first three principal components. We considered four main factors that might affect how muscles are grouped into synchronous synergies:

1. The temporal sequence of hand velocities (4 movement directions).
2. The frequency component of oscillations (vertical vs. horizontal figure-eight).
3. Anatomical constraints of different joint configurations (frontal vs. sagittal planes).
4. The type of movement (discrete vs. discrete-rhythmic).

The search for potential effects of factors 1 and 4 addressed the primary questions that motivated our study, i.e., how might time series of movement directions affect the grouping of muscles into modules or synergies? Thus, all seven subjects were asked to perform trials to allow these two contrasts. The other two factors (figure orientation and workspace) addressed secondary questions that provided interesting benchmarks with which to compare the primary results. For practical reasons, therefore, we asked only 4 of our subject to perform figure eights in both the vertical and horizontal directions and only 3 of our subject to perform movements in both the frontal and sagittal planes. The results of each of these contrasts are described below. The loading

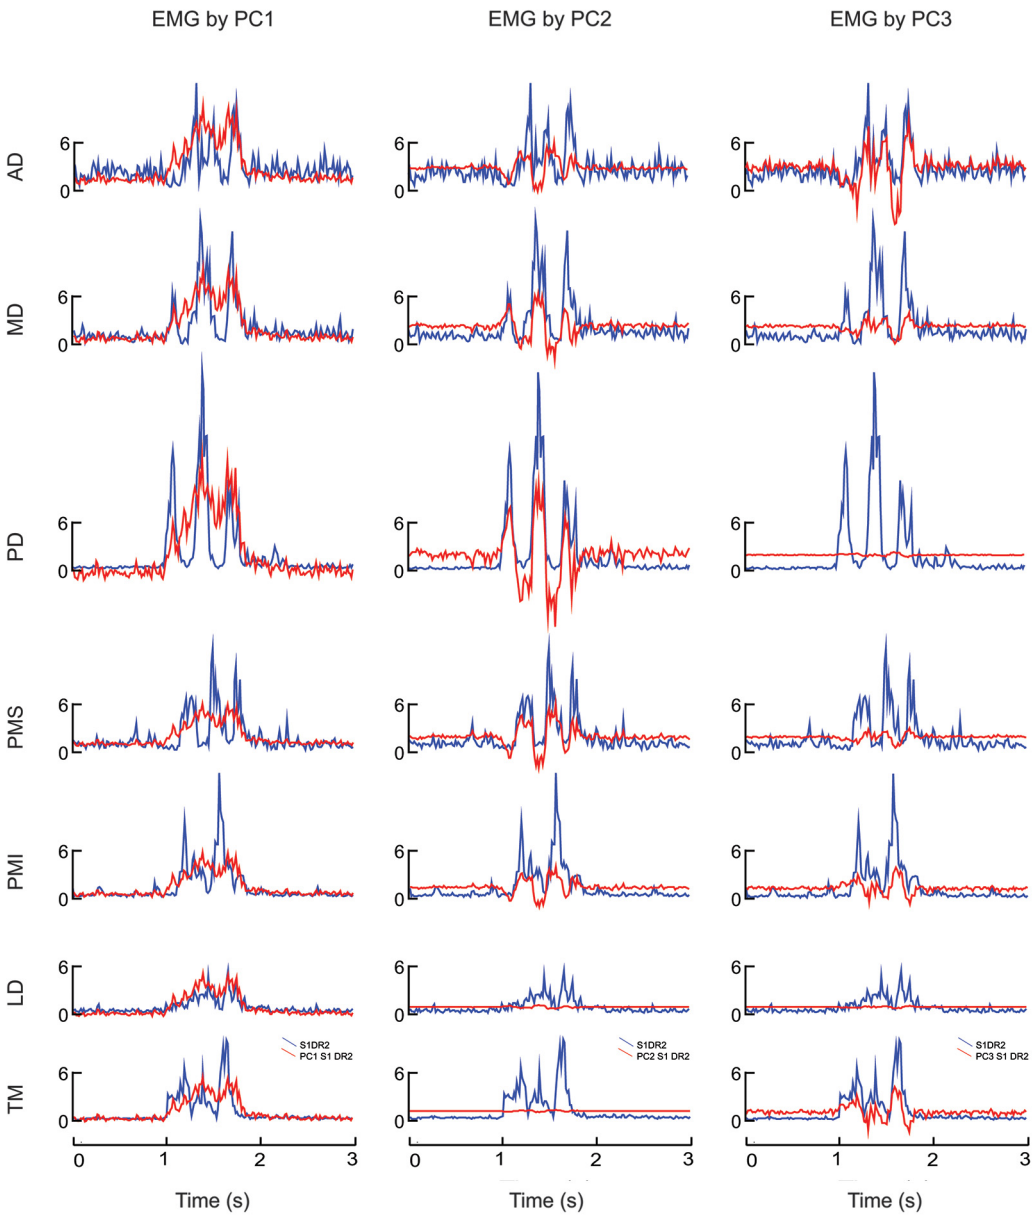

FIGURE 2 | EMG reconstructed by principal component analysis applied to one typical movement (figure-eight initiated in the down-right direction). Each column shows the EMG signal within each muscle associated with PC1 (left column), PC2 (middle column) and PC3 (right column). Blue traces show the actual smoothed EMG signal, whereas red shows the EMG signal reconstructed by the each weighted PC waveform. AD: anterior deltoid, MD: medial deltoid, PD: posterior deltoid, PMS: pectoralis major superior, PMI: pectoralis major inferior, LD: latissimus dorsi and TM: teres major.

vectors averaged across subjects are shown in **Figure 4** while **Figure 5** shows the contribution of each muscle to each of the first three principal components for each subject and each condition. The details of the statistical tests are reported in **Table 1**.

Movement direction

All seven subjects performed the figure-eight movement two times in each of the four possible directions. The loadings within a given PC were remarkably similar across the four different movement directions. There was no significant difference between the loading vectors computed across subjects for each direction ($p > 0.2$, see **Table 1**) and one-way ANOVA test conducted separately on each muscle loading for each PC confirmed that the loadings assigned to each muscle did not change for any of the first three PCs as a function of movement direction.

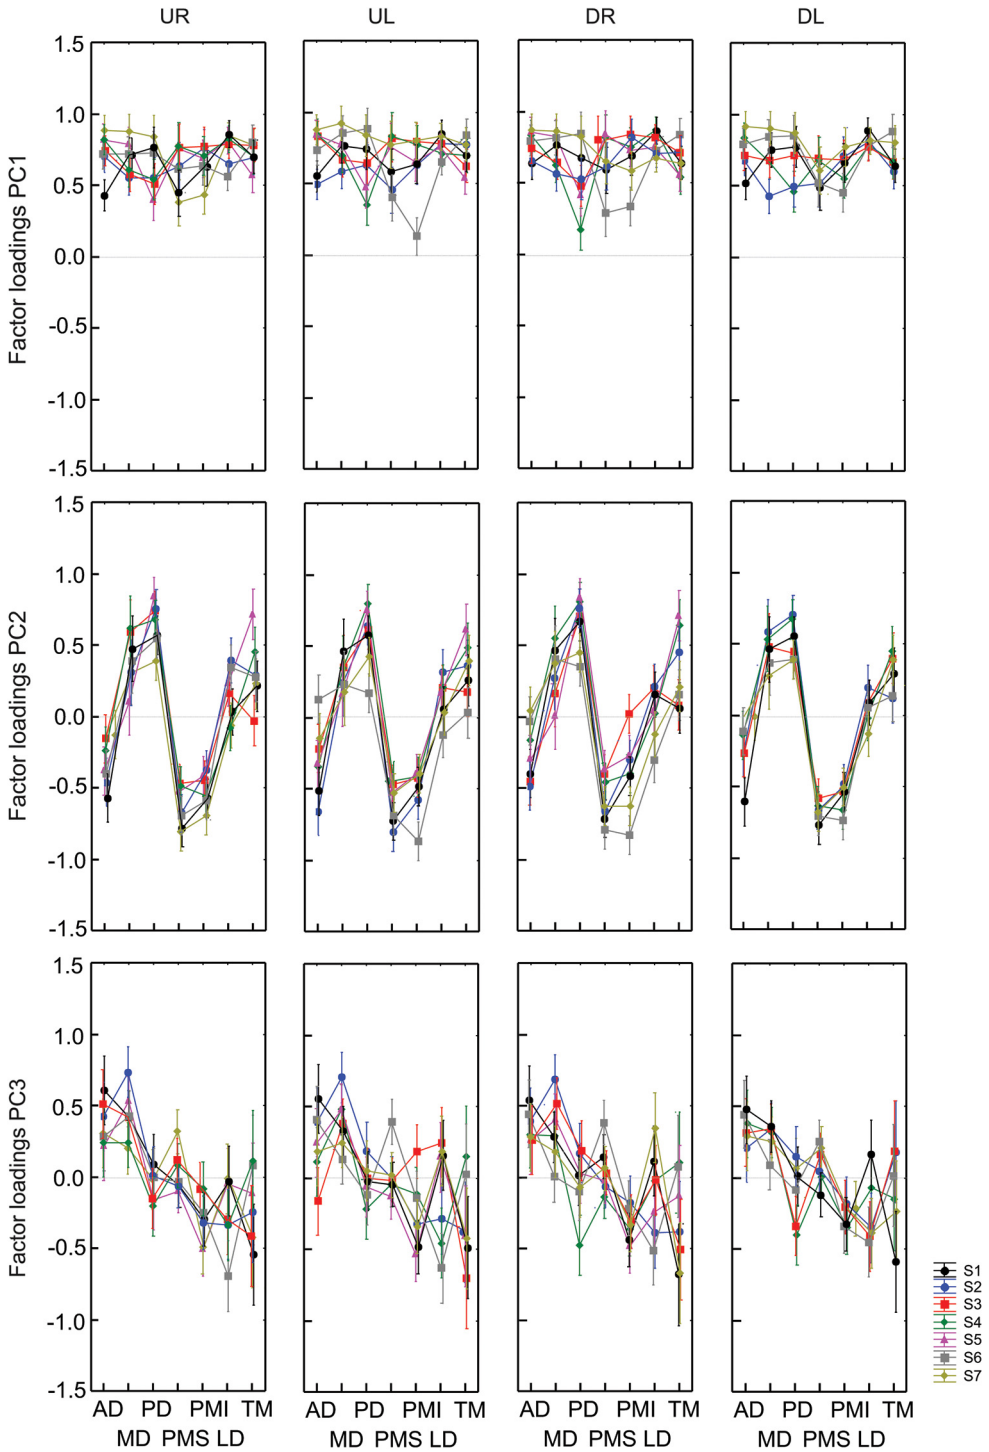

FIGURE 3 | Factor loadings (weighting) for PC1, PC2 and PC3 and each initial direction of vertical figure eights for all subjects. Each graph represents factors loadings for each muscle for a given direction and PC. Results from each of 7 subjects are identified by colors and symbols. PC are organized by row while the direction of movements are displayed in columns.

Figure-eight orientation

Four subjects traced out figure eights in both the vertical and horizontal orientations in the frontal plane. The average loading vectors across subjects were qualitatively very similar for the two orientations. Nevertheless, some reliable differences were detected. The MANOVA test of loading vectors was significant for

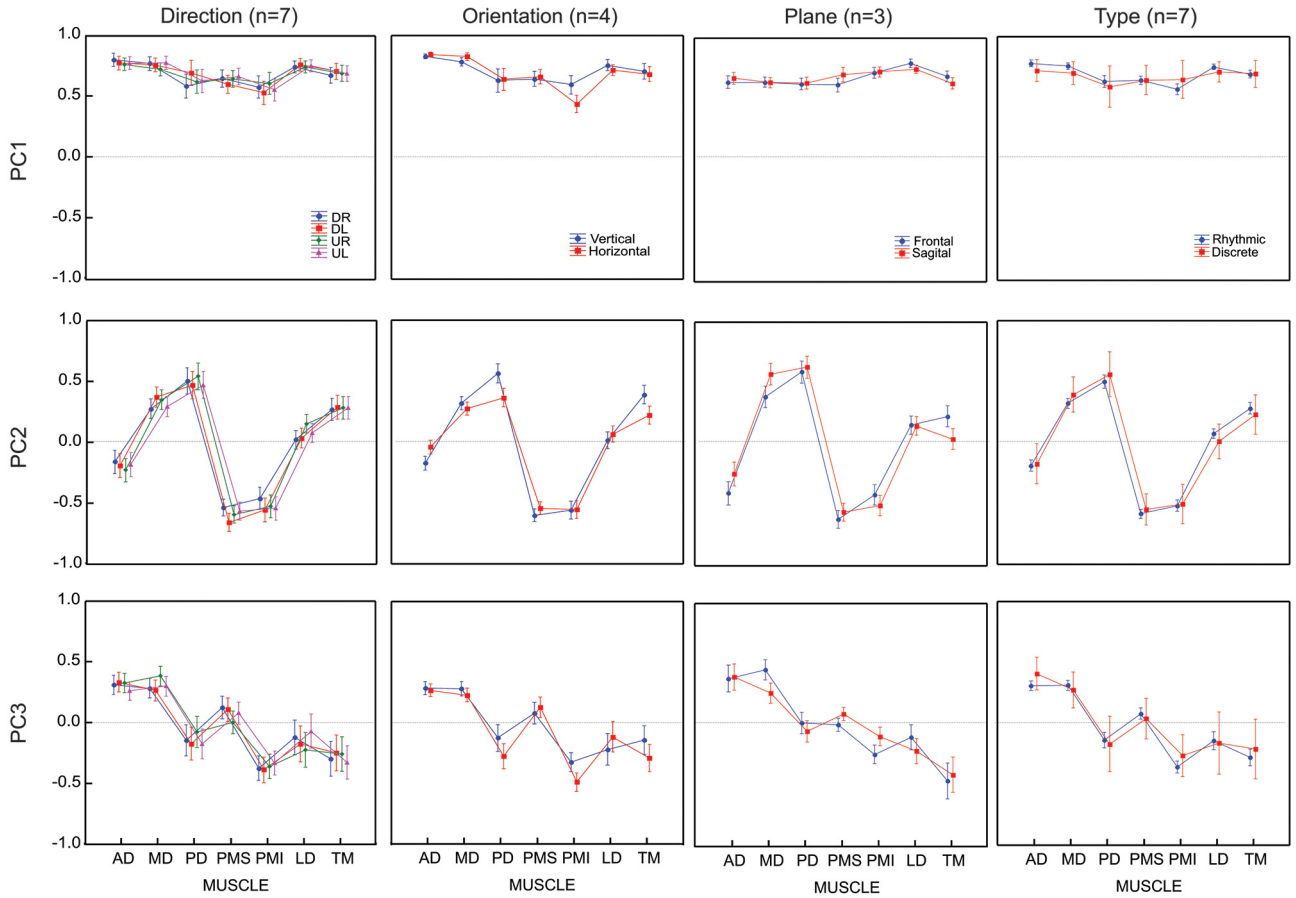

FIGURE 4 | Average loadings for each PC (un-rotated principal component analyses) and for 4 movement conditions (4 movement directions, 2 movement orientations, 2 movement planes and 2 movement types). Movement conditions are displayed in columns. Each PC is displayed in rows. Each graph presents the average loadings for each muscle for each PC and each condition (identified by color and symbols).

each of the three PCs ($p < 0.01$). One-way ANOVAs computed *post-hoc* showed that PD, PMI and TM all had significantly greater weight (more negative values) in PC3 for the horizontal vs. vertical orientations. There was a concomitant decrease in the weight of PMI in PC1 and of PD and TM in PC2. AD had somewhat less influence in PC2 (less negative weight) in the horizontal figure eight, but there was no change in AD"s contribution to either PC1 or PC3.

Frontal vs. sagittal plane

Three subjects performed the figure eight movements in two different nominal orientations of the outstretched arm: with the arm extended straight ahead (frontal plane) and with the arm stretched out straight to the side (sagittal plane). Again, the loadings for each PC were qualitatively similar between the two conditions, but with some small variations. The MANOVA showed only a marginally significant difference between the planes for PC1 ($p = 0.0206$) but statistically reliable difference between the planes for PC2 and PC3 ($p < 0.01$). One-way ANOVAs applied *post hoc* demonstrated that PMS had a slightly greater influence in PC1, MD had a greater influence and AD and TM had lesser influences on PC2 and MD and PMI had less weight in PC3, in the sagittal compared to the frontal plane of movement.

Discrete vs. discrete-rhythmic movements

All seven subjects performed both the figure eights and the point-to-point movements in the frontal plane. As for the comparison between movement directions, there was no apparent difference in the principal components computed for the discrete-rhythmic figure eights and the discrete point-to-point movements. The MANOVA showed no significant difference ($p > 0.4$) between movement types for any of the three principal components PC1, PC2 and PC3.

VARIMAX ROTATION

Compared to the un-rotated principal components computed for S1 (**Figure 1**), the varimax rotation for the same subject (**Figure 6**) grouped muscles into components (synergies) in a quite different fashion. Rather than identifying a "co-activation" module and two "reciprocal" modules, as seen for the first three principle components, the three varimax components could be described

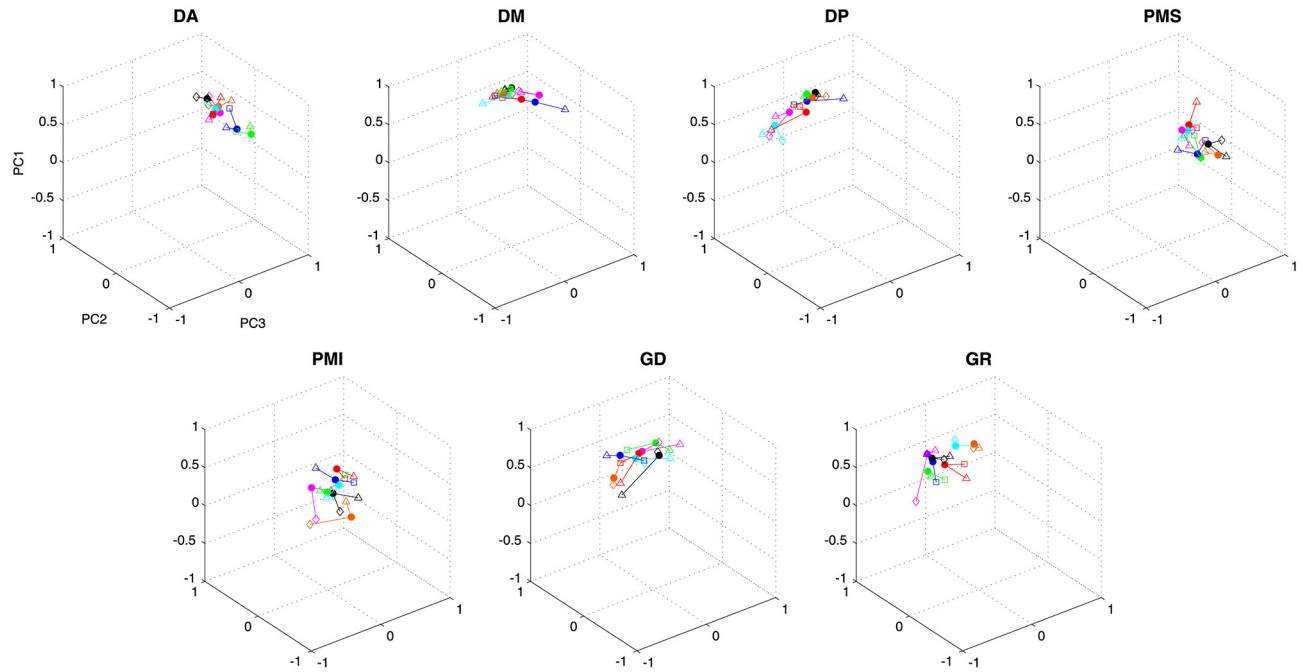

FIGURE 5 | Contribution of each muscle to the first three principal components. Individual data points show the average weighting for each subject in each condition. Data from a single subject are grouped by color and by connecting lines, while symbols indicate the different conditions (filled circles—vertical figure eight in the frontal plane; triangles—discrete movements in the frontal plane; squares—horizontal figure eight in the frontal plane; diamonds—vertical figure eight in the sagittal plane).

as one that drives more-or-less rightward rotations (MD, PD, LD), one that drives more or less leftward rotations (AD, PMS, PMI), and one that favors muscles with a component of action in the downward direction for movements of the outstretched arm (PMI, LD, TM). But this is a gross over-simplification and the participation of the different muscles in the three varimax loading vectors, which was much more mixed in terms of direction of action. Indeed, even if VM1 is dominated by muscles that rotate the outstretched arm rightward (MD, PD), other muscles (LD, TM) participate just as much in VM1 as in VM3. Similarly, PD contributes as much to VM3 as it does to VM1.

Figure 7 shows the comparison of average loading for VM1, VM2 and VM3 as a function of movement direction (UR, UL, DR, DL), figure-eight orientation (horizontal, vertical), movement plane (frontal or sagittal) and movement type (discrete-rhythmic or discrete). **Figure 8** shows the contribution of each muscle to each varimax component, computed separately for each subject and each condition. The only highly reliable difference found in the MANOVA analysis of these data (see **Table 2**) was in the comparison between the vertical and horizontal figure-eight orientations ($p < 0.01$ for VM1 and VM3; $p = 0.056$ for VM2). *Post-hoc* analyses showed fewer and statistically weaker differences ($p < 0.05$) in the loading for individual muscles, compared to the equivalent tests applied to the principal components.

COMPARING PCA VS. VARIMAX

By mathematic principle, the varimax rotation of the three first principal components explains the same amount of variance in the data as the first three principal components do themselves. So one cannot say that one decomposition is to be preferred over the other on that basis. We instead asked whether the PCA or varimax decomposition was more invariant across subjects and conditions. Two observations suggest that the first three principal components were somewhat more regular than the corresponding varimax rotation. First, in the k-means clustering process that we used to assign the PCA vectors to the PC1, PC2 or PC3 groups and to assign the varimax vectors to the VM1, VM2 and VM3 groups, one would expect that if the three orthogonal vectors are aligned across subjects and conditions, the k-means algorithm should assign one vector from each individual decomposition to each group. If the orientation of the three vectors varies significantly, however, from the mean, a given vector might fall between two clusters, causing two vectors from the same decomposition to be assigned to the same group. This happened 3 times for the principal components and 21 times for the varimax decompositions, out of a total of 117 movements. Second, an ANOVA applied to the distance from the mean for each component cluster (PC1, PC2, PC3, VM1, VM2, VM3) showed a significant main effect ($F_{(5,696)} = 50.69$, $p < 0.001$) and a planned comparison showed a significant difference overall between the principal component clusters and the varimax clusters ($F_{(1,696)} = 36.09$, $p < 0.001$). Scheffe's *post-hoc* analysis showed the PC1 had the least average distance; PC2 and VM2 were next, followed by PC3, VM1 and VM3. Thus, overall the principal component decomposition was less variable across movements, with

the difference being mainly attributed to the lower inter-trial variability of the co-activation component defined by PC1.

DISCUSSION

In this study we looked for modularity in patterns of muscle activation used to perform discrete-rhythmic movements, a class of movements typical of handwriting (Hogan and Sternad, 2007), and we compared the underlying structure with that identified for discrete movements performed in eight different directions in the frontal plane. We asked subjects to draw figure eights in different directions, in different orientations and in two different nominal arm postures. Thus, in addition to the main comparison between discrete and discrete-rhythmic movements, we also considered how the underlying modules might be tuned as a function of the directional, biomechanical and rhythmic constraints.

PCA, and other forms of factor analysis, have in recent years become an important tool to identify the muscular synergies underlying human movement, from reaching (d'Avella et al., 2003; Bizzi et al., 2008) to locomotion (Ivanenko et al., 2004; Dominici et al., 2011) passing through complex movements (Weiss and Flanders, 2004; Klein Breteler et al., 2007; Danna-Dos-Santos et al., 2008). Here we used PCA and the varimax rotation as means to identify structure in the activation of different muscles.

Both the three principal component vectors and the three varimax vectors were remarkably stable across the different movement directions, figure-eight orientations, joint configurations (movement plane) and the types of movement (discrete or rhythmic). There were small, but measurable differences in loading between the figure-eight orientations (horizontal or vertical) and between the movement's planes (frontal or sagittal). It should be noted, however, that fewer subjects performed the movements in each of these two conditions, whereas as all 7 subjects performed the figure eights and discrete movements in the frontal plane. It is possible that the orientation and movement-plane comparisons were more sensitive to inter-individual changes between conditions due to the lower N in each case. Furthermore, we do not exclude the possibility that loadings change between movement directions and movement types for individual subjects. But the main result, in the context of the questions evoked in the Introduction, is that overall the synchronous synergies, whether identified through PCA or varimax rotation, were no more affected by the type of movement (rhythmic or discrete) than by changing the time series of movement directions, the organization of oscillations in cyclic movements or the biomechanical constraints. This observation runs counter to our hypothesis by which we expected the CNS to exploit the redundant degrees of freedom within the system to select synergies that would be best adapted to the performance of one or the other type of movement. Our component analyses suggest that three main modules can be extracted for the movements described here, because they capture the bulk of the variation in EMG signals. For the un-rotated principal components, the first component showed a general co-activation of all the muscles, irrespective of the type of movement or the initial direction. This co-activation started and ended with the movement despite the fact that before and after the movement the arm was held in a static position. The co-contraction induced by PC1 would tend to stiffen the arm and thus serve to stabilize the arm's posture before, during and after the movement and to tune the impedance of the limb to meet the demands of the movements to follow. The second and the third principal components each showed a pattern of reciprocal activation but differed in terms of how the muscles were grouped. Whereas the second module encompassed muscles that are antagonistic in terms of their horizontal direction of action, the same muscles were divided in the third module according to their vertical direction of action. Under this decomposition, the actual movement would then be realized by two reciprocal synergies represented by PC2 and PC3. According to the parlance proposed by Hogan and Sternad (2012), PC1 would constitute a "mechanical impedance" synergy while PC2 and PC3 would each be representative of "oscillation" synergies. Such a decomposition would be particularly adapted to rhythmic movements

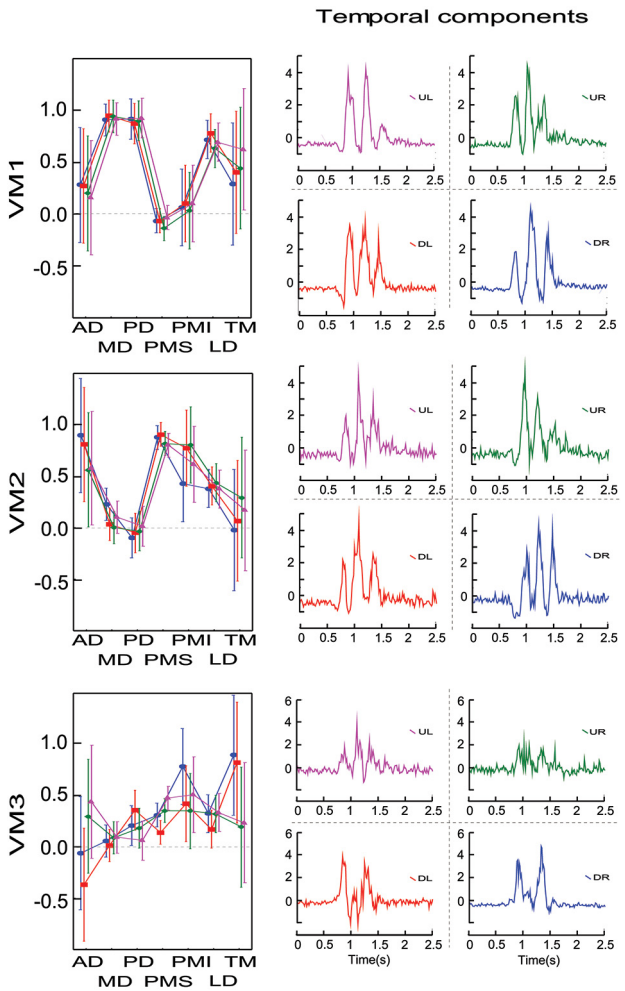

FIGURE 6 | Factor loadings and time course for the varimax components for one representative subject and for each initial direction movement. Left column presents the mean factor loadings for VM1, VM2 and VM3 for each of the 7 muscles recorded. Right column presents the temporal component for each varimax component and each direction.

were each reciprocal synergy could be associated with a separate oscillator.

In contrast, each of the varimax components manifested only non-negative weightings (on average). The varimax decomposition would be consistent with "sub-movement" synergies that would tend to push the limb in one direction or another through the activation of a set of agonistic muscles, without the automatic co-activation or reciprocal de-activation of the effective antagonists (Hogan and Sternad, 2012). The varimax decomposition is more representative of a vector strategy in which each underlying module drives the limb in a given direction, reflecting the fact that muscle can pull, but not push, and thus cannot be negatively active. Modulation of limb impedance can, nevertheless, be achieved through the varimax decomposition, even if there is no identified co-activation module *per se*. Co-activation, and thus impedance modulation, could be achieved by recruiting simultaneously VM1, VM2 and VM3, while cyclic movements could be achieved by various activations of the same modules to generate movement in different directions.

METHODOLOGY

One might ask to what extent the details of the analysis procedures play a role in the modules that we observed. For instance, it is known that PCA are potentially sensitive to the normalizations applied to the input data. In this study we set out to compute the principal components on a movement-by-movement basis, thus allowing us to examine the stability of the principal component decompositions across repeated movements in the same conditions and across different conditions by using standard statistical methods such as ANOVA.[1] But the algorithms for PCA transform the incoming data to be centered on zero with variance equal to one, essentially normalizing the data on a trial-by-trial basis. By doing so, we open up the possibility that factor decompositions might change from one movement to the next due to the scaling factors that also changed from trial to trial. Surprisingly, our data showed that the decompositions were very stable, despite potential variability stemming from the normalization procedure. Our trial-by-trial normalization represents the more conservative method vis-à-vis our conclusions that synchronous muscular synergies vary little between discrete and discrete-rhythmic movements.

A second, perhaps more fundamental question is that of the factorization methods used to analyze the data. Different approaches of factor analysis have been used in the past to extract synergies, and the results obtained depend on the method used (Tresch et al., 2006). Here we compared the results from two different methods, varimax vs. unrotated principal components. Can one claim that the varimax is a better description of the underlying neural structure than the un-rotated principal components, or vice versa, based on our empirical observations? Both the un-rotated principal components and the varimax decompositions are mathematically valid solutions that describe equally well the variance of the various EMG signals. We therefore asked whether one or the other provided a more consistent representation of muscle activation patterns across subjects and across movements. In our conditions we found that the principal component decomposition was less variable than the varimax decomposition when computed on a trial-by-trial basis. One might expect to see such a result if the neural hardware indeed organizes muscles into a fixed set of synergies according to PC1, PC2 and PC3. Thus, these observations support the hypothesis that muscles are organized in a set of co-contraction and reciprocal synergies. These observations do not, however, constitute a definitive proof, due to properties of the principal component computation. Principal component vectors are in fact the eigenvectors of a covariance

[1]However, that the discrete movements were normalized as a set (i.e., the EMG from each muscle was divided by its maximum value across all 8 movements) and the principal component analysis was applied to each set individually. This makes sense in that through the comparison of these data with the figure eights we were testing the null hypothesis (which actually proved to be true) that figure eight movements are constructed as a serial concatenation of modules used to produce discrete movements.

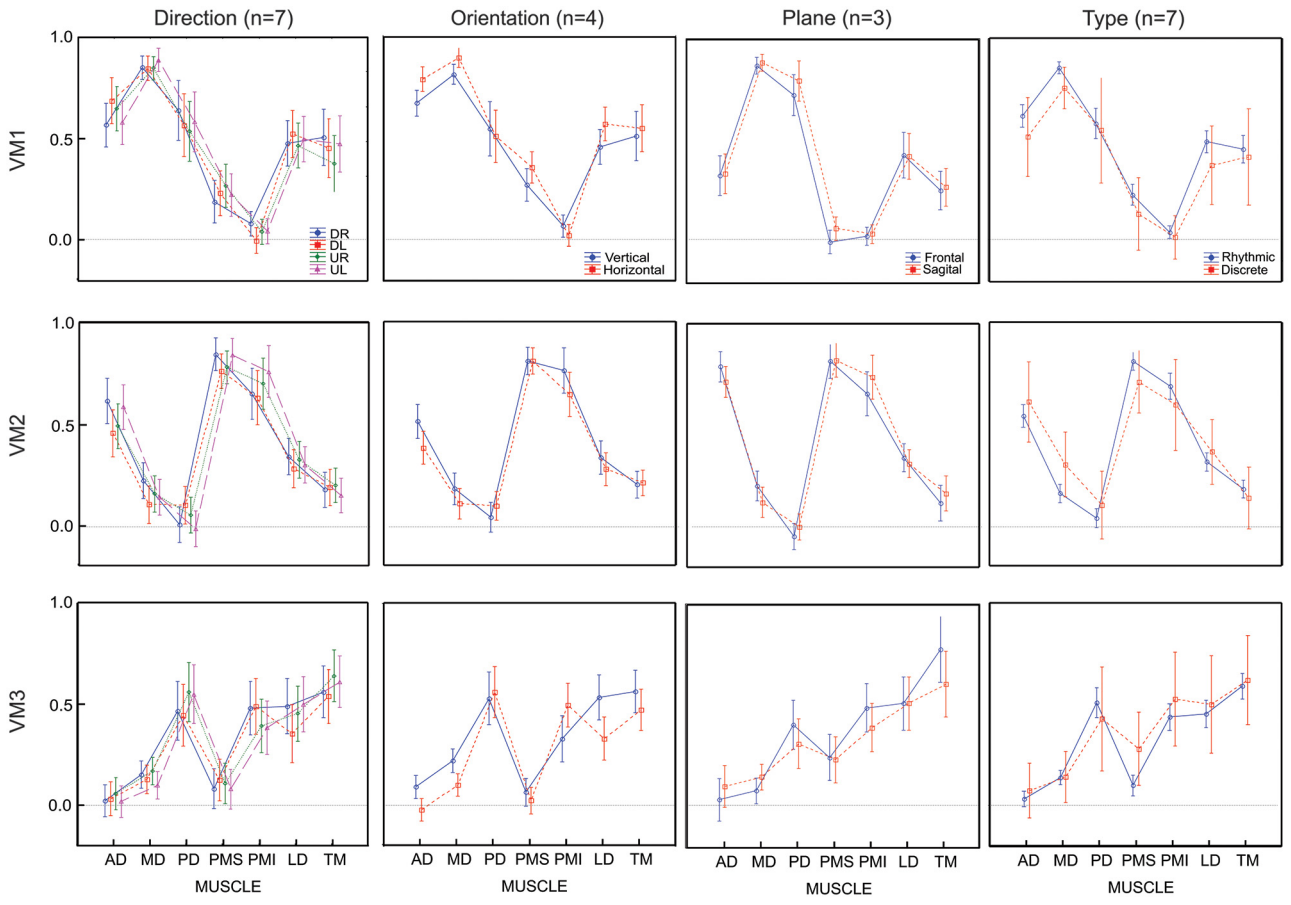

FIGURE 7 | Average loadings for each varimax component (VM) and for 4 movement conditions (4 movement directions, 2 movement orientations, 2 movement planes and 2 movement types). Movement conditions are displayed in columns, varimax components are displayed by rows. Each graph presents the average loadings for each muscle for each PC and each condition identified by color and symbols.

matrix. Those vectors are distinct and well defined when the eigenvalues corresponding to each vector are different. Had the first and second principal components accounted for similar amounts of variance in the EMG, the directions of the first and

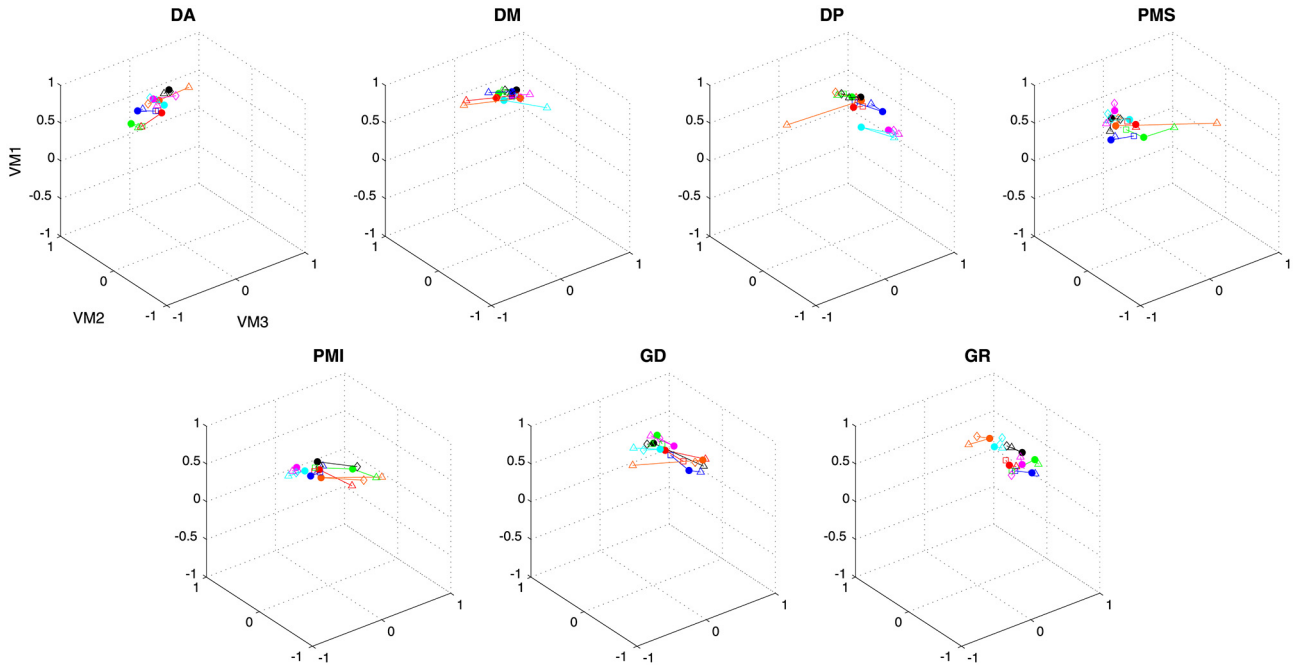

FIGURE 8 | Contribution of each muscle to the first three varimax components. Individual data points show the average weighting for each subject in each condition. Data from a single subject are grouped by color and by connecting lines, while symbols indicate the different conditions (see caption, **Figure 5**).

second PCs would be ill-defined and one would expect them to vary considerably just due to measurement noise. By analogy, the process of finding the varimax solution might add variability across trials if the optimal solution is not sharply defined in each case.

By considering the un-rotated principal components and the varimax rotation of the same data we have therefore evoked an interesting contrast in the way that movements can be generated through the action of muscles. We note, however, that this clear contrast between the two identification strategies was a fortuitous outcome of our experimental conditions. The varimax rotation that we used here does not explicitly seek to generate only positive loading factors for muscles; it just happened to do so for the movement studied here. Recent studies (Ivanenko et al., 2004; Tresch et al., 2006; d'Avella et al., 2008; Delis et al., 2014) have employed the technique of non-negative factorization to explicitly find such solutions. Similarly, PCA does not explicitly seek to group muscles into a co-contraction module plus reciprocal activation, but that also happened to be the outcome of the analysis of our data. Future studies could use instead a factorization algorithm that explicitly looks to organize components in this manner. For instance, a hierarchical factor analysis could be use, where the "secondary" factor would identify the co-contraction unit while a rotation of the primary vectors to maximize "reciprocity" could provide an appropriate solution for future studies.

The comparison of the two factorial decompositions presented here and the discussion above should therefore serve as a cautionary tale for future studies. From the purely mathematical analysis presented here, one cannot claim with high confidence that we have identified the neural structure of modules or synergies based only on the correlations between muscle activations. As we have shown here, the grouping of muscles into purported synergies through component analysis of EMG will depend highly on the *a priori* choice as to what type of factor analysis is performed and on the experimental conditions. Additional information is needed before one can state a clear preference for one decomposition over another. In our companion article, we endeavored to do just that, by using an artificial dynamic recurrent neural network to search for the relationship between EMG and movement. Nevertheless, the simple fact that 3 components can account for a large part of the variance in EMG signals, regardless of which rotation is used, is consistent with what one would predict if activation patterns are organized into synergies as a means of reducing the number of degrees of freedom in the mapping from desired movement to muscle activations.

IMPLICATIONS FOR NEURAL MECHANISMS

One can see in these analyses that, whichever decomposition is considered (PCA or varimax) two muscles might be agonistic in one synergy and antagonistic in another. It would be difficult to understand how the same muscle, if activated as a whole, could participate properly in both synergies. If we refer to the preferred action direction of motor units of the deltoid muscle (Herrmann and Flanders, 1998), most of the motor units exhibit a cosine tuning function showing a unique preferred direction. Thus, whereas a single muscle may

be shared across muscle synergies, this sharing may be realized by incorporating the motor units of a given muscle into each synergy according to the preferred direction of each motor unit.

Transitions from fast discrete movements to rhythmic movement (Sternad et al., 2013) as well as transitions from slowly continuous movement to sub-movements (Teeken et al., 1996; van der Wel et al., 2009) reveal that the underlying controls for discrete and rhythmic movements are based on the same modules. Our results provide further evidence that muscular synergies underlying both types of movement are the same. Despite the fact that at the cerebral level the control of discrete vs. rhythmic movements has been shown to implicate different cortical areas (Schaal et al., 2004), the fact that directional discrete movements and rhythmic figure-eight present no differences in the three first principal components identified at the muscular level supports the hypothesis that discrete and rhythmic movements present the same neural control (Sternad et al., 2000, 2002; Sternad and Dean, 2003), at least at the level of synchronous muscular synergies.

The organization of those modules might, however, reflect higher levels of processing as well. In the case of our principal component decomposition, control would be shared between a co-contraction module and two reciprocal modules, the latter of which were surprisingly well aligned with the vertical and horizontal directions of movement (see also our companion paper for further evidence of this point). It is likely not a coincidence that the modules are oriented along these two canonical directions. One might hypothesize that the horizontal/vertical orientations of PC2 and PC3 are linked to the spatial characteristics of the figure eight, which was intrinsically orientated with the horizontal and vertical. But the PCA of our discrete movements was carried out separately from the computations on the figure eights, yet we found the same groupings in either case. Since the eight movement directions were equally spaced in all directions in the frontal plane, bias in the directions of movement cannot explain this phenomenon. Gravity itself acting on the arm could provide an explanation, as one might argue that the up/down synergies could take advantage of gravity as a driving force, reducing the amplitude of EMG modulation needed to produce movement in the vertical direction. But our EMG signals were normalized muscle-by-muscle, removing this as a possible explanation as well. On the other hand, there is ample evidence that human perception and visuomotor coordination is preferentially tuned to the vertical dimension tied to a multi-modal reference frame that includes the body axis and gravity (Howard, 1982; Paillard, 1991; Gentaz et al., 2001; McIntyre and Lipshits, 2008; Tagliabue and McIntyre, 2012). The organization of muscular synergies, which may be implemented at the level of the periphery, might nevertheless be tuned based on constraints defined in supraespinal areas involved with the processing of spatial information (Bizzi and Cheung, 2013).

CONCLUSIONS

In this study we set out to compare discrete and discrete-rhythmic movements, in terms of synchronous muscular synergies than can be identified through principal component and varimax factor analysis. To this question we found a remarkably clear result: the invariance of the synchronous synergies, be they identified by principal components or varimax factors. This result suggests that a common mechanism underlies both types of movements, at least in terms of purported synergies that underlie the generation of muscle activation patterns. It is perhaps somewhat surprising that the CNSc does not exploit the additional degrees of freedom for generating forces to tune the system differently for these two classes of movements.

The secondary question of whether the principal components or varimax decompositions better represent the modules use to produce a certain class of upper-limb movements remains open. The un-rotated principal components suggested an organization based on a co-contraction module plus two modules for reciprocal activation, one horizontal and the other vertical. The varimax decomposition indicated instead a set of three basis vectors used to construct forces in different directions. Based on the analyses presented here, we argue for the co-contraction plus reciprocal organization, because of the somewhat less variability in the principal component decomposition and on conceptual grounds. Nevertheless, the arguments presented here are admittedly not conclusive. In our companion article we search for further evidence to support our hypothesis by using an artificial neural network to identify the functional significance, in terms of movement, of the modules identified here.

Muscle synergies have been proposed as a way for the central nervous system (CNS) to simplify the generation of motor commands and they have been shown to explain a large fraction of the variation in the muscle patterns across a variety of conditions. However, whether human subjects are able to control forces and movements effectively with a small set of synergies has not been tested directly. Here we show that muscle synergies can be used to generate target forces in multiple directions with the same accuracy achieved using individual muscles. We recorded electromyographic (EMG) activity from 13 arm muscles and isometric hand forces during a force reaching task in a virtual environment. From these data we estimated the force associated to each muscle by linear regression and we identified muscle synergies by non-negative matrix factorization. We compared trajectories of a virtual mass displaced by the force estimated using the entire set of recorded EMGs to trajectories obtained using 4–5 muscle synergies. While trajectories were similar, when feedback was provided according to force estimated from recorded EMGs (EMG-control) on average trajectories generated with the synergies were less accurate. However, when feedback was provided according to recorded force (force-control) we did not find significant differences in initial angle error and endpoint error. We then tested whether synergies could be used as effectively as individual muscles to control cursor movement in the force reaching task by providing feedback according to force estimated from the projection of the recorded EMGs into synergy space (synergy-control). Human subjects were able to perform the task immediately after switching from force-control to EMG-control and synergy-control and we found no differences between initial movement direction errors and endpoint errors in all control modes. These results indicate that muscle synergies provide an effective strategy for motor coordination.

Keywords: non-negative matrix factorization, isometric force, reaching movements, myoelectric control, modularity, electromyography

INTRODUCTION

How the CNS coordinates a large number of muscles to control forces and movements is a long standing issue in neuroscience. Muscle synergies, coordinated recruitment of groups of muscles with specific activation balances or temporal profiles, have been proposed as building blocks employed by the CNS to simplify the generation of forces or movements (Jacobs and Macpherson, 1996; Tresch et al., 1999; Bizzi et al., 2002; d'Avella et al., 2003; Flash and Hochner, 2005; Giszter et al., 2007; Ting and McKay, 2007; Bizzi et al., 2008; d'Avella and Pai, 2010; Lacquaniti et al., 2012; Bizzi and Cheung, 2013; d'Avella and Lacquaniti, 2013). A small number of muscle synergies, identified by multidimensional factorization techniques such as non-negative matrix factorization (NMF) (Lee and Seung, 1999), independent component analysis (ICA) (Bell and Sejnowski, 1995), and other iterative algorithms (d'Avella and Tresch, 2002; Tresch et al., 2006; Omlor and Giese, 2011), have been shown to explain a large fraction of the variation in the muscle patterns in a variety of vertebrate species (Tresch et al., 1999; Saltiel et al., 2001; d'Avella et al., 2003; Hart and Giszter, 2004; Ivanenko et al., 2004; Cheung et al., 2005; Ting and Macpherson, 2005), across different behaviors and experimental conditions (d'Avella and Bizzi, 2005; Cappellini et al., 2006; d'Avella et al., 2006, 2008, 2011; Ivanenko et al., 2007; Torres-Oviedo and Ting, 2007; Overduin et al., 2008; Torres-Oviedo and Ting, 2010; Dominici et al., 2011; Hug et al., 2011; Chvatal and Ting, 2012; Frere and Hug, 2012; Roh et al., 2012; Chvatal and Ting, 2013; d'Andola et al., 2013; Gentner et al., 2013). These observations provide support to the existence of muscle synergies as neural control strategy employed by the CNS for motor coordination. However, they do not directly demonstrate that a small number of synergies is sufficient to generate the functional output of muscle patterns, i.e., the forces or movements necessary for accomplishing a task (Alessandro et al., 2013). Thus, in order to validate muscle synergies as a neural control strategy their functional consequences need to be investigated.

Torres-Oviedo et al. (2006) first investigated the functional consequences of muscle synergies by extracting synergies simultaneously from EMGs and foot contact forces during postural responses to multidirectional stance perturbations in cats. Such functional muscle synergies were able to explain both muscle activation patterns and endpoint forces in a range of postural configurations, thereby supporting a functional role for the synergies. A common set of functional muscle synergies were then also

found to explain different types of postural responses in human subjects (Chvatal et al., 2011). Furthermore, forward dynamics simulations using a musculoskeletal model of the human trunk, pelvis, and legs have shown that a small number of muscle synergies are sufficient to perform the basic sub-tasks of walking in two (Neptune et al., 2009) and three (Allen and Neptune, 2012) dimensions. More recently de Rugy et al. (2013) addressed the question of the functional consequences of muscle synergies in the context of isometric force generation at the wrist. They estimated forces as a linear function of EMGs recorded from five wrist muscles. Subject used such estimated forces to perform a force reaching task. de Rugy and collaborators then compared the forces estimated using EMGs with the forces estimated using synergies extracted from the EMGs. Four synergies explained most of the variation in the muscle patterns but they were not able to accurately reproduce the forces estimated using the recorded EMGs. However, estimated and real forces were not compared and it is not clear whether the apparent inaccuracy of the forces estimated using the synergies is specific to the wrist system.

Here, we extended the analysis of de Rugy et al. (2013) to a more complex and redundant system. We recorded muscle activity from 13 arm and shoulder muscles in humans performing a force reaching task in which a cursor in a virtual environment was displaced according to either the recorded isometric force (force-control) or the force estimated from the recorded EMGs (EMG-control). We compared the cursor trajectories executed during EMG-control with the trajectories reconstructed using synergies, as in de Rugy et al. (2013). However, we also performed two additional comparisons. First, we investigated the reconstruction of trajectories executed in force-control using synergies and individual muscles. Second, to explicitly validate the synergy hypothesis as a possible control principle, we directly tested whether subjects were able to control movements with synergies. We let subjects perform the force reaching task in force-control, in EMG-control, and in synergy-control, i.e., by projecting online each sample of the recorded muscle patterns in the synergy space, and we compared their performances across the three conditions.

We found that, across subjects, 4–5 synergies could capture adequately the EMG data variation but they were not sufficient to reconstruct the trajectories executed in EMG-control with the same endpoint accuracy, thus extending to the arm the results obtained for the wrist by de Rugy et al. (2013). However, when we compared the reconstructions of trajectories executed in force-control using individual muscles and synergies we did not find any significant difference in several performance measures. These results demonstrate that individual muscles and synergies perform equally well in the prediction of the applied forces that were generated by human subjects. Finally, we found that humans were not only able to perform the task immediately after switching from force-control to EMG-control and synergy-control, but they also did not show any differences in performance between the three conditions. These results demonstrate that human subjects can achieve similar performances in an isometric reaching task using a small number of synergies and using individual muscles.

MATERIALS AND METHODS

We asked naïve participants to reach targets on a virtual desktop by displacing a cursor (i.e., a virtual spherical handle) according to: (1) the force applied on a physical handle (force-control); (2) the force estimated from the EMG activity recorded from many shoulder and arm muscles (myoelectric or EMG-control); (3) the force estimated from the combination of the recorded EMG signals through a set of muscle synergies (synergy-control). Initially the reaching task was performed under force-control and, for each individual participant, the force and EMG data collected were used to estimate an EMG-to-force matrix by multiple linear regressions. EMG data collected during force-control or during EMG-control were also used to identify muscle synergies by non-negative matrix factorization. Such synergies were then used to reconstruct cursor trajectories executed in force- and EMG-control and to execute trajectories in synergy-control.

PARTICIPANTS

14 right-handed naïve subjects (mean age 26.0 years, *SD* 3.5, age range 20–34, 9 females) participated in the experiments after giving written informed consent. All procedures were conducted in conformance with the Declaration of Helsinki and were approved by the Ethical Review Board of Santa Lucia Foundation.

EXPERIMENTAL SET-UP

Subjects sat in front of a desktop on a racing car seat with their torso immobilized by safety belts, their right forearm inserted in a splint, immobilizing hand, wrist, and forearm. The center of the palm was aligned with the body midline at the height of the sternum and the elbow was flexed by approximately 90°. The subjects' view of their hand was either occluded by a 21-inch LCD monitor inclined with its surface approximately perpendicular to the subjects' line of sight when looking at their hand (**Figure 1A**) during Experiment 1 (see Experimental Protocols below) or by a mirror displaying the virtual scene co-located with the real desktop positioned above the mirror (**Figure 1B**) during Experiment 2. After calibration, the monitor could display a virtual desktop matching the real desktop, a spherical cursor matching, at rest, the position of the center of the palm and moving on a horizontal plane, and spherical targets on the same plane (**Figure 1C**). A steel bar at the base of the splint was attached to a 6-axis force transducer (Delta F/T Sensor, ATI Industrial Automation, Apex, NC, USA) positioned below the desktop to record isometric forces and torques. Surface electromyographic (EMG) activity was recorded from the following 13 muscles acting on the shoulder and elbow: brachioradialis (BracRad), biceps brachii short head (BicShort), biceps brachii long head (BicLong), triceps brachii lateral head (TriLat), triceps brachii long head (TriLong), infraspinatus (InfraSp), anterior deltoid (DeltA), middle deltoid (DeltM), posterior deltoid (DeltP), pectoralis major (PectMaj), teres major (TerMaj), latissimus dorsi (LatDorsi), middle trapezius (TrapMid). EMG activity was recorded with active bipolar electrodes (DE 2.1, Delsys Inc., Boston, MA), band-pass filtered (20–450 Hz) and amplified (gain 1000, Bagnoli-16, Delsys Inc.). Force and EMG data were digitized at 1 KHz using an A/D PCI board (PCI-6229, National Instruments, Austin, TX, USA). The virtual scene was rendered by a PC workstation with a refresh rate of 60 Hz using custom software. In Experiment 2 the scene was rendered stereoscopically using a 3D graphic card (Quadro Fx 3800, NVIDIA Corporation, Santa Clara, CA, USA) and shutter glasses (3D Vision P854, NVIDIA). Cursor position information was processed by a second

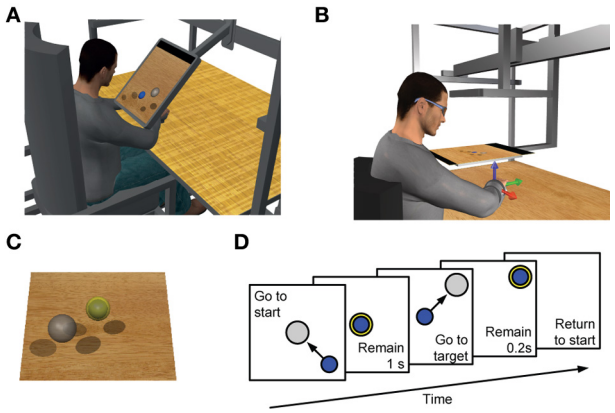

FIGURE 1 | Experimental setup and trial sequence. Subjects sat in front of a desktop and applied forces on a transducer attached to a forearm, wrist, and hand splint. In Experiment 1 a LCD monitor **(A)** and in Experiment 2 a mirror **(B)** occluded the subject's hand and displayed a virtual scene co-located with the real desktop. **(C)** Transparent spheres positioned on a horizontal plane with centers at the same height as the center of the palm indicated force targets that the subjects were instructed to reach with a smaller spherical cursor moving on the same plane according to the force applied (force-control) or estimated from EMGs recorded from 13 arm and shoulder muscles (EMG-control, see Materials and Methods), or estimated from recorded EMGs recombined using a set of synergies extracted using NMF (synergy-control, see Materials and Methods). **(D)** Subjects were instructed to perform a center-out reaching task in which they had to maintain the cursor in a central start location for 1 s, reach a target as soon as it appeared at one of 8 peripheral locations, and maintain the cursor at the target for 0.2 s. **(A)** and **(C)** adapted from Berger et al. (2013); **(B)** adapted from Borzelli et al. (2013).

workstation running a real-time operating system and transmitted to the first workstation. Cursor motion was simulated in real time using an adaptive mass-spring-damper (MSD) filter (Park and Meek, 1995). Either the actual force recorded by the transducer (force-control), or the force estimated in real-time from the recorded and rectified EMGs (myoelectric or EMG-control) using a linear mapping (EMG-to-force matrix, *see below*), or the force estimated in real-time from synergies using the EMG-to-force matrix (synergy-control, *see below*), was applied to a virtual mass attached to a reference position through a critically damped spring. The position of the cursor corresponded to the position of the virtual mass. The reference position matched the position of the center of the palm. To maintain fast response to changes in force while reducing the effect of myoelectric noise, the simulated mass was adapted dynamically according to the time derivative of the applied force magnitude. Further details can be found in Berger et al. (2013).

EXPERIMENTAL PROTOCOLS

In all experiments subjects initially performed two blocks of trials in force-control. In the first force-control block, the mean maximum voluntary force (MVF) along 8 directions (separated by 45 deg) in the horizontal plane was estimated as the mean of the maximum force magnitude recorded across 16 trials in which subjects were instructed to generate maximum force in each direction. Subjects were then instructed to move the cursor quickly from the rest position to a target in one of the 8 directions by applying forces on the splint. At the beginning of each trial (**Figure 1D**) subjects were requested to maintain the cursor within a transparent sphere at the central start position for 1 s (tolerance of 2% MVF). Next, a *go* signal was given by displaying a transparent target sphere while the start sphere disappeared. Subjects were instructed to reach the target as quickly as possible and to remain there for 0.2 s (tolerance of 2% MVF). After successful target acquisition the cursor and the target disappeared indicating the end of the trial. Trials had to be completed within 2 s from the *go* signal. In the second force-control block subjects performed 72 trials to targets positioned at force magnitudes corresponding to 10, 20, and 30% of MVF (random order within cycles of 8 directions). After this block there was a 5 min pause to process the recorded data in order to construct the myoelectric controller. All subsequent blocks consisted of 24 trials with targets at 20% MVF in random order within cycles of 8 directions.

Experimental protocol 1

Eight participants (numbered from 1 to 8) performed this protocol. Data collected in force-control and EMG-control mode in our previous study (Berger et al., 2013) were used in this study to reconstruct cursor trajectories with synergies. After two initial blocks of trials in force-control the rest of the experiment was performed in EMG-control. For the purpose of the present analysis we only considered the force-control block and the second EMG-control block. Further details of the experimental protocol are described elsewhere (Berger et al., 2013).

Experimental protocol 2

Six participants (numbered from 9 to 14) performed this protocol. After the initial two blocks of trials performed in force-control, the system switched to synergy-control, using the subject specific synergies from the initial force-control block (synergy-control, *see below*). After 6 blocks of synergy-control, three blocks of force-control were introduced; this was followed by 6 blocks of EMG-control. At the end of the experiment a final block in force-control was performed.

EMG-TO-FORCE MAPPING

If the arm is in a fixed posture, the force generated at the hand is approximately a linear function of the activation of muscles acting on shoulder and elbow:

$$\mathbf{f} = \mathbf{H}\mathbf{m} + \mathbf{e_f} \quad (1)$$

where $\mathbf{f}$ is the generated 2-dimensional force vector, $\mathbf{m}$ is the 13-dimensional vector of muscle activations, and $\mathbf{H}$ is a matrix relating muscle activation to force (dimensions 2×13), and $\mathbf{e_f}$ is a 2-dimensional vector of force residuals. The EMG-to-force matrix ($\mathbf{H}$) was estimated using multiple linear regressions of each applied force component, low-pass filtered (2nd order Butterworth, 1 Hz cutoff), with EMG signals recorded during the initial force-control block (dynamic phase, i.e., time from target go until the target has been reached), low-pass filtered (2nd order Butterworth, 5 Hz cutoff), and normalized to the maximum EMG activity during the generation of MVF. We verified that the choice of filter parameters for the estimation of the $\mathbf{H}$

matrix did not affect the quality of the force reconstruction during EMG-control by investigating different force and EMG cutoff frequencies. **Figure 2A** illustrates an example of the columns of the EMG matrix (i.e., the force associated to each muscle, $\mathbf{h_i}$) estimated in subject 2.

SYNERGY EXTRACTION

Muscle synergies were identified by NMF (Lee and Seung, 1999) from EMG patterns from the go signal to target acquisition (dynamic phase):

$$\mathbf{m} = \mathbf{W}\mathbf{c} + \mathbf{e_m} \tag{2}$$

with $\mathbf{W}$ a $M \times N$ synergy matrix whose columns are vectors specifying relative muscle activation levels (N number of synergies, and M number of muscles), and $\mathbf{c}$ a N-dimensional synergy activation vector, and $\mathbf{e_m}$ is a M-dimensional vector of muscle activation residuals. For the comparison between trajectories executed in EMG-control and their reconstruction using synergies EMG patterns recorded during EMG-control were used for synergy extraction. For the comparison of trajectories from data collected during force-control EMG patterns recorded during force-control were used for synergy extraction. EMG patterns were first low-pass filtered (2nd order Butterworth filter, 5 Hz cutoff frequency) and rectified, their baseline noise level was then subtracted, and finally they were normalized to the maximum EMG activity of each muscle recorded during the generation of MVF. Baseline noise was estimated at the beginning of the experiment and updated periodically throughout the experiment while the subject was relaxed. For each possible N from 1 to M, the extraction algorithm was repeated 10 times and the repetition with the highest reconstruction R^2 was retained. **Figure 2B** illustrates an example of the set of 4 synergies extracted in subject 2.

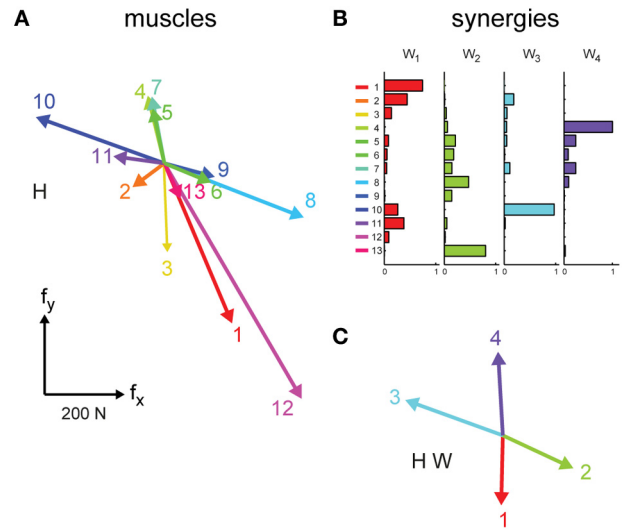

FIGURE 2 | EMG-to-force mapping and synergies. (A) EMG-to-force matrix H estimated for subject 2 in Experiment 1 from EMG and force data recorded during the performance of the task in force-control. Each column of H, representing the planar force generated by one muscles, is illustrated by a colored arrow (1: brachioradialis, 2: biceps brachii short head, 3: biceps brachii long head, 4: triceps brachii lateral head, 5: triceps brachii long head, 6: infraspinatus, 7: anterior deltoid, 8: medial deltoid, 9: posterior deltoid, 10: pectoralis major, 11: teres major, 12: latissimus dorsi, 13: middle trapezius). **(B)** Muscle synergies (matrix W) identified by non-negative matrix factorization from the EMG data of subject 2 collected in the force-control block of Experiment 1. Each column of W, a vector specifying a specific pattern of relative level of muscle activation, is illustrated by color-coded horizontal bars. **(C)** Forces associated to the muscle synergies [W, shown in **(B)**] through the EMG-to-force matrix [H, shown in **(A)**], i.e., the columns of the matrix product H W (synergy-to-force matrix). Adapted from Berger et al. (2013).

NUMBER OF SYNERGIES

For each subject the number of synergies adequately capturing the EMG data (N) was selected according to the fraction of data variation explained, defined as $R^2_{EMG} = 1\text{-}SSE_{EMG}/SST_{EMG}$, where SSE_{EMG} is the sum of the squared muscle activation residuals and SST_{EMG} is the sum of the squared residuals of the muscle activation from its mean vector. We considered two criteria. The first criterion was a threshold of 0.9 on R^2_{EMG}. The second criterion was based on the detection of a change in slope in the curve of the R^2 value as a function of N. A series of linear regressions were performed on the portions of the curve included between N and its last point (M). N was then selected as the minimum value for which the mean squared error of the linear regression was less than 10^{-4}. In case of mismatch between the two criteria, the larger N was chosen.

EMG- AND SYNERGY-CONTROL

Output forces $\mathbf{f}$ during EMG-control were computed using the EMG-to-force mapping ($\mathbf{H}$) and the recorded muscle activity $\mathbf{m}$ (compare EMG-to-force mapping), i.e., by

$$\mathbf{f} = \mathbf{H}\,\mathbf{m} \tag{3}$$

thus allowing for individual muscle control. During synergy-control muscle activity was substituted by the product of the initially extracted subject-specific synergies ($\mathbf{W}$) and estimated synergy coefficients ($\hat{\mathbf{c}}$), i.e., by $\mathbf{f} = \mathbf{H}\,\mathbf{W}\,\hat{\mathbf{c}}$, where $\mathbf{H}\,\mathbf{W}$ is the synergy-to-force mapping (illustrated in **Figure 2C** for subject 2). Synergy coefficients were estimated by projecting recorded muscle activity onto the synergy space, i.e., by $\hat{\mathbf{c}} = \mathbf{W}^{+}\,\mathbf{m}$, where $\mathbf{W}^{+}$ is the pseudo inverse of $\mathbf{W}$, corresponding to estimating $\hat{\mathbf{c}}$ from $\mathbf{m}$ as least squares solution of $\mathbf{m} = \mathbf{W}\,\mathbf{c}$. Thus, during synergy-control output forces were computed as:

$$\mathbf{f} = \mathbf{H}\,\mathbf{W}\,\mathbf{W}^{+}\mathbf{m} \tag{4}$$

TRAJECTORY RECONSTRUCTION USING EMGS AND SYNERGIES

Cursor trajectories executed in EMG-control, i.e., computed online as the displacement of a virtual mass-spring-damper system under the force estimated by Equation 3, were reconstructed using synergies, i.e., by computing offline how the cursor would have been displaced using the forces computed by Equation 4. Similarly, cursor trajectories executed in force-control, i.e., computed online as the displacement of a virtual mass-spring-damper system under the recorded force, were reconstructed using EMGs, i.e., using the forces computed by Equation 3, and synergies, i.e., using the forces computed by Equation 4.

PERFORMANCE MEASURES

We compared cursor trajectories driven by EMGs, i.e., either executed in EMG-control (EC) or reconstructed by EMGs (ER) during force-control, with trajectories reconstructed by synergies (SR) during either EMG- or force-control, by assessing the fraction of EMG-driven trajectory variation explained, $R^2_{traj} = 1 - SSE_{traj}/SST_{traj}$, where SSE_{traj} is the sum of the squared trajectory residuals and SST_{traj} is the sum of the squared residuals of the EMG-driven trajectory from its mean vector. We also compared cursor trajectories computed from recorded forces with trajectories reconstructed by EMGs (ER) or synergies (SR) during force-control by assessing the fraction of force-driven trajectory variation explained with a similarly defined $R^2_{traj\text{-}force}$ measure. Both such measures quantified the similarity of the entire time course of two sets of trajectories. We then also compared performances at the beginning of the movement, quantifying an initial angle error, and at the end of each movement, quantifying an endpoint error. Initial angle error was defined as the angular deviation of the initial movement direction of the cursor with respect to target direction. The angular deviation was computed as $abs(\vartheta_{target} - \vartheta_{cursor})$, where ϑ_{target} is the target direction and ϑ_{cursor} is the direction of the displacement between the position of the cursor at movement onset and at the first following peak of its tangential velocity. Taking the absolute value avoided cancellations when averaging the values of the angular deviations across targets with different signs for the difference between target direction and cursor initial direction. Endpoint error was defined as the Euclidean distance, normalized to target distance from the origin, between the target position and the mean cursor position during the 0.2 s following the cursor's entrance into the target region. Finally, in Experiment 2, we compared the fraction of unsuccessful trials, i.e., the fraction of trials in which the cursor did not reached and remained in the target within the instructed time intervals, during the task execution in EMG-control and in synergy-control.

STATISTICAL ANALYSIS

Differences in performance measures were assessed either by *t*-test statistics (paired, two-tailed) if the data were distributed normally (according to a Lilliefors test) or by Wilcoxon ranksum test otherwise.

RESULTS

SYNERGY RECONSTRUCTION OF CURSOR TRAJECTORIES DURING EMG-CONTROL

To address the question whether a small set of muscle synergies not only explains a large fraction of the variation of the muscle activity but can also generate the forces necessary to perform an isometric reaching task accurately, we compared the trajectories performed by human subjects during EMG-control (EC) with the trajectories reconstructed using the subject-specific synergies (synergy-reconstructed, SR). **Figures 3A,B** illustrate examples of EC (*green*) and SR (*red*) trajectories for 8 different targets in one subject. **Figure 3C** shows the corresponding filtered EMGs traces (*gray area*) and their synergy reconstruction (*red line*) using four synergies (**Figure 2B**). These synergies adequately captured the muscle patterns across directions and muscles. For each direction a different combination of synergy coefficients is used (**Figure 3D**), e.g., in direction 0° (1st column) synergy 2 and 4 are recruited, whereas in direction 225° (6th column) synergies 1 and 3 are recruited. The directional tuning of all four synergies is well captured by a cosine functions (**Figure 3E**, see also Borzelli et al., 2013; Gentner et al., 2013). The SR trajectories show a high similarity to the EC trajectories in each of the eight target directions. To quantify similarity, we first computed the fraction of EC trajectory variation (R^2_{traj}) explained by trajectories reconstructed using for each subject a number of synergies adequately capturing the EMG data variation (R^2_{EMG}, see Methods) which varied across subjects between 4 and 5 (see **Table 1**). On average across subjects ($n = 8$) we found that SR trajectories reconstructed accurately EC trajectories (mean R^2_{traj} value 0.96 ± 0.03 *SD*, range: 0.89–0.98, **Table 1**). We then assessed the mean similarity of EC and SR trajectories as a function of the number of synergies (N) used for the reconstruction (**Figure 4A**, averages across subjects, $n = 8$). Five synergies were sufficient to reconstruct the EC trajectories with an average R^2_{traj} value larger than 0.9 (mean R^2_{traj} values were 0.89 and 0.97, for $N = 4$ and 5, respectively).

To assess the performance of the synergy reconstruction at the beginning of the movement, we then compared the initial angle error of EC and SR trajectories (**Table 1** and **Figure 4B**). Using for each subject a number of synergies adequately capturing the EMG data variation (see **Table 1**), we did not find any significant differences between the mean initial angle error of EC and SR trajectories (**Table 1**, $p = 0.087$, *t*-test, $n = 8$). **Figure 4B** (*red*) shows the mean initial angular error of SR trajectories as a function of the number of synergies (N), averaged across subjects ($n = 8$), in comparison with the mean error of EC trajectories (*green*). While the trajectories reconstructed with 4 synergies had a significantly larger angle error than EC trajectories ($p = 0.027$, $N = 4$, $n = 8$, *t*-test with mean values ± *SD* of 15.1 ± 5.5°, with respect to 8.9 ± 2.5° in EC), there was no significant difference between the error of EC trajectories and the error of trajectories reconstructed using 5 synergies ($p = 0.14$, $N = 5$, $n = 8$, *t*-test, mean value ± *SD*: 14.7 ± 10.2).

To assess the performance of the synergy reconstruction at the end of the movement and to make a direct comparison to the results of de Rugy et al. (2013), we also estimated the endpoint error of the trajectories (**Table 1** and **Figure 4C**). When comparing the endpoint error of the EC and SR trajectories we found similar results to those of de Rugy et al. (2013). Using for each subject a number of synergies adequately capturing the EMG data variation (see **Table 1**) we found a significant difference between the mean endpoint errors of EC and SR trajectories ($p = 0.00015$, Wilcoxon ranksum test, $n = 8$). Comparing the endpoint errors of EC and SR trajectories as a function of the number of synergies, we also found a significant difference between average endpoint errors for both four and five synergies ($p = 0.0002$ and $p = 0.0003$, for $N = 4$ and $N = 5$, Wilcoxon ranksum test, $n = 8$. Mean ± *SD* 0.22 ± 0.12 and 0.12 ± 0.05 for $N = 4$ and $N = 5$, respectively, compared to 0.067 ± 0.005 during EC). However, the analysis of individual subjects revealed a high inter-subject variability (**Figure 4D**). There was no significant difference between the endpoint error of EC and SR trajectories using 5 synergies for three out of eight subjects ($p = 0.3481$, $p = 0.2883$, and

Table 1 | Number of synergies estimated from EMG-patterns in EMG-control (Experiment 1), fraction of EMG data variation explained, and performance measures for individual subjects of EMG-control trajectories (EC) and trajectories reconstructed using synergies (SR).

Subject Id	1	2	3	4	5	6	7	8	Mean ± *SD*
Number of synergies	5	4	5	4	5	5	5	4	4.6 ± 0.5
R^2_{EMG}	0.93	0.95	0.95	0.95	0.93	0.96	0.93	0.93	0.94 ± 0.01
R^2_{traj} (EC reconstruction by SR)	0.97	0.98	0.98	0.97	0.96	0.98	0.89	0.94	0.96 ± 0.03
Initial angle error [deg] (SR)	10.5	9.8	17.0	13.4	30.1	6.0	30.5	8.0	15.7 ± 9.6
Initial angle error [deg] (EC)	14.4	8.1	9.3	7.7	8.1	6.1	9.7	7.4	8.9 ± 2.5
Endpoint error (SR)	0.12	0.10	0.11	0.11	0.17	0.11	0.20	0.17	0.14 ± 0.04
Endpoint error (EC)	0.08	0.06	0.06	0.07	0.07	0.06	0.07	0.07	0.07 ± 0.005

$p = 0.9589$ for subjects 2, 4, and 8, with $N = 5$) and for one subject using 4 synergies ($p = 0.0764$ for subject 1).

In summary, we found on average a high similarity between cursor trajectories under EMG-control and trajectories reconstructed using a set of synergies which adequately explained EMG data variation. Moreover, the mean initial angle error, indicative of the accuracy of the feed-forward commands, was not different between trajectories executed in EMG-control and trajectories reconstructed using synergies. However the mean endpoint error, more sensitive to feedback control, was larger for trajectories reconstructed using synergies than for trajectories executed using EMG-control of individual muscles.

SYNERGIES RECONSTRUCTION OF CURSOR TRAJECTORIES DURING FORCE-CONTROL

As inaccuracies in the EMG-to-force mapping could be corrected by online adjustments in EC while inaccuracies in the synergy-to-force mapping could not be corrected in the offline reconstruction by synergies, we also compared the trajectories reconstructed using the EMG data (ER) recorded while human subjects performed the isometric reaching task in force-control (FC) with the trajectories reconstructed using subject specific synergies (SR). We quantified the similarity of ER trajectories with SR trajectories by computing the fraction of ER trajectory variation explained by SR trajectories (R^2_{traj}, **Table 2** and **Figure 5A**). When we used, for each subject, a number of synergies adequately explaining EMG data variation (**Table 2**), we found, across subjects ($n = 8$), a mean R^2_{traj} value of 0.88 ± 0.08 *SD* (**Table 2**). When we considered the mean R^2_{traj} value as a function of the number of synergies (**Figure 5A**), we found that the mean R^2_{traj} value was 0.85 ± 0.10 with four synergies and 0.93 ± 0.06 with five. We also compared how ER and SR trajectories reconstructed FC trajectories by computing the ratio of the fraction of FC trajectory variation explained ($R^2_{traj\text{-}force}$) by SR and by ER trajectories (**Table 2** and **Figure 5B**). Selecting a number of synergies, for each subject, adequately capturing EMG data variation we found a mean $R^2_{traj\text{-}force}$ ratio (SR/ER) of 0.92 ± 0.11 (*SD*). Averaging the $R^2_{traj\text{-}force}$ ratio across subjects as a function of the number of synergies (**Figure 5B**) we found that 5 synergies reached a value of 0.96 ± 0.09 (*SD*). Thus, during force-control, we found a high similarity between the trajectories reconstructed using the entire set of recorded muscles and those reconstructed using only a small number of synergies.

We then compared the initial angle error of ER and SR trajectories. **Figure 5C** shows the average errors for ER trajectories and SR trajectories using, for each subject, a number of synergies which captured EMG data variation adequately. We found no significant differences between mean errors for ER and SR trajectories ($p = 0.26$, *t*-test, $n = 8$, mean ± *SD* 18.5 ± 8.2° and 15.5 ± 5.3 for ER). We also found no significant difference between the mean angle error of ER trajectories and the mean error of SR trajectories reconstructed using 4 synergies ($p = 0.17$ for $N = 4$ synergies, *t*-test, $n = 8$, with mean values of 18.4 ± 5.9° for SR and as above for ER). Finally, comparing the endpoint error of ER to SR trajectories (**Table 2** and **Figure 5D**) we found no significant differences between the average errors using the subject-specific number of synergies ($p = 0.19$, $n = 8$, Wilcoxon ranksum test, mean ± *SD*: 0.46 ± 0.09 for SR and 0.40 ± 0.06 for ER) as well as when using 4 synergies for all subjects ($p = 0.10$, $n = 8$, Wilcoxon ranksum test, mean ± *SD* for SR: 0.46 ± 0.09). Thus individual muscles and synergies showed similar performance during force-control.

PERFORMANCE DURING SYNERGY-CONTROL, EMG-CONTROL, AND FORCE-CONTROL

We then investigated how well subjects were able to control the cursor directly with the synergy activation estimated online from the recorded EMGs, i.e., in synergy-control (SC) mode, by comparing their performances in FC, SC, and EC. In SC we used for each subject a number of synergies adequately capturing EMG data variation (**Table 3**). Subjects were able to control the cursor in SC and EC mode immediately after FC. **Figure 6A** shows examples of the trajectories for the first three movements in each of the eight directions performed in each control mode by one subjects. In these examples, all trials except one (bottom right target in EC) were successful. On average across subjects only 2.8 ± 3.4% (*SD*) of the trials in SC and 3.5 ± 6.7% of the trials in EC were unsuccessful while all trials were successful in FC for all subjects. The differences in the fraction of unsuccessful trials between all conditions were not significant (*t*-test, $n = 6$; SC–EC: $p = 0.72$; FC–SC: $p = 0.10$; FC–EC: $p = 0.26$).

We first assessed the subjects' performance by comparing initial angle errors (**Figure 6B**). There was no significant difference in angle error for the pairwise comparisons of the three different control modes (FC–SC: $p = 0.067$; SC–EC: $p = 0.15$; FC–EC: $p = 0.13$, *t*-test, $n = 6$, mean values ± SD for FC, SC, and EC, respectively, were: 7.7 ± 2.5, 11.6 ± 3.8, and 9.7 ± 3.9°). We then

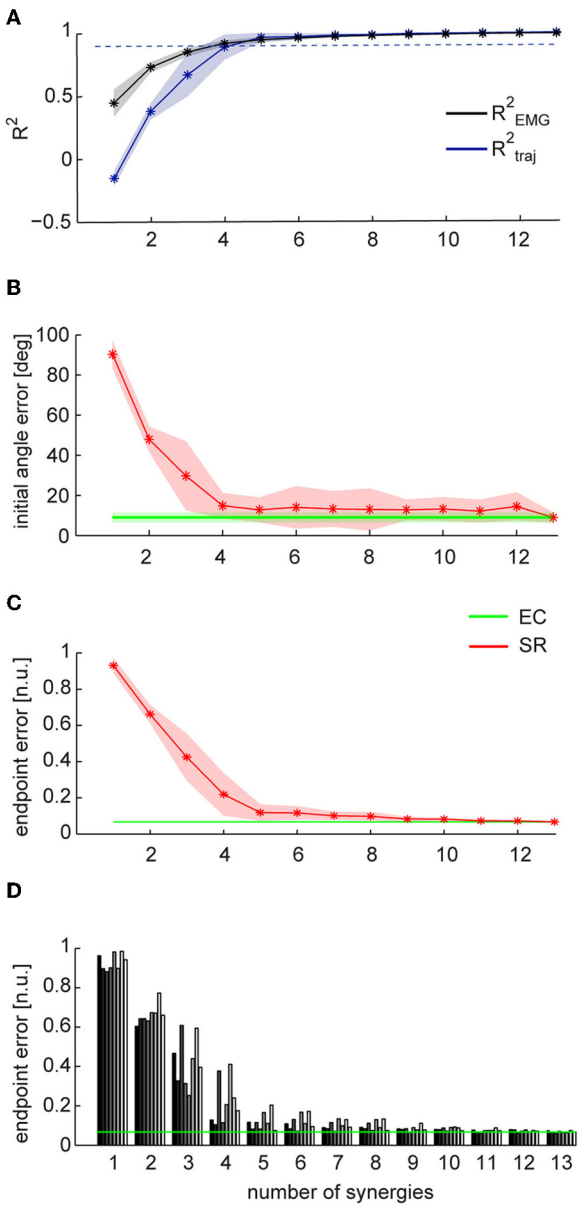

FIGURE 4 | Comparison between trajectories executed in EMG-control and trajectories reconstructed using synergies. (A) Mean fraction of EMG data variation explained by synergies (R^2_{EMG}, *black*) and mean fraction of EC trajectory variation explained by SR trajectories (R^2_{traj}, *blue*) as a function of the number of synergies ($n = 8$, shaded areas indicate SD, dashed line indicate 0.9 R^2). **(B)** Mean initial angle error for EC and SR trajectories as a function of the numbers of synergies. **(C)** Mean endpoint error (normalized to target distance from the origin, *n.u.: normalized units*) for EC and SR trajectories as a function of the number of synergies.**(D)** Endpoint error of SR trajectories for individual subjects (bars with different gray levels) as a function of the number of synergies. Average endpoint of EC trajectories across subject is indicated by the *green* line.

investigated the endpoint error (**Figure 6C**). We also found no significant difference in the endpoint error for the pairwise comparisons of the three different control modes (FC–SC: $p = 0.94$; FC–EC: $p = 0.89$; SC–EC: $p = 0.91$, t-test, $n = 6$, mean values ± *SD* for FC, SC, and EC, respectively, were: 0.072 ± 0.005, 0.070 ± 0.006, and 0.067 ± 0.006). In summary, during all three control modes subjects were able to control the cursor accurately and there were no significant differences in initial angular error and endpoint error.

DISCUSSION

As in many previous studies, we found that a small number of muscle synergies explained a large fraction of the variation of the muscle patterns recorded during different task conditions. In this study, however, we focused on the question whether a small number of muscle synergies can accurately generate the forces involved in the task and, ultimately, whether muscle synergies can be used to perform the task effectively. We first tested whether trajectories of a virtual mass displaced by EMG activity recorded from 13 arm muscles during an isometric reaching task could be reconstructed with similar accuracy using the combinations of the same muscle activities into a small number of muscle synergies identified by NMF. Our results showed that the trajectories reconstructed using 4–5 synergies were as accurate as the trajectories obtained by displacing a virtual cursor according to the hand force estimated from EMGs recorded from the entire set of muscles when considering the initial movement direction error but not in terms of endpoint error. However, these results were not consistent across subjects, as for some subjects we found no difference in endpoint error using 4 or 5 synergies. We then assessed whether the availability of feedback in EMG-control mode could explain the lower endpoint accuracy of the synergies by comparing the reconstructions of the trajectories executed in force-control using synergies and using the entire set of muscles. Indeed, in force-control cursor movements depended only on the applied force and did not provide any information on the inaccuracy likely present in the EMG-to-force and synergy-to-force mappings used for the reconstruction. Trajectories reconstructed using synergies were not significantly different from trajectories reconstructed using individual muscles suggesting that the difference between the trajectories generated during EMG-control and their reconstruction by synergies observed in some subjects were due to online adjustments performed during the EMG-control mode. Finally, we explicitly tested whether human subjects were able to control a virtual cursor and to perform successfully a force reaching task by synergy recruitment. In synergy-control mode the cursor movement depended only on the portion of the recorded EMGs that could be reconstructed by synergy combinations. Subjects were able to control the cursor in synergy-control mode immediately after switching from force-control mode and there were no significant differences in performance between the three control modes.

As mentioned in the Introduction, several studies have provided evidence supporting the hypothesis that movements are controlled by a limited set of modules or muscle synergies. However, most of these studies focused on how well synergies describe muscle patterns, showing that a small number of synergies capture a large fraction of the muscle pattern variation across task conditions and often that such synergies are robust across different tasks, but they did not directly address the question whether synergies can be used by the CNS to effectively

Table 2 | Number of synergies estimated from EMG-patterns in force-control (Experiment 1), fraction of EMG data variation explained, and performance measures for individual subjects of trajectories reconstructed using EMGs (ER) and synergies (SR) during force-control.

Subject Id	1	2	3	4	5	6	7	8	Mean ± *SD*

accomplish a task. Thus, in order to validate the synergy hypothesis it must be demonstrated that a small number of synergies are sufficient to generate the forces or movements necessary for accurate task performance. Two recent studies have addressed the functional role of the muscle synergies underlying postural responses to stance perturbations in cats (Torres-Oviedo et al., 2006) and in humans (Chvatal et al., 2011) by using NMF to simultaneously extract synergies from EMG data and kinetic data (contact forces, center of mass accelerations). Such functional muscle synergies could explain both muscle activation patterns and kinetic data in a range of postural configurations and in different types of responses, suggesting that muscle synergies are responsible for the control of specific biomechanical functions shared across task conditions. Consistent functional roles of muscle synergies have also been demonstrated in dynamic simulations of human pedaling and walking (Raasch and Zajac, 1999; Neptune et al., 2009; Allen and Neptune, 2012). Identification of functional muscles synergies, however, relies on the assumption of a linear relationship between EMGs and kinetic variables which might be valid only in limited conditions. Similarly, accurate forward dynamic simulations using muscle synergies depend on many musculoskeletal parameters that are difficult to validate and require fine-tuning of the muscle excitation patterns. Thus, these studies do not provide direct evidence that a small set of muscle synergies is sufficient for achieving accurate task performance.

A recent study by de Rugy et al. (2013) investigated the relation between synergies and task performance in humans by comparing force trajectories generated under EMG-control during an isometric reaching task, similar to the one used in the present study but involving only five wrist muscles, with the trajectories reconstructed using muscle synergies. One advantage of this experimental approach is that task performance depends on a well-defined linear transformation of the recorded EMGs, even if such linear mapping is not an accurate estimate of the real EMG-to-force mapping. de Rugy and collaborators found that four synergies on average explained more than 90% of the EMG data variation but they reconstructed cursor trajectories with a much higher endpoint error than the error of the trajectories executed in EMG-control. The authors claimed that synergy decomposition introduces substantial task space errors and concluded that applying synergy decomposition onto a set of available muscles appears of little use to best reconstruct the motor output in task space.

In the present study we have addressed the issue of whether muscle synergies can accurately reconstruct and generate forces in a number of ways. First, we performed the same analysis that de Rugy and collaborators performed on the wrist system (using EMG activity recorded from five muscles) on the more complex arm system (using EMG activity recorded from 13 muscles). We compared the endpoint error of cursor trajectories during EMG-control of a reaching task with the endpoint error of trajectories reconstructed using synergies. We found, on average across subjects, that a small number of synergies were not sufficient to reach the same endpoint accuracy as during EMG-control, thus replicating for the arm the results by de Rugy et al. (2013) for the wrist. However, investigation of individual subjects showed that this result was inconsistent across subjects. For half of the subjects synergy reconstruction using 4 or 5 synergies was sufficient to reach the same performance as during EMG-control. Moreover, as our subjects were instructed to reach the target with a fast reaching movement and were not required to minimize endpoint error, we also compared the entire cursor trajectories and the initial directional error and we found no significant differences between EMG-control and reconstruction with a number of synergies adequately explaining the EMG data.

Second, as the comparison of EMG-control and synergy reconstruction may be biased by the use of online feedback, we also compared EMG and synergy reconstruction of cursor trajectories generated by recorded forces. In EMG-control cursor trajectories are generated by forces estimated using EMG signals and not by the recorded forces and subjects were able to exploit feedback to correct inaccuracies in the estimated EMG-to-force mapping. However, inaccuracies in the synergy-to-force mapping may require different corrections unavailable in the offline synergy reconstruction. We therefore argue that in order to conclude that synergy decomposition decreases task performance with respect to individual muscle control, one needs either to compare experimental conditions in which online corrections to both EMG-to-force and synergy-to-force inaccuracies are possible (as in our second experimental protocol), or to compare the reconstructions, using individual muscles and synergies, of trajectories executed in force-control mode, in which neither EMG-to-force nor synergy-to-force inaccuracies can be corrected. When we compared the trajectories reconstructed using synergies and using individual EMGs using data collected while the task was performed in force-control mode we did not find any significant difference.

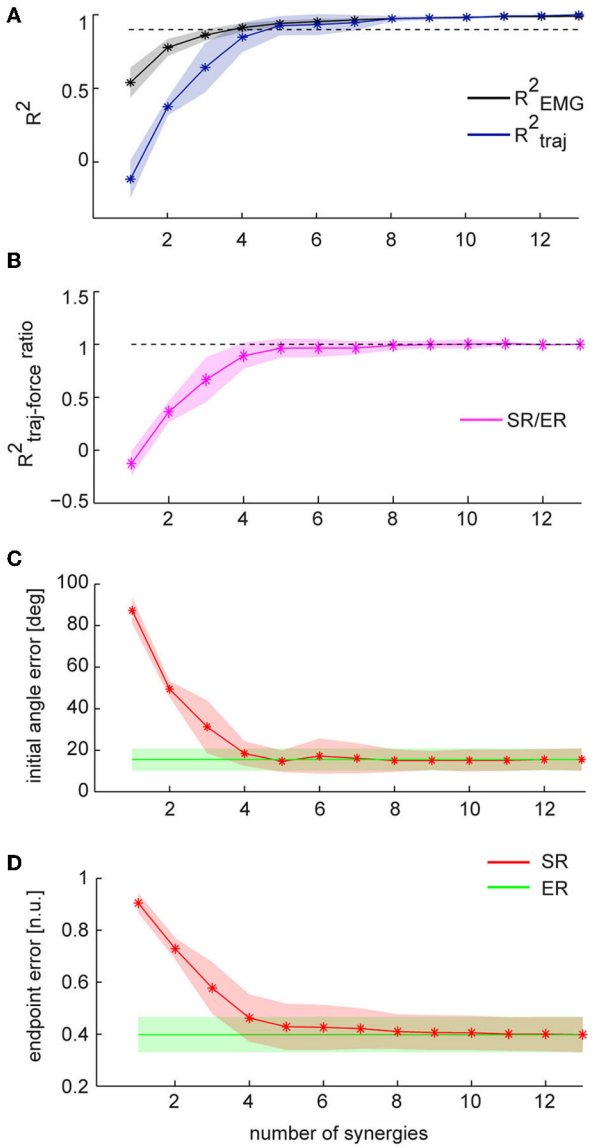

FIGURE 5 | Comparison between trajectories reconstructed using individual muscles and synergies during task performance in force-control. Trajectories reconstructed using EMG data (ER) are shown in *green*; trajectories reconstructed using synergies (SR) are shown in *red*. **(A)** Mean fraction of EMG data variation explained by synergies (R^2_{EMG}, *black*) and mean fraction of ER trajectory variation explained by SR trajectories (R^2_{traj}, *blue*) as a function of the number of synergies ($n = 8$, shaded areas indicate SD, dashed line indicate 0.9 R^2). **(B)** Mean of the ratio between the fraction of FC trajectory variation ($R^2_{traj\text{-}force}$) explained by SR trajectories and the fraction of FC trajectory variation explained by ER trajectories. Dashed line indicate a ratio of 1. **(C)** Mean initial angle error for ER and SR trajectories as a function of the numbers of synergies. **(D)** Mean endpoint error (normalized to target distance from the origin) for ER and SR trajectories as a function of the number of synergies.

These results indicate that the trajectories reconstructed using synergies are not as accurate as the trajectories executed in EMG-control because of online feedback corrections during EMG-control.

Third, we directly demonstrated the effectiveness of a small number of synergies in generating the forces involved in a reaching task by showing that subjects were able to control the cursor accurately with the synergies. We compared performances when subjects controlled the cursor with synergies to performances in EMG-control and force-control. Remarkably, subjects were able to perform the task immediately after switching from force-control to synergy-control and they did not show significant differences in initial angle error and endpoint error between the three control models. These results show that subjects were able to control a cursor in a reaching task using synergies with similar performance as during force-control and EMG-control.

Finally, de Rugy et al. (2013) examined the wrist system, which has a relatively low muscle redundancy, and it might not require synergistic control. They also drew similar conclusions analyzing arm muscle pattern that were simulated as to generate the target forces, using an EMG-to-force mapping derived from a biomechanical model, with minimal summed squared muscle activations (Fagg et al., 2002). They justified the use of simulated data for assessing the task efficacy of muscle synergies also in the more complex arm system with the observation that wrist simulated data show a fraction of variance explained by synergy decomposition and endpoint error of trajectories reconstructed using synergies similar to those obtained with experimental data. However, the similarity between simulated and experimental data in the weakly redundant wrist system might be due to the lack of synergistic control in such system. In contrast, simulated data might have a different synergy decomposition than experimental data collected in the arm system if this is controlled synergistically. In fact, a recent study by Borzelli et al. (2013) investigating muscle patterns of the arm underlying isometric force generation has shown that the estimated minimum effort recruitment of individual muscles does not adequately capture the observed muscle activation patterns. Thus, using simulated muscle patterns de Rugy et al. (2013) did not test whether a small number of synergies could achieve good task performance in the arm system. Not surprisingly the simulated data had a high dimensionality and the synergy decomposition resulted in higher aiming errors than individual muscles. However, if the data had been generated by combinations of a small number of synergies their decomposition into the same number of synergies would have achieved the same task performance as individual muscles. Thus, the results of these simulations, because they depend on the assumptions made for data generation, cannot lead to any conclusion on whether the CNS does employ synergies for simplifying control.

The number of synergies used for reconstructing cursor trajectories executed in force- and EMG-control and for projecting recorded EMG data in synergy-control is a critical parameter that has a major effect on the task space accuracy. We selected the number of synergies, a free parameter in the NMF decomposition of the EMG data, comparing the EMG data variation accounted by different number of synergies (R^2_{EMG}). We considered two criteria used in many previous studies of muscle synergies: the minimum number of synergies with R^2_{EMG} over 90% (Tresch et al., 1999; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006; Roh et al., 2012; Delis et al., 2013) and the number of synergies at which the slope of the R^2_{EMG} curve has a change in

Table 3 | Number of synergies extracted from EMG-patterns in force-control (Experiment 2), fraction of EMG data variation explained, and performance measures for individual subjects of trajectories executed in force-control (FC), synergy-control (SC), and EMG-control (EC).

Subject Id	9	10	11	12	13	14	Mean ± *SD*
Number of synergies	5	5	7	6	5	5	5.5 ± 0.8
R^2_{EMG}	0.92	0.93	0.97	0.93	0.95	0.92	0.93 ± 0.02
Initial angle error [deg] (FC)	6.4	12.0	6.3	7.9	8.9	4.8	7.7 ± 2.5
Initial angle error [deg] (SC)	8.7	13.9	18.4	9.4	10.7	8.8	11.6 ± 3.8
Initial angle error [deg] (EC)	6.6	14.9	12.6	7.0	12.2	5.0	9.7 ± 3.9
Endpoint error (FC)	0.070	0.075	0.078	0.068	0.074	0.065	0.072 ± 0.005
Endpoint error (SC)	0.075	0.075	0.073	0.060	0.070	0.067	0.070 ± 0.006
Endpoint error (EC)	0.064	0.061	0.077	0.069	0.065	0.070	0.067 ± 0.006

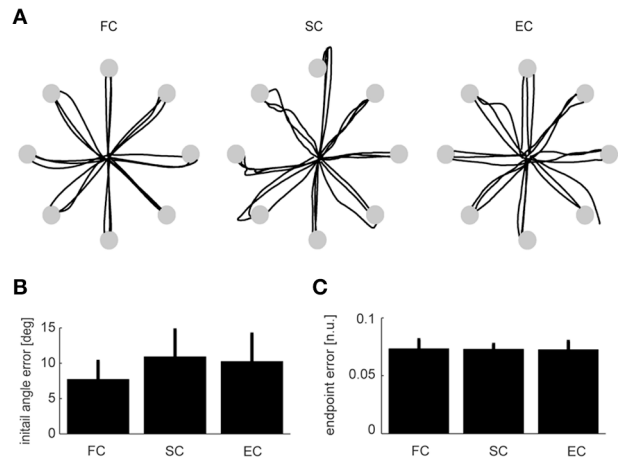

FIGURE 6 | Comparison between trajectories during force-control, synergy-control, and EMG-control. (A) Examples of cursor trajectories during the execution of individual trials to the eight different targets during force-control (FC, *left*), synergy-control (SC, *middle*), and EMG-control (EC, *right*) for subject 9. Cursor trajectories are shown up to the time of arrival at the target (gray disks) or until the end of the trials in the target was not reached. **(B,C)** Averages across subjects (Experiment 2, $n = 6$) of the mean initial angle error **(B)** and mean endpoint error **(C)** over all the trials in the first block performed in FC, SC, and EC. Error bars indicate SD across subjects. All pairwise comparisons were not significant (see text).

slope (d'Avella et al., 2003; Cheung et al., 2005; d'Avella et al., 2006; Tresch et al., 2006; Delis et al., 2013). When the number of synergies selected by the two criteria did not match we chose the largest number to ensure the best reconstruction of the EMG data when analyzing task performance. However, both criteria depend on *ad-hoc* thresholds and they do not ensure the selection of the correct number of synergies. Importantly, we noticed that adding a single synergy may sometimes have a small effect on R^2_{EMG} but a large effect on the quality of the reconstruction of EMG-control trajectories using synergies (R^2_{traj}) (see **Figure 4D**, subject 3). Thus, the lower task performance of the trajectories reconstructed using synergies, in addition to the lack of feedback driven adjustments to synergy-to-force inaccuracy discussed above, might also be due to the inappropriate selection of the number of synergies for some of the subjects. However, the number of synergies selected with our criterion did allow to perform the task in synergy-control with accuracy similar to that of force- and EMG-control, suggesting that the criterion was adequate and that the lower performance of synergy-reconstructed trajectories executed in EMG-control was mainly due to the lack of appropriate feedback. Finally, task performance in synergy-control could be used as a new criterion for the selection of a number of synergies, especially for synergy-based myoelectric control applications. It would simply require testing an increasing number of synergies and selecting the number that ensures performance comparable to that obtained with individual muscles.

In conclusion, the investigation of a 2-dimensional force reaching task demonstrated that a complex arm muscle system can be effectively controlled by a small number of synergies. Our results suggest that muscle synergies are employed by the CNS to cope with the high number of degrees-of-freedoms in the musculoskeletal system and to simplify movement coordination. However, the fact that we did not find evidence for any significant reduction in performance using muscle synergies cannot definitively prove whether or not synergies are actually employed by the CNS. Further insights into the synergy hypothesis may be gained by testing subjects' adaptation to perturbation. In a recent study (Berger et al., 2013) we have shown that adaption to virtual surgeries, i.e., perturbation of the muscle-to-force mapping, depends on the compatibility of the surgery with the synergies. Human subjects adapted strikingly faster after compatible virtual surgeries, in which a full range of movements in the task space could be achieved recombining the initially identified synergies, than after incompatible virtual surgeries, for which new or modified synergies would be required. Muscle synergies might thus allow for faster adaptation to perturbation and to environmental demands. Comparing adaptation to perturbation directly under synergy-control and EMG-control might therefore shed further light into possible control strategies employed by the CNS. Synergy-control could moreover be useful for achieving intuitive simultaneous and proportional control of myoelectric prostheses (Jiang et al., 2009, 2013), and robot arms (Artemiadis and Kyriakopoulos, 2010) and for the development of novel diagnostic tools and rehabilitation approaches (Safavynia et al., 2011). Specifically, rehabilitation exercises in a virtual environment with synergy-control might promote recovery of movement skills in stroke patients by facilitating the recruitment of spared muscle synergies (Cheung et al., 2009, 2012) and the re-organization of altered ones (Roh et al., 2013).

ACKNOWLEDGMENTS

This work was supported by the Human Frontier Science Program Organization (RGP11/2008), the European Union FP7-ICT program (Adaptive Modular Architectures for Rich Motor skills, AMARSI, Grant 248311). We thank Daniele Borzelli for help with setting up and making illustrations of the experimental apparatus and Benedetta Cesqui for useful discussions.

Little is known about the integration of neural mechanisms for balance and locomotion. Muscle synergies have been studied independently in standing balance and walking, but not compared. Here, we hypothesized that reactive balance and walking are mediated by a common set of lower-limb muscle synergies. In humans, we examined muscle activity during multidirectional support-surface perturbations during standing and walking, as well as unperturbed walking at two speeds. We show that most muscle synergies used in perturbations responses during standing were also used in perturbation responses during walking, suggesting common neural mechanisms for reactive balance across different contexts. We also show that most muscle synergies using in reactive balance were also used during unperturbed walking, suggesting that neural circuits mediating locomotion and reactive balance recruit a common set of muscle synergies to achieve task-level goals. Differences in muscle synergies across conditions reflected differences in the biomechanical demands of the tasks. For example, muscle synergies specific to walking perturbations may reflect biomechanical challenges associated with single limb stance, and muscle synergies used during sagittal balance recovery in standing but not walking were consistent with maintaining the different desired center of mass motions in standing vs. walking. Thus, muscle synergies specifying spatial organization of muscle activation patterns may define a repertoire of biomechanical subtasks available to different neural circuits governing walking and reactive balance and may be recruited based on task-level goals. Muscle synergy analysis may aid in dissociating deficits in spatial vs. temporal organization of muscle activity in motor deficits. Muscle synergy analysis may also provide a more generalizable assessment of motor function by identifying whether common modular mechanisms are impaired across the performance of multiple motor tasks.

Keywords: locomotion, posture, muscle synergy, motor control, electromyography

INTRODUCTION

Humans and animals are able to robustly move over diverse terrains and withstand challenging disturbances to balance during locomotion. Achieving these remarkable behaviors requires precise and dynamic coordination of multiple muscles across the limbs and trunk via hierarchical neural pathways. However, little is known about how the nervous system integrates the concurrent control of locomotion and balance functions over different movement contexts. Neural circuits for locomotion have been identified in the mammalian spinal cord, and can endogenously produce rhythmic motor patterns to muscles (Brown, 1911; Grillner, 1975; Rossignol et al., 1996). These patterns can be modified by sensory feedback (Forssberg et al., 1980; Quevedo et al., 2000; Rossignol and Bouyer, 2004) and motor planning mechanisms (Drew et al., 2002) that alter the gait pattern. Perturbations to walking can elicit long-latency muscle responses (Tang et al., 1998; Chvatal and Ting, 2012) as well as alter the locomotor rhythm during stumbling corrective responses (Pijnappels et al., 2005; van Der Linden et al., 2007). During standing balance control, perturbations evoke coordinated long-latency responses in muscles that help to return the body to postural equilibrium; these require brainstem integration of multisensory cues (Macpherson and Fung, 1999; Deliagina et al., 2008).

Are there common neural mechanisms underlying the control of walking and reactive balance control, and how are these mechanisms integrated during natural movements? Recent research demonstrates the neural control of muscles may be modular, organized in functional groups often referred to as muscle synergies (Tresch et al., 1999; Giszter et al., 2007; Ting and McKay, 2007; Drew et al., 2008; Chiel et al., 2009; Yakovenko et al., 2011). Each muscle synergy is proposed to specify a fixed pattern of co-activation across multiple muscles at any given time point. Muscle synergies have been used to describe muscle coordination during a variety of motor behaviors including balance control (Torres-Oviedo and Ting, 2007), walking (Ivanenko et al., 2004; Clark et al., 2010; Chvatal and Ting, 2012), reaching (D'Avella et al., 2006; Muceli et al., 2010), and grasping (Hamed et al., 2007; Acharya et al., 2008; Overduin et al., 2008). Moreover, common muscle synergies have been identified across different motor behaviors such as frog swimming, kicking, and jumping (Hart and Giszter, 2004; Cheung et al., 2005; D'Avella and Bizzi, 2005; Cheung et al., 2009), forward and backward locomotion (Raasch and Zajac, 1999; Ting et al., 1999), and across reactive balance conditions (Torres-Oviedo and Ting, 2010; Chvatal et al., 2011). Based on these findings, we hypothesize that a common set of muscle synergies may be recruited by parallel neural pathways

governing voluntary, reactive, and automatic motor behaviors in the upper and lower limbs. Muscle synergy analysis may thus provide a more generalizable assessment of motor function in neuromotor deficits, providing more specific information about functional deficits that may guide more targeted rehabilitation interventions.

It has been demonstrated that the phasic recruitment of muscle synergies underlies variability in locomotor behaviors such as pedaling and walking (Ting et al., 1999; Ivanenko et al., 2004; Krouchev et al., 2006; Clark et al., 2010; Lacquaniti et al., 2012). During locomotion, specific muscle synergies have been associated with a particular phase of the gait cycle (Ivanenko et al., 2004; Krouchev et al., 2006; Clark et al., 2010), despite differences in how muscle synergies are defined (Safavynia and Ting, 2012). Furthermore, the order of recruitment has been shown to be consistent across conditions, such as when subjects concurrently perform voluntary tasks (Ivanenko et al., 2005) or shift from walking to running (Cappellini et al., 2006). Moreover, recruitment of muscle synergies within a particular phase of gait has been shown to be modulated systematically as a function of walking speed, and also to account for cycle-by-cycle variability in the locomotor pattern (Clark et al., 2010). These variations in muscle synergy recruitment may reflect changing task demands across gait conditions. Muscle synergies may be organized to produce specific whole-limb or whole-body biomechanical functions during locomotion (Raasch and Zajac, 1999; Neptune et al., 2009; Allen and Neptune, 2012) such that altering the phase, amplitude, or duration of muscle synergy recruitment may produce a variety of locomotor behaviors (Raasch and Zajac, 1999; Ting et al., 1999; McGowan et al., 2010). This is consistent with the idea that muscle synergies reflect motor modules that allow the nervous system to produce consistent biomechanical functions.

Rapid and complex changes in the coordination of muscles are required to recover from discrete perturbations that produce large disruptions to the locomotor pattern. In response to unexpected obstacles, slipping, waist pulls, or surface heights, immediate and delayed changes to muscle activity and kinematics have been observed (Tang et al., 1998; You et al., 2001; Ferber et al., 2002; Misiaszek, 2003; Oddsson et al., 2004; Chambers and Cham, 2007; van Der Linden et al., 2007; Bachmann et al., 2008; Shinya and Oda, 2010). Perturbations typically alter the duration of stance and swing phase such that changes in stance duration, step length, and step width are observed within the perturbed step (Oddsson et al., 2004) and can continue in subsequent steps (Patla, 2003). Corrective muscular responses at long latencies (∼100 ms) following perturbations are observed in both the stance and swing limb (Tang et al., 1998; Bachmann et al., 2008) and appear to be superimposed upon the locomotor pattern (Gorassini et al., 1994; Hiebert et al., 1994). Moreover, different motor strategies to maintain whole-body stability can be evoked, consistent with the idea that long-latency responses are organized to maintain task-level goals (Nashner, 1976; Horak and Macpherson, 1996; Carpenter et al., 1999; Chvatal et al., 2011), and not simply limb posture (cf. autogenic reflex). We recently demonstrated that the same muscle synergies recruited phasically during overground walking were also recruited at long-latencies in response to discrete perturbations to walking (Chvatal and Ting, 2012). However, it remains unknown whether these long-latency responses are similar in organization to those evoked during perturbations to standing balance, which would support the idea of a common mechanism mediating balance responses across movement contexts.

In discrete perturbations to standing balance control, the modulation of a few muscle synergies can robustly explain variations in muscle activity across reactive balance responses during different perturbations to standing. In response to multidirectional support-surface perturbations, muscle synergy recruitment is directionally tuned to perturbation direction, and generates a specific biomechanical function (e.g., ground-reaction force direction) to restore the center-of-mass (CoM) in both humans and animals (Ting and Macpherson, 2005; Torres-Oviedo et al., 2006; Chvatal et al., 2011). Moreover, the multidirectional recruitment of muscle synergies during standing balance can be predicted based on the deviation of CoM kinematics from the upright, static state, such that they reflect the task-relevant error for maintaining postural equilibrium and orientation (Safavynia and Ting, 2013). Variations in muscle activity from trial to trial in identical perturbation conditions (Torres-Oviedo and Ting, 2007; Safavynia and Ting, 2012) as well as across biomechanical contexts [e.g., standing with wide, narrow, crouched, or single-limb stance (Torres-Oviedo et al., 2006; Torres-Oviedo and Ting, 2010)], can be accounted for by the differential modulation of a common set of muscle synergies for balance. Furthermore, muscle activity and the resulting force production during reactive non-stepping and stepping responses were explained by a common set of muscle synergies (Chvatal et al., 2011), demonstrating the robustness of the muscle synergy organization and function in mediating a variety of balance behaviors.

Here, we hypothesized that a common set of lower-limb muscle synergies mediate reactive balance and walking. Recent studies during perturbed locomotion demonstrate that locomotor muscle synergies are recruited at long-latencies following discrete perturbations to walking (Chvatal and Ting, 2012; Oliveira et al., 2012). This suggests that muscle synergies recruited rhythmically for locomotion may also be recruited during atypical phases of gait due to sensorimotor feedback mechanisms governing long-latency balance responses. However, it is not known whether the same muscle synergies are recruited during long-latency balance responses evoked during standing and walking. To compare muscle activity during directional balance control, we imposed twelve directions of support-surface perturbations during standing and walking at self-selected and slow speeds. First, we predicted that reactive balance to multidirectional perturbations across contexts, e.g., during standing and walking, were mediated by common muscle synergies. We then predicted muscle activity in both reactive balance and overground walking were also mediated by common muscle synergies. Our results suggest that a common set of muscle synergies is differentially recruited by neural circuits mediating reactive balance across movement contexts and for locomotion.

METHODS

In order to determine whether common muscle synergies are recruited during postural responses to perturbations in different

dynamic contexts, we recorded postural responses to ramp and hold translations of the support surface during standing balance as well as during walking at both self-selected and slow walking speeds. Perturbations in twelve directions in the horizontal plane were delivered in random order in each condition. Muscle synergies were extracted from both the standing balance and walking conditions, as well as from trials of unperturbed walking. Muscle synergies and recruitment coefficients from each condition were compared to give insight into neural mechanisms underlying each condition.

DATA COLLECTION

Seven healthy subjects (four male, three female) between the ages of 19 and 26 responded to support surface translations according to an experimental protocol that was approved by the Institutional Review Boards of Georgia Institute of Technology and Emory University. All subjects gave informed consent before participating in each of three experimental blocks (standing balance, self-selected speed walking, and slow walking). The order in which the blocks were presented was randomized for each subject.

In the standing balance block, subjects stood on an instrumented platform that translated in 12 equally spaced directions in the horizontal plane (see **Figure 1**). Subjects were instructed to maintain balance without stepping if possible. The platform's displacement was 12.4 cm, velocity was 35 cm/s, and acceleration was 0.5 g. Five trials of each of the 12 directions of perturbation were collected in random order. All subjects were able to maintain balance without taking a step.

In the walking blocks, subjects walked overground slowly (0.6–0.7 m/s) or at a self-selected pace (1.2–1.5 m/s) for approximately 7.5 m, or 7 gait cycles. Subjects were instructed to maintain

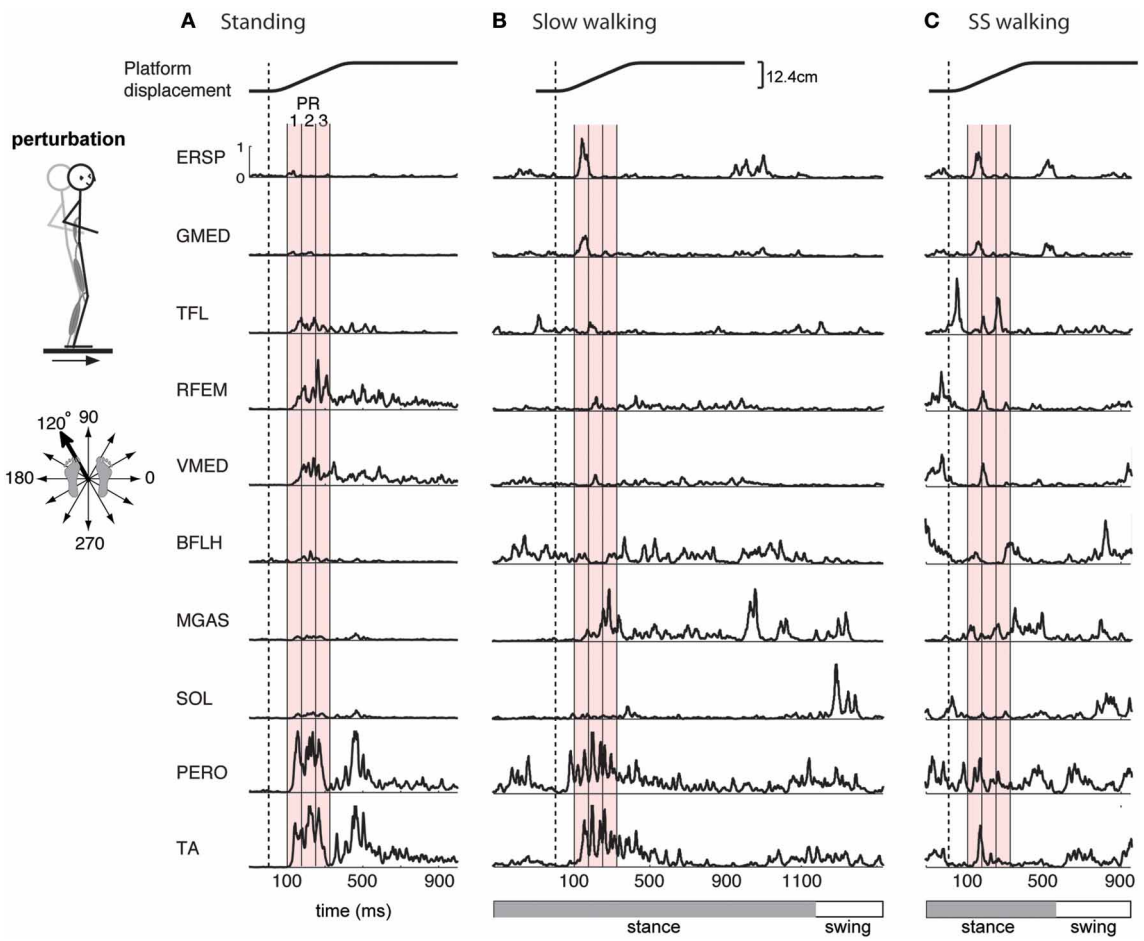

FIGURE 1 | Examples of EMG activity in perturbation responses during (A) standing, (B) slow walking, and (C) self-selected speed walking. Responses to a forward and leftward perturbation of the support surface during each condition are shown. Balance perturbations were induced by ramp-and-hold displacement perturbations in 12 evenly spaced directions in the horizontal plane. EMG responses occur 100-ms after the onset of platform motion (vertical dashed line). Shown here are erector spinae (ERSP), gluteus medius (GMED), tensor fascia lata (TFL), rectus femoris (RFEM), vastus medialis (VMED), biceps femoris (BFLH), medial gastrocnemius (MGAS), soleus (SOL), peroneus (PERO), and tibialis anterior (TA) responses. Mean EMG activity was calculated for 3 time bins during the automatic postural response (PR), indicated by the red shaded region, beginning 100 ms (PR1), 175 ms (PR2), and 250 ms (PR3) following perturbation. One complete gait cycle is shown for each walking speed, and the horizontal bar indicates stance (gray) and swing (white) phase. Perturbations during walking were administered in early stance.

a pace as closely as possible to a metronome beat. Subjects listened to 4 metronome beats and then began walking at self-selected time after the metronome was silenced. In slow trials the metronome was set at 60 bpm, and in self-selected trials the metronome pace was matched to each subject's preferred pace, determined when they first arrived. Subjects began walking with their right foot, and data collection began on the third step to eliminate any variability associated with gait initiation. Eight trials of unperturbed walking were collected at the beginning of each block, in which the subject knew there would be no perturbation. In the remaining trials, subjects were told that there may or may not be a perturbation. Twelve trials of unperturbed walking were collected randomly in between the perturbation trials in order to capture any anticipatory responses. In perturbed trials, perturbations (displacement 12.4 cm, velocity 40 cm/s, acceleration 0.7 g) were applied as subjects crossed the instrumented platform halfway along the path, during early stance phase of the right leg. The perturbation was applied when the ground reaction force of the right foot reached ∼60% of body weight as measured by force plates (AMTI, Watertown, MA) embedded in the platform. Perturbation direction was randomized, and three trials of each direction for each walking speed were collected. Data from the four cardinal directions of perturbations and from unperturbed walking trials were analyzed and published previously (Chvatal and Ting, 2012).

Surface EMG activity was recorded from sixteen muscles of the lower-back and leg on the subject's right side, the stance leg in perturbed walking. Muscles recorded included: vastus lateralis (VLAT), rectus femoris (RFEM), rectus abdominis (REAB), biceps femoris long head (BFLH), semitendinosus (SEMT), adductor magnus (ADMG), erector spinae (ERSP), abdominal external oblique (EXOB), vastus medialis (VMED), tibialis anterior (TA), medial gastrocnemius (MGAS), lateral gastrocnemius (LGAS), soleus (SOL), peroneus (PERO), tensor fasciae latae (TFL), and gluteus medius (GMED). EMG data were sampled at 1080 Hz, high pass filtered at 35 Hz, de-meaned, rectified, and low-pass filtered at 40 Hz, using custom MATLAB routines. Additionally, kinetic data was collected at 1080 Hz from force plates under the feet, and kinematic data was collected at 120 Hz using a motion capture system (Vicon, Centennial, CO) and a custom 25-marker set that included head-arms-trunk (HAT), thigh, shank, and foot segments.

DATA PROCESSING

In order to identify muscle synergies, we first generated EMG data matrices from each condition as follows:

In the standing balance condition, three time bins during the automatic postural response were analyzed (Torres-Oviedo and Ting, 2007; Chvatal et al., 2011). The automatic postural response (APR) has been well-characterized and occurs ∼100 ms following the perturbation (Horak and Macpherson, 1996). Due to variations in muscle activity during this APR, we further divided it into three 75-ms time bins beginning 100 ms (PR1), 175 ms (PR2), and 250 ms (PR3) after perturbation onset (**Figure 1A** red shaded areas). Mean muscle activity for each muscle during each time bin was calculated for each trial. These numbers were assembled to form the data matrix used for subsequent muscle synergy analysis, which consisted of 3 time bins × 12 directions × 5 trials = 180 points for each of the 16 each muscles.

Similarly, in the perturbed walking conditions we also analyzed three 75-ms time bins to characterize the reactive response to perturbation. Mean muscle activity was calculated during three time bins beginning 100 ms, 175 ms, and 250 ms after the perturbation (**Figure 1B** red shaded areas). For perturbed walking, the data matrix consisted of 3 time bins × 12 directions × 3 trials = 108 points for each of the 16 each muscles.

In the unperturbed walking condition, at least three complete gait cycles for each trial were included in the analysis. EMG data were downsampled by averaging the data in 75-ms time bins (Chvatal and Ting, 2012). Reducing the size of the time bins to 10 ms during walking did not affect the number or structure of muscle synergies in prior studies (Chvatal and Ting, 2012), as well as for the current paper (not shown). Time-courses of EMG from unperturbed walking trials of each subject were concatenated to form the data matrix. The size of the data matrix varied across subjects and walking speeds since no time-normalization was performed on walking cycles, but each subject's data matrix had greater than 1044 points for each of the 16 muscles.

For all conditions, the activation of each muscle in each subject was normalized to the maximum activation observed during the unperturbed walking trials at the self-selected walking speed. The elements of each row of a data matrix (each muscle) constructed from unperturbed walking trials at the self-selected speed therefore ranged from 0–1. Identical normalization factors from the unperturbed self-selected walking condition were used for all other conditions for each subject. Tuning curves were generated by plotting the activation of each muscle with respect to perturbation direction within a given time bin.

EXTRACTION OF MUSCLE SYNERGIES

We extracted muscle synergies from each data matrix of EMG recordings using non-negative matrix factorization (NNMF) (Lee and Seung, 1999; Tresch et al., 1999), which has previously been used for muscle synergy analysis (Ting and Macpherson, 2005; Torres-Oviedo and Ting, 2007). NNMF assumes that a muscle activation pattern, M, in a given time period is comprised of a linear combination of a few muscle synergies, W_i that are each recruited by a synergy recruitment coefficient, c_i. Therefore, a particular muscle activation pattern, M, would be represented by:

$$M = c_1W_1 + c_2W_2 + c_3W_3 + \ldots$$

where W_i specifies the relative contributions of the muscles involved in synergy *i*. Each muscle synergy has a fixed composition, and each is multiplied by a scalar recruitment coefficient, c_i, which changes over time and across conditions. Prior to extracting muscle synergies, each muscle vector in the data matrix was normalized to have unit variance to ensure equal weighting in the muscle synergy extraction. After extracting muscle synergies, the unit variance scaling was removed from data so that each muscle's data was returned to the scale where 1 is the maximum activation during self-selected speed unperturbed walking, in order to permit comparison of responses and muscle synergies across conditions.

Muscle synergies for reactive balance were identified independently in each of the three perturbation conditions: standing, slow walking, and self-selected walking. We extracted 1–16 muscle synergies, and the goodness of fit of the data reconstruction using each number of muscle synergies was quantified by variance accounted for (VAF), defined as 100 × uncentered Pearson's correlation coefficient (Zar, 1999; Torres-Oviedo et al., 2006). The number of muscle synergies selected to describe each dataset *(Nsyn)* was determined by choosing the least number of synergies that could account for greater than 90% of the overall VAF. We added the further local criterion that muscle synergies also accounted for greater than 75% VAF in each muscle and each perturbation direction. This local fit criterion was more stringent and ensured that relevant features of the data set are reproduced. VAF for each muscle (VAFmus) quantified the extent to which the muscle synergies accounted for variability in the activity of individual muscles across all time bins, perturbation directions, and trials. VAF for each perturbation direction (VAFcond) quantified the extent to which the muscle synergies accounted for the variability in muscle activation patterns formed by the response of all 16 muscles to a single perturbation direction during one time bin across all trials.

To validate the similarity of muscle synergies in reactive balance responses across movement contexts, we further identified muscle synergies using two additional methods that combined perturbation conditions. First, muscle synergies identified from perturbation responses during standing were used to reconstruct the responses during the two walking perturbation conditions. Condition-specific muscle synergies were extracted from walking perturbation response data that was not accounted for by the standing muscle synergies. To this end, we used an iterative algorithm that held fixed the muscle synergies extracted from standing data while optimizing a new set of muscle synergies extracted from the remainder of the variability in the walking perturbation data not accounted for by the standing muscle synergies (Cheung et al., 2009; Torres-Oviedo and Ting, 2010; Chvatal et al., 2011). As a second validation, we extracted muscle synergies from a data matrix containing all three perturbation conditions combined, and compared these to the muscle synergies identified from the independent data sets. In a combined extraction, there is a possibility of one condition dominating the others, so most of the results presented are comparisons of the muscle synergies identified from the independent datasets.

Muscle synergies for walking were first identified from unperturbed walking. Since we previously showed that the similar muscle synergies are identified when each walking speed is analyzed individually (Chvatal and Ting, 2012), one set of muscle synergies was extracted from a data matrix consisting of both self-selected speed unperturbed walking catch trials and slow unperturbed walking catch trials, and these muscle synergies were termed "walking" muscle synergies. For each subject, we selected the least number of muscle synergies (*Nsyn*) that satisfied both the global criterion of reconstructing at least 90% of the overall variance (VAF = 90%) as well as the local criterion of reconstructing at least 75% of the variability in each muscle (Chvatal and Ting, 2012). Once *Nsyn* was selected for each condition, the muscle synergies were used to reconstruct the EMG patterns, and measured and reconstructed data were compared for a particular muscle, time bin, and perturbation direction for each trial to examine the ability of the muscle synergies to account for inter-trial variations. Similarities between measured and reconstructed data were quantified using r^2 and VAF.

We used two methods to validate the similarity of muscle synergies for reactive balance during standing and unperturbed walking. First, muscle synergies identified from perturbation responses during standing were used to reconstruct unperturbed walking data and *vice versa*. Using the algorithm described above, walking-specific muscle synergies were extracted from unperturbed walking data that was not accounted for by the standing muscle synergies, and standing-specific muscle synergies were extracted from standing perturbation response data that was not accounted for by the walking muscle synergies. Significant differences between reconstructions using the various muscle synergy sets were determined using paired t-tests. Second, we also extracted muscle synergies from a data matrix containing both unperturbed walking data and standing perturbation response data combined. To ensure an equal amount of walking and standing data in the combined data matrix, only a single trial of unperturbed walking at each walking speed was included. We first verified that the muscle synergies extracted from the single trial of walking at each speed were similar to the walking muscle synergies described above.

MUSCLE SYNERGY COMPARISON

To determine similarity in muscle synergies across conditions, we compared muscle synergies extracted from reactive balance during standing and walking, as well as from reactive balance compared to unperturbed walking. When comparing two sets of muscle synergies, we calculated correlation coefficients (r) between each muscle synergy vector in the first set and each in the second set. A pair of muscle synergies were considered "similar" if they had $r > 0.623$, which corresponds to the critical value of r^2 for 16 muscles [$r^2 = 0.388$; $p = 0.01$; see Chvatal et al. (2011) for muscle synergy comparison details].

Across perturbation conditions, we compared the tuning curves of similar synergies to determine if they were recruited for similar perturbation directions in different contexts. We examined the composition and tuning of any condition-specific muscle synergies to determine their potential similarity in function.

RESULTS

DIFFERENCES IN INDIVIDUAL MUSCLE ACTIVATION ACROSS PERTURBATION CONDITIONS

The muscles activated in response to different perturbation directions was generally similar in standing and walking, but could vary greatly in magnitude (**Figure 1**). For example, in one subject, in response to a forward, rightward perturbation, TA and PERO were strongly activated in standing and slow walking, but more weakly activated in the self-selected walking condition; RFEM was activated strongly in standing but less so in walking; trunk muscles ERSP and GMED were strongly recruited in walking but less so in standing (**Figure 1**). Differences in muscle activity across standing and walking conditions were observed across perturbation directions and conditions (**Figure 2**). For example, agonist

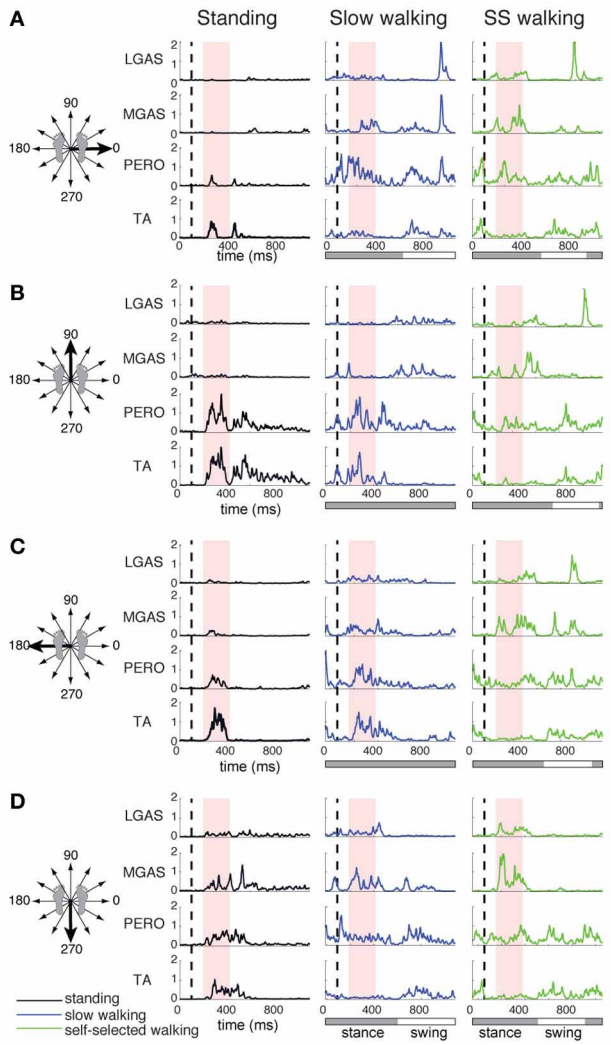

FIGURE 2 | Lateral gastrocnemius (LGAS), medial gastrocnemius (MGAS), peroneus (PERO), and tibialis anterior (TA) activity during perturbation responses during standing (black), slow walking (green), and self-selected walking (blue), for (A) a rightward perturbation, (B) a forward perturbation, (C) a leftward perturbation, and (D) a backward perturbation. Vertical dashed line indicates perturbation onset and the red shaded box indicates the perturbation response time window used here for analysis: 100–325 ms after perturbation onset. For walking trials, the horizontal bar indicates stance (gray) and swing (white) phases. Muscle activity was averaged across each of 3 time bins during the postural response time window and plotted against perturbation direction to generate tuning curves shown in **Figure 3**.

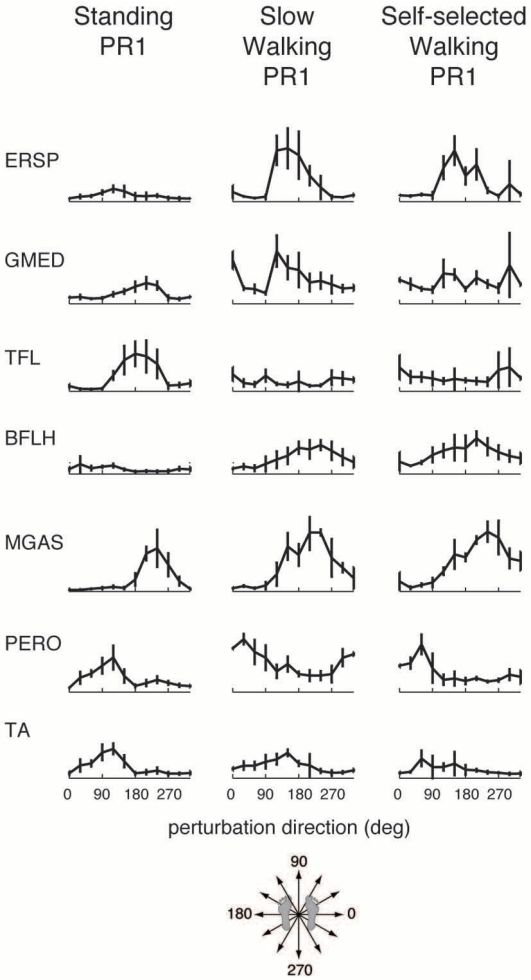

FIGURE 3 | Muscle tuning curves from perturbation responses during standing, slow walking, and self-selected walking speeds for a representative subject. Shown are the mean tuning curves ± standard deviations in PR1 across trials in each perturbation direction. Some muscles have consistent tuning across perturbation conditions (standing, slow walking, self-selected walking), while other muscles have different tuning across conditions.

pairs of muscles such as MGAS/LGAS and PERO/TA which were activated similarly in perturbation responses during standing had distinct activation patterns in perturbation responses during walking.

Muscle tuning curves revealed some differences in the directional tuning of muscles across perturbation conditions (**Figure 3**). For example, ERSP had the same preferred direction (forward/leftward perturbations) in all conditions, but was more highly activated in response to perturbations during walking compared to standing. TFL had a different preferred direction of activation in standing (forward/leftward perturbation) compared to walking (rightward perturbations). MGAS was recruited in similar directions (backward perturbations) and magnitudes in response to perturbations during both standing and walking.

COMMON MUSCLE SYNERGIES IN PERTURBATION RESPONSES DURING STANDING AND WALKING

For each perturbation condition, on average, we identified 5.2 ± 0.9 muscle synergies (range 4–7, **Figure 4**) that explained the variance in muscle activation patterns across directions, time bins, and trials. In perturbation responses during standing, 5.6 ± 0.8 muscle synergies per subject (range 5–7) were sufficient to account for >90% total variability and >75% variability in each muscle and condition (all 3 time bins, 12 perturbation directions,

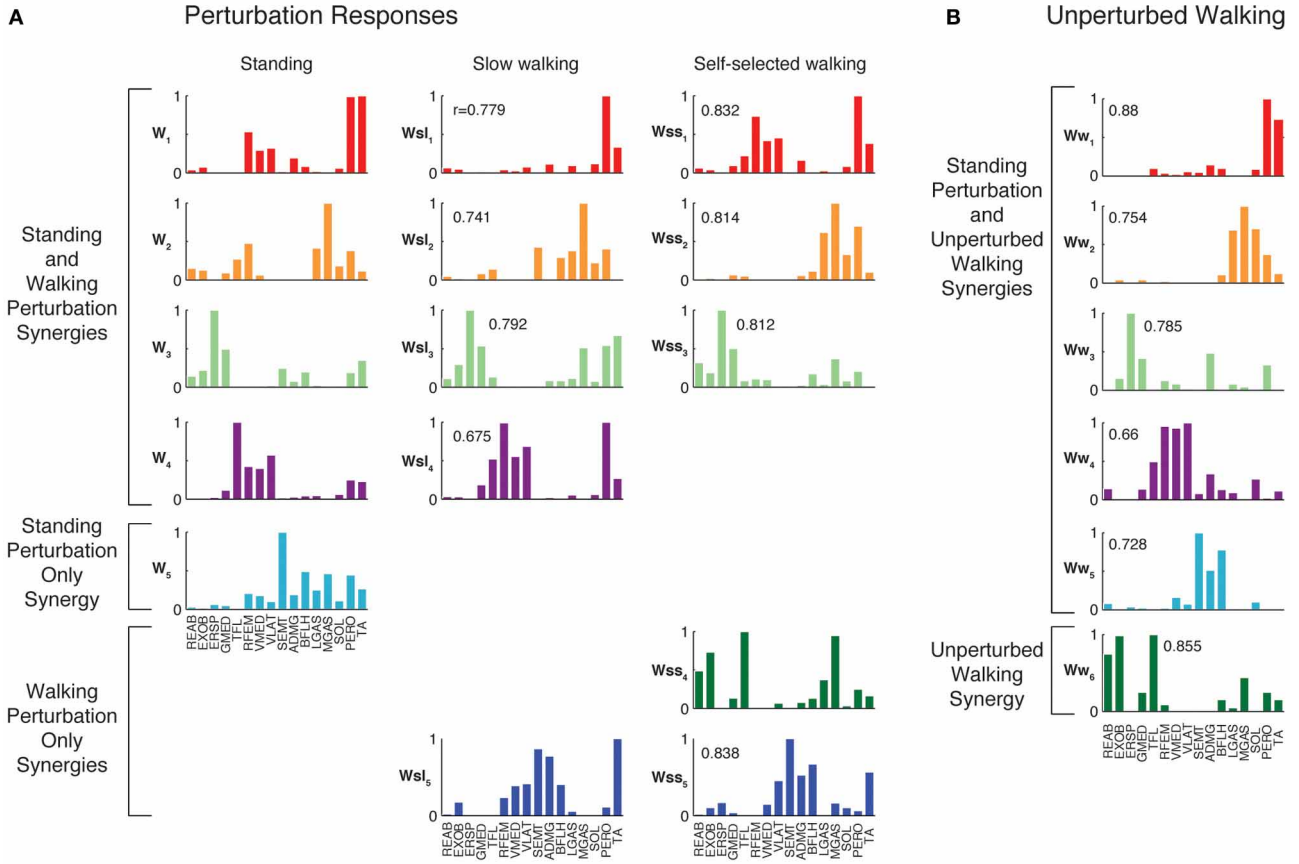

FIGURE 4 | Muscles synergies extracted from each experimental condition. (A) Muscle synergies extracted from perturbation responses during standing, slow walking, and self-selected walking. All but one of the muscle synergies used in slow walking perturbation responses was similar to those used in standing balance postural responses. All but one of the muscle synergies used in self-selected walking perturbation responses was similar to those used in standing and/or slow walking postural responses. Correlations between each muscle synergy vector and the corresponding muscle synergy from standing balance are shown. **(B)** Muscle synergies extracted from unperturbed walking. Muscle synergies extracted from standing balance perturbation responses were similar to those extracted from the entire timecourse of many trials of unperturbed walking. In this subject, one additional muscle synergy was identified from unperturbed walking that was not identified in standing postural responses.

across 5 trials of each) in the EMG data. In perturbation responses during slow walking, 4.9 ± 0.7 muscle synergies (range 4–6) were sufficient to explain the same amount of variability. In perturbation responses during self-selected walking, 5.1 ± 1.2 muscle synergies (range 4–7) were sufficient to explain the same amount of variability. Individual muscles were recruited by multiple muscle synergies; for example, PERO was recruited strongly by W_1, but also was recruited by W_2 and W_5.

When muscle synergies were extracted separately from each perturbation condition, we found similarities in most of the muscle synergies identified (**Figure 4**). Of the muscle synergies extracted from perturbation responses during standing, 3.6 ± 1.0 (range 2–5) were identified in perturbation responses during slow walking, and 3.1 ± 0.9 (range 2–4) in perturbation responses during self-selected walking (**Table 1**). Of the 1 to 3 muscle synergies that were identified in perturbation responses to each walking condition that were not identified in perturbation responses to standing, one was similar between the perturbation responses during both walking conditions (e.g., Wsl_5 and Wss_5, **Figure 4**) for five subjects. The remaining muscle synergy identified in perturbation responses to self-selected walking was similar to a muscle synergy identified in unperturbed walking for most subjects, which will be discussed in detail later.

When muscle synergies extracted from perturbation responses during standing were used to reconstruct perturbation responses during walking, 1.7 ± 0.5 (range 1–2) additional muscle synergies specific to slow walking perturbations, and 2.4 ± 0.8 (range 1–3) additional muscle synergies specific to self-selected walking perturbations were required to explain the variability. Across subjects, the minimum VAF across muscles was significantly lower when only muscle synergies from standing perturbations were used to reconstruct walking perturbation responses than when muscle synergies extracted from walking perturbations were used (minimum VAFmus $= 67.7 \pm 11.6\%$ vs. $82.4 \pm 4.6\%$; $p < 0.001$). The reconstruction was improved once additional walking perturbation-specific muscle synergies were extracted, as evidenced by an increase in the minimum muscle VAF (minimum VAFmus $= 82.3 \pm 3.6\%$; $p < 0.001$). For all subjects, at least one

of the walking perturbation-specific muscle synergies were similar to those identified from walking perturbations alone. For one subject all walking perturbation-specific muscle synergies were similar to walking perturbation synergies, for four subjects all but one were similar, for one subject all but two were similar, and in one subject all but three were similar.

Finally, we compared muscle synergies extracted above to those identified when all three perturbation conditions were combined. Across subjects, 6.6 ± 1.3 synergies could explain >90% VAF and >75% VAF in each muscle across all three perturbation conditions. For three subjects, all of the condition-specific muscle synergies were also identified from the combined data. For the other four subjects, at least one of the condition-specific muscle synergies were identified from combined perturbation response data. For muscle synergies that were similar across conditions, similar recruitment coefficients were identified from the combined dataset and each condition individually (VAF $= 90.6 \pm 3.6\%$, $r = 0.90 \pm 0.04$).

MUSCLE SYNERGY TUNING ACROSS PERTURBATION CONDITIONS

The differential recruitment of similar muscle synergies accounted for the differences in individual muscle patterns we observed during perturbation responses in both standing and walking. We found different magnitude and directional tuning of muscle synergies that were similar in standing and walking perturbation conditions (**Figure 5**). For example, W_1, W_2, and W_3 were used in perturbation responses during standing as well as during both walking conditions. Muscle synergy recruitment tuning curves revealed differences in the both the magnitude and directional tuning of muscle synergies across perturbation conditions. For example, W_2 was recruited for backward perturbations during both standing and walking, and W_3 was recruited during postural responses to medial/lateral perturbations in all conditions, but both were more highly recruited in response to perturbations during walking compared to standing. W_1 had a different preferred direction of activation in standing (forward and backward perturbations) compared to walking (rightward/forward perturbations).

The muscle synergies identified in standing but not walking perturbation responses were generally recruited for forward or backward perturbations. Four subjects had a muscle synergy tuned for backward perturbations in standing but not walking perturbation responses (**Figure 6A**), and separate set of four subjects had a muscle synergy tuned for forward perturbations

Table 1 | Number of muscle synergies used in each condition and number of similar muscle synergies used across different conditions.

Number of muscle synergies	Standing perturbation responses	Slow walking perturbation responses	Self-selected walking perturbation responses	Unperturbed walking
Identified per condition	5.6 ± 0.8 (range 5–7)	4.9 ± 0.7 (range 4–6)	5.1 ± 1.2 (range 4–7)	6.9 ± 1.2 (range 5–8)
Shared with standing perturbation responses	–	3.6 ± 1.0 (range 2–5)	3.1 ± 0.9 (range 2–4)	3.4 ± 1.1 (range 2–5)

The first row shows the total number of muscle synergies identified across all subjects for each condition. The second row indicates the number of muscle synergies identified in standing perturbation responses that were also identified in each of the other conditions.

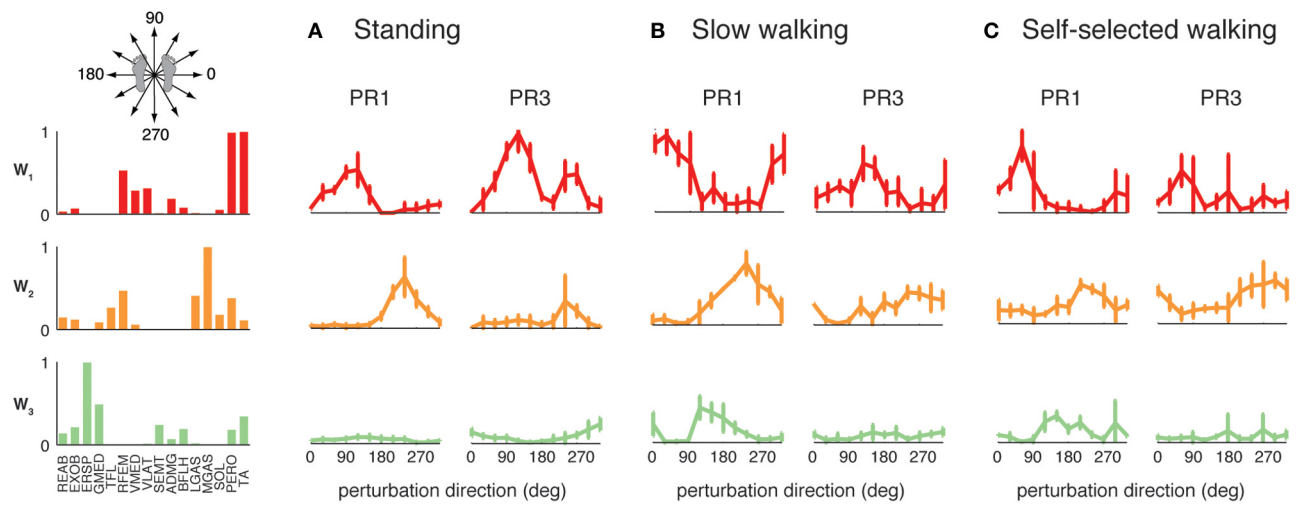

FIGURE 5 | Recruitment of muscle synergies common to perturbation responses during standing and walking. W_1, W_2, and W_3 were used in **(A)** standing perturbation responses as well as perturbation responses during **(B)** slow and **(C)** self-selected walking. W_2 was recruited for backward perturbations in all conditions, whereas W_3 was recruited for medial/lateral perturbations. W_1 was recruited for anterior/posterior perturbations in standing perturbation responses, and for anterior and lateral perturbations in walking perturbation responses.

in standing that was not used in perturbation responses during walking (**Figure 6B**). For example, W_4 was highly recruited during standing to move the CoM backward in PR3 during standing responses, but was not identified in perturbation responses during walking (**Figure 6A**), consistent with the goal of moving the CoM forward for forward progression. Similarly, we identified other muscle synergies that were highly recruited to move the center of mass forward in standing that were not used during walking (**Figure 6B**), presumably because the whole-body forward momentum carries the CoM forward during walking.

The muscle synergies specific to perturbation responses during walking were recruited for medial/lateral perturbations. For example, muscle synergies having strong contributions from hamstring muscles and TA (e.g., **Figure 4**, Wsl_5 and Wss_5) were recruited following leftward perturbations during walking (**Figure 7A**). Additional muscle synergies using PERO and TFL were recruited following rightward perturbations during walking (**Figure 7B**) and resembled a muscle synergy previously identified to emerges in postural responses during standing on one leg (Torres-Oviedo and Ting, 2010). An additional muscle synergy identified in perturbation responses during self-selected walking (Wss_4), was similar to a muscle synergy identified in unperturbed walking (Ww_6, **Figure 4**, $r = 0.86$), and was not strongly recruited in any perturbation direction, possibly playing a trunk stabilization role.

COMMON MUSCLE SYNERGIES IN PERTURBATION RESPONSES AND UNPERTURBED WALKING

Although unperturbed walking generally required a greater number of muscle synergies than perturbation responses during standing, the compositions of several muscle synergies used for walking and standing postural control were similar (see **Figure 4**). In unperturbed walking, on average, 6.9 ± 1.2 muscle synergies (range 5–8) from walking data from both walking speeds were sufficient to explain the variability in the data (VAF overall $= 91.5 \pm 1.2\%$, VAFmus $= 91.0 \pm 5.1\%$). Across subjects, 3.4 ± 1.1 of the muscle synergies used in perturbation responses during standing were similar to those used in unperturbed walking (range 2–5).

When standing perturbation muscle synergies were used to reconstruct unperturbed walking, and vice versa, reconstruction quality decreased (minimum VAFmus $= 79.8 \pm 2.7\%$ decreased to $48.4 \pm 13.6\%$, $p = 0.001$; and minimum VAFmus $87.4 \pm 3.8\%$ decreased to $56.2 \pm 21.6\%$, $p = 0.009$, respectively). With the addition of condition-specific muscle synergies, reconstructions were improved (minimum VAFmus $= 76.7 \pm 7.3\%$, $p = 0.002$; and minimum VAFmus $= 82.3 \pm 4.6\%$, $p = 0.007$, respectively). When muscle synergies extracted from perturbation responses during standing were used to reconstruct unperturbed walking, 3.5 ± 0.9 (range 3–5) additional muscle synergies specific to walking were identified in order to meet reconstruction criteria, consistent with our observation that a greater number of muscle synergies are used in unperturbed walking as compared to perturbation responses during standing. When muscle synergies extracted from unperturbed walking were used to reconstruct perturbation responses during standing, 2.0 ± 0.8 (range 1–3) additional muscle synergies specific to standing perturbations were required to explain the variability.

Across subjects, 6.0 ± 0.6 synergies could explain >90% VAF and >75% VAF in each muscle when standing perturbation data and unperturbed walking data were combined. For all subjects, 5.1 ± 0.9 (range 4–6) of the muscle synergies identified from standing balance perturbations and 4.3 ± 1.0 (range 3–6) of the muscle synergies identified from unperturbed walking were also identified when standing and walking data were combined.

Condition-specific muscle synergies reflected differences in the biomechanical demands of each conditions. For example, muscle

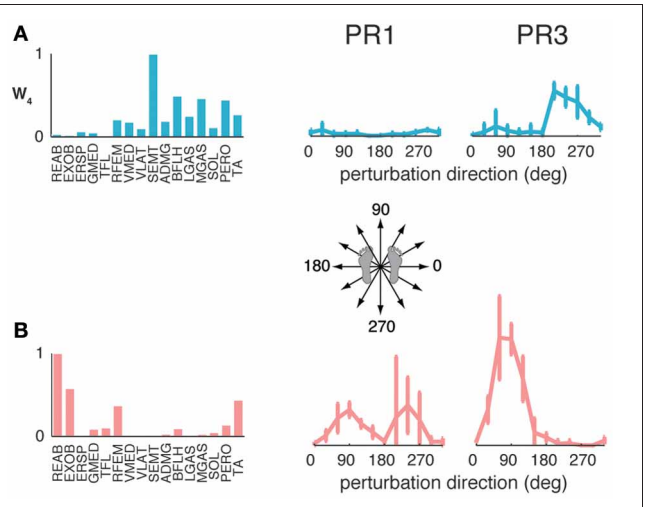

FIGURE 6 | Recruitment of muscle synergies identified in perturbation responses during standing but not walking. Muscle synergies used in standing perturbation responses that were not used in walking perturbation responses were recruited for **(A)** backward or **(B)** forward perturbation directions, shown for two different subjects.

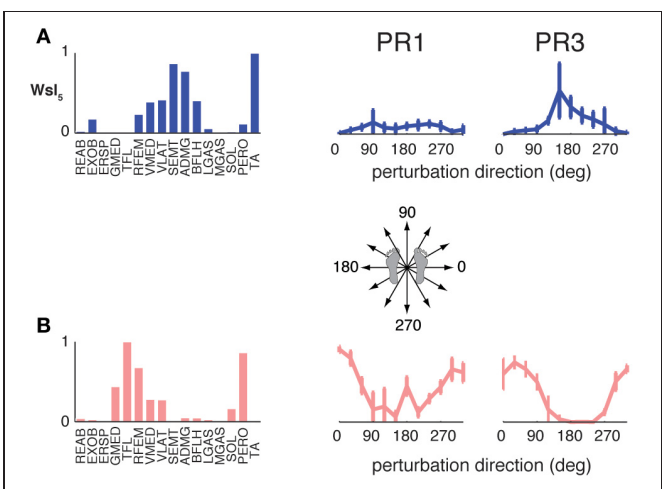

FIGURE 7 | Recruitment of muscle synergies identified in perturbation responses during walking but not standing. Muscle synergies used in walking perturbation responses that were not used in standing perturbation responses were recruited for **(A)** leftward or **(B)** rightward perturbation directions, shown for two different subjects.

synergies used in unperturbed walking that were not used in perturbation responses during standing were comprised of hip/trunk muscles and recruited throughout the gait cycle, suggesting they may play a role in trunk stabilization during walking (**Figure 8**, Ww_6). The muscle synergies used in perturbation responses during standing but not in unperturbed walking either had large contributions from TFL and were active for medial/lateral perturbations, or had large contributions from TA and PERO and were active for anterior perturbations (not shown). Some muscle synergies used for posterior CoM movements were common to both perturbation responses during standing and unperturbed walking, but were not identified in perturbation responses during walking (i.e., W_4, **Figure 4**).

DISCUSSION

Our results suggest that a common set of muscle synergies form a motor repertoire for both locomotion and reactive balance control. Our work unifies several different studies demonstrating a modular organization underlying variations in motor patterns across different walking and balance conditions. For example, step-by-step variation in muscle activity during walking as well as changes in muscle activity across walking speeds can all be explained by differential recruitment of walking muscle synergies as task demands change (Clark et al., 2010; Chvatal and Ting, 2012). Similarly, a common set of muscle synergies for reactive balance has been shown to underlie trial-by-trial differences in muscle activation patterns both within and across perturbation conditions (Torres-Oviedo and Ting, 2007, 2010; Chvatal et al., 2011). To bridge balance and walking behaviors, our study was the first to examine responses to perturbations during walking over 12 directions in the horizontal plane. We demonstrate that two different motor behaviors: walking and reactive balance, may in fact be constructed by a common set of muscle synergies. Our prior work also demonstrated that anticipatory changes in the walking pattern could also be described by change in the recruitment of a fixed set of walking muscle synergies (Chvatal and Ting, 2012). Thus, our study supports that idea that muscle synergies form a general repertoire of motor actions that can be recruited by a variety of different neural pathways for voluntary, rhythmic, and reactive motor behaviors (Chvatal and Ting, 2012).

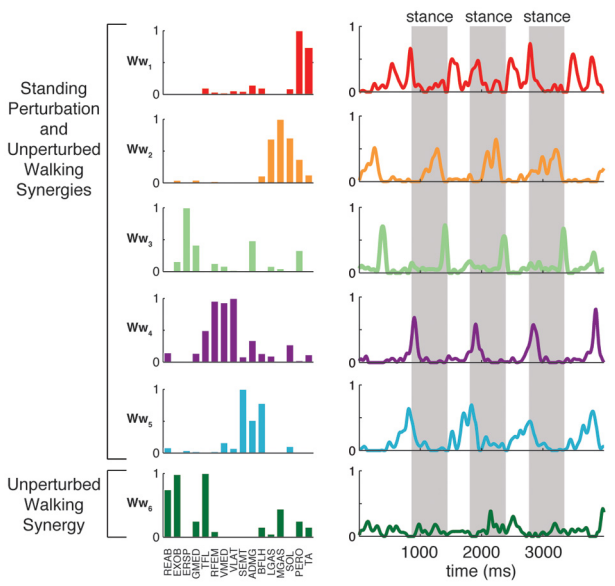

FIGURE 8 | Recruitment of muscle synergies identified in unperturbed walking. Ww_6 was identified from unperturbed walking but not during perturbation responses in any condition. Shown are the recruitment coefficients for a single trial of unperturbed walking at the self-selected speed. The gray boxes indicate stance phase.

Our findings support prior work demonstrating that changes in the modular organization of walking affect both walking and balance function. For example, the number of muscle synergies for walking is often reduced in the paretic limb of individuals with post-stroke hemiplegia (Clark et al., 2010) or their organization is modified (Gizzi et al., 2011). The reduction in muscle synergies is correlated not only to walking speed (Clark et al., 2010), but also to measures of balance control during standing (Bowden et al., 2010). In Parkinson's disease (PD), a reduced number of muscle synergies has been identified during walking (Rodriguez et al., 2013), but the relationship to postural instability, a cardinal sign of PD, is unknown. Further, degradation in upper limb function after stroke may be a result of changes in the modular organization of long-latency responses (Trumbower et al., 2010, 2013). These initial studies suggest that muscle synergy analysis may be a powerful tool for distinguishing specific deficits in muscle coordination leading to functional impairments that may be generalized across different motor behaviors.

Muscle synergies may therefore form the lowest level of the motor control hierarchy, recruited by parallel descending pathways mediating a wide variety of motor behaviors. Because muscle synergies only prescribe the spatial coordination of muscles to produce a motor function at a given instant in time, they may be concurrently recruited by different neural circuits mediating motor behaviors with common task-level goals. During locomotion, spinal mechanisms specifying the locomotor rhythm are known to be distinct from the spatial patterning of muscles across the limbs (Lafreniere-Roula and McCrea, 2005). Moreover, spatial patterning by muscle synergies is not modified by sensory feedback (Hart and Giszter, 2004; Cheung et al., 2005; Kargo et al., 2010) and is thought to be downstream of the rhythm generation mechanisms (Burke et al., 2001; McCrea and Rybak, 2008). Further evidence suggests that the same muscle synergies can also be recruited by cortical mechanisms to alter the locomotor pattern during motor planning and obstacle avoidance during locomotion (Drew, 1988; Drew et al., 2002, 2008), or anticipation of a balance perturbation during walking (Chvatal and Ting, 2012). Similarly, in reactive balance, the temporal patterning of the long-latency sensorimotor feedback response also appears to be independent of the precise spatial patterning of muscles defined by muscle synergies (Welch and Ting, 2009; Torres-Oviedo and Ting, 2010; Chvatal et al., 2011). Both voluntary and reactive balance responses are thought to be mediated by brainstem pathways (Schepens and Drew, 2004; Deliagina et al., 2008; Schepens et al., 2008; Lyalka et al., 2009) and may recruit different muscles synergies depending upon task demands. In reduced preparation, common muscle synergies are used in both

automatic and reactive motor behaviors (Cheung et al., 2005; Kargo and Giszter, 2008; Roh et al., 2011). Therefore, muscle synergies may form a modular repertoire of actions that is specific to any given motor task, but recruited by a variety of neural pathways governing different motor behaviors.

As long-latency response to perturbations are modified with task-level goals during posture and movement, it is likely that common mechanisms govern reactive balance responses in standing and walking. Following perturbations during both standing (Horak and Nashner, 1986; Torres-Oviedo and Ting, 2007) and walking (Pijnappels et al., 2005; van Der Linden et al., 2007; Chvatal and Ting, 2012) muscles exhibit similar long-latency responses (∼100 ms in humans). Moreover, long-latency responses coordinate the stance and swing limbs even when afferent inputs originate from a single limb (Dietz et al., 1989; Tang et al., 1998; Dietz and Duysens, 2000; Ting et al., 2000; Reisman et al., 2005; Duysens et al., 2013). Therefore, in contrast to short-latency responses that simply return the limb posture to the original configuration (Horak and Macpherson, 1996), long-latency motor patterns reflect abstract task-level goals such as controlling endpoint or CoM motion, which cannot be specified by independent joint-level controllers and require multisensory information. Moreover, it has been shown in both the upper and lower extremity that long-latency responses are modulated by motor planning, obstacle avoidance, and voluntary movement goals (Marsden et al., 1972, 1981; Carpenter et al., 1999; Pruszynski et al., 2009; Shemmell et al., 2010; Pruszynski and Scott, 2012) and are influenced by cortical contributions (Evarts and Tanji, 1976; Cheney and Fetz, 1984; Taube et al., 2006; Pruszynski et al., 2011). Accordingly, we previously found that reactive balance responses during whole-body reaching were modified to support target acquisition (Trivedi et al., 2010). Similarly, in this study, muscle synergy W_4 is recruited in reactive balance during standing to move the CoM backwards, but not during walking, presumably so as not to inhibit forward progression. Likewise, our recent studies further demonstrate that the recruitment of muscle synergies during reactive balance reflect task-relevant error, e.g., deviation of the CoM from the upright condition (Safavynia and Ting, 2013), even when perturbations are imposed when the body is already deviated from the desired state. Therefore, long-latency mechanisms which restore the body to the upright equilibrium state during standing balance appear to be modified during voluntary movements and walking to support the return of the body to the desired trajectory (Pozzo et al., 1990; Borghese et al., 1996).

Here, differences observed in muscle synergies identified across walking and reactive balance conditions could be explained by differences in the task-level goals. Muscle synergies that appear to be specific to walking perturbations were similar to a previously identified muscle synergy in perturbations during standing on one leg (Torres-Oviedo and Ting, 2010). Therefore, these muscle synergies likely reflect the additional biomechanical challenges associated with single limb stance, whether it occurs during standing or walking. Although this muscle synergy was not used in unperturbed walking, it might be expected to contribute to walking conditions that require more non-sagittal plane control such as turning (Courtine and Schieppati, 2003). Further, muscle synergies used during sagittal plane motions in standing balance recovery were absent in perturbations to walking, consistent with the different goals for CoM motion in standing and walking. For example, some muscle synergies were recruited following forward perturbations in standing to move the CoM forward back to the original position, but were not identified in walking (**Figure 6B**); presumably the forward momentum of the body during walking was sufficient to move the CoM forward in response to forward perturbations during walking. Similarly, following backward perturbations which caused the body to fall forward, W_4 was recruited in standing to move the CoM back to the original position (**Figure 6A**), whereas in walking these perturbations were consistent with the goal of moving the CoM forward for forward progression, so recruiting W_4 was not necessary. Furthermore, these muscle synergies for posterior CoM movements identified in perturbation responses during standing but not walking were actually found to contribute to unperturbed walking, likely acting to decelerate the limb near the end of swing. Additionally, some muscle synergies involving hip and trunk muscles used in unperturbed walking that were not found in the standing perturbation responses measured here (Ww6, **Figure 8**) are similar to muscle synergies that emerge under more dynamic perturbations in standing balance that were hypothesized to stabilize trunk orientation (Safavynia and Ting, 2013). Together these findings suggest that muscle synergies provide a motor repertoire for the lower limbs and trunk across diverse balance and locomotor behaviors.

A complementary notion of modularity in locomotion has focused on the generation of temporal patterns during locomotion. A set of fixed temporal patterns governing muscle activity has been identified during walking, even when voluntary actions are concurrently performed (Ivanenko et al., 2004, 2005). These studies demonstrated that the neural mechanisms governing rhythmic generation of motor commands may also be modular. However, reactive balance is clearly a feedback response that depends closely on the characteristics of the perturbation (Lockhart and Ting, 2007; Welch and Ting, 2009), and as we have shown here, the temporal response to perturbations in reactive balance is likely controlled independent from the locomotor rhythm. When using NMF to identify fixed temporal patterns, the spatial muscle coordination pattern necessarily varies across timepoints, as detailed in Safavynia, 2012 (Safavynia and Ting, 2012). However, it is likely that the fixed temporal patterns for locomotor rhythm generation recruit spatially-fixed muscle activation patterns, such as the muscle synergies identified here. Dissociating modularity in the temporal and spatial domains requires a hierarchical analysis procedure to first identify modularity in spatial muscle activity, followed by modularity in temporal muscle activity (Safavynia and Ting, 2012, 2013). Our results suggest that reactive balance responses during walking are achieved by distinct mechanisms governing reactive balance, which may be superimposed upon the rhythmic walking patterns and recruit a common set of spatially-fixed muscle synergies.

Although muscle synergies can explain a large proportion of variability observed in muscle activity, using muscle synergy analysis to draw conclusions about neural mechanisms has limitations. First, the selection of the number muscle synergies could vary depending on the method used. Typically, to ensure that the

results are physiologically interpretable, several different criteria must be achieved. Overall VAF is typically a poor indicator of the goodness of fit, whereas as local criteria, such as the VAF for a particular experimental condition or phase of gait reflect the degree to which actual muscle coordination patterns are reconstructed (Ting and Chvatal, 2010). Remaining variability in muscle activity may reflect sensorimotor noise, or other neural mechanisms such as short-latency reflex responses and may not be accounted for by recruitment of muscle synergies (Ting, 2007). In particular, heterogenic reflex responses (Nichols, 1994) may have different organization than muscle synergies for long-latency responses and voluntary movements (Trumbower et al., 2013). Further, motoneuron excitability may vary with joint angle (Hyngstrom et al., 2007), causing differences in apparent muscle synergy composition across postures. One strength of the muscle synergy analysis is that the number of independent motor command signals is not affected by crosstalk in EMG signals, however, crosstalk will alter the apparent composition of muscle synergies extracted. While it is not possible to dissociate co-activation from crosstalk in adjacent muscles, muscle synergy analysis can identify whether a muscle is activated independent from an adjacent muscle even in the presence of crosstalk. Here, we only performed comparisons of muscle synergies within the same subject, such that effects of any possible crosstalk would carry over from one condition to the next, and do not affect conclusions about similarity of muscle synergies across conditions. However, such crosstalk could be more problematic when comparing muscle synergies across subjects. Finally, the number of muscle synergies that can be identified is limited by the number of muscle signals analyzed as well as by the number of disparate conditions examined. Therefore, the number of muscles recorded and the number of experimental conditions must both be sufficiently high such that a sufficiently diverse set of muscle coordination patterns is represented in the dataset. Nonetheless, given the appropriate experimental design, muscle synergy analysis can help describe and potentially predict muscle coordination patterns in a functional and physiologically-relevant way.

A modular organization of spatial motor patterns may be a common principle for control of the upper and lower limbs useful for discerning mechanisms of motor deficit. Although muscle synergies for the upper and lower limbs may have different neural substrates, common principles likely govern their recruitment and organization. Muscle synergies for reaching may be organized by pyramidal cells in the motor cortex which project to multiple motoneurons. (Holdefer and Miller, 2002; Gentner and Classen, 2006; Overduin et al., 2008; Gentner et al., 2010; D'Avella et al., 2011). Pyramidal cells can also project to reticulospinal (Davidson et al., 2007) and propriospinal interneurons (Rathelot and Strick, 2009; Alstermark and Isa, 2012) which may explain residual motor function following stroke (Davidson and Buford, 2006). Muscle synergies for lower-limb movements are more likely encoded in the spinal cord (Hart and Giszter, 2004, 2010; Cheung et al., 2005; Kargo et al., 2010) and recruited by different neural pathways in the spinal cord, brainstem, and higher brain regions (Roh et al., 2011). By dissociating spatial from temporal aspects of motor coordination, muscle synergy analysis may aid in identifying neural impairments that are not evident in current clinical measures of motor function (Wolf et al., 1997; Coote et al., 2009; Hackney and Earhart, 2010). Such information may be important in identifying specific neural pathways that should be targeted for rehabilitation interventions, as well as for predicting generalized deficits in motor behaviors that are not specific to the particular tasks performed.

The purpose of the present study was to determine whether subjects who have learned a complex motor skill exhibit similar neuromuscular control strategies. We studied a population of experienced gymnasts during backward giant swings on the high bar. This cyclic movement is interesting because it requires learning, as untrained subjects are unable to perform this task. Nine gymnasts were tested. Both kinematics and electromyographic (EMG) patterns of 12 upper-limb and trunk muscles were recorded. Muscle synergies were extracted by non-negative matrix factorization (NMF), providing two components: muscle synergy vectors and synergy activation coefficients. First, the coefficient of correlation (r) and circular cross-correlation (r_{max}) were calculated to assess similarities in the mechanical patterns, EMG patterns, and muscle synergies between gymnasts. We performed a further analysis to verify that the muscle synergies (in terms of muscle synergy vectors or synergy activation coefficients) extracted for one gymnast accounted for the EMG patterns of the other gymnasts. Three muscle synergies explained $89.9 \pm 2.0\%$ of the variance accounted for (VAF). The coefficients of correlation of the muscle synergy vectors among the participants were 0.83 ± 0.08, 0.86 ± 0.09, and 0.66 ± 0.28 for synergy #1, #2, and #3, respectively. By keeping the muscle synergy vectors constant, we obtained an averaged VAF across all pairwise comparisons of $79 \pm 4\%$. For the synergy activation coefficients, r_{max}-values were 0.96 ± 0.03, 0.92 ± 0.03, and 0.95 ± 0.03, for synergy #1, #2, and #3, respectively. By keeping the synergy activation coefficients constant, we obtained an averaged VAF across all pairwise comparisons of $72 \pm 5\%$. Although variability was found (especially for synergy #3), the gymnasts exhibited gross similar neuromuscular strategies when performing backward giant swings. This confirms that the muscle synergies are consistent across participants, even during a skilled motor task that requires learning.

Keywords: motor modules, muscle coordination, nonegative matrix factorization, motor primitives, electromyography, backward giant circle, gymnastics

INTRODUCTION

Understanding how the central nervous system controls movement of the human body is a challenging question due to the biomechanical redundancy of the neuromusculoskeletal system, which is referred to as Bernstein's degrees of freedom problem (Bernstein, 1967). For example, at the neuromuscular level, the same movement can be performed by different muscle coordination strategies across trials (Torres-Oviedo and Ting, 2007) and/or between subjects (Ryan and Gregor, 1992; Hug et al., 2004). Low-dimensional modules formed by muscles activated in synchrony, referred to as muscle synergies, have been proposed as building blocks that may simplify the construction of motor behaviors (Ivanenko et al., 2003; d'Avella and Bizzi, 2005; Ting and McKay, 2007; Torres-Oviedo and Ting, 2007; Ting and Chvatal, 2010). The decomposition of multiple surface electromyographic (EMG) signals can be used to extract these synergies. This decomposition algorithm is based on two components: "muscle synergy vectors" which represent the relative weighting of each muscle within each synergy; and a "synergy activation coefficient" which represents the recruitment of the muscle synergy over time (Torres-Oviedo and Ting, 2007; Hug et al., 2011). Some previous research has proposed that temporal recruitment patterns are invariant while the weights can change across subjects/test conditions (Ivanenko et al., 2004, 2005; Cappellini et al., 2006; Dominici et al., 2011). Others have suggested that the muscle synergies are spatially fixed (i.e., muscle weightings are invariant) across subjects/test conditions while temporal recruitment patterns can change (Saltiel et al., 2001; Hart and Giszter, 2004; Torres-Oviedo and Ting, 2007; Hug et al., 2011; Safavynia and Ting, 2012). In line with this latter proposition, it has been shown during both postural (Torres-Oviedo and Ting, 2010) and locomotor tasks (Hug et al., 2011; Chvatal and Ting, 2012) that muscle synergy vectors (i.e., muscle weightings) are robust across various mechanical constraints allowing the temporal recruitment to vary according to the task demand. Moreover, altering the recruitment pattern of spatially fixed muscle synergies can produce different motor behaviors in animals (Cheung et al., 2005; Kargo et al., 2010).

As proposed by Safavynia et al. (2011), the acquisition of new motor skills can encourage the development of new muscle synergies, change the composition of existing synergies, and/or change their temporal activation. Through the process of learning, the modulation of the number and/or the composition of muscle synergies has been identified for postural tasks in humans (Asaka et al., 2008; Danna-Dos-Santos et al., 2008) and for reach-to-grasp tasks in rodents (Kargo and Nitz, 2003). Simultaneously with improving performance, the composition of the muscle synergies modulates toward consistent patterns across the animals, in terms of both synergy composition and temporal recruitment (Kargo and Nitz, 2003). Hug et al. (2010) reported similar muscle synergies among trained cyclists. However, one common feature of the movements studied in the aforementioned studies is that they can be considered as fundamental or basic movement skills (mainly locomotor and balance skills) and consequently all healthy subjects would be able to perform them with similar mechanical performance in terms of both kinematics and kinetics. As evidence, kinetic patterns in terms of both effective force and mechanical effectiveness are very similar between untrained subjects and trained cyclists (Sanderson, 1991; Mornieux et al., 2008).

The purpose of the present study was to determine whether experts exhibit similar neuromuscular control strategies during a complex motor skill. In other words, did the learning process necessary to perform this task led to similar muscle synergies or did each individual develop specific synergies related to their personal anthropometric, anatomical, or muscular characteristics? In order to answer these questions, we looked at a homogeneous population of nine experienced gymnasts performing giant swings on a high bar. This cyclic movement is interesting because it requires learning, as untrained subjects are unable to perform this task. As proposed by Wulf and Shea (2002), motor tasks can be qualified as "complex" if they cannot be mastered in a single session. Consequently, we considered the gymnastic backward giant swing on a high bar as a complex motor skill that would provide a contrast to fundamental motor skills such as balance, walking, or pedaling. For the purpose of this study, we used a non-negative matrix factorization (NMF) algorithm to identify muscle synergies from surface electromyographic recordings performed on 12 upper-limb and trunk muscles of the right side. In light of recent studies (Chvatal and Ting, 2012; Safavynia and Ting, 2012), we hypothesized that performing a complex motor performance would result from the recruitment of similar spatially fixed muscle synergies, which would be flexibly recruited over the giant swings, across all individuals.

MATERIALS AND METHODS

PARTICIPANTS

Nine gymnasts performing at national level (age: 19.8 ± 2.5 years, height: 171 ± 8 cm, body mass: 66 ± 8.1 kg) and with 14 ± 3 years of training experience participated in this study. They were informed of the purpose of the study and methods used before providing written consent. The local ethics committee (University of Nantes) approved the study, and all the procedures conformed to the Declaration of Helsinki (last modified in 2004).

PROTOCOL

Participants were asked to perform two sets of 11–12-linked backward giant swings, with 3–5 min of rest period in-between. A giant swing was defined as a complete rotation of the subject around the high bar. In this study, we considered the beginning and the end of a giant swing as when the gymnast was in the vertical position under the bar (**Figure 1**). To manage a complete rotation around the bar, the gymnasts can vary their body length to account for the loss of velocity due to the effect of friction between the hands and the bar. The gymnasts extend their body away from the bar to lengthen his radius of gyration during the descent phase, and shorten their body in the ascent phase (Sevrez et al., 2009). To do this and in line with the recommendations from the point code of the International Gymnastic Federation, the elbow and knee joints should be maintained in extension and only flexion-extension of the shoulder and hip joints are authorized for varying the body length.

MATERIALS AND DATA COLLECTION

Motion analysis

The giant swings were recorded with a video camera (Casio Exilim EX-ZR100, Casio Computer Co. Ltd., Tokyo, Japan) in the main plane of movement (i.e., sagittal plane) with a sampling frequency of 120 Hz. The camera was placed along the longitudinal axis of the bar at a distance of 5 m and a height of 2.60 m, equivalent to the height of the bar from the landing mat. The placement of the video camera had to cover a sufficient range to record the entire body of the gymnast during the giant swing, with the high bar at the center of the field. The calibration square was 1 × 1 m and the origin of the inertial coordinate system was located at the center of the bar in its neutral position. The x-axis was defined as the horizontal axis in the main plane of movement. The y-axis was defined as the vertical axis. The angular position of the gymnast from the bar was defined as the angle formed by the axis linking the femoral trochanter (hip marker) with the bar and the y-axis of reference (below the bar). To reconstruct a multi-segment model of the gymnast, adhesive strips were placed on defined body locations for use as markers. The digitization of body marks was performed using Skillspector© software (Video4coach, Svendborg, Denmark) for the lower extremity (ankle, knee, and hip joints) and the upper extremity (wrist, elbow, and shoulder joints). The trunk was delineated by the shoulder and the hip. Thus, the model was composed of five segments (**Figure 2**): the arm, forearm, trunk, thigh, and leg. The masses and moments of inertia of different segments were calculated using an anthropometric table (de Leva, 1996), which was adjusted with consideration that the digitized model had one upper and one lower limb. Position data was smoothed using a 4th order low-pass Butterworth filter with a cut-off frequency of 5 Hz.

Surface electromyography

From the assumption of symmetry in the actions of both upper limbs during the execution of the elements on the high bar, and to avoid electrocardiogram artifacts, the activity of 12 muscles

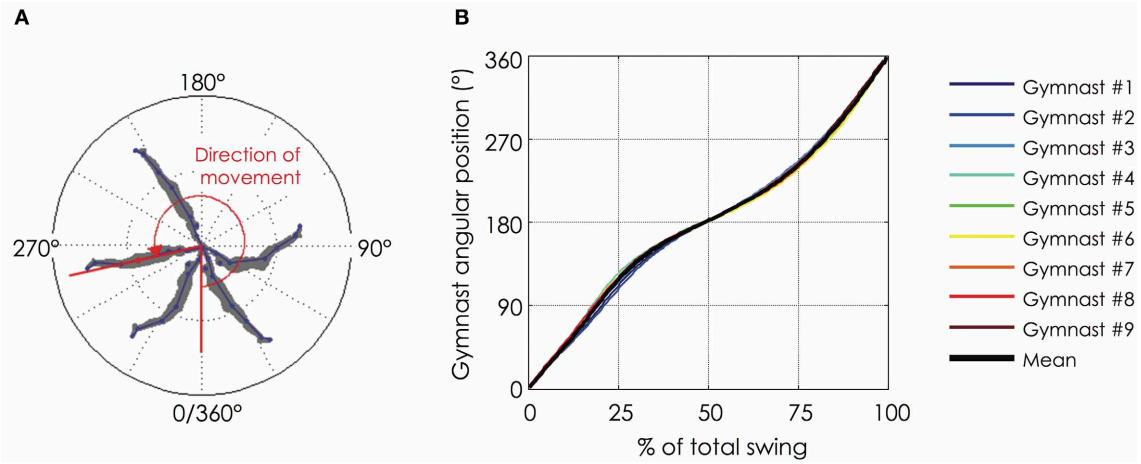

FIGURE 1 | Angular position of the gymnast during a backward giant swing. (A) The angular position of the gymnast from the bar was defined as the angle formed by the axis linking the femoral trochanter (hip marker) with the bar and the vertical axis of reference (below the bar); **(B)** Evolution of the angular position of the gymnast as a function of the normalized time of the backward giant swing. The black bold line represents the mean value of the group while the thin color lines represent mean value among 9 successive giant swings for each gymnast. The gymnasts performed their backward giant swings in a very similar fashion (for more details see section "Mechanical Data"). The relationship between the angular position and the normalized time of the backward giant swing is not linear. The lower part (0–90° and 270–360°) is shorter than the upper part (90–270°) of the giant swing.

of the right side of the body was recorded: flexor digitorum (FD), short head of the biceps brachii (BBsh), long head of the biceps brachii (BBlh), lateral head of the triceps brachii (TB), clavicular (anterior) and scapular (posterior) parts of the deltoideus (DC and DS, respectively), upper part of the trapezius (TZ), latissimus dorsi (LD), sternocostal part of the pectoralis major (PM), rectus abdominis (RA), erector spinae at level of L4 (ES), and rectus femoris (RF). The surface EMG recordings were made using self-adhesive Ag/AgCl pairs of electrodes (Blue sensor N, Ambu, Denmark) with an inter-electrode distance of 20 mm (center-to-center). The electrodes were placed longitudinally with respect to the underlying muscle fiber arrangement (de Luca, 1997) and were located according to the recommendations of Surface EMG for Non-Invasive Assessment of Muscles (SENIAM) (Hermens et al., 2000) when available. For back muscles (TZ, LD, and ES), the electrodes position was according to de Sèze and Cazalets (2008). Skin was shaved and cleaned with alcohol and ether to minimize impedance before applying the electrodes. The wires connected to the electrodes were secured carefully with adhesive tape to avoid any movement-induced artifacts. Raw EMG signals were preamplified close to the electrodes (gain 375, bandwidth 8–500 Hz) at a sampling rate of 1000 Hz (ME6000, Mega Electronics Ltd., Kuopio, Finland). The EMG device was firmly attached on a belt during execution of the giant swings.

EMG-video synchronization

To synchronize the motion capture with the EMG recordings, percutaneous muscular stimulation (model DS7A, Digitimer Ltd., Letchworth Garden City, UK) was performed on the forearm muscles of the gymnast prior to and subsequent to each set of 12-linked giant swings. Both video and EMG were recorded when the stimulation was applied, bringing a brief artifact on the EMG signal of the FD muscle and lighting a LED in the field of the video camera.

DATA ANALYSIS

Biomechanical profile of the giant swing

Kinematic and dynamic variables were extracted from the motion capture such as the horizontal and vertical positions of the center of gravity (CG) of each segment and of the gymnast's model (in m), the angular velocity of the gymnast (ω_G, in °/s), and the shoulder and hip flexion-extension angle (in degree). Herein a flexion of the shoulder joint refers to a decrease in the trunk-upper arm angle of the digitized model, which is in contrast to the clinical frontal shoulder flexion that generally corresponds to an increasing angle between the trunk and the arm. The moment of inertia (I_G, in kg.m^2) around the gymnast's CG and the gymnast's total body energy (E_{Tot}, in Joule/kg) were calculated. The moment of inertia around the gymnast's CG was computed as follows:

$$I_G = \sum_{i=1}^{5} \left[I_i + (M \cdot m_i) \cdot d_i^2 \right], \tag{1}$$

where I_i was the moment of inertia of the ith segment, M the mass of the gymnast, m_i the mass of the ith segment, d_i the distance between the CG of the ith segment and the CG of the whole gymnast's body. According to de Leva (1996), the moment of inertia of each segment i was equal to:

$$I_i = (M \cdot m_i) \cdot (l_i \cdot r_i)^2, \tag{2}$$

where l_i was the length of the ith segment and r_i was the radius of gyration of the ith segment about the transversal axis expressed as a proportion of the segment length.

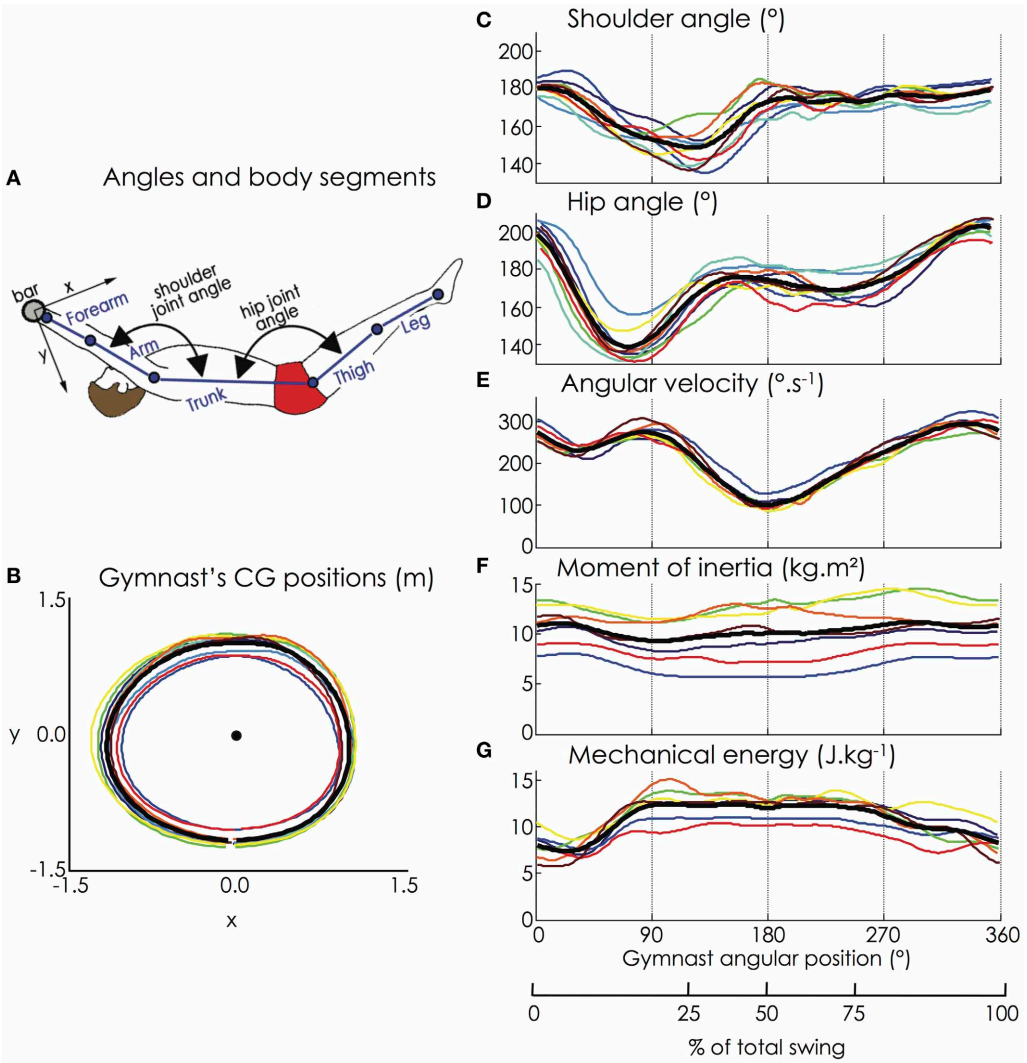

FIGURE 2 | (A) Joint angles and body segments of the gymnast model; **(B)** Horizontal and vertical positions of the gymnasts' CG; **(C)** Flexion-extension of the shoulder joint; **(D)** Flexion-extension of the hip joint; **(E)** Angular velocity of the gymnast model (hip marker); **(F)** Moment of inertia, and **(G)** Mechanical energy of the gymnast model. The black bold line represents the mean value of the group while the thin color lines represent the mean value among 9 successive giant swings for each gymnast (for the color legend, see **Figure 1**). Except for the moment of inertia that exhibited a high interindividual variability due to large time shifts, all the biomechanical variables were similar among the participants.

According to Arampatzis and Brüggemann (2001), the gymnast's total body energy was equal to:

$$E_{\mathrm{Tot}} = \sum_{i=1}^{5} (1/2 \cdot (M \cdot m_i) v_i^2 + 1/2 \cdot I_i \omega_i^2 + (M \cdot m_i) g h_i), \quad (3)$$

where v_i was the linear velocity of the ith segment, ω_i the angular velocity of the ith segment, g the acceleration due to gravity, and h_i the height of the ith segment center of gravity. E_{Tot} was normalized to the body mass of the gymnast for comparison purpose. The examined variables (positions of the CG of the gymnast, joint angles, angular velocity, moment of inertia, and mechanical energy) were presented as a function of the body position angle, from 0 to 360° with 0° corresponding to the vertical axis below the high bar.

Extraction of muscle synergies

As inter-cycle variability contains important information for identifying the muscle synergies (Clark et al., 2010; Ting et al., 2012), they were extracted from a set of nine consecutive giant swings, with the first and last giant swing being automatically removed. EMG signals were band-pass filtered (20–450 Hz, Butterworth filter, 2nd order), rectified, smoothed with a zero lag low-pass filter (9 Hz, Butterworth filter, 2nd order), and time-normalized in order to obtain 200 data points for each giant swing. EMG was normalized to the maximum level of activity across all giant swings (Turpin et al., 2011a). Therefore, as

is classically done in studies focusing on muscle synergies, the degree of muscle activity was not taken into consideration.

NMF was performed from this dataset. For this purpose, we implemented the Lee and Seung (2001) algorithm. Matrix factorization minimizes the residual Frobenius norm between the initial matrix and its decomposition, and is given as:

$$\mathbf{E} = \mathbf{WC} + \mathbf{e} \tag{4}$$

$$\min_{\substack{W \geq 0 \\ C \geq 0}} \| \mathbf{E} - \mathbf{WC} \|_{\mathrm{FRO}} \tag{5}$$

where **E** is a p-by-n initial matrix (p = number of muscles and n = number of time points), **W** is a p-by-s matrix (s = number of synergies), **C** is a s-by-n matrix, and e is a p-by-n matrix. $\|\bullet\|_{\mathrm{FRO}}$ establishes the Frobenius norm, **W** represents the muscle synergy vectors matrix, **C** is the synergy activation coefficients matrix, and **e** is the residual error matrix. The algorithm is based on iterative updates of an initial random guess of **W** and **C** that converge to a local optimal matrix factorization [see Lee and Seung (2001) for more details]. To avoid local minima, the algorithm was repeated 20 times for each subject. The lowest cost solution was kept (i.e., minimized squared error between original and reconstructed EMG patterns). The initial matrix **E** consisted of 9 consecutives giant swings for the 12 muscles. As each giant swing was interpolated to 200 time points, **E** was a 12-row and 1800-column matrix.

We iterated the analysis by varying the number of synergies between 1 and 12 and then selected the least number of synergies that accounted for >90% of variance accounted for (VAF) (Torres-Oviedo et al., 2006) or until adding an additional synergy did not increase VAF by >5% of VAF (Clark et al., 2010). Mean total VAF was defined as (Torres-Oviedo et al., 2006):

$$\mathrm{VAF} = 1 - \frac{\sum_{i=1}^{p} \sum_{j=1}^{n} (e_{i,j})^2}{\sum_{i=1}^{p} \sum_{j=1}^{n} (E_{i,j})^2} \tag{6}$$

As the determination of the correct number of muscle synergies is not a trivial matter (Tresch et al., 2006), we further confirmed our results by using the best linear fit (BLF) method which selected the smallest n such that a linear fit of the "VAF" vs. "number of synergies" curve, from n to 12, had a residual mean square error of less than 5×10^{-5} [i.e., the point at which the VAF curve plateaus to a straight line; see Cheung et al. (2005); Ajiboye and Weir (2009)]. Finally, we used a method reported by Cheung et al. (2009), named "knee point (KP)" herein. Briefly, the "VAF" vs. "number of synergies" curve was constructed from both the original EMG dataset and an unstructured EMG dataset generated by randomly shuffling the original dataset across time and muscles. n was then defined as the point beyond which the original-slope drops below 75% of the surrogate-slope. This corresponds to the number beyond which any further increase in the number of extracted synergies yields a VAF increase smaller than 75% of that expected from chance.

We calculated VAF for each muscle ($\mathrm{VAF}_{\mathrm{muscle}}$) to ensure that each muscle activity pattern was well accounted for by the extracted muscle synergies [for further details, see Hug et al. (2011)]. Finally, to further determine the subject-specific dimensionality of the data we calculated, for each gymnast, VAF for each of the extracted muscle synergies.

Cross-validation of the extracted muscle synergies

To verify the within-subject consistency of the extracted muscle synergies, we used a cross-validation procedure as proposed by previous research (e.g., Cheung et al., 2005, 2009; Ting and Chvatal, 2010). For each participant, we checked that the muscle synergy vectors extracted for one set of giant swings (first set) accounted for the EMG patterns in the other set. To do this, the muscle synergy matrix (muscle synergy vectors) was held fixed in the algorithm and the coefficients matrix was free to vary [for additional details, see Hug et al. (2011)].

Between-subject similarity

The comparison of the shape (i.e., waveform) of mechanical patterns, individual EMG patterns and synergy activation coefficients was assessed using two criterions: the Pearson's correlation coefficient (r) and the circular cross-correlation coefficient ($r_{\max}$). We also calculated the absolute lag times that assess differences in the timing of the activations (i.e., the magnitude of the time shift between mechanical patterns, EMG patterns or between synergy activation coefficients) as the lag time at the maximum of the cross-correlation function. As we are aware of the fact that r-values, $r_{\max}$-values and lag times provide some redundant information, we chose to report all of these indexes to increase our ability to compare our results with other studies that did not necessary report all these types of information. The index of similarity corresponded to both the averaged r- and $r_{\max}$-value between each pair of participants.

We then determined the similarity of muscle synergy vectors across participants by calculating a Pearson's correlation coefficient between each pair of participants. Based on the same principle that was previously described by Safavynia and Ting (2012), we considered a pair of muscle synergy vectors to be similar if $r = 0.71$, which corresponds to the critical value of r for 10 degrees of freedom (i.e., 12 − 2 muscles) at $p = 0.01$. However, because the NMF algorithm constrains muscle weightings to be non-negative, one would expect positive correlation by chance (Safavynia and Ting, 2012). Therefore, for each extracted synergy we generated 1000 random permutations of the weightings obtained from the extraction of the muscle synergy vectors. Then we calculated the r-value for each pair (36 pairs × 1000 iterations = 3600 r-values) and for each synergy, yielding a distribution of r-values expected by chance. An r-value of 0.71 corresponded to the 99th percentile of the distribution. Consequently, we considered a pair of muscle synergy vectors with a $r = 0.71$ more similar than expected by chance, and thus muscle synergy vectors with a $r < 0.71$ were considered different.

To further assess the similarity of the muscle synergies between the gymnasts, we checked that the muscle synergies extracted from one gymnast accounted for the overall and individual EMG patterns of each of the other gymnasts. The first step aimed at identifying the robustness of the muscle synergy vectors across

the subjects. To do this, the muscle synergy vectors matrix extracted from one subject (i.e., control subject herein, $\mathbf{W}_{control}$) was held fixed in the NMF algorithm while the activation coefficient matrix of the compared subject ($\mathbf{C}_{subject}$) was free to vary (Torres-Oviedo et al., 2006; Hug et al., 2011). $\mathbf{C}_{subject}$ was initialized with random values and iteratively updated until convergence. The EMG data matrix of the compared subject ($\mathbf{E}_{subject}$) was provided to the algorithm with the following update rule (Lee and Seung, 2001):

$$(C_{subject})_{ij} \leftarrow (C_{subject})_{ij} \frac{(W_{control}E_{subject})_{ij}}{(W_{control}W_{control}C_{subject})_{ij}} \quad (7)$$

This process was performed for each of the 72 pairwise comparisons (nine gymnasts compared with the eight others). The overall VAF and VAF_{muscle} were used to quantify the success of the fixed muscle weightings and the newly computed synergy activation coefficients to reconstruct the EMG patterns. A $VAF_{muscle} > 75\%$ was considered satisfying (Torres-Oviedo and Ting, 2007). The second step was similar to the first but aimed to determine the robustness of the activation coefficients across the participants by fixing the activation coefficients matrix ($\mathbf{C}_{control}$) while the muscle synergy vectors matrix ($\mathbf{W}_{subject}$) was free to vary. Finally, a Two-Way ANOVA (factors: muscles and reconstruction methods, i.e., fixed muscle synergy vectors vs. fixed synergy activation coefficients) was used to determine whether VAF_{muscle} differed between the muscles and was influenced by the reconstruction method (fixed vectors vs. fixed coefficients). *Post-hoc* analyses were made with Scheffe's tests. The level of significance was $p = 0.05$.

RESULTS

MECHANICAL DATA

Figure 2 depicts the kinematic and dynamic data computed from the motion capture of the giant swings. Due to the hip and the shoulder flexion, the gymnasts managed to increase their angular velocity (on average from 230 to 275°/s between 35 and 90° of the giant swing), which when associated with the decrease in the moment of inertia of the gymnast, allowed an increase in mechanical energy to a sufficient level to attain the handstand position above the bar (i.e., 180° of the giant swing).

Relative to the horizontal and vertical positions of the CG of each segment of the gymnast's model, the indices of similarity (i.e., r and r_{max}) were extremely high, ranging from 0.98 ± 0.02 to 1.00 ± 0.00. Regardless of the height of the participants, the trajectory of the CG of the gymnast's model was similar among them (**Figure 2**) with an averaged r-value and r_{max}-value of 1.00 ± 0.00. The averaged absolute lag time between each pair of participants was below 1% of the giant swing for each kinematic parameter (horizontal and vertical position of the segments' and gymnast's CG). The indices of similarity for the shoulder and hip joint angles, the angular velocity, the moment of inertia, and the mechanical energy of the gymnast are reported in **Table 1**. Except for the moment of inertia that exhibited a low averaged r-value (0.32 ± 0.55 and range: -0.81 to 0.97) due to large time shifts (averaged lag time $= 17.2 \pm 17.3\%$; range: 0.5–50.0% of the giant swing), all the biomechanical variables were similar among the participants. The lag that leads to differences in moment of inertia was mainly attributable to participant #7 who exhibited a moment of inertia in anti-phase relative to the other participants. This confirms that our population of gymnasts was homogeneous as they performed their backward giant swings similarly in terms of kinematics as well as dynamics.

Table 1 | Similarity of the kinematic and dynamic parameters across participants.

	r	r_{max}	Lag (%)
Shoulder angle	0.83 (0.36–0.96)	1.00 (1.00–1.00)	4.1 (0.0–11.5)
Hip angle	0.88 (0.62–0.98)	1.00 (1.00–1.00)	2.1 (0.0–5.5)
Angular velocity	0.97 (0.95–0.99)	1.00 (0.99–1.00)	0.9 (0.0–2.5)
Moment of inertia	0.32 (−0.81–0.97)	1.00 (0.99–1.00)	17.2 (0.5–50.0)
Mechanical energy	0.89 (0.77–0.97)	1.00 (0.99–1.00)	2.2 (0.0–4.5)

Values are mean (min-max). Lags were calculated as the lag times that maximized the cross-correlation function and correspond to the absolute time shift between the two waveforms (% giant swing).

Except for the moment of inertia that exhibited a low averaged r-value due to large time shifts (about 17% of the giant swing), all the biomechanical variables were similar among the participants.

INDIVIDUAL EMG PATTERNS

For each participant, the EMG patterns for the 12 muscles investigated are depicted in **Figure 3**. The inter-subject indices of similarity (i.e., r and r_{max}) are reported in **Table 2**. The averaged r-value between each pair of participants was 0.70 ± 0.20, and ranged from 0.26 (DC) to 0.89 (FD). The averaged r_{max}-value was 0.90 ± 0.05, and ranged from 0.83 (DC) to 0.96 ± 0.02 (FD and RA). While the pattern of activity of some muscles exhibited high similarity between participants (e.g., FD, BBlh, LD, RA, ES, and RF), others were more variable (e.g., BBsh, TB, DC, DS, and TZ). The higher r_{max}-values compared with r-values showed that the variability between participants can be partly explained by time shifts of the EMG patterns. Indeed, we found an absolute lag time ranging from 1.5% (ES) to 18.5% (DC) in the giant swing (**Table 2**). The largest time shifts were observed for BBsh, DC, and TB muscles and were mainly attributable to participant #6 and #7 (**Figure 3**).

NUMBER OF EXTRACTED MUSCLE SYNERGIES

Figure 4A depicts the cumulative percentage of variance explained by each number of muscle synergies. Using the criterion previously described (i.e., VAF > 90% or until adding an additional synergy did not increase VAF by >5%), three synergies were identified for all the participants. When applying the BLF method, 6 out of 9 participants exhibited 3 muscle synergies (**Figure 4B**). When applying the KP method describing by Cheung et al. (2009), 8 out of 9 participants exhibited 4 muscle synergies (**Figure 4B**). These three analyses reveal that all (or most of) the participants exhibited the same number of muscle synergies (100% for the threshold method, 66% for BLF, and 89% for KP). Because it has not been demonstrated that one of this methods is more accurate than another to determine the correct

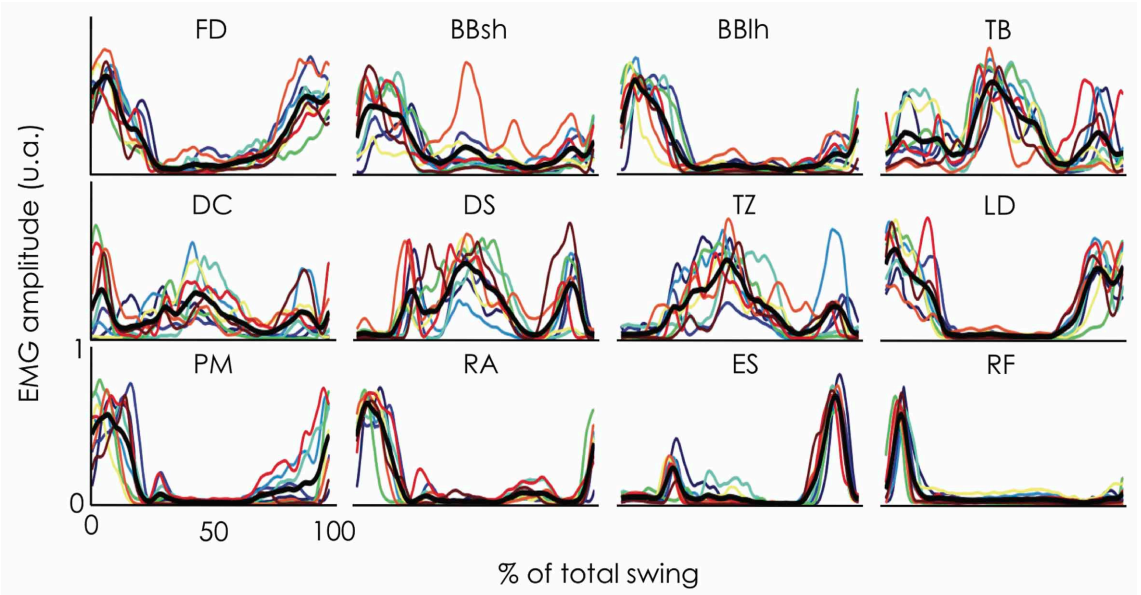

FIGURE 3 | Electromyographic (EMG) envelope for 12 muscles obtained in nine gymnasts during linked backward giant swings. Each profile represents an individual EMG pattern averaged across 9 consecutive giant swings and is expressed as a function of the percentage of the giant swing (0 and 100% correspond to the vertical position of the gymnast under the bar). The black bold line indicates the mean profile across the nine gymnasts while the thin color lines represent the individual data (for the color legend, see **Figure 1**). EMG was normalized to the maximum level of activity across all giant swings. While the pattern of activity of some muscles exhibited high similarity between participants (e.g., FD, BBlh, LD, RA, ES, and RF), others were more variable (e.g., BBsh, TB, DC, DS, and TZ). Variability between participants can be partly explained by time shifts of the EMG patterns. FD, flexor digitorum; BBsh, short head of the biceps brachii; BBlh, long head of the biceps brachii; TB, lateral head of the triceps brachii; DC, clavicular part of the deltoideus; DS, scapular part of the deltoideus; TZ, upper part of the trapezius; LD, latissimus dorsi, PM, sternocostal part of the pectoralis major; RA, rectus abdominis; ES, erector spinae at level of L4; RF, rectus femoris.

number of muscle synergies and because three muscle synergies were found to characterize the data in 2 out of the 3 methods, we decided to use three muscle synergies for all the participants for the subsequent analysis.

Three muscle synergies accounted for a mean VAF of $89.9 \pm 2.0\%$ (range: 86.1–92.5%) and the VAF_{muscle} ranged from 70.9 ± 8.5 to $92.8 \pm 4.3\%$ (**Figure 4C**). While VAF_{muscle} of BBsh, DC, and TZ was lower than 75% for some participants (1–2, depending on the muscle), VAF_{muscle} consistently dropped below 75% for RF. The VAF explained by each of the three extracted muscle synergies is depicted in **Figure 5** for each gymnast. We observed between-subject variability, especially for synergy #2 and #3 (coefficient of variation = 6.3, 34.7, and 53.9% for synergy #1, #2, and #3, respectively). This variability can be explained mainly by the fact that VAF was higher for synergy #3 compared to synergy #2 for participant #1 and #2, while it was to the contrary for all the other participants (**Figure 5**).

WITHIN-SUBJECT CONSISTENCY OF THE EXTRACTED MUSCLE SYNERGIES

An individual example (participant #6) of the three muscle synergies extracted during both the first and the second set is depicted in **Figure 6**. The cross-validation procedure showed that the muscle synergy vectors extracted for the first set of linked backward giant swings explained $87.9 \pm 2.7\%$ (range: 83.5–91.7%) of the variability of the dataset obtained during the second set. To further assess the repeatability of the extracted muscle synergies, we compared the two sets of giant swings. Both the synergy activation coefficients and the muscle synergy vectors exhibited good repeatability. The averaged r-value over the three muscle synergies was 0.93 ± 0.05 (range: 0.88–0.98) for the synergy activation coefficients and 0.93 ± 0.06 (range: 0.87–0.98) for the muscle synergy vectors.

Overall, these results clearly show that the muscle synergies were robust for a given participant allowing us to interpret a difference between participants as different motor control strategies rather than as methodological issues.

BETWEEN-SUBJECT VARIABILITY OF THE EXTRACTED MUSCLE SYNERGIES

The three extracted muscle synergies are depicting in **Figure 7**. The temporal activation of muscle synergies (i.e., synergy activation coefficients) was consistent across participants [r-value of 0.87 (range: 0.53–0.98), 0.76 (range: 0.50–0.87), and 0.72 (range: −0.03–0.98) for synergy #1, #2, and #3, respectively; r_{max}-value of 0.96 (range: 0.87–0.99), 0.92 (range: 0.86–0.98), and 0.95 (range: 0.85–0.99) for synergy #1, #2, and #3, respectively]. The higher r_{max}-values compared with r-values suggest that variability between participants is partly explained by time shifts. The mean absolute lag time was $4.3 \pm 2.1\%$ of the giant swing and ranged from $2.7 \pm 1.9\%$ (synergy #1) to $6.7 \pm 9.9\%$ (synergy #3) of the giant swing. The larger time shift observed in synergy #3

Table 2 | Between-subject variability of the EMG profiles.

	r	r_{max}	Lag (%)
Flexor digitorum	0.89 (0.75–0.96)	0.96 (0.92–0.99)	2.1 (0.0–6.0)
Biceps brachii (short head)	0.55 (0.03–0.96)	0.85 (0.67–0.98)	13.3 (0.0–40.5)
Biceps brachii (long head)	0.80 (0.44–0.98)	0.93 (0.83–0.99)	3.2 (0.0–8.5)
Triceps brachii	0.52 (0.04–0.90)	0.86 (0.71–0.97)	9.0 (0.0–46.0)
Deltoideus (anterior part)	0.26 (−0.37–0.81)	0.83 (0.71–0.94)	18.5 (0.0–48.0)
Deltoideus (posterior part)	0.58 (0.02–0.83)	0.84 (0.66–0.94)	5.4 (0.0–46.0)
Trapezius	0.59 (0.14–0.91)	0.86 (0.67–0.96)	5.8 (0.0–24.0)
Latissimus dorsi	0.82 (0.49–0.96)	0.92 (0.81–0.99)	2.9 (0.0–12.0)
Pectoralis major	0.74 (0.49–0.98)	0.90 (0.73–0.99)	4.1 (0.0–10.0)
Rectus abdominis	0.86 (0.51–0.99)	0.96 (0.89–0.99)	2.4 (0.0–7.5)
Erector spinae	0.87 (0.58–0.98)	0.95 (0.89–0.99)	1.5 (0.0–4.0)
Rectus femoris	0.86 (0.46–0.97)	0.94 (0.85–1.00)	1.6 (0.0–4.5)

Values are mean (min-max). Lags were calculated as the lag times that maximized the cross-correlation function and correspond to the absolute time shift between the two waveforms (% giant swing).

While the pattern of activity of some muscles exhibited high similarity between participants (e.g., FD, BBlh, LD, RA, ES, and RF), others were more variable (e.g., BBsh, TB, DC, DS, and TZ). As r_{max}-values are very high, variability between participants can be partly explained by time shifts of the EMG patterns.

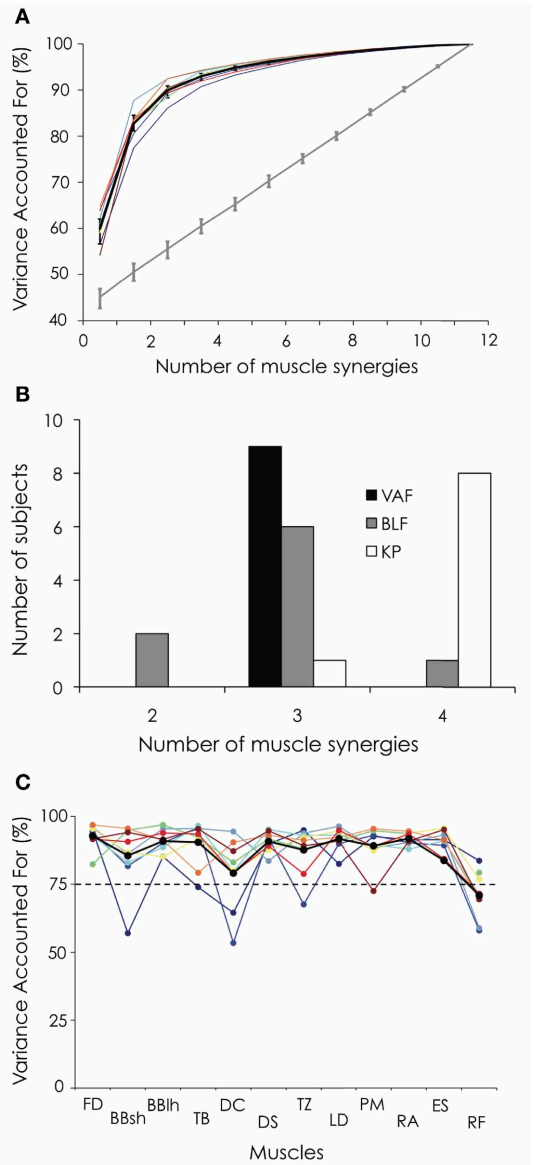

FIGURE 4 | Variance accounted for (VAF) and number of extracted muscle synergies. (A) The percentage of variance accounted for is depicted for each participant as a function of the number of extracted synergies. Error bars indicate the 95% bootstrap confidence interval across the participants for both the VAF calculated from the original data set (black bold line) and the VAF calculated from the unstructured EMG dataset generated by randomly shuffling the original dataset across time and muscles (gray bold line). **(B)** Number of extracted muscle synergies based on the VAF threshold method (VAF), the best linear fit method (BLF, Cheung et al., 2005) and the knee point method (KP, Cheung et al., 2009). **(C)** VAF_{muscle} is depicted for each participant and each muscle. For both Panels (**A** and **C**), the black bold line indicates the mean profile across the nine gymnasts. Abbreviations for individual muscles are described in the legend of **Figure 3**. For the color legend, see **Figure 1**.

compared to synergy #1 and #2 was mainly attributable to participant #5. Indeed, its peak of activation occurred during the first half of the swing (<50% of the total swing), while the other participants had their peak of activation coefficients in the second half of the swing (**Figure 7**).

Concerning the muscle synergy vectors, we found an averaged *r*-value of 0.83 (range: 0.62–0.97), 0.86 (range: 0.64–0.98), and 0.66 (range: 0.03–0.97) for synergy #1, #2, and #3, respectively. Considering the critical *r*-value of 0.71 (see methods), four pairwise comparisons (out of 36 possibilities, i.e., 11%) were different for synergy #1, two (6%) were different for synergy #2, and 13 were different for synergy #3 (36%). This clearly shows that the composition of synergy #1 and #2 was consistent across participants while the composition of synergy #3 was more variable, as highlighted by **Figure 7**.

As explained in the Methods, two additional analyses have been performed to test the similarity of the muscle synergies between participants. First, by keeping the muscle synergy vectors constant, we obtained an averaged VAF across all pairs of $79.3 \pm 3.7\%$ (range: 70.6–87.5%). The VAF_{muscle} ranged between $48.2 \pm 9.9\%$ (DC) and $86.8 \pm 2.4\%$ (RA). Relative to the preset threshold of VAF_{muscle} >75%, the EMG patterns of the BBsh, DC, and RF muscles were not correctly reconstructed (**Figure 8**). By keeping the synergy activation coefficients constant, the averaged VAF was $72.4 \pm 4.8\%$ (range: 60.2–82.9%). The VAF_{muscle} ranged between $56.1 \pm 3.8\%$ (DC) and $83.0 \pm 5.4\%$ (FD). Relative to the preset threshold of VAF_{muscle} >75%, the EMG pattern of the BBsh, TB, DC, DS, TZ, PM, ES, and RF muscles were not correctly reconstructed (**Figure 8**). The Two-Way ANOVA showed a significant main effect for both "muscle" and "reconstruction method" ($p < 0.01$). More precisely, VAF_{muscle} was significantly lower when the synergy activation coefficients were fixed than when muscle synergy vectors were fixed ($70.2 \pm 10.5\%$

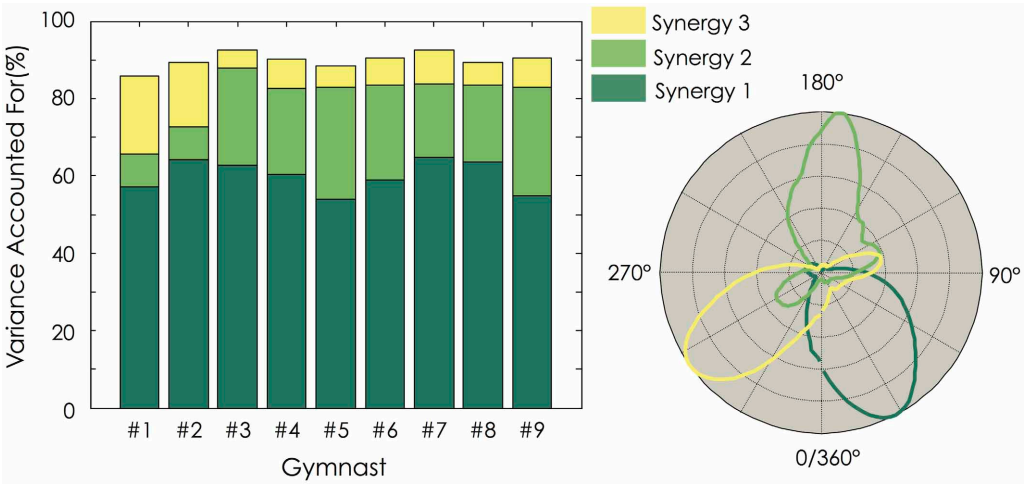

FIGURE 5 | Variance Explained For (VAF) for each of the three extracted muscle synergies. For each gymnast, VAF explained by each of the three extracted muscle synergies was calculated (**Left panel**). The temporal activation of each muscle synergy is depicted as a function of the mean angular position (**Right panel**). For all the gymnasts, it clearly appears that the dimensionality in their EMG data was mainly explained by the first muscle synergy. Gymnasts #1 and #2 exhibited a higher VAF by the third synergy than the second one. This strategy differs from the seven other gymnasts.

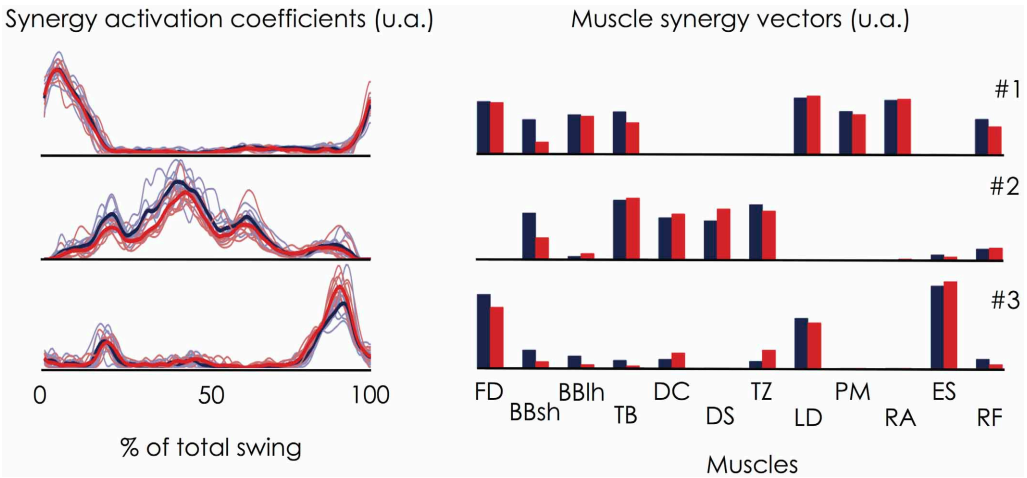

FIGURE 6 | Within-subject consistency of the muscle synergies extracted during the two sets of linked backward giant swings. This figure depicts an individual example (Participant #6). On the left panel, the thin lines correspond to the synergy activation coefficient extracted for each giant swing and the bold lines correspond to the averaged profile over the 9 consecutive giant swings. Red stands for the set #1 and blue stands for the set #2. The corresponding muscle synergy vectors are depicted on the right panel. This figure clearly shows that the muscle synergies were robust for a given participant. Indeed, the cross-validation procedure showed that the muscle synergy vectors extracted for the first set of linked backward giant swings explained 87.9 ± 2.7% (range: 83.5–91.7%) of the variability of the dataset obtained during the second set. Abbreviations for individual muscles are described in the legend of **Figure 3**.

vs. 75.4 ± 14.1%, respectively). VAF_{muscle} was significantly lower for BBsh, DC, DS, TZ, and RF muscles than for the others. Overall, these results suggested that the muscle synergy vectors were more consistent across the gymnasts than the synergy activation coefficients.

DISCUSSION

The results of the present study outlined three muscle synergies that accounted for the EMG patterns during giant swings on a high bar. The relative consistency of muscle synergies across trained gymnasts confirms that muscle synergies are consistent across participants (Torres-Oviedo and Ting, 2007; Cheung et al., 2009; Hug et al., 2011; Turpin et al., 2011b; Chvatal and Ting, 2012), even during a skilled motor task requiring learning.

METHODOLOGICAL CONSIDERATIONS

As done in previous research (Turpin et al., 2011a), EMG activity from each muscle was normalized to its peak value from all of the cycles. Note that this normalization procedure only provides information about the level of muscle activity in relation

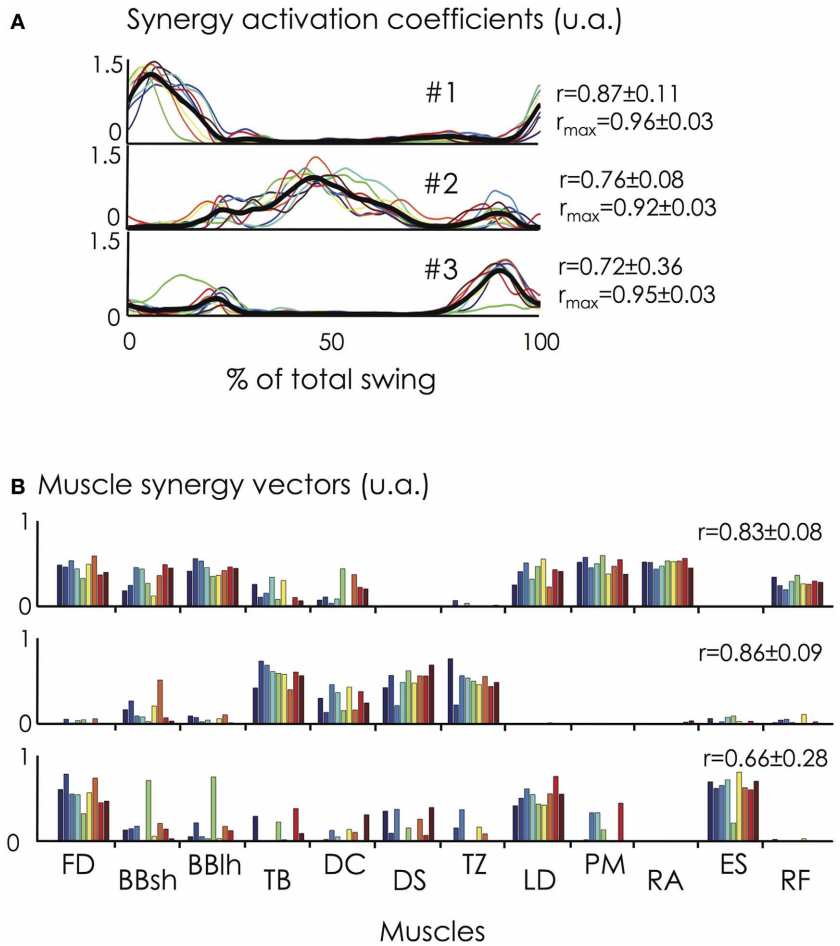

FIGURE 7 | Synergy activation coefficients (*C*) and muscle synergy vectors (*W*) across the nine gymnasts. (A) The synergy activation coefficients are shown at the top of the figure for all the participants and for the three extracted synergies (solid lines in different colors). The synergy activation coefficients are expressed as a function of the percentage of the giant swing (0 and 100% correspond to the vertical position of the gymnast under the bar). The mean synergy activation coefficient over all the participants is represented by the black bold line. **(B)** The muscle synergy vectors are shown at the bottom of the figure for all the participants. Individual muscle weightings are depicted for each muscle within each synergy. *r*- and/or r_{max}-values correspond to the averaged value between each pair of participants. Synergy #1 mainly involved trunk and hip flexor muscles (e.g., LD, PM, RA, RF) at the beginning of the ascendant phase of the swing. Synergy #2 mainly involved arm (TB) and shoulder muscles (DC, DS, TZ) and was activated during the upper part of the giant swing. Finally, synergy #3 mainly involved FD, ES, and LD and is activated to ensure the grip on the bar and the hip extension of the gymnast. For muscle abbreviations, see the **Figure 3** legend. For the color legend, see **Figure 1**.

to this peak value (i.e., waveform of the EMG patterns). In other words, while interindividual variability in terms of degree of muscle activity can exist, the present study only focuses on the EMG waveform variability. This choice was motivated by the fact than an ideal normalization method to quantify the degree of muscle solicitation does not exist (Burden, 2010). Whatever the normalization method, a part of the observed variability would have been attributable to methodological considerations. Consequently, we considered a muscle synergy as a covariation of muscle activation where the output level of this activation was not taken into consideration.

By quantifying the interindividual variability using *r*-values, r_{max}-values, and lag times, our goal was to compare our results with those of the literature. However, it should be kept in mind that the smoothing of both the EMG patterns and the synergy activation coefficients, can influence the *r*-values (Hug, 2011). As a wide variety of low-pass filters have been used in the literature aimed at extracting muscle synergies during locomotor tasks, e.g., from 4 Hz in Clark et al. (2010) to 40 Hz (Chvatal and Ting, 2012), caution must be taken when comparing the results of interindividual variability from studies that used different cut-off frequencies.

FUNCTIONAL ROLES OF MUSCLE SYNERGIES

The extracted muscle synergies were well related to the mechanics of the giant swing. Synergy #1 mainly involved the trunk and hip flexor muscles (e.g., LD, PM, RA, RF) at the beginning of the ascendant phase of the swing that would allow the gymnast to decrease his moment of inertia, and gain some mechanical energy and angular velocity to attain the handstand position.

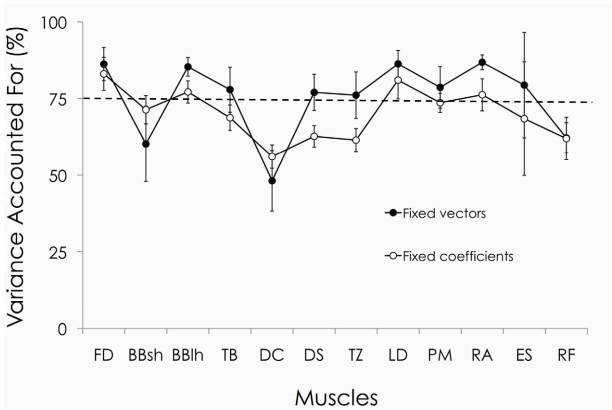

FIGURE 8 | VAF_{muscle} obtained by keeping either the muscle synergy vectors constant or the synergy activation coefficients. Two additional analyses have been performed to test the similarity of the muscle synergies between participants (see "Materials and Methods" section). First, by keeping the muscle synergy vectors constant, we obtained on averaged a VAF_{muscle} ranging between $48.2 \pm 9.9\%$ (DC) and $86.8 \pm 2.4\%$ (RA). Relative to the preset threshold of $VAF_{muscle} > 75\%$, the EMG patterns of BBsh, DC, and RF muscles were not correctly reconstructed. By keeping the synergy activation coefficients constant, the VAF_{muscle} ranged between $56.1 \pm 3.8\%$ (DC) and $83.0 \pm 5.4\%$ (FD). Relative to the preset threshold of $VAF_{muscle} > 75\%$, the EMG pattern of BBsh, TB, DC, DS, TZ, PM, ES, and RF muscles were not correctly reconstructed. For muscle abbreviations, see **Figure 3** legend.

The forearm muscle (FD) was also involved in synergy #1 to firmly grip the bar [which was highly in tension in that phase of the swing (Cagran et al., 2010)] while arm (BBsh, BBlh) muscles were solicited to stiffen elbow and glenohumeral joints, respectively. Synergy #2 mainly involved the arm (TB) and shoulder muscles (DC, DS, TZ) and was activated during the upper part of the giant swing. In light of the inverse dynamic model of a ground handstand (Kerwin and Trewartha, 2001), synergy #2 was activated to support the body weight. The activation profile of synergy #2 also showed a second lower peak near the end of the descendant phase of the giant swing, simultaneously with the peak in activity for synergy #3 and with the peak in angular velocity. The angular velocity of the gymnast increased due to the gravitational acceleration up to this peak, which might coincide with the end of the "fall-like" part of the giant swing and with the highest tensile load on the high bar (Cagran et al., 2010). Therefore, the arm and shoulder muscles of synergy #2 (TB, DC, DS, TZ), plus the trunk muscles of synergy #3 (LD) were activated to limit the extension and the tensile load within the shoulder joint. Finally, the other muscles of synergy #3 ensured the grip on the bar (FD) and hip extension (ES) of the gymnast's body. This arch-like position of the body would set the tension in the flexor chain muscles and favor the subsequent shoulder flexion during the ascending section (Frère et al., 2012).

INTERINDIVIDUAL VARIABILITY OF THE NEUROMUSCULAR CONTROL STRATEGIES

Interindividual variability in EMG patterns has often been reported at the level of individual muscles (Ryan and Gregor, 1992; Guidetti et al., 1996; Hug and Dorel, 2009; Hug et al., 2011). It is also the case in the present study where some individual EMG patterns (e.g., BBsh, TB, DC, DS, and TZ) exhibited interindividual variability that seems to be higher than the variability reported during pedaling (Hug et al., 2010). This difference may be explained by several factors, such as the number of degrees of freedom (closed vs. open kinematic chain for pedaling and giant swing, respectively) and the higher smoothing of the EMG profiles in the study by Hug et al. (2010), which may increase the similarity of the waveform (Hug et al., 2012).

It is unclear whether this variance in muscle activation across subjects would arise from variance in the motor program itself. In some cases, different muscle synergies have been identified in subpopulations (Torres-Oviedo and Ting, 2007). For instance, Torres-Oviedo and Ting (2007) extracted in some participants a muscle synergy specific to a knee-bending strategy during balance control. In contrast, despite a relatively high interindividual variability of some individual muscles, Hug et al. (2010) reported similar modular organization of muscle coordination (in terms of number of extracted muscle synergies, composition, and temporal activation) across trained cyclists during pedaling. In the present study, three consistent muscle synergies accounted for the EMG patterns in trained gymnasts during a giant swing, as reported in other cyclic tasks such as pedaling and rowing (Hug et al., 2010; Turpin et al., 2011b). Despite the overall similarity of both muscle synergy vectors and synergy activation coefficients across gymnasts, some differences occurred (36% of the pairwise comparisons of muscle synergy vectors), mainly for synergy #3. As this synergy is activated at the end of the descendant phase, the variability of the muscle synergy vectors may be explained by a lower muscular demand. Indeed, during the descendant phase of the giant swing, muscular torque accounted for less than gravitational and inertial torques to enable the arch-like position of the gymnast (Sevrez et al., 2012). According to previous studies demonstrating that the spatial components of the muscle synergies are related to biomechanical functions (Ting and Macpherson, 2005; Torres-Oviedo and Ting, 2007; McKay and Ting, 2008), this low muscular demand might involve subtle subject-specific muscle synergy compositions. High tensile load was determined at the end of the descending phase of the giant swing (Cagran et al., 2010). To counteract this tensile load, gymnasts stiffened the shoulder joint likely by the second peak of activity visible in synergy #2 rather than by synergy #3. This may confirm the relationship between muscle synergy composition and functional demand. This also confirms previous observations that although some muscle synergies are very robust across subjects, others are more variable (Hug et al., 2010).

A key bit of information provided by the synergy analysis regards the number of extracted muscle synergies that have been proposed to reflect the complexity of motor control (Clark et al., 2010). As justified in the Methods section, we extracted the same number of muscle synergies for all the participants. However, the determination of the correct number of muscle synergies is not a trivial matter (Tresch et al., 2006) and despite the use of different criterion, we cannot affirm that all the participants exhibit the same number of muscle synergies and thus that they exhibit the

same complexity of motor control. However, the low coefficient of variations (mean/SD × 100) in VAF values (ranging from 0% for 12 muscles synergies to 7% for 1 muscle synergies; 2.2% for 3 muscle synergies) highly suggests that the gymnasts possess a very similar dimensionality in their EMG data.

NEUROPHYSIOLOGICAL INTERPRETATIONS

The present results showed a strong similarity in neuromuscular control strategies across the experts during a skilled motor task (**Figure 7**). This consistency in muscle synergies might reflect the existence of lower-level neural control structures that can be flexibly modulated to result in complex, learned movements as previously suggested (Cheung et al., 2005; Ting and McKay, 2007; Torres-Oviedo and Ting, 2007; Hug et al., 2011; Chvatal and Ting, 2012). During skill learning, it has been shown that the modulation of muscles synergy composition emerged up to a stable state allowing a subsequent change in the temporal profile of the muscle synergies (Kargo and Nitz, 2003). This suggests that muscle synergies may be formed by adaptive processes in relationship to the experiences of each individual. Consequently, the relatively good similarity of muscle synergies observed between the gymnasts could be explained by their similar training experience. It should also be noted, however, that instead of constructing new muscle synergies during the learning process, it is also possible that the extracted muscle synergies have been adapted from existing synergies (Safavynia et al., 2011). Although numerous studies have suggested that the central nervous system produces movement through a flexible combination of muscle synergies (Ting and McKay, 2007), it should be kept in mind that other research has suggested that the synergies better reflect task constraints (Kutch et al., 2008; Valero-Cuevas et al., 2009). Therefore, the consistency observed in the present study might also be explained by the mechanical requirements demanded by the task and would only signify that the observed synergies are compatible with the execution of a backward giant swing. As we studied only one condition (without varying constraints), we were not able to test this hypothesis. However, although mechanical constraints were similar across individuals, high interindividual variability was evident for some EMG patterns (e.g., DS, TZ, TB, **Figure 3**), confirming that different muscle activity patterns may lead to similar mechanical patterns, or task performance (Chvatal et al., 2011).

The higher VAF and VAF_{muscle} values obtained when muscle synergy vectors were fixed compared to fixed coefficients of activation further suggest that muscles synergies are spatially fixed while their temporal patterns of recruitment can vary (Chvatal and Ting, 2012; Safavynia and Ting, 2012). This spatial consistency of the nervous control of motor behavior might support the notion that descending cortical signals represent neuronal drives that select, activate, and flexibly combine muscle synergies specified to networks in the spinal cord and/or brainstem (Hart and Giszter, 2004; Cheung et al., 2005). In this way, it has been shown that only the temporal activation of muscle synergies (and not the spatial structure) is altered by deafferentation or cortical stroke in humans (Cheung et al., 2005, 2009).

CONCLUSION

Although variability was found (especially for synergy #3), the gymnasts exhibited gross similar neuromuscular strategies when performing several consecutive giant swings. This confirms that muscle synergies are consistent across participants, even during a skilled motor task requiring learning. Further investigations are necessary to both confirm that these muscle synergies reflect lower-level neural control rather than biomechanical constraints and to understand whether they are constructed during the learning process or whether they have been adapted from existing synergies.

Recent studies have reported evidence that the motor system may rely on a modular organization, even if this behavior has yet to be confirmed during motor adaptation. The aim of the present study is to investigate the modular motor control mechanisms underlying the execution of pedaling by untrained subjects in different biomechanical conditions. We use the muscle synergies framework to characterize the muscle coordination of 11 subjects pedaling under two different conditions. The first one consists of a pedaling exercise with a strategy freely chosen by the subjects (Preferred Pedaling Technique, PPT), while the second condition constrains the gesture by means of a real time visual feedback of mechanical effectiveness (Effective Pedaling Technique, EPT). Pedal forces, recorded using a pair of instrumented pedals, were used to calculate the Index of Effectiveness (*IE*). EMG signals were recorded from eight muscles of the dominant leg and Non-negative Matrix Factorization (NMF) was applied for the extraction of muscle synergies. All the synergy vectors, extracted cycle by cycle for each subject, were pooled across subjects and conditions and underwent a 2-dimensional Sammon's non-linear mapping. Seven representative clusters were identified on the Sammon's projection, and the corresponding eight-dimensional synergy vectors were used to reconstruct the repertoire of muscle activation for all subjects and all pedaling conditions ($VAF > 0.8$ for each individual muscle pattern). Only 5 out of the 7 identified modules were used by the subjects during the PPT pedaling condition, while 2 additional modules were found specific for the pedaling condition EPT. The temporal recruitment of three identified modules was highly correlated with *IE*. The structure of the identified modules was found similar to that extracted in other studies of human walking, partly confirming the existence of shared and task specific muscle synergies, and providing further evidence on the modularity of the motor system.

Keywords: muscle synergies, modularity, cycling, biomechanical function, instrumented pedals, pedaling effectiveness, biofeedback

INTRODUCTION

The study of the neuro-physiological mechanisms underlying movement production has a long fascinating history (Bernstein, 1967). In the last decade the scientific community has been focusing its attention on the possibility of simplifying the role of the central nervous system (CNS) for the production of movement, by hypothesizing that the complex muscle coordination shown during the execution of a variety of motor acts relies on a simple combination of motor modules (d'Avella et al., 2003). Experimental evidence has been provided that surface ElectroMyoGraphic signals (sEMG) recorded from many muscles during the execution of movement can be represented by the combination of a reduced number of muscle synergies. The latter constitute modules of muscle co-activation that—flexibly combined through amplitude scaling and time shifting mechanisms—can accurately reconstruct the repertoire of muscle activation for many motor tasks (d'Avella et al., 2003). Muscle synergies have been investigated in motor tasks like running (Cappellini et al., 2006), postural responses (Torres-Oviedo and Ting, 2007), pedaling (Hug et al., 2010), walking in normal and pathologic conditions (Ivanenko et al., 2004; Clark et al., 2010; Monaco et al., 2010) and upper limb reaching (d'Avella et al., 2008; Cheung et al., 2012). From this background it emerges that the muscle synergies paradigm seems to fairly represent the neural strategies underlying the control of movement, with motor modules characteristic for each task and robustly shared among different subjects, in terms of both temporal and spatial organization of the muscle activity. Moreover, the existence of a few shared and task-specific muscle synergies during the execution of different movements in the freely moving frogs (d'Avella and Bizzi, 2005) and the existence of separate modules during the coordination of locomotion with voluntary actions (Ivanenko et al., 2005), provides further evidence of modularity.

Nevertheless, the fact that muscle synergies actually reflect neural strategies has been criticized, and it has been hypothesized that they simply reflect the biomechanical constraints during movement execution (Kutch and Valero-Cuevas, 2012). As a matter of fact, a neuro-physiological mechanism able to fully

justify the muscle synergy model is still lacking (Tresch and Jarc, 2009).

The linkage between muscle coordination and the mechanical outcome of movement has recently provided further insight into the modular control of movement through the use of simulation studies of human gait (Neptune et al., 2009). It has also been shown that scaling in amplitude and shifting in time the same small number of fixed motor modules leads to the satisfaction of altered mechanical task demands, and that the main modifications occur in the recruitment of those modules recognized as responsible of that particular biomechanical sub-function (Cheung et al., 2009; McGowan et al., 2010).

Modification of the mechanical constraint has also been investigated in cycling tasks executed by trained subjects, where it has been shown that the same few modules are shared among subjects and among different pedaling conditions, with limited adaptations in the synergy activation coefficients (Hug et al., 2011).

Even if cycling gesture is a quasi-constrained exercise with controllable experimental conditions, little is known about the effect of the pedaling technique (i.e., a mechanical factor in terms of force orientation on the pedal along the pedaling cycle) on the structure of the muscular coordination and on the underlying structure of the motor modules. Analysis of forces through the use of instrumented pedals can provide an insight about the effect of different pedaling techniques on muscle coordination (Mornieux et al., 2008). Many variables involved in cycling, such as physiological and metabolic factors, could influence the mechanical outcome and they are functionally connected to the evaluation of the athletes' performance (Zameziati et al., 2006). The concept of mechanical effectiveness in cycling is one of these, and it is directly related to the ability of the subject to orient the pedal forces so that all the expressed forces participate to the propulsive action. Index of mechanical effectiveness, defined as the ratio between the tangential force component and the total one, has been used as an indicator of cycling behavior and it has been put in relation with other parameters such as muscular efficiency or metabolic consumption (Mornieux et al., 2006; Zameziati et al., 2006).

In this study we enrolled untrained subjects to investigate whether a change in the pedaling technique, induced by a visual feedback of mechanical effectiveness, is accomplished by neuromuscular adaptations in modular motor control. In order to do this, we described the pedaling gesture from a biomechanical point of view by combining pedal forces, measured by instrumented pedals, and multi-muscle surface EMG recordings. Our main hypothesis is that when passing from a subject freely chosen pedaling technique to a novel one imposed by the visual feedback of mechanical effectiveness, EMG patterns could change altering the synergy recruitment rather than the structure or the number of the motor modules as a consequence of motor adaptation.

MATERIALS AND METHODS

PARTICIPANTS

Eleven male voluntary subjects (aged 27.4 ± 2.5 years) participated to the study. Each subject had no previous experience with professional cycling and reported less than 50 km riding in the previous 3 years. None of them reported previous history of lower limb pathology or surgery. The subjects were informed about the possible discomforts deriving from the experimental protocol and agreed to participate through an informed consent. The study was carried out according to the principles of the declaration of Helsinki.

PEDAL FORCES RECORDINGS AND FEEDBACK OF MECHANICAL EFFECTIVENESS

Pedal forces were recorded by means of a pair of custom two-components instrumented clipless pedals, measuring the two orthogonal components of force F_x and F_z (respectively parallel and orthogonal to the pedal surface as in **Figure 1**, with an accuracy of 0.1% and a range of 2000 N), together with the angle θ_p between the direction of the crank arm and a direction orthogonal to the pedal surface (Bibbo et al., 2009a). The pedals use a KEO clip-less fastening. F_x and F_z components of force were acquired using a previously developed recording wireless system (iPED) (Bibbo et al., 2009b) that provides the tangential and radial force components, according to the Equations 2 and 3:

$$F_{\text{tot}} = \sqrt{F_x^2 + F_z^2} \tag{1}$$

$$F_{\text{tg}} = F_x \cos\left(\theta_p\right) + F_z \sin\left(\theta_p\right) \tag{2}$$

$$F_{\text{rd}} = -F_x \sin\left(\theta_p\right) + F_z \cos\left(\theta_p\right) \tag{3}$$

The iPED system also provides the index of mechanical effectiveness (*IE*), determined as reported in Equation 4:

$$IE = \frac{\int_0^{2\pi} F_{\text{tg}}\left(\theta_p\right) d\theta_p}{\int_0^{2\pi} F_{\text{tot}}\left(\theta_p\right) d\theta_p} \tag{4}$$

IE is an index theoretically varying in the range $[-1, 1]$ and approaches 1 as the tangential force profile overlaps the total one

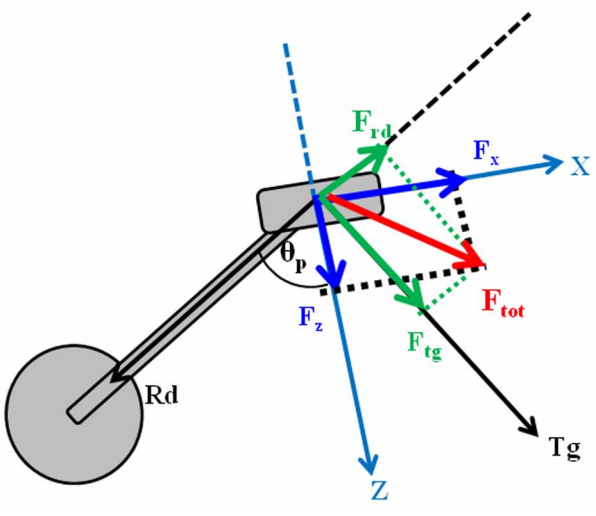

FIGURE 1 | Pedal forces in the pedal reference system (X-Z) and in the rotating one (Tg-Rd).

along the whole pedaling cycle. *IE* was used as a global indicator of performance, while the subjects were provided with a real time visual feedback of instantaneous mechanical effectiveness IE_i drawn on a polar plot (**Figure 2**), and defined as follows:

$$IE_i(\theta_p) = \frac{F_{tg}(\theta_p)}{F_{tot}(\theta_p)} \quad (5)$$

IE_i is drawn as a vector whose magnitude is proportional to the instantaneous mechanical effectiveness and whose phase is proportional to the pedal angle.

In this way, the subjects were helped to effectively orient the forces along the pedaling cycle, receiving real time information about which sector of the cycle they had to improve to reach an optimal pedaling technique (Bibbo et al., 2012). An entirely filled circle thus corresponds to $IE = 1$.

EXPERIMENTAL PROTOCOL

The experimental protocol was carried out on an aerodynamically braked cycle-simulator equipped with the instrumented pedals described in the previous section and standard 170 mm cranks. Before the execution of the exercises, the subjects performed a 10-min warming up session. At the end of the warm up the subjects performed a 10 s all-out trial, with the aim of determining the maximum reachable power output (resulting in 634.4 ± 85.5 W). The experimental procedure started after a 3-min rest period and consisted of two different sub-maximal pedaling exercises, each one lasting 2 min: the first exercise consisted in a 2-min pedaling task with a strategy freely chosen by the subject (Preferred Pedaling Technique, PPT). At the end of the first exercise, the subjects, having no previous knowledge about the concept of mechanical effectiveness in cycling, were instructed by the experimenter on how to follow the visual feedback of IE_i and on how to optimally orient the forces on the pedal. After a familiarization with the feedback system, the subjects executed a second pedaling exercise consisting of a 2-min pedaling task aided by feedback (Effective Pedaling Technique, EPT). For both exercises the subjects were asked to adopt the same freely chosen pedaling cadence (resulting in 67.3 ± 5.7 rpm and corresponding to 120.6 ± 17.1 W of power output) with a comfortable seated position on the saddle. Such a protocol was chosen in order to avoid the occurrence of any sign of neuro-muscular alterations due to fatigue (Conforto and D'Alessio, 1999), which could negatively bias the execution of the exercises (Castronovo et al., 2012).

sEMG RECORDINGS

sEMG data were recorded from the following eight muscles of the dominant leg, defined as the leg the subjects usually used to kick a ball: Gluteus Maximus (Gmax), Biceps Femoris long head (BF), Gastrocnemius Medialis (GAM), Soleus (SOL), Rectus Femoris (RF), Vastus Medialis (VAM), Vastus Lateralis (VAL), and Tibialis Anterior (TA). These muscles were chosen because they are deemed representative of the main muscular groups acting across the three main degrees of freedom involved in cycling, which are hip flexion-extension (RF, Gmax, BF), knee flexion-extension (RF, VAL, VAM, BF, GAM), and ankle plantar-flexion (GAM and SOL) and dorsi-flexion (TA) (So et al., 2005; Hug and Dorel, 2009). A pair of Ag/AgCl electrodes was applied on each muscle, following the SENIAM recommendations (Hermens et al., 2000). Before applying the electrodes, the skin was shaved and cleaned to improve the electrode/skin impedance. sEMG data were collected with a wireless system (BTS FREEEMG 300, BTS s.p.a.) equipped with eight bipolar wireless channels, sampled at 1000 samples/s and digitized at 14 bits. All the sEMG signals were synchronized with the force data coming from the instrumented pedals. Preliminary results including part of these data were previously published (De Marchis et al., 2012).

DATA PREPROCESSING

sEMG signals were filtered in the band (20–450) Hz, preprocessed for noise removal (Conforto et al., 1999), full-wave rectified and low-pass filtered at 4 Hz with a 3rd order Butterworth filter to obtain the signal amplitude envelope (Neptune et al., 2009). Each muscle pattern was amplitude normalized to the maximum value

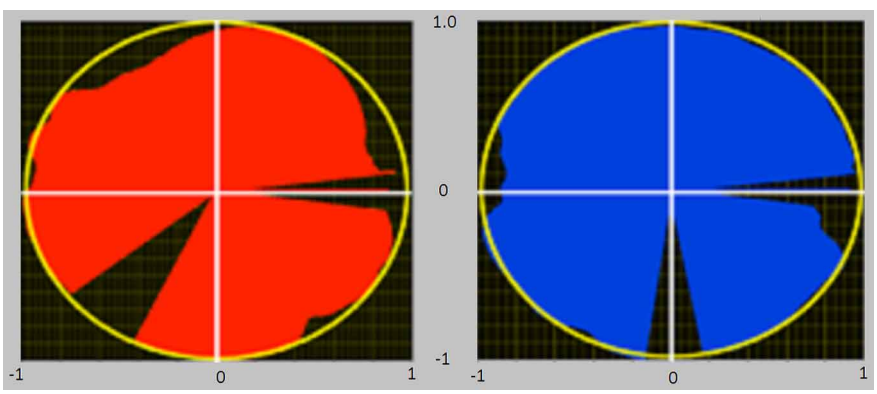

FIGURE 2 | Visual feedback of the instantaneous mechanical effectiveness, based on a polar plot diagram. At the end of each completed cycle an image was presented to the subjects, consisting of the polar plots reported in figure. The filling of each circle in different angular sectors/angular positions is proportional to *IE* in that sector/angular position. If the circle is entirely filled (red for left pedal and blue for right pedal), then *IE* equals 1. The polar representation gives information regarding the different phases of the pedaling cycle in which the pedaling technique must be improved.

of the envelope across the two pedaling conditions (i.e., PPT and EPT). Time scale was normalized by interpolating each sEMG envelope and each force component for each cycle on 100 data points, each one representative of the integer percentage of the pedaling cycle. A pedaling cycle was defined as the complete revolution of the crank starting from Top Dead Center (TDC, 0°), passing through Bottom Dead Center (BDC, 180°) and back to TDC in a 360° cycle.

MUSCLE SYNERGIES EXTRACTION

Muscle synergies were extracted by means of Non-negative Matrix Factorization (NMF) (Lee and Seung, 1999) applied to the matrix $\boldsymbol{M}$ containing the envelopes of the eight muscles: the algorithm looks for an approximate solution of the kind $M \cong WxH$ by minimizing the matrix norm $||M - WH||$, where $\boldsymbol{M}$ is the initial matrix containing the envelopes of the signal from each muscle, $\boldsymbol{W}$ is a $8 \times \boldsymbol{s}$ matrix of the synergy vectors and $\boldsymbol{H}$ is a matrix containing the time-varying activation profiles, $\boldsymbol{s}$ being the number of modules specified before the NMF application. The convergence is ensured by the use of multiplicative update rules for each iteration of the algorithm.

The applied procedure followed the hypothesis that the number of synergies is not fixed from cycle to cycle, but the subjects can select a subset of modules belonging to the space of the possible basis vectors. This is particularly true for the feedback condition, in which the subjects adopt a new pedaling technique and may thus explore the space of muscle coordination to accomplish the biomechanical demands. We did not make any assumption about the similarity between modules, so that the dimensionality of the space of the basis vectors explored by the subjects is a-priori unknown.

For each subject and for each pedaling condition (PPT and EPT), the entire data set was divided into multiple episodes with each containing three consecutive cycles. A set of muscle synergies was then extracted from every of these episodes. The number of muscle synergies $\boldsymbol{s}$ for the reconstruction of the matrix $\boldsymbol{M}$ for each episode was chosen by calculating the Variance Accounted For (VAF) by the reconstruction WxH for each muscle activation profile, defined by Equation 6:

$$VAF_i = \frac{\sum_{j=1}^{k} (M_{ij} - R_{ij})^2}{\sum_{j=1}^{k} (M_{ij})^2} \tag{6}$$

where $\boldsymbol{R} = WxH$ is the matrix emerging from the synergy model, $\boldsymbol{k}$ is the number of samples and $\boldsymbol{i}$ indicates the muscle taken into account for VAF_i calculation. The number of extracted synergies $\boldsymbol{s}$ was varied between 1 and 8 for VAF_i calculation, and $\boldsymbol{s}$ was chosen as the smallest number able to explain at least the 90% of the variance for each muscle. This approach is stringent enough to ensure a proper reconstruction of the original EMG signals in each cycle.

All the extracted modules were then pooled across subjects and conditions in order to obtain the whole synergy matrix $\boldsymbol{W}_{\mathbf{all}}$ containing all the extracted synergy vectors from all the pedaling cycles for all the subjects.

SYNERGY DISCOVERY

A synergy discovery procedure was then applied to the matrix $\boldsymbol{W}_{\mathbf{all}}$ by performing a 2-dimensional non-linear Sammon's mapping (Sammon, 1969): briefly, this analytic procedure is based on mapping a dataset of k L-dimensional vectors belonging to the L-space (i.e., the 8-dimensional space of muscle synergy vectors in this study) to set of k N-dimensional vectors in the N-space (with $N < L$ and usually set to $N = 2$ or 3) by preserving the inherent data structure. The inter-point distance defined in the L-dimensional space is maintained in the projected N-dimensional space by using an error minimization procedure. This is achieved by minimizing an error criterion which penalizes differences in distances between points in the original L-space and the corresponding points in the projected N-space. The error function to be minimized is defined as follows:

$$E = \frac{1}{\sum_{i=1}^{k-1} \sum_{j=i+1}^{k} d_{ij}} \sum_{i=1}^{k-1} \sum_{j=i+1}^{k} \frac{(d_{ij} - d_{ij}^*)^2}{d_{ij}} \tag{7}$$

where k is the number of vectors in both the original and projected dataset, d_{ij} is the Euclidean distance between the i-th and j-th points in the L-space, d_{ij}^* is the Euclidean distance between the i-th and j-th points in the N-space. The error function is minimized using a second order steepest descent procedure (Sammon, 1969; De Ridder and Duin, 1997).

This procedure has been followed with the aim of establishing the dimensionality underlying $\boldsymbol{W}_{\mathbf{all}}$, that is the number of representative modules. The interpretation and clustering of the Sammon's 2-D distribution allows a quantification of the number of underlying basis vectors, by observing their groupings on the 2-D map.

The number of underlying basis vectors composing $\boldsymbol{W}_{\mathbf{all}}$, was obtained by applying a hierarchical clustering (Ward minimum variance method, Matlab Statistics Toolbox) to the Sammon's map values, in order to organize it in clusters in the 2-D space. These clusters were used to group the synergy vectors contained in $\boldsymbol{W}_{\mathbf{all}}$, and the representative basis vectors were calculated as the average $\boldsymbol{W}$ within each cluster, leading to the representative basis vectors $\boldsymbol{W}_{\mathbf{basis}}$.

SYNERGY ACTIVATION ANALYSIS

After applying the clustering, we performed a Non-negative Reconstruction (NNR, Muceli et al., 2010) on all the consecutive cycles (60 in average for each trial) for each subject and for each pedaling condition: NNR consists of applying NMF by keeping $\boldsymbol{W}$ fixed and letting $\boldsymbol{H}$ update at each algorithm iteration with the following rule:

$$H_{rc} \leftarrow H_{rc} \frac{(W_{\text{basis}}^T M)_{rc}}{(W_{\text{basis}}^T W_{\text{basis}} H)_{rc}} \tag{8}$$

where the indexes r and c are referred to each component of the defined matrixes, and T denotes the transposed matrix. The temporal activation $\boldsymbol{H}$ for each component of $\boldsymbol{W}_{\mathbf{basis}}$provides information about the recruitment of that synergy within the trial

cycle by cycle. The information related to the recruitment $\boldsymbol{H}$ of each component of $\boldsymbol{W}_{\mathbf{basis}}$ was put in relation to the index *IE* cycle by cycle. The amount of activation of a synergy was expressed as the area underlying the temporal profile of activation within each cycle. The ability of the $\boldsymbol{W}_{\mathbf{basis}}$ to reconstruct the repertoire of muscle activations from the set of all the consecutive cycles for all the subjects was evaluated by determining VAF_i for each muscle.

STATISTICAL ANALYSIS

Differences between force profiles, indexes of effectiveness, muscle activation patterns, and muscle synergy activation coefficients were assessed by using a one-way ANOVA with conditions (PPT and EPT conditions) as factors, with statistical significance coming from p-values lower than 0.05. All the differences were evaluated in four different sectors of the pedaling cycle, with each sector defined according to Hug et al. (2008), and roughly corresponding to the following: 1st sector is around TDC, 2nd sector refers to the down-stroke phase, 3rd sector roughly corresponds to the part around BDC, 4th sector is related to the up-stroke phase, with the corresponding EMG sectors defined by taking into account the electromechanical delay (Conforto et al., 2006; Hug et al., 2008).

In order to check that each obtained NNR reconstruction is significantly different from that expected from chance, we used a procedure similar to that used in Cheung et al. (2012): we compared the obtained VAF_i reconstruction values with those expected from chance $\boldsymbol{VAF}_{\mathbf{shuffle}}$: for each reconstruction, 100 random synergy vectors were generated by shuffling the muscle components of each $\boldsymbol{W}_{\mathbf{basis}}$ vector, and the obtained $\boldsymbol{VAF}_{\mathbf{shuffle}}$ values expected from chance were compared with the reference VAF_i reconstruction value.

RESULTS

In this section, pedal force profiles are shown for the two pedaling conditions, and the corresponding possible changes in the EMG profiles and the underlying muscle synergies are reported as potential signs of neuromuscular adaptations to an altered pedaling technique.

MODIFICATION OF THE FORCE PROFILES

When passing from the PPT condition to the EPT one there is a significant improvement in *IE* ($IE_{\mathrm{PPT}} = 0.41 \pm 0.09$, $IE_{\mathrm{EPT}} = 0.68 \pm 0.14$, $p < 0.005$). As outlined in **Figure 3A**, feedback of mechanical effectiveness helps the subjects to effectively orient the forces on the pedal, leading the profile of F_{tg} to follow the trend of F_{tot} along all the cycle, while this happens only in the down-stroke phase during the PPT condition. The effective force application mainly consists of a reduction of the average F_{tot} value along the first half of the pedaling cycle and an increase in F_{tg} during the second half ($p < 0.005$); this action is associated with the reduction in amplitude of the radial force component profile F_{rd} along

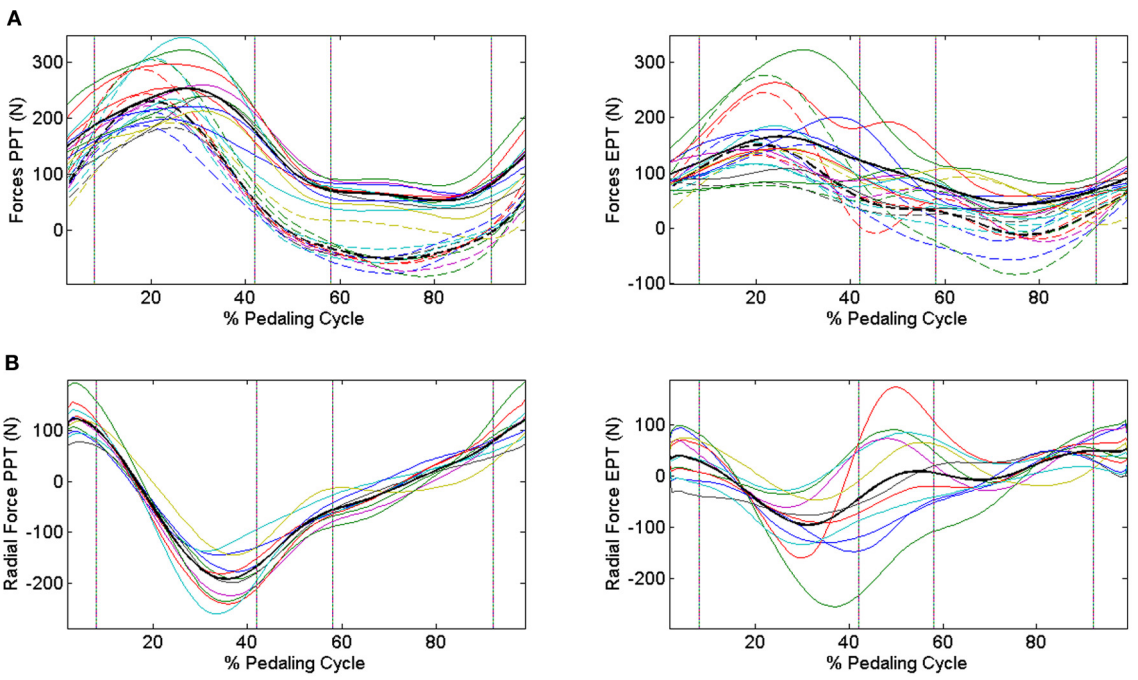

FIGURE 3 | Modifications in the force profiles when changing the pedaling technique through *IE* feedback. Upper panels **(A)** Dashed lines represent tangential components, continuous lines represent total force components, and bold black lines are the profiles averaged across subjects. Different colors refer to different subjects. PPT condition left panel: F_{tg} follows the trend of F_{tot} only in the down-stroke phase. EPT condition right panel: subjects improve their mechanical effectiveness, projecting the forces in such a way to lead F_{tg} to approach F_{tot} also during the pull-back and pull-up phases. Lower panels **(B)** Radial force components in the two conditions. PPT condition left panel: distribution of the dissipated forces is spread over a wide range of values. EPT condition right panel: radial components are reduced within a narrower range around 0 N, highlighting the improvement in the pedaling strategy. Black lines represent average F_{rad} profiles.

all the cycle, as shown in **Figure 3B**. This action is reflected on the instantaneous index of effectiveness (IE_i), showing an increased level in the second part of the cycle, in particular for sectors 3 and 4 (**Figure 4**).

NEUROMUSCULAR ADAPTATIONS

The change in the distribution of the force profiles described in the previous section is accompanied by some adaptations in the activation of each muscle, particularly evident as an increased level of activity for BF, GAM, RF, and TA (**Figure 5**), a reduction in the activity of the mono-articular knee extensors (VAM and VAL) in the 1st sector, and an increased tonic activity for Gmax and SOL muscles. (Statistically significant values reported in **Table 1**).

During the cycle by cycle synergies extraction, from 3 to 5 synergies were extracted, and they were used to populate the matrix $\boldsymbol{W}_{\mathbf{all}}$. Seven clusters were indentified from the 2-dimensional Sammon's projections of $\boldsymbol{W}_{\mathbf{all}}$ pooled across the two pedaling conditions (**Figure 6**). The corresponding centroids $\boldsymbol{W}_{\mathbf{basis}}$ in the 8-dimensional space contain information about the structured information in the data. When passing from PPT to EPT there is a stability in the location of the clusters on the map; two zones (red and green in **Figure 6**) were more populated in EPT, meaning that additional basis vectors are explored in the EPT condition.

Synergy activation coefficients H (**Figure 7**) were obtained by applying NNR on each set of consecutive cycles (60 in average for each subject) by keeping $\boldsymbol{W}_{\mathbf{basis}}$ fixed. The NNR allowed a reconstruction with mean VAF_i values for each muscle always higher than 0.9 (except for Gmax, presenting anyway a satisfying reconstruction level). All the obtained VAF values were significantly higher than those expected from chance by applying NNR with $\boldsymbol{W}_{\mathbf{shuffle}}$ ($p < 0.01$ for each muscle in **Table 2**).

In the PPT pedaling condition only the first four modules ($\boldsymbol{W}_{1-4}$, **Figure 7**) showed a significant level of activity. The first module $\boldsymbol{W}_1$ consists of the co-activation of two mono-articular knee extensor muscles (VAM and VAL) and a bi-articular one (RF, also crossing the hip joint), and it is active during the first part of the pedaling cycle. $\boldsymbol{W}_2$ mainly consists of the activity of two ankle plantar-flexors (SOL and GAM) together with G_{max}, and it is active within the first quarter of the cycle. $\boldsymbol{W}_3$ involves the co-activation of two bi-articular knee flexors (BF and GAM), and it is active around BDC. $\boldsymbol{W}_4$ is composed by the activity of RF and TA and intervenes in the last quarter of the cycle before TDC.

In the EPT condition subjects showed an altered recruitment of the synergies active in PPT, and use additional synergies belonging to $\boldsymbol{W}_{\mathbf{basis}}$. $\boldsymbol{W}_1$ and $\boldsymbol{W}_2$ are less active ($p < 0.05$, **Table 1**), while $\boldsymbol{W}_3$ and $\boldsymbol{W}_4$ show an increased level of activation within the functional sectors in which they are recruited ($p < 0.005$). The change in the distribution of the values on the Sammon's map consists on the activation of two additional modules. $\boldsymbol{W}_5$ consists of the co-activation of knee flexor muscles and TA, and it is active within sectors 3 and 4. $\boldsymbol{W}_6$ occurs just before TDC and it is mainly composed by a merging of synergies $\boldsymbol{W}_1$ and $\boldsymbol{W}_4$(RF, vastii and TA). $\boldsymbol{W}_7$ mainly reflects the tonic activity of Gmax and SOL during the EPT condition.

SYNERGY ACTIVATION COEFFICIENTS AND MECHANICAL EFFECTIVENESS

The activation of synergies $\boldsymbol{W}_3$, $\boldsymbol{W}_4$, $\boldsymbol{W}_5$ is related to the change in mechanical effectiveness (correlation values in **Table 3**). The

coefficient of variation revealed that these are the only synergies relevantly correlated with *IE*, since they show a lower coefficient of variation *CV* (**Table 3**), meaning that their behavior is consistent across subjects.

DISCUSSION

The obtained results seem to support the existence of a modular motor control in humans, with few muscle synergies shared among different subjects and able to reconstruct the variable muscle activation repertoire shown under different pedaling conditions. Pedal force measurements together with the use of a visual feedback of mechanical effectiveness allowed a controlled change in the pedaling strategy, which resulted in the ability of orienting the pedal forces in a direction almost completely tangential to the circle spanned by the pedal, thus confirming the validity of the used protocol.

When the subjects chose their PPT, they adopted a strategy which was mainly based on the propulsive action during the down-stroke phase (TDC – BDC, 0–180°), where the tangential component of force is almost coincident with the total force, while F_{tg} becomes negative during the second part, meaning that the action of the leg slightly opposed the propulsive action, so that most of the propulsion was generated by the down-stroke action of the other leg. Besides F_{tg}, a dissipated radial component of force F_{rd} was present all over the cycle. The obtained values of *IE* are in line with previous studies measuring mechanical effectiveness during pedaling with a self-selected strategy (Sanderson, 1991; Mornieux et al., 2006; Zameziati et al., 2006).

When the subjects adopted an effective strategy, F_{tg} tended to follow the profile of F_{tot} also in the second part of the cycle (BDC – TDC, 180–360°), and this action was accompanied by a reduction in F_{tot}. This behavior can be associated with the reduction of the radial force component resulting in a significant increase of the index of mechanical effectiveness *IE*.

ADAPTATION IN THE MODULAR CONTROL OF PEDALING ACROSS DIFFERENT PEDALING TECHNIQUES

A episode-by-episode synergy extraction procedure and the subsequent clustering on the Sammon's non-linear projection allowed the identification of seven basis muscle synergy vectors. In order to satisfy the mechanical requirement the subjects switched between the available modules to form different motor programs (Kargo and Nitz, 2003).

Pedaling with a low mechanical effectiveness was accomplished by using a modular muscle coordination mainly characterized by four muscle synergies which were able to account for most of the variance of the EMG data.

Passing to a mechanically EPT resulted in a modification of the mechanical demand which was accompanied by a modification in the muscle activation patterns with respect to the PPT condition, and additional modules were activated to explain the variance of the data. We therefore speculate that these

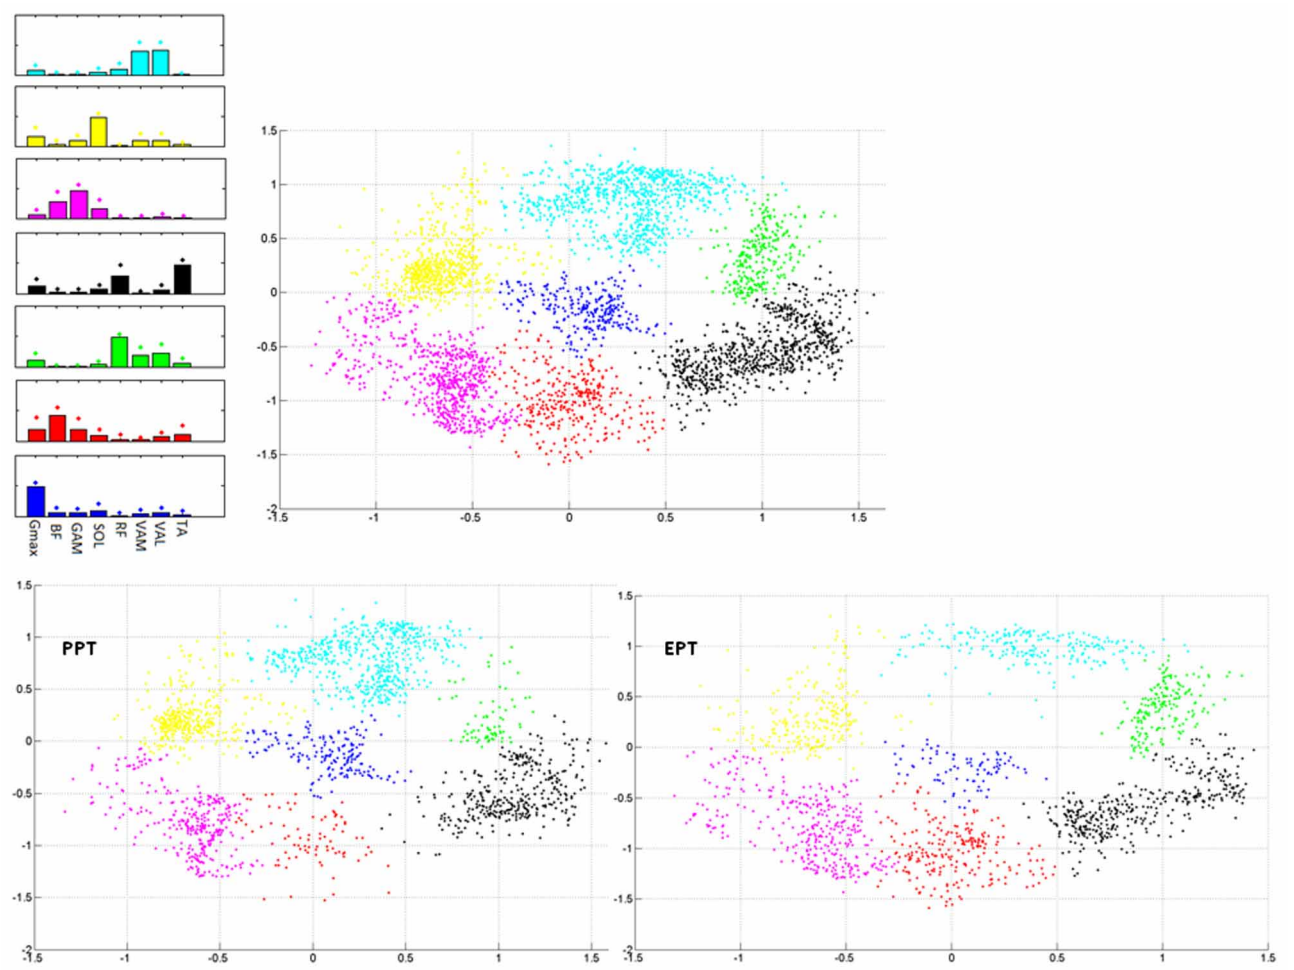

FIGURE 6 | Sammon's maps. Right upper panel: Sammon projections of W_{all}. Different colors refer to the different identified clusters on the map. Each point corresponds to the projection of a single synergy vector of W_{all}. **Left upper panel**: 8-D average synergy vectors (mean + SD in figure) among the elements of W_{all} belonging to the 2-D clusters identified on the map. **Lower panels:** Sammon's distribution related to the synergy vectors of W_{all} extracted from the PPT (left panel) and EPT (right panel) conditions.

additional muscle synergies may represent a neural mechanism reflecting short term adaptation, where the subjects tend to adopt the already learnt muscle coordination shown in PPT, and they add modules to achieve the imposed mechanical requirement.

FUNCTIONAL INTERPRETATION OF THE MUSCLE SYNERGIES

The structure of the extracted muscle synergies may be associated to different biomechanical sub-functions during the pedaling cycle (**Figure 7**):

$\boldsymbol{W_1}$, mainly consisting of knee extensors activity (VAM, VAL, RF), acts during the first part of the cycle and it is key to power production during the down-stroke phase, when the knee joint passes from a flexed position (TDC) to an almost completely extended one (BDC).

$\boldsymbol{W_2}$ involves the co-activation of SOL, GAM, and G_{max}. The main action of the two ankle plantar-flexors (SOL and GAM) may be responsible for the ankle angle variations during the pedaling cycle. This synergy might thus contribute to the fine control of the ankle movement preparing the pull back phase.

$\boldsymbol{W_3}$ is characterized by the activity of two bi-articular knee flexors (BF and GAM), and it starts just before BDC, when the knee joint begins its flexing action in the second part of the cycle.

$\boldsymbol{W_4}$ is a synergy characterized by the co-activation of RF and TA, and it intervenes during the last quarter of the cycle, in the transition phase between up-stroke and down-stroke passing around TDC, during the hip flexion action, propelling the crank toward the end of flexion.

$\boldsymbol{W_5}$ is a synergy specific for the pedaling condition EPT, mainly consisting of the co-activity of knee flexors (BF and GAM), Gmax and TA muscle and it may be responsible, together with $\boldsymbol{W_3}$ and $\boldsymbol{W_4}$, of the pull-up action during up-stroke.

$\boldsymbol{W_6}$ appears in EPT and it seems to consist of a merging between modules $\boldsymbol{W_1}$ and $\boldsymbol{W_4}$. It is active during the last part of the cycle and it may be related to an adaptation of the transition phase around TDC. $\boldsymbol{W_7}$ clearly presents a tonic recruitment

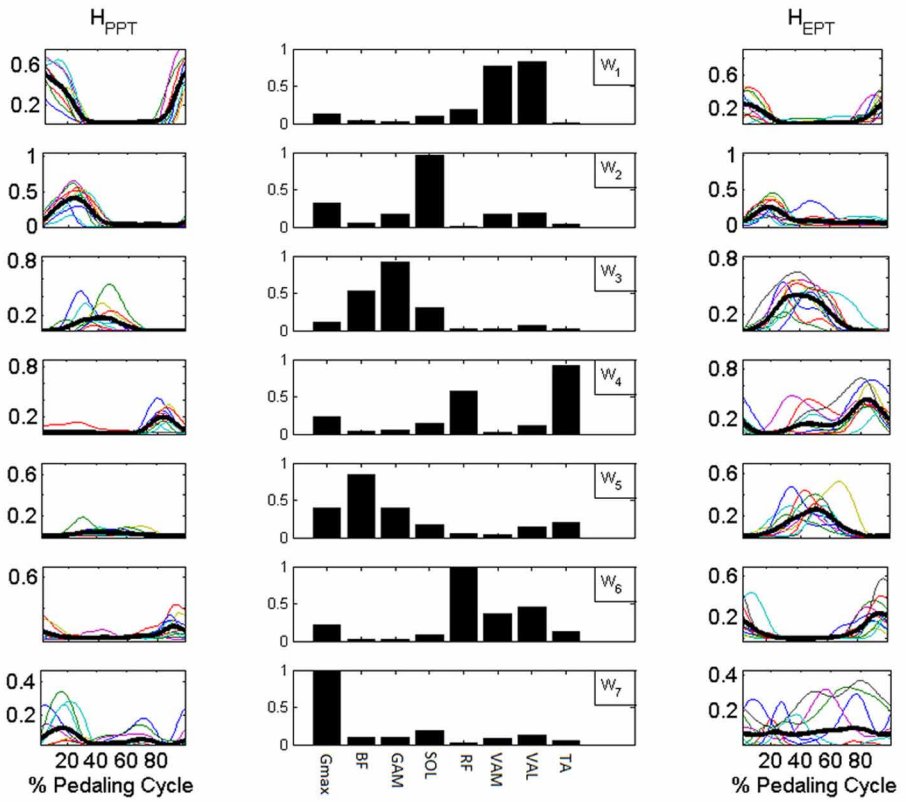

FIGURE 7 | Synergy activation coefficients H extracted with NNR by using W_{basis}. Central column: components of W_{basis}. **Side columns**: synergy activation coefficients extracted for the reconstruction of the muscle activation patterns of the PPT condition (H_{PPT} left column) and of the EPT condition (H_{EPT} right column). Subjects switch between additional modules to accomplish the different mechanical requirements of the EPT pedaling condition.

Table 2 | VAF_i values and $VAF_{shuffle}$ values.

	VAF_i	$VAF_{shuffle}$
Gmax	0.88 ± 0.13	0.72 ± 0.09
BF	0.95 ± 0.04	0.71 ± 0.06
GAM	0.98 ± 0.01	0.76 ± 0.04
SOL	0.98 ± 0.01	0.78 ± 0.02
RF	0.92 ± 0.07	0.70 ± 0.07
VAM	0.96 ± 0.01	0.77 ± 0.02
VAL	0.97 ± 0.01	0.79 ± 0.03
TA	0.97 ± 0.01	0.69 ± 0.14

There is a statistically significant difference between the VAF_i values obtained by reconstruction with W_{basis} and VAF_i values obtained from shuffled versions of the original basis vectors.

Table 3 | Correlation between the temporal evolution of the synergy recruitment and the temporal evolution of IE.

	Mean *r*	±*SD*	*CV*
H1	−0.46	0.47	1.02
H2	−0.29	0.52	1.79
H3	0.65	0.24	0.37

H5	0.65	0.21	0.32
H6	0.42	0.43	1.02
H7	0.16	0.55	3.44

Mean ± SD for each activation coefficient is reported, together with the coefficient of variation CV. H_3, H_4, H_5 are the only components to show a robust behavior across subjects, as indicated by the low CV value.

along the cycle reflecting the tonic components of Gmax and SOL in EPT.

Passing from PPT to EPT, the activation coefficients $\boldsymbol{H}$, obtained as a NNR by using $\boldsymbol{W_{basis}}$, show some adaptations, involving the amplitudes rather than the timings, which may reflect the satisfaction of the new mechanical requirements imposed by the feedback; this is particularly evident for the synergies *#3* and *#4*, where $\boldsymbol{H_3}$ and $\boldsymbol{H_4}$ show a significant increase that contributes to the modifications of the orientation in F_{tg}, leading to the improvement of the *IE*. $\boldsymbol{W_5}$ displays a level of activation comparable to the one shown by the other synergies, meaning that its action co-participates to the increase of the pedaling propulsion, in particular to power the pedal during the up-stroke phase. On the contrary, $\boldsymbol{W_1}$ and $\boldsymbol{W_2}$ which are active during the first part of the cycle, show a reduced activation which may be due to the contribution of the other leg while pulling-up.

The intervention of W_5 is in accordance with what outlined in previous studies (Mornieux et al., 2010), where an increased activity of BF and TA was reported in elite cyclists pedaling with a feedback of mechanical effectiveness. Interestingly, these two muscles were found to be in synergy as well in a mechanically altered pedaling, when they were found to be co-active after a phase shift of the hamstrings activation during backward pedaling in a phase-reversal of the main biomechanical functions (Ting et al., 1999). This aspect might confirm the evidence that W_5 is an available module for the accomplishment of cycling in different conditions.

CONTRIBUTION OF THE MODULES TO MECHANICAL EFFECTIVENESS

By analyzing the correlation between the synergy activation coefficients cycle-by-cycle and the *IE*, it emerges that those synergies which show an increased activity during EPT (i.e., W_3, W_4, W_5), also show a significant correlation with *IE*, confirming their contribution to the change in the pedaling technique.

EVIDENCE OF A BETWEEN-TASK SHARED MODULAR ORGANIZATION: THE CASE OF HUMAN WALKING

The fascinating hypothesis that some muscle synergies can be task-specific and other may be shared between different tasks (d'Avella and Bizzi, 2005), seems interestingly confirmed in our study. In particular, 4 out of the 7 synergies identified in the present study are highly similar to those extracted in other studies of human walking (W_1, W_2, W_4, W_5), but they are recruited in a different order during the movement cycle between the two tasks (**Figure 8**). This similarity is more evident when the comparison is carried out with studies using the same decomposition technique (Neptune et al., 2009; Clark et al., 2010), so that a common interpretation can be drawn. According to the modules extracted in (Neptune et al., 2009; Clark et al., 2010), W_1 (knee-extensors) is active in walking during the early stance phase providing body support, W_2 (ankle plantar-flexors and gluteus) intervenes during late stance and contributes to swing initiation, W_4 (RF and TA) is recruited just before stance and provides dorsiflexion during and just after heel strike, W_5 (Hamstrings and TA) decelerates the leg at the end of swing.

It is worth noting that two completely different tasks like walking and cycling, which basically involve the same body segments in the lower limbs, share some modules, but these modules are activated in a different way in order to satisfy the current task requirements in terms of both kinematics and kinetics. While W_3(BF and GAM) seems to be specific for a task like cycling, W_5 seems to be shared with walking but it appears in cycling only when a change in the biomechanical requirement is present, providing further evidence that a small set of motor modules can account for a variety of motor tasks through a simple selective activation and combination of modules. This aspect, related to motor adaptation, is in accordance with the theoretical functioning of the structure of a modular controller, since the use of an already existing module allows a faster adaptation to a perturbation in the task that is likely to be compatible with the modules (d'Avella and Pai, 2010).

ASPECTS RELATED TO TRAINING AND REHABILITATION

With respect to the study carried out on trained cyclists (Hug et al., 2010), where 3 synergies were extracted, here we extracted 4 synergies in the PPT. Despite the possible effect of the EMG processing techniques and the criterion used to choose the number of modules, a possible explanation could be attributed to the different power output expressed by the two studied populations, since an higher power output would increase the signal-to-noise ratio and would lead to a reduced number of synergies explaining an higher amount of *VAF*. An alternative hypothesis is that the difference in the number of synergies may be also due to a possible reorganization in the recruitment of the modules in trained subjects (Chapman et al., 2008), mainly consisting in the simultaneous recruitment of the modules W_2 and W_3, and this may be a sign of the differences between the two studied populations of cyclists. Even if the merging of motor modules has been observed for stroke patients and it was able to explain the main

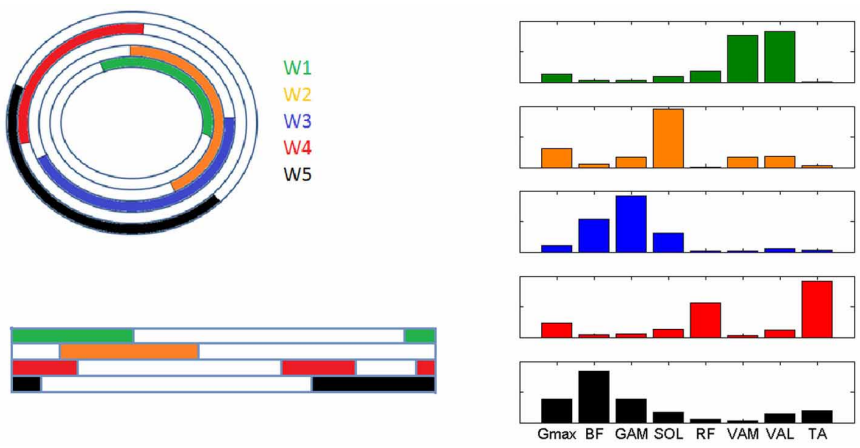

FIGURE 8 | Graphical representation of the intervals of recruitment of the 5 muscle synergies characterizing the analyzed pedaling conditions (PPT and EPT, W_{1-5} represented outwards in color code) and the corresponding recruitment of the synergies in the study by Neptune et al. (2009) (W_{1-5} represented downwards with the same color code, step cycle indicated from one heel strike to the next one).

biomechanical impairments during upper and lower limb movements (Clark et al., 2010; Cheung et al., 2012), up to now it is not known if a simultaneous recruitment of separate motor modules is feasible in healthy conditions, and if it can lead to improved performance in terms of metabolic or muscular efficiency as a consequence of expertise.

The possible spatio-temporal re-organization of the modules could be studied for the functional evaluation of the cycling performance in both healthy and pathologic conditions. For example, this could emerge from relating the adaptations in modularity with the evolution of physiological factors such as muscular efficiency (Zameziati et al., 2006) or muscle fatigue (Theurel et al., 2011), or from providing a neuro-rehabilitation program based on cycling (Ambrosini et al., 2012), by relating the changes in modularity to the changes in the mechanical outcome of movement.

POSSIBLE METHODOLOGICAL LIMITATIONS

The methodological approach used in the present study, consisting on the extraction of muscle synergies on an episode-by-episode basis, is subject-specific and is able to highlight intra-subject variation in muscle synergies. Nevertheless, it may not be able to characterize the behavior of the participant sample as a whole, since it might fail in capturing common features that could emerge only by decomposing data pooled across subjects and conditions.

Another possible limitation might rely in the use of the synchronous synergy model: in fact, up to now, it is not known whether the application of the time-varying synergy model could extract features otherwise not accessible when studying cyclic movements of the lower limbs.

CONCLUSIONS

Our results provide further evidence that the motor system might rely on the combination of a reduced number of motor modules for the control of movement. A small number of synchronous muscle synergies, scaled in amplitude and adjusted in time, are able to account for most of the variance of the EMG data. These modules are shared among subjects and across modifications in the mechanical requirements for the execution of the pedaling gesture imposed by the feedback, with the main adaptations occurring in those modules deemed responsible for a particular biomechanical sub-function (i.e., pulling up during the up-stroke phase).

Adapting to a new pedaling technique imposed by the feedback seems to be accomplished by exploring an already learnt modular structure, which is not pedaling-specific, but it is mostly shared with the one generally found in human gait. This aspect opens further perspectives in neuro-rehabilitation, e.g., by inserting cycling-based programs for the functional recovery of pathologic gait.

With respect to the study carried out by Kargo and Nitz (2003), where it was shown that skill learning is achieved by increasing the probability of selecting the most efficacious motor programs, our study only took into account a very reduced time slot of exercise, so that an immediate effect of training on a possible tuning of muscle synergies is not visible. Based on the previous observations, further studies should analyze the effect of short or long periods of training with biofeedback on the structure of muscle synergies in cycling, in order to establish if a modification in modularity occurs by altering the structure of the synergy vectors, or by selecting different motor programs. Aiming at this, and in order to overcome possible limitations of the present study, also the inter-limb coordination should be taken into account.

We present and apply a method that uses point process statistics to discriminate the forms of synergies in motor pattern data, prior to explicit synergy extraction. The method uses electromyogram (EMG) pulse peak timing or onset timing. Peak timing is preferable in complex patterns where pulse onsets may be overlapping. An interval statistic derived from the point processes of EMG peak timings distinguishes time-varying synergies from synchronous synergies (SS). Model data shows that the statistic is robust for most conditions. Its application to both frog hindlimb EMG and rat locomotion hindlimb EMG show data from these preparations is clearly most consistent with synchronous synergy models ($p < 0.001$). Additional direct tests of pulse and interval relations in frog data further bolster the support for synchronous synergy mechanisms in these data. Our method and analyses support separated control of rhythm and pattern of motor primitives, with the low level execution primitives comprising pulsed SS in both frog and rat, and both episodic and rhythmic behaviors.

Keywords: synergy, primitives, synchronous synergy, time-varying synergy, point process

INTRODUCTION

The efficient control of an organism's motor architecture poses significant difficulties for the central nervous system. In particular, control of the limbs is an ill-posed problem: too many possible solutions are available to perform a particular motion for the nervous system to find the correct combinations of muscles in a timely manner. As a solution to this problem, a variety of modular control strategies have been presented (Giszter et al., 1989, 1991, 1992, 1993, 2007, 2010a,b; Mussa-Ivaldi et al., 1990, 1994; Bizzi et al., 1991, 1992; Mussa-Ivaldi, 1992; Mussa-Ivaldi and Giszter, 1992; Giszter and Kargo, 2000, 2002; Kargo and Giszter, 2000a,b; Mussa-Ivaldi and Bizzi, 2000; Mussa-Ivaldi and Solla, 2004; Cheung et al., 2005, 2009; d'Avella and Bizzi, 2005; d'Avella et al., 2006; Tresch et al., 2006; Bizzi et al., 2008). Modular control of motor structures reduces the number of independent points of control for the system and therefore reduces the number of degrees of freedom available in the execution of a movement.

TYPES OF MODULARITY

Specifying that the motor system employs a modular control scheme does not, in the end, tell us very much. There are many different kinds of motor modularity. For example, some groups have found evidence of "kinematic modularity" or regular, repeated structure in movements or the planning level of movements (Viviani and Terzuolo, 1982; Hogan, 1984; Sosnik et al., 2004; Chiovetto et al., 2010; Omlor and Giese, 2011). In contrast, and perhaps as complement to kinematic modularity, there is execution modularity, or modular organization in the control mechanisms underlying performance of a particular task or set of tasks. Many examples of execution modularity have been reported in recent years and include such examples as central pattern generators (Grillner, 2006), half center oscillator models, blends (Stein et al., 1986; Stein, 1989), motor primitives (Giszter et al., 1991, 1993; Hart and Giszter, 2004, 2010), and time-varying synergies (d'Avella et al., 2006).

We are interested in examining two of these forms of execution modularity in detail. The first group, synchronous synergies (SS) (Hart and Giszter, 2004, 2010; Kargo et al., 2010), are built from synergistic groups of muscles activated with a fixed time course. Work done, both in our lab and several others, supports the observation that most movements generated by an unconstrained frog can be represented as the summation of multiple motor primitive style elements (Bizzi et al., 1991; Giszter et al., 1992; Mussa-Ivaldi and Giszter, 1992; Giszter et al., 1993; Mussa-Ivaldi and Bizzi, 2000). However, some researchers have advanced time-varying synergies an alternative to the motor primitive model (d'Avella et al., 2006). In this model, temporally coordinated (but not necessarily synchronous) drives are supplied to groups of muscles. These time-varying synergies are thought to form sequence units. Kinematic strokes form modules, and the time-varying synergy (TVS) might be thought to correspond to such higher order task units. Such time-varying drives, as formulated in theory, may be dilated uniformly across their temporal duration, as required by the task. In the TVS model described above, there is a strong connection between the duration of a sequence of a pulses on several muscles and the temporal widths of the pulses supplied to those

muscles, i.e., uniform temporal scaling across the entire motor compositional unit.

To distinguish these two frameworks: "spatial/synchronous muscle synergies" and time-varying synergies we have examined how these models constrain the onset and peak timings of muscle activity viewed as point processes. To do this we will construct models of point processes reflecting both synchronous and TVS schemes. We show that distinct point process statistics arise. We plan to test the hypothesis that real electromyogram (EMG) activity recorded in frogs resembles activity that one would expect to see generated by a synchronous synergy model of motor production, rather than a TVS model of motor production and examine the degree to which statistics computed on real EMG data from 10 hindlimbs of the bullfrog resembles the statistics computed on each model.

There have been many metrics and procedures developed for quantifying the level of synchronous activity between sets of point processes. Many of these statistics have attempted to quantify synchronicity in terms of metrics computed between pairs of spike trains, such as cross corellograms and joint peristimulus time histograms (Ellaway and Murthy, 1985; Adams et al., 1989; Datta and Stephens, 1990; Nordstrom et al., 1990, 1992; Bremner et al., 1991a,b; Datta et al., 1991; Ushiba et al., 2002), although most of these metrics show significant sensitivity to the density of events within measured intervals (Bremner et al., 1991a,b; Kim et al., 2001). Higher order synchronization (between three timestamps) has been examined and quantified using such tools as the snowflake plot (Perkel et al., 1975; Czanner et al., 2005). However, statistics on synchronicity for time series of arbitrary dimensionality are lacking. Since the number of muscles participating in synergies is not necessarily fixed, this lack represents a problem for comparison of time series representing the activation of differing types of multi-muscle synergies. In light of these difficulties, in order to make comparisons between such processes, we have developed a metric that shows sensitivity to the degree of onset or peak synchronization over a wide range of parameters. We have performed extensive testing of this statistic using data from models of both synchronous motor synergy strategies and TVS strategies. We then apply this statistic to frog motor pattern data.

METHODS

All experimental data from frogs and rats used in this paper for exposition was obtained under strict compliance with USDA and PHS guidelines, and with full oversight of the Drexel University College of Medicine IACUC.

DATA CONSTRUCTION

Both real data and modeled data were used and tested in the developed type of discriminant analysis.

Real EMG data collection

Real EMG data were derived from 10 spinalized frogs, with recording electrodes in 10 hindlimb muscles. (RA, RI, AD, SM, GL, VI, BI, SA, VE, ST). Frogs were anaesthetized, spinalized, and decerebrated. Ball electrodes, constructed as in (Hart and Giszter, 2004) were implanted in these 10 muscles of the hindlimb. After at least a day of recovery, EMG recordings were made during a variety of frog behaviors at 2 kHz. EMGs were recorded using a Cerebus 128-channel data acquisition system (Blackrock Microsystems) and saved to a file. Files were imported into the MATLAB™ programming environment for analysis. Imported EMG data were rectified, smoothed using an 80 point, triangular window, moving average filter, and down sampled to 250 Hz. The data were then saved to a MATLAB MAT-file and retained for later analysis.

Basic model data generation parameters. The basic model was defined as a renewal process, constructed on intervals of variable duration, ranging between 90 and 250 ms. Every $\Delta =$ 90–250 ms, an interval value was drawn from a Poisson interval distribution (exponential), and a pulse or sequence of pulses was placed at the cumulative sum of intervals up to that draw. The distribution of intervals constructed in this manner was approximately Poisson, with a maximum interval cutoff below $2 \times \Delta$ ms (because every interval is populated with a draw). There was also some distortion away from true Poisson at the longer time scales, due to the fact that the Poisson process "reboots" at the edge of every Δ ms interval. We tested and compared several different point process distributions. However, these did not affect our basic discrimination findings and here we focus entirely on the Poisson process results.

DISCRIMINANT METHOD

We examined the effect of varying several synergy parameters on the subsequent discriminability of synchronous and time-varying synergies from one another using point process model statistics, and to distinguish the sum of time intervals between local maxima in each type of time series. These parameters were the density of synergies on an interval (ρ), the number of muscles per synergy (σ) and the number of simultaneous muscles in TVS models (η). We do not assume any *a priori* knowledge of σ in real-world data, although we do know that the majority of primitives examined in our work generally contribute significantly to between ∼2 and 4 muscles (Hart and Giszter, 2004), and because synergistic groupings with more or less muscles are possible.

Two distributions were used to model σ. The first distribution was sharply peaked and σ was permitted to vary between 2 and 10 muscles, with a maximum likelihood occurring at around 3 muscles. A second flat distribution, in which all values of σ are equiprobable, was also used. Other parameters, such as pulse amplitude were not expected to have a significant effect, based on the structure of the onset or peak-picking algorithm (the peak detection algorithm identifies all peaks above the noise threshold based on their resemblance to a template peaked waveform) but were examined as well. For each model run, the total number of synergies was selected, at random, from a Gaussian distribution with a mean and median of ∼4 synergies/run, omitting negative results.

Synchronous Synergy Model Construction (SS model) Modeled data were constructed using the two different models (synchronous vs. time-varying), and used to act as the main poles of comparison for real data in this discrimination task.

The first model (**Figure 1A**) represented an idealization of SS or motor primitives. This model was constituted of several simultaneous pulses delivered to a subset of channels ("muscles") that are multiplied by a channel-specific gain. The EMG was constructed on intervals of 500 ms and the density (ρ) of possible synergies delivered on a single interval was varied between 0 and 5. Each simulated EMG would be constructed of several distinct synergies. The number of distinct synergies to be used in the entire constructed data set was selected and allowed to vary stochastically between different realizations, with care being taken not to include any duplicate synergies. (As an example of this constraint, if there were 8 muscles in one synergy, then only 2 non-identical and non-overlapping or disjoint synergies could be drawn, one synergy with 8 muscles and the second synergy with the remaining 2 muscles). We then created and drew from a distribution representing the number of possible muscles (σ) participating in each of these synergies. As mentioned in the preceding section, this distribution was permitted to be either a peaked function (reaching a maximum between 2 and 4 muscles per primitive, consistent with observed data) or a flat function where primitive muscle membership numbers were all equiprobable. For each synergy, we then randomly selected "muscles" from the 10 available muscles.

SS synergies were modeled as occurring in episodic motor patterns. After a time of occurrence of the first SS synergy (the episode onset) was chosen, other SS synergies were positioned to occur following. To accomplish this, the (randomly selected) following SS synergies in the motor pattern were assigned random onset times on the 250 ms interval following a first "seed" synergy event of the episode. This created a point process representation of motor pattern under the SS model. A continuous signal was then constructed for each synergy's component muscles, and then these were combined to obtain the different activity patterns on each virtual EMG channel. More specifically, we proceeded as follows: A gaussian pulse forming the "seed synergy" with a time course of around 300 ms was placed at each of the point process sampled motor pattern event times. Each synergy pulse occurring on the interval was positioned shifted from the "seed synergy event" by a small amount, drawn from an exponential distribution, with a mean value of 250 ms and a median of 153 ms. Given that several synergies may in this way be invoked on the same interval, it is thus possible that there may be several overlapping pulses in a motor pattern "event" interval. In this case, the amplitudes of each pulse of an individual muscle's activity occurring in overlapping synergies were summed together. After the synergies were positioned in time the EMG signals were next calculated in this way. White noise was then added to all EMG channels of the model, with a maximum noise amplitude of 5% the maximum value of the clean signal. Amplitudes of each Synergy pulse were assumed to be either the same, or to be drawn from a normal distribution, with a mean value of 0.5, and truncated at amplitude values of 0 and 1. Amplitude effects on final results were negligible.

Time-varying synergy model construction (TVS model)

The second model (**Figure 1B**), used in this analysis was constructed to simulate various instantiations of a TVS model of motor control. A single pulse event was created and placed on a 250 ms interval at a randomly drawn time. Delays for the remaining pulse events from the drawn time ranged from −100 to 100 ms and were sampled from an exponential distribution with a mean of 100 ms (the sign of the delay was selected randomly). These shifted pulse events were then delivered to a subset of channels ("muscles") that were multiplied by a channel-specific gain. A small number of such TVS were then randomly selected to be a set used in an individual realization, by repeating a randomly selected member of the set at the (Poisson distributed) synergy event times. Each such constructed synergy occurrence was scaled in time in its overall duration by a factor that was drawn from an exponential distribution with a mean of 2. This

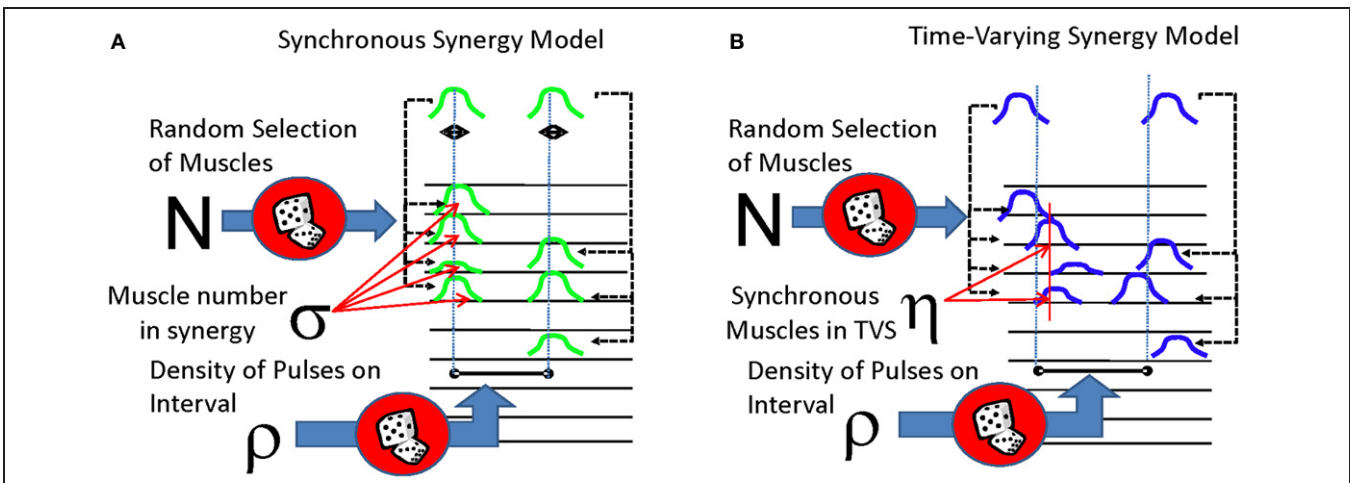

FIGURE 1 | Two forms of synergistic muscle activity compared in this analysis. (A) Synchronous synergy model. Pulses are multiplexed to several muscles to several muscles, with tight coordination of temporal activity of each pulse. **(B)** Time-varying synergy model. Pulses are sent to several muscles with some time delay between them, and the entire set of pulses and delays may be dilated or contracted as necessary. In both models, the delay between different synergys is drawn from an exponential distribution (or in a few cases, from a uniform distribution).

created a point process representation of motor pattern variations under the TVS model. Apart from these changes, the TVS model continuous signal representation was then constructed as in the SS case. TVS models could thus range from models in which there were no synchronous drives delivered to any muscles, to models in which synchronous drives are supplied to many muscles in the TVS, while other muscles in a synergy are asynchronously activated. This latter variant could in principle be thought of as a TVS containing within it some number of SS.

Discriminant analysis of real and model data

Simulated data from both TVS and SS models were compared with rectified, filtered, and downsampled examples of real data from frogs.

Peak/Onset times were extracted from each channel of real or simulated EMG by thresholding the EMG to 2 standard deviations above its mean value and identifying all points which exceeded this value. We then used a sliding gaussian pulse of duration 250 ms to discriminate values over the predefined threshold which represented peaks in the recorded data. We chose this peak width as it most closely reflected the dominant time scale observed in EMG recordings in bullfrog (Hart and Giszter, 2004). However, this peak discrimination process was simply to subject both real and artifically created data to a similar workflow and any errors introduced in peak or onset selection. Peaks were identified as those points over the amplitude threshold where the correlation with the sliding Gaussian pulse is more than 2 standard deviations over the mean correlation value (**Figure 2A**). This criterion nearly always (>95% of the time) found the correct local maximum in a sequence of data. We then chose the times taken from one chosen sample channel of EMG as "reference times" to be used in the ensuing analysis. The times of peak occurrence on other channels were identified via the thresholding algorithm described above and the difference from the reference times were calculated on each successive 250 point time window defined around each reference time. Peak time differences were rank ordered within each window and the mean time difference on the intervals were calculated.

A cumulative statistic Q was then created for the time window by summing time differences (**Figures 2B,C**) as follows:

$$Q = \frac{\sum_{t_{\mathrm{ref}}} \sum_{t_i} (|t_i - t_{\mathrm{ref}}|) \times \Theta(|t_i - t_{\mathrm{ref}}|)}{N} \quad (1)$$

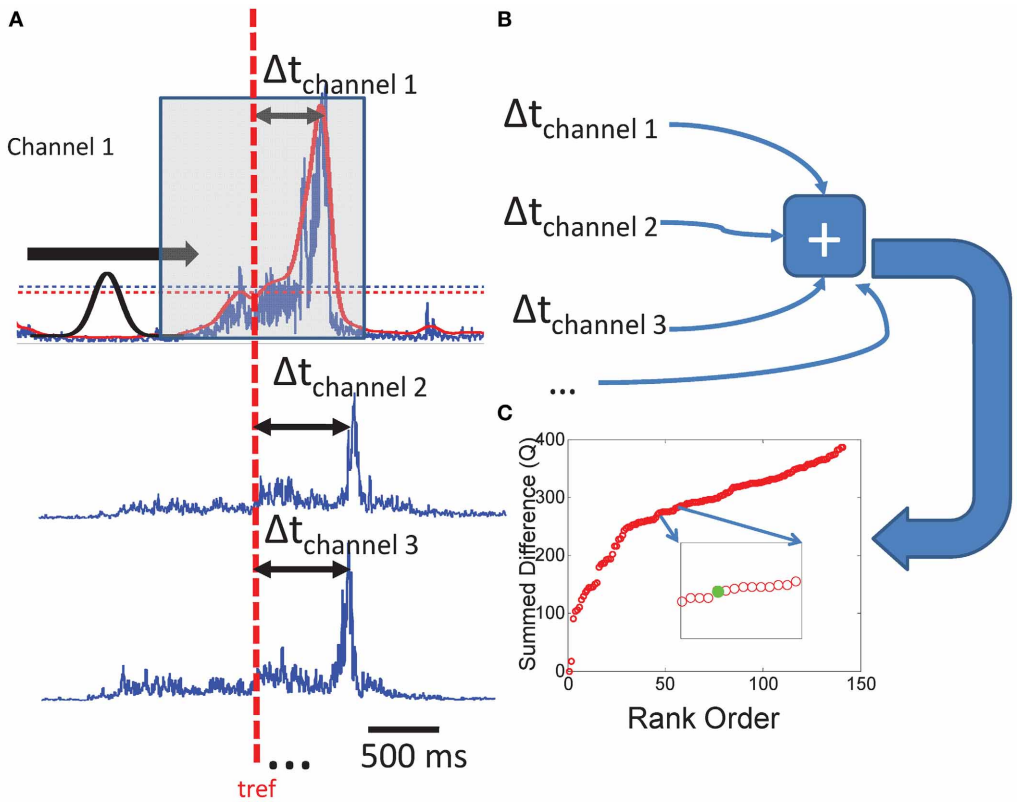

FIGURE 2 | Calculation of the Q statistic. (A) On an interval ranging from −250 to 250 ms, we identify peaks in a rectified and smoothed set of EMG waveforms by sliding a gaussian waveform along the intervals and identifying points of maximum correlation with amplitudes larger than a rejection amplitude (more than 2 sds the mean EMG activity). Peak times are subtracted from a randomly drawn reference time from each interval, and the **(B)** absolute differences are summed over that interval. **(C)** The same procedure is performed for all such non-overlapping intervals on the data set. The resultant Q values are rank ordered for the purpose of comparing distributions from different sets of data.

where Θ is a step function with value 1 when its argument is < 250, and 0 otherwise. t_i is the time of a peak in the window, t_{ref} is the reference time, and N is the total number of pulse events in the analysis window.

The procedure for calculating Q was then repeated for the next time window in the record defined by the reference channel and reference times. We calculated Q values for each segment of the real data files, as well as each segment of both model implementations. This analysis was carried out on all runs of each model. Reference channels used were randomly assigned. In some instances all channels were tested as reference and compared. Choice of reference had little effect on statistics. This statistic, Q, captures the deviation of the peak clustering in SS and TVS patterns from that observed or expected in an unconstrained random distribution of pulse times, which was constrained to neither SS or TVS structure. The composite interval structures captured in the measure Q, will deviate from predictions based on uncorrelated point process assumptions, due to the correlations and constraints on intervals imposed by synergy structures. For example, the expectation of interval differences in unconstrained Poisson processes will be that they effectively represent the result of a Poisson process of higher rate, reflecting the independent constituent process rates. In contrast, SS constraints enforce short intervals in the joint process, and TVS enforce longer intervals, and also short intervals to the extent that SS are found within the TVS sequences.

Discriminant scaling analysis of real data

To compare models and data we used the cumulative distributions of the statistic Q. Given the likelihood that connected peaks in TVS data will be farther apart than in SS data, we expected that data consistent with a TVS model will have larger values of this statistic than data consistent with SS models. Given a set of randomly drawn reference times, and for any distribution of pulses on a given interval, the maximum likelihood (ML) of the absolute value of the difference between Q values computed from a set of reference times and the distribution of pulses will be nonzero. If data is described perfectly by a SS model, Q-values will cluster around the ML value for this model, more or less normally, by the central limit theorem. Q-values from data better described by a TVS model will cluster around the ML Q-value for TV synergies. Taking the difference between Q values for each model (Qss, Qtvs) and the real data (Qreal) we arrive at two error distributions, both approximately normal.

We further anticipated that by rescaling (i.e., dilating) small time differences in EMG peak times in SS models, we will eventually obtain Q-statistics characteristic of, or similar to a TVS model, or a non-SS random pulse pattern.

Rescaling of synergies was done in constructed data as follows. During construction of simulated data sets, time-varying synergies were generated according to the procedure outlined above and were then rescaled by a variable factor. Each synergy was scaled independently before adding it to the data. Consequently, synergies consisting of only a single muscle were not shifted in time, nor was the stochastic rate at which synergies were generated scaled, leaving the length of the time series intact. Constructed SS were scaled in an analogous fashion, although in this case the rescaling factor was applied to the small temporal jitter between pulses in a primitive (See previous section for details of SS contruction).

To scale real data for comparison, we first identified likely synergies by identifying near-synchronous pulses in different EMG channels. Any pulses with a time difference of less than 5 ms were selected as potential SS and retained for dilation and statistical analysis. Those collections of pulses that appeared more often than expected due to random chance (2 SD > average frequency of occurrence calculated from 50 shuffles of time indexes of all peaks detected in a record) were identified as "synchronous synergies" for the purpose of this analysis. The small jitter between the pulses in each such synergy were then scaled as above. Scaling was relative to the mean midpoint time for each synergy/collection of pulses, so early pulses were shifted backward and late pulses forward.

As stretch of intervals outside of 250 ms is impossible in our formulation i.e., it invalidates the interval for the analysis (it will push timestamps into next window), it follows that, dilation should not significantly move the Q difference distribution of TVS data. In contrast, dilation of the SS model data was expected to yield cumulative Q values that were eventually more statistically similar to the original TVS Q values computed. Assuming real data is described by the SS model, subjecting the data to this procedure should yield Q distributions that are similar to TVS distributions. If real data is better described by the TVS model, one would expect little change in cumulative Q upon performing the dilation operation. With this in mind, we took the timestamps associated with peak times in real data and scaled the differences in timestamps over scale factors that ranged between x2 to x20 and calculated Q values at each scale-step. Scaling the differences in timestamps and scaling the underlying waveforms made no difference, as the peak picking algorithm identifies the same peak for a pulse, regardless of its width. Differences between the median Q at each scale and the original unscaled median Q-value were retained.

Are primitive timing and dynamics related?

We also used more data-driven techniques to further assess the likelihood that synergies in the bullfrog consisted of SS style constructions, which has been our working hypothesis in prior research. To do this, we performed two analyses on real frog EMG data. In keeping with the Gottlieb work showing triphasic activation of muscle groups during movements (Gottlieb, 1998), we examined timing relationships within triplets of pulses extracted from frog EMG data. We first performed regressions of pulse widths for each pulse in a triplet against both the pulse widths of the other members of that triplet, and against the time delay between pulse 1 and pulse 2, as well as between pulse 2 and pulse 3. In order to assess the main sources of variance to the resultant regression coefficients, we then performed a principal components analysis on these coefficients, and generated projection biplots to assess the relative significance of the contribution of each component. Additionally, we took the entire sequence of pulse widths and pulse time differences, treated each of these variables as covariates for an independent component analysis (ICA) in order to assess the relative independence of each of the

variables. Additional details on this analysis are provided in the Results section below.

RESULTS

DIFFERENCE OF Q STATISTIC FOR SS AND TVS MODEL DATA

We constructed 25 time series for each parameter set as above (Poisson interval distributed events) and calculated Q values on simulated TVS and simulated SS models for each sampling on these series. For a single draw from a distribution with six components and an $\eta = 1$ and a $\rho = 1/90$ we found that the Q distributions were easily distinguished from one another. The rank ordering of Q values from each SS and TVS distribution (**Figure 3A**), or the cumulative probabilities for each distribution (**Figure 3B**) were clearly and cleanly distinguishable from each other. Additionally, we compared Q statistics from the distribution of uniformly distributed synergy events (see above) with those calculated using the Poisson interval distribution, for each of the chosen sets of parameter values. Q statistics could not be discriminated between the uniform and Poisson generators using paired *t*-tests (comparison of TVS statistics: $p = 0.34$, SS statistics $p = 0.75$). Lowering ρ to 1/250 did not appreciably alter the situation.

EFFECTS OF DIFFERENT PARAMETERS

As previously mentioned, we recognized that varying the parameters σ, ρ, and η has the potential to alter our ability to discriminate the outcomes of these different models. There are several different parameters that must be examined for their effect on the discriminability of TVS and SS models. First, the number of synergies must be considered. Secondly, each synergy may be constituted by a variable number of muscles. The distribution of the number of muscles in a synergy may also have an effect on discriminability. Q values calculated on two muscle synergies will tend toward smaller summed differences than in five muscle synergies by nature of the number of items measured and summed. This aspect of the statistic is unavoidable. Finally, the number of synergies on each interval used to calculate a Q value can impact the value of the Q parameter as well.

The number of synergies on an interval can have a drastic impact on the value of Q, as can the form of the TVS synergy itself. Therefore, we examined each 250 ms interval of our constructed data, and looked at the number of pulses on that interval.

EFFECT OF VARYING σ

For small values of σ (the number of muscles per synergy), we find that the TVS, SS and real local Q distributions are very hard to discriminate. Q values that are very similar persist over all three models for a range of ρ values (**Figure 3C**), but begin to clearly diverge at a σ value of five or six muscles per primitive. For higher σ values, TVS and SS Q values are easily discriminated from one another. Real values, and SS synergies are much more similar than real and TVS values. The reason for this is easy to see. At small values of σ, only one or two muscles participate in a given synergy. Thus it becomes more difficult to say whether

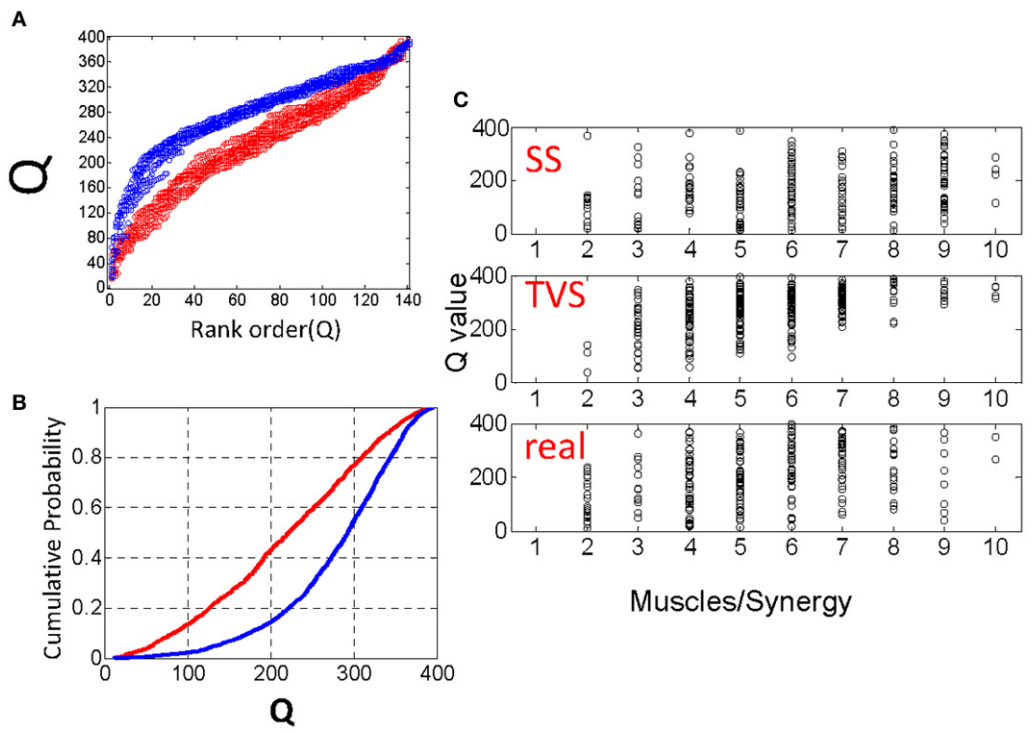

FIGURE 3 | (A) Comparison of rank ordered Q statistics from five runs of the basic TVS model (blue) (**ρ** = peaked distribution, **σ** = 3, **η** = 1) and five runs of the basic SS model. **(B)** cumulative probability of the same Q distributions. **(C)** Comparison of the effect of ρ on local Q statistics for SS models, TVS models, and real data. Note that as ρ increases, Q statistics tend toward higher for TVS models than for real or SS constructed model data.

a given synergy is time-varying or not. At larger values, there are many pulses on an interval. For TVS, many of these pulses will be separated by significant time delays, resulting in a higher Q statistic. For SS, the pulses will be more tightly coordinated, yielding a lower Q statistic.

EFFECT OF VARYING ρ AND η

Because σ (the number of muscles per synergy) tends to be around three or four muscles for both SS and TVS models as described in the literature and since σ and η (the number of simultaneous muscles in a TVS model) are going to be somewhat coupled, we chose to examine the effect on model discriminability of varying ρ and η simultaneously.

For our purposes, we are classifying as "synchronous" only those synergy models in which all muscle activations in a given synergy are simultaneous (within some error δ). Synergy models containing two or more out of phase muscle activations (with the remainder occurring at variable times) will be considered, for the purposes of this study, as "time-varying."

Given this classification, we chose to examine how varying the number of simultaneous muscles in a TVS model interacts with the density of primitives on a 200 ms interval to impact the discriminability of TVS and SS models. We did this by identifying the points at which TVS and SS distributions were maximally discriminable, a measure which coincides with the Kolmogorov-Smirnov (KS) statistic. KS statistics for the discriminability of TVS and SS models, as a function of these variables are shown in **Figure 4**. TVS and SS models were constructed using both peaked (**Figure 4A**) and flat (**Figure 4B**) muscle/synergy distributions. As can be seen, for the peaked distribution, KS statistics were significant for a wide range of combinations of parameters. Further, the number of simultaneous muscles within a synergy did not appear to significantly impact the significance of these differences even at the lowest synergy density. For the peaked distributions, the Q statistic failed to distinguish TVS and SS models for high numbers of muscles (>4) in combinations that occurred only rarely on an interval (black floor in **Figure 4C**). Expanding the interval, or increasing the data set, might abolish this dead zone of discrimination. For the flat distribution of primitives, for all combinations of these variables, TVS and SS models were easily discriminable across all tested conditions.

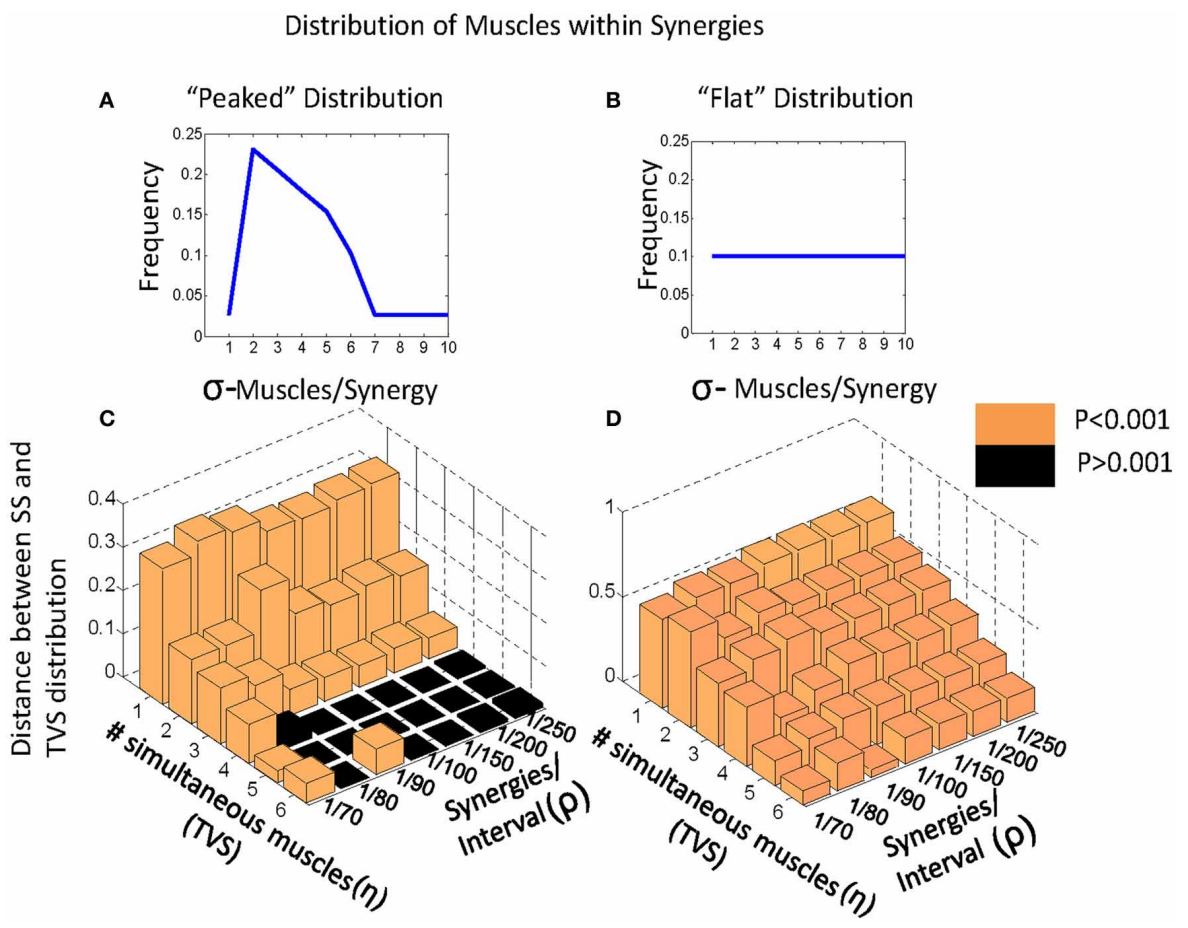

FIGURE 4 | Varying model parameters alters discriminability of models. (A) A sharply peaked distribution. **(B)** A flat synergy distribution. **(C)** The peaked distribution resulted in easy discrimination of TVS models from SS models at an alpha level of 0.001 for up to three simultaneous synergies in TVS models. **(D)** The flat synergy distribution results in discrimination of TVS models from SS models for all values of ρ (density of synergies on an interval) and all η (the number of simultaneous muscles in a TVS).

DISTANCE BETWEEN REAL DATA AND SS DATA vs. REAL DATA AND TVS DATA

We next calculated Q values for five records of real EMG activity (see methods). We then compared the middle of this Q distribution (Qreal) to the middle of Q distributions calculated for SS (Qss) and TVS (Qtvs) models at each of the parameter values examined above. We plotted the distance between Qreal and Qss against that between Qreal and Qtvs. Note that where the two distributions are broadly discriminable, either for synergy densities drawn from a peaked distribution (**Figure 5A**) or a flat distribution (**Figure 5B**) the distances between Qreal and Qss were smaller than Qreal and Qtvs (**Figures 5C**,**D**). Further, the real data is found ***beyond*** the model SS cumulative curve, rather than between the SS and TVS curves. The real data thus exhibited stronger SS statistics than our artificially created data. Accordingly, the cumulative distributions support the idea that the SS hypothesis for real data is likely still stronger than the $p < 0.001$ calculated for the artificial data. However, we limit our assessment to this value here.

EFFECTS OF FORCING DILATION ON DATA AND Q STATISTICS

The construction of the Q statistic provides an additional test for the presence of SS synergies, based on a dilation manipulation of the synergies' time scale within the analysis window. The analogy is to using a higher powered microscope field, the intervals are dilated but some fall out of the analysis window field of view. If we assume that a particular distribution of pulses were constituted primarily of time-varying synergies with a maximum time scale of less than 200 ms (reasonable for frogs given that most movements are executed in under a half second), then finding the time of each pulse with respect to some arbitrary reference time on each interval and then scaling these times by a constant dilation within each interval should not impact the Q statistic significantly. In pure TVS synergies lacking SS components, or non-synergy processes, this scaling would simply push a few of the pulses out of the analysis window interval for computing Q values. So the Q value before dilation minus the Q value computed after dilation should often be near zero. In contrast, for a SS model, it should be possible to dilate all the short pulse times (with respect to a reference time) while keeping them all in the analysis window. As short intervals are highly associated with SS synergies (e.g., Krouchev et al., 2006; Markin et al., 2012)—dilation in the analysis window affects SS quite a lot, first altering Q statistics, before the Q statistics plateau. The statistic will plateau at the point at which pulses are pushed into the next computational interval). A new statistical measure then is obtained from the

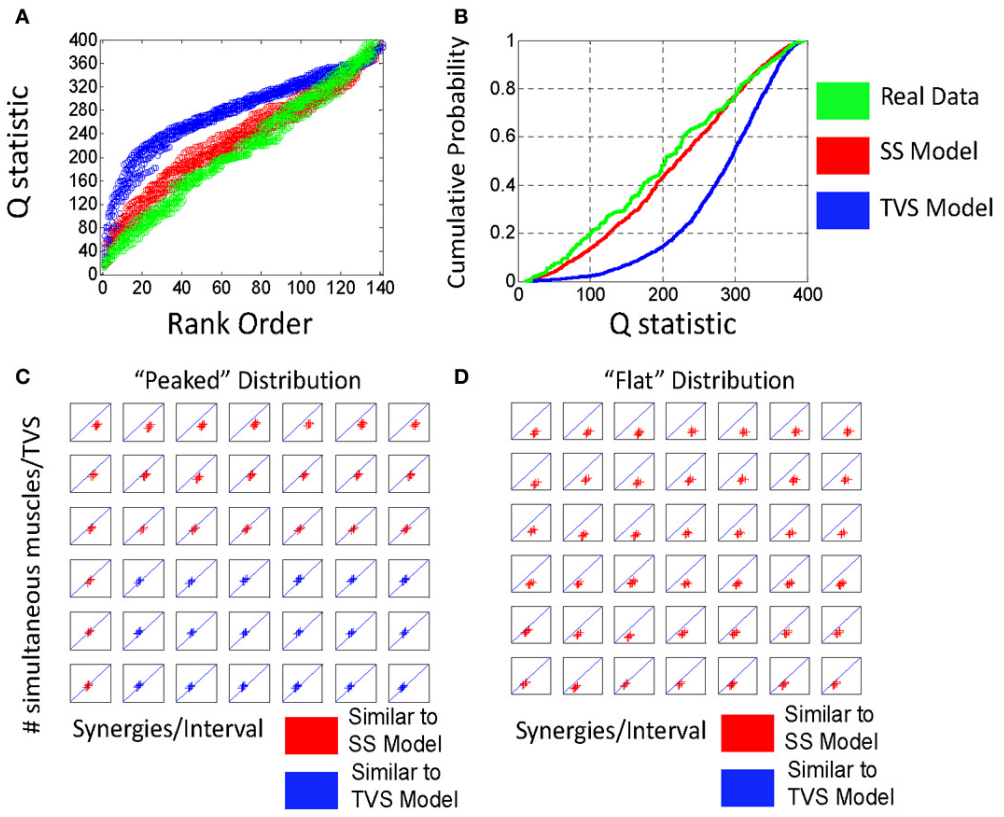

FIGURE 5 | Q statistically classifies real from EMG data as a synchronous synergy strategy for range of discriminability of the statistic. Linear discriminant separates Qss-Qreal (y axis) and Qtvs-Qreal (x axis). **(A)** In data drawn from the peaked distribution. **(B)** Cumulative probability shows TVS/SS distinction. **(C)** For peaked distribution (see **Figure 4A**) we find that for a range of discriminable parameters (see **Figure 4A**) plotted points are less than unity, indicating Qss-Qreal < Qtvs-Qreal. All parameter pairs ρ and η show Qss-Qreal < Qtvs-Qreal. **(D)** For flat distribution (see **Figure 4B**) all parameter pairs ρ and η Qss-Qreal < Qtvs-Qreal. In both cases, this is consistent with a model where EMG activity is generated via an SS-type strategy.

difference of the Q statistic after the dilation minus that of the unaltered data. This new difference in Q statistic should rise to a plateau at a particular scale value. We found that the dilation of real data time intervals does tend to push the Q statistic for dilated data toward the Q distributions for TVS data, and obviously this is captured in the difference. This is shown to be the case in **Figure 6A**. As the real data is dilated (**Figure 6B**), the cumulative distribution moves from its position beyond the synthetic SS model data, and crosses over to lie between the SS and TVS cumulative distributions. Furthermore (**Figures 6C,D**), the difference between dilated and unaltered data Q statistics in model data is close to zero for TVS synergies (tQ cannot be significantly altered as the analysis intervals are dilated) but increases significantly for real data or SS model synergies. This observation holds true for both peaked and flat synergy density distribution models.

CONNECTION BETWEEN PULSE TIMING AND SCALING OF MUSCLE ACTIVATION

TVS models predict a certain degree of covariance between the time scale of individual EMG activation and the relative timing of pulses in a synergy (d'Avella and Bizzi, 2005; d'Avella et al., 2006). Therefore, separate from the Q statistic analysis, we also chose to examine the functional dependence of primitive duration on the time delay between primitives. We explored this in wipes with a three primitive sequence, largely following work on triphasic bursts in human reaching (Gottlieb, 1998). We wanted to examine the degree to which primitive duration varied within these three primitive sequences, as well the dependency of primitive duration on pulse timing within a short sequence of primitive activity. Occurrences for each triplet were shuffled and significant three primitive sequences in the original data were identified by finding those triplets with z-scores greater than 2 (based on the statistics of the shuffled data). For each occurrence of a significant triplet, we calculated regression coefficients between (a) the durations of pulse 1 (D1) and pulse 2 (D2), (b) pulse 2 and pulse 3 (D3), (c) time of pulse 2-time of pulse 1 (t2-t1) and the time of pulse 3—the time of pulse 1 (t3-t1), (d) all cross terms (i.e., pulse duration 1 vs. time delay between pulse 1 and pulse 2). A principal components analysis was performed on the calculated regression coefficients, and the first two principal components were retained and plotted against one another (**Figure 7A**). Each of the regression coefficients was plotted on these axes as well. The regression coefficients between pulse widths (a, b) tended to align with the second principal component (**Figure 7A**, red lines) while the regression coefficients between pulse time delays (c) aligned

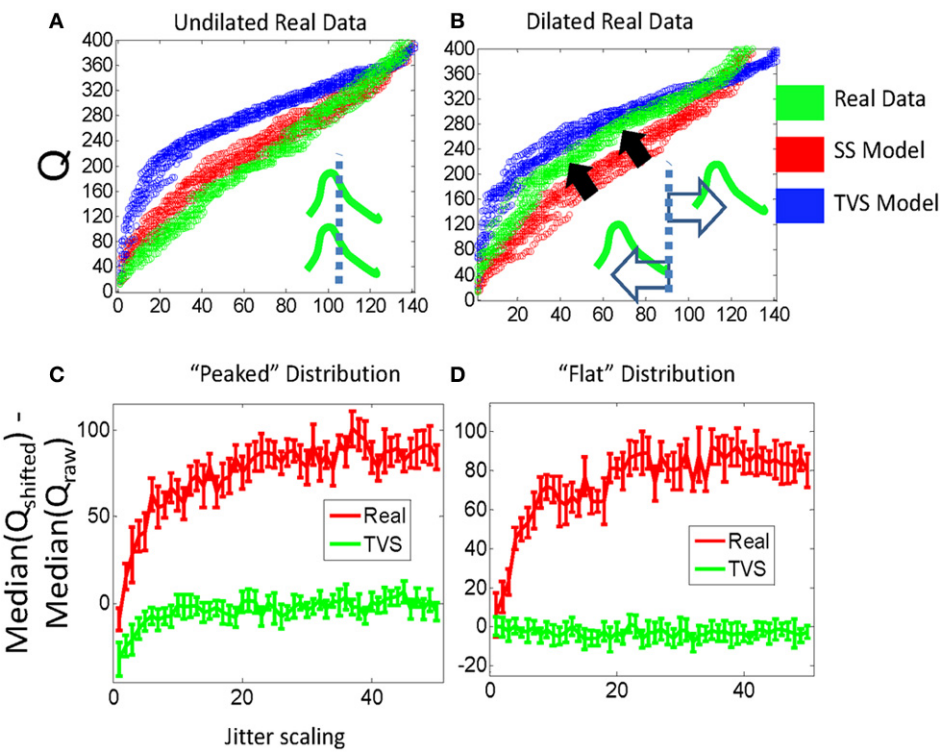

FIGURE 6 | Stretching the interval between jittered pulses causes real data that resembles SS model data to begin to resemble data generated by a TVS strategy, for a fixed analysis window. (A) The Q statistic distribution of real data (green, left) which is clearly SS in form, is moved toward the Q statistic distribution of the TVS model data when intervals between real data are scaled linearly with an unscaled analysis window **(B)**. **(C)** Peaked σ-distribution: comparing the difference between scaled Q stats of real data and their unscaled values with scaled TVS Q values and the unscaled Q values implies real data is clustered more tightly around particular time scales (i.e., there is more room to scale intervals within the window before a timestamp is forced into the next counting interval and drops from the statistic) compared to TVS generated data. **(D)** Flat σ-distribution: note the nearly identical performance to that in **(C)**.

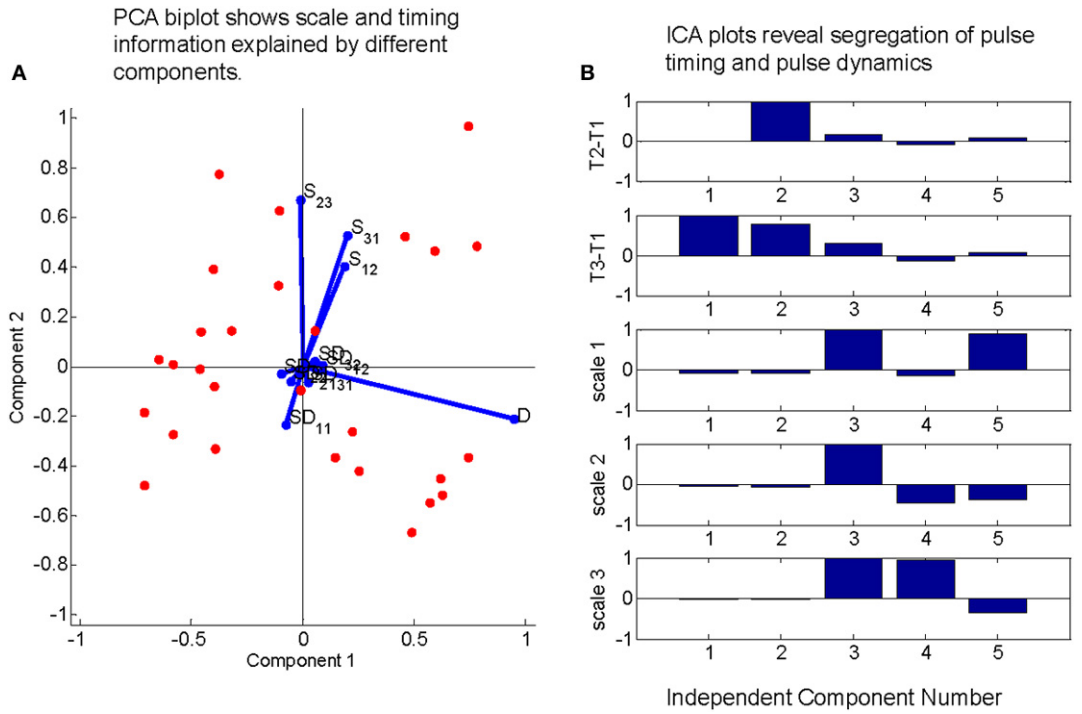

FIGURE 7 | Direct tests of whether pulse durations and pulse intervals are independent. PCA on regressions between inter pulse delays and pulse duration time scales and ICA of delays and timescales together do not support a time-varying synergy model for real frog data. **(A)** Regression coefficient between pulse widths (D) and those between pulse time delays (S12, S31, and S23) in triplets of active motor primitives are large relative to cross terms. Additionally, these large terms align with axes defined by two largest principal components. **(B)** Mixing matrix coefficients from an independent component analysis on time series defined by each peak time difference from first element in each triplet concatenated to the scale of the pulses during counting interval demonstrate a strong segregation of time-scale related information and peak time related information. Taken together, these results indicate that the duration of pulses in the EMG do not scale linearly with the variations in the interval to their time of occurrence, which is a prediction of a TVS model.

strongly with the first principal component. Cross term regression coefficients tended to be smaller than either of these and were distributed more or less equally between the principal component axes.

As a second test, for each occurrence of each significant three primitive sequence, we placed the t2-t1 values for each word occurrence in one row of a multidimensional array, t3-t1 in another row, and D1, D2, and D3 in the final three rows. The resulting multidimensional array was treated as a time series and decomposed using an independent components analysis (ICA). The resultant mixing weights (**Figure 7B**) show a clear segregation between the time scale components (the final three components that project to D1, D2, D3) and the pulse occurrence components (the first two components which project to the t2-t1 and t3-t1 series.

CYCLIC PATTERNS—SS AND TVS COMPARED IN RAT TREADMILL WALKING

We examined the behavior of the Q statistic and related measures in rat ambulation, where cyclic patterns occur. The value of the Q statistic would be very limited if use was confined only to non-rhythmic motor behaviors. Surrogate TVS and SS data sets were constructed as in the methods. Calculation of the Q statistic was performed as described in the methods. We limited the counting time window to 400 ms in order to better deal with the compressed time scale of pulse activation observed in EMGs recorded from treadmill walking rats. Pulse widths extracted from data at a mean step rate of 1.0 step/cycle did not appear to exhibit significant variability (**Figure 8A**), an observation that was confirmed when we compared pulse widths against the actual step cycle length (**Figure 8B**).

We then sought to systematically vary step cycle duration and observe the effect on the Q statistic and pulse scaling (**Figures 9A,B**). We noted that the distribution of Q values did not exhibit any noticeable trend as step cycle duration was varied, either in TVS and SS models, or in real data (**Figure 9A**). The Kolmogorov Smirnov test showed the rat interval structure deviated from TVS significantly ($p < 2.3$ E-15) and also from expected SS ($p < 5.2$ E-11). However, once again, as in the frog data, for the rat, the real data is found ***beyond*** the model SS cumulative curve, rather than lying between the SS and TVS curves. The discontinuity observed in the real rat EMG data Q statistic curve in **Figure 9** is due to overlapping occurrence of two nearly-simultaneous, but apparently distinct, muscle groups on some trials. Because of these short-interval follow-on synergies in the rat data, the Q statistic could not go much above a certain value on the intervals where these overlaps occurred, because the short time separation between them lowered Q significantly and

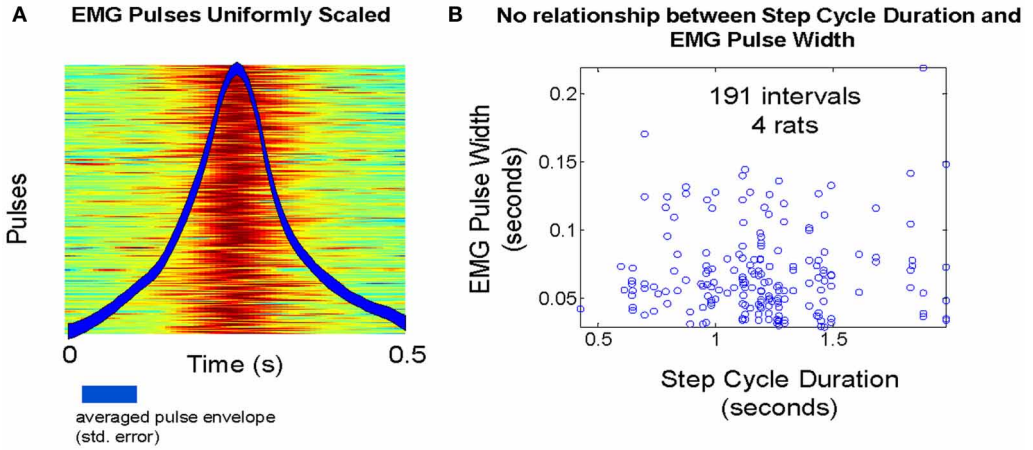

FIGURE 8 | (A) Temperature plot of pulse amplitudes during treadmill walking in one animal. Overlay: average pulse waveform over all steps. **(B)** Step cycle duration variability does not appear to induce any systematic variability in EMG pulse full width at half max, as a TVS model predicts.

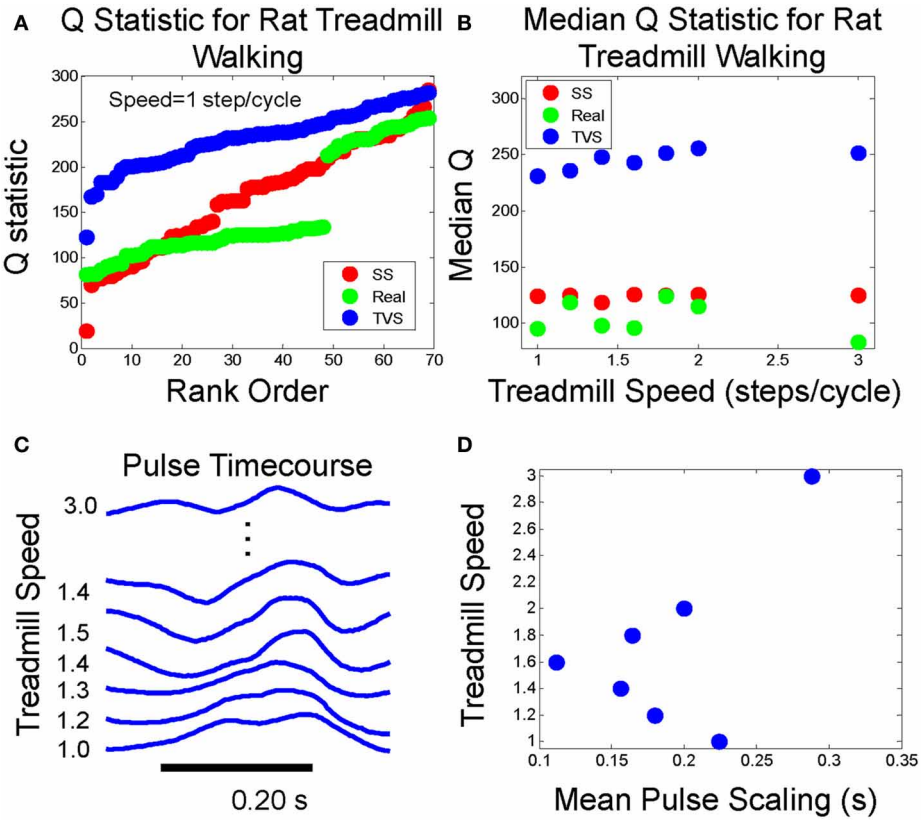

FIGURE 9 | (A) Q statistic computed on rat walking on treadmill at 1 step/cycle compared to Q statistics for cyclic runs of SS and TVS model. **(B)** Median Q statistics for real, SS, and TVS models as a function of treadmill speed. **(C)** Example pulse waveforms at each treadmill speed. **(D)** Mean pulse duration scaling relationship with increasing treadmill speed is non-monotonic.

thus created the low values and the discontinuity seen in the Q value population rank order. This was a situation not explicitly modeled in either the TVS or SS cyclic model data. However, it does not appear to affect our results discrimination using median values (**Figure 9B**) but may account for the *increased* distance of rat data from TVS curves. Examining pulse time course as a function of step cycle duration (**Figures 9C,D**) we observed that there does not appear to be a strong monotonic trend relating

cycle duration and the scaling of pulse widths. Q statistics of the real data favored the SS models over TVS patterns, even in these cyclic repeating "pattern generator" data, consistent with separation of pattern formation and rhythm generation (Rybak et al., 2006; McCrea and Rybak, 2007, 2008).

DISCUSSION

There is significant controversy in motor control as to the nature and origin of the strategy used for reduction of dimensionality. Many kinds of primitive—synchronous synergy, or TVS or motor pattern "block," or kinematic stroke—have been advanced as the fundamental organizational units for the great bulk of motor activities. To date it has proven difficult to identify which organizational strategy is used in the assembly of a given motor pattern observed during behavior.

Prior work has used onset or peak timings in EMG to explicitly cluster patterns into SS (Krouchev et al., 2006; Drew et al., 2008; Markin et al., 2012). We here presented a newly developed set of tests, that are capable of discriminating presence of TVS and SS based on onset or peak timing statistics prior to any explicit clustering of data. In part, the largest value of our method is that it is applicable to the EMG time series prior to any synergy extraction or fitting processes and free of assumptions about the precise type or numbers of synergies. After this new analysis, other synergy extraction procedures, guided by the discriminant results could be applied to extract the synergy structures with better precision. We investigated the statistical properties of a range of TVS and SS models for the construction of muscle activity and found that the Q statistic we developed represented a good discriminant over a large range of parameters when applied to the EMG time series in this way.

RANGE OF APPLICABILITY OF Q

For a large range of parameters, it is possible to discriminate models arising from a TVS model from those arising out of a SS model by examining the EMG (or mixed) output time series' Q statistic. We varied three parameters in modeling phase of this study: the density of synergies occurring on an interval (ρ), the number of muscles per synergy (σ) and the number of simultaneous muscles in a TVS model (η). In general, the models became harder to discriminate as η increased (i.e., for mixed models), and we also observed that varying the shape of the synergy membership (σ) distribution appeared to have the strongest effect on the significance of these discriminations.

These limitations on results are not surprising: If most primitives have between 2 and 4 synchronous muscles active during their activation (as is the case in the peaked distribution) it will become much more difficult to discriminate TVS constructed data from SS data as the number of synchronous muscles mixed into the set of time-varying synergies increases. In effect, the time-varying synergies look more and more like SS in this case, because of the larger number of small delays. However, we found that in real data sets from rats and frogs the Q statistic we found was unambiguous, and was structurally always clearly in the SS model domain. In fact the real data Q statistic curve was "more" SS (i.e., further from the TVS curve) than the randomly generated family of SS data curves, and in both instances (frog and rat) the data lay further beyond these SS curves rather than between SS and TVS. The Q statistic of actual real world motor patterns and synergy data is a specific realization of one of the SS family of realizations and apparently strongly different.

As a test of the generalizability of this approach, we did the analysis of cyclic data using treadmill walking data from adult rats. The behavior of the Q statistic was qualitatively the same, although some adjustment had to be made for the fact that bursts of activity in rat EMG tend toward shorter time scales in the rat, at least during treadmill walking behaviors, and short latency synergy burst overlaps occurred in some cycles. Our Q statistic results for the rat were consistent with the idea of separation of rhythm and pattern components of CPG output suggested by McCrea and Rybak. The Kolmogorov Smirnov test shows the rat interval structure deviates from TVS significantly ($p < 2.3$ E-15) and also from expected SS ($p < 5.2$ E-11). However, the Q aligns well with SS Q behavior over much of its range (**Figure 9A**). We attribute the deviation in mid range to the cyclical pattern of locomotion, occasional closely overlapped or near synchrony of specific synergies during the cycle, and consequent deviations from the levels of intermittency used in the original simulations of motor patterns generating the expected Q distributions. A more complete exploration of the Q statistic and other interval-pulse-scaling metrics in the cyclic patterns may provide significant insight into the mechanisms underlying locomotor flexibility in quadrupedal mammals.

WHAT Q TELLS US ABOUT SYNERGIES IN THE FROG

We compared SS to time-varying synergies using a linear discriminant analysis with the Q statistic. Differences were taken between Q value from each model and Q values computed on real data. These differences were then plotted against one another and a separatrix representing equal differences was used as a criterion for classification. Those "below" the line represented values where Qtvs-Qreal was greater than Qss-Qreal. I.E, i.e., these points were "closer" to a SS model than a TVS model. The separatrix used in this case was thus a line with slope of 1.

A broadly similar pattern was seen to that in the preceding section. Discrimination was possible for synergies with muscle densities (σ) drawn from a flat distribution, but became more difficult for σ drawn from the peaked distribution as η (number of simultaneous muscles in a synergy) was increased. The results for comparison of frog data to a flat σ distribution are unambiguously indicative of an SS model. Assuming instead that the σ is from a peaked distribution in frogs, it is still most likely the case that synergies observed in the bullfrog during a variety of reflex and locomotor tasks arise only from SS. The only alternative would be very weak scaling of time-varying and very high jitter synergies, within which most muscles are activated synchronously. This alternative may beg the question, and weakens the TVS formulation elegance and simplicity of more strongly coupled units. It also may not match other measures of synergy compositionality. The real data lay outside the bounds of both the TVS and SS curves, below the SS curves in both rat and frog. In the rat, inspection of a discontinuity revealed an intermittent coactivation of two synergies caused the discontinuous and outward deviation. Similar coactivations occur in frogs

(e.g., in wiping behaviors). The statistics associated with these tight coactivations or "synergies of synergies" were not well represented in our simulations and would have been very rare in our generator processes. However, the processes noted would further differentiate the point process statistics between TVS and SS rather than collapsing them together, and should not be assumed *a priori*.

As a final check on the discrimination we used an interesting side effect of the Q statistic that we discovered, namely that rescaling the pulse times, thereby moving some pulses outside the bounds of the 250 ms counting interval does not appreciably change the TVS Q statistic, but significantly alters the SS Q statistic. We used this as an additional check to ascertain whether TVS or SS models statistics better explain observed EMG data from the frog. Because the statistic is only sensitive to rescaling within each counting intervals, rescaling the time differences between nearly SS results in large changes to the Q statistic relative to the unscaled data. These increases in ΔQ occur with increasing scaling, until plateauing at a particular ΔQ value (the point at which "rescaled" pulses are pushed into the next counting window). Rescaling TVS (time-varying synergies) fails to alter ΔQ appreciably for TVS models. Consonant with the other results so far, performing these operations on real EMG data we found that the data rescaled as one would expect SS to scale. The coactive synergies noted above in real frog and rat data would likely have further exacerbated these scaling effects.

Taken together, these data and analyses lead to the following conclusion: at least in the bullfrog, and SS model, or synergist coactivation of groups of muscles appears to be the norm. Any strategies similar to the TVS model are much more of an exception, at least within this preparation.

Covariance of muscle activation and pulse timing

As a final check for any evidence of time-varying synergies in the frog, given the Q statistic results, we explored directly whether the time differences between pulses in a three pulse triplet depended at all on the pulse widths in that sequence. This would indicate correlated time-rescaling. PCA performed on regression coefficients between pulse time differences and time widths found that the most significant contributions to variance were entirely from components closely aligned to either the time difference axes, or pulse width axes. In contrast, PCs representing regression cross terms between pulse widths and pulse time differences contributed to very much less variance to the overall data set. The results thus indicate that there is little overlap or covariation between pulse width and pulse time/phasing differences and that the bulk of the variation of the delay between pulses in the EMG is independent of the variations underlying pulses durations. This observation is inconsistent with the notion of a uniformly scaled TVS, but matches the Q statistic data presented here. In frogs other data support SS structure based on ICA decomposition (Hart and Giszter, 2004), neural analyses (Hart and Giszter, 2010) and explicit physiological perturbations. We have demonstrated the ability to recruit SS synergies as single pulses (Kargo and Giszter, 2000a,b), and perturb them separately within a motor pattern (Kargo and Giszter, 2008), both inconsistent with TVS descriptions.

To bolster the temporal structure observations here, we performed an ICA on all time differences in the data set, and the corresponding pulse widths. We found that the resulting mixing matrixes indicated very little mixing between pulse width and time differences, with components contributing primarily to one or the other category of time series. This observation is also inconsistent with uniformly or correlated scaling of pulse duration and sequence as expected in TVS. The rat cyclic data also showed a lack of correlation between pulse duration and cycle duration in our data.

In summary, we present a new analysis working directly with EMG peak or onset data to differentiate synchronous and TVS patterns prior to full decomposition. These analyses applied to data from frog and rat support composition of frog and rat motor patterns as independent rhythms and synchronous synergy pulses, consistent with a separated control of the rhythm/phase and pattern compositional elements. These separated controls may be important to allow the force/effector compositional controls to adjust as needed to support the next level of task composition. Unitary task elements at the kinematic and kinetic levels of task description occur in reaching, and locomotion, but adaptation of these to momentary conditions may require less stereotypy in the supporting compositionality of muscle synergy bursts and pattern.

The octopus arm is a muscular hydrostat and due to its deformable and highly flexible structure it is capable of a rich repertoire of motor behaviors. Its motor control system uses planning principles and control strategies unique to muscular hydrostats. We previously reconstructed a data set of octopus arm movements from records of natural movements using a sequence of 3D curves describing the virtual backbone of arm configurations. Here we describe a novel representation of octopus arm movements in which a movement is characterized by a pair of surfaces that represent the curvature and torsion values of points along the arm as a function of time. This representation allowed us to explore whether the movements are built up of elementary kinematic units by decomposing each surface into a weighted combination of 2D Gaussian functions. The resulting Gaussian functions can be considered as motion primitives at the kinematic level of octopus arm movements. These can be used to examine underlying principles of movement generation. Here we used combination of such kinematic primitives to decompose different octopus arm movements and characterize several movement prototypes according to their composition. The representation and methodology can be applied to the movement of any organ which can be modeled by means of a continuous 3D curve.

Keywords: octopus, motion analysis, kinematic motion primitives (kMPs), 3D reconstruction, muscular hydrostat

INTRODUCTION

Octopuses are considered to be among the most developed and intelligent animals in the invertebrate kingdom, where at least part of their skills can be attributed to the high maneuverability of their arms and the capacity of the peripheral nervous system to process sensory information and control arm movements. The octopus uses its arms for various tasks such as locomotion, food gathering, hunting, and sophisticated object manipulation (Wells and Wells, 1957; Fiorito et al., 1990; Mather, 1998). The versatile and adaptive nature of octopus movements is mainly due to the flexible nature of the octopus arms which do not contain any rigid skeleton. The octopus arm is a muscular hydrostat built of closely packed arrays of muscle fibers organized in three main muscle groups: parallel, perpendicular, and helical that runs obliquely to the long axis (Matzner et al., 2000). A constant volume constraint that holds for muscular hydrostats allows forces to be transferred between the longitudinal and the transverse muscle groups. The movements of a muscular hydrostat are based on combinations of four elementary movements that can occur at any location: elongation, shortening, torsion, and bending (Kier and Smith, 1985). Therefore, both structural support and force transmission are achieved through the arm's musculature, such that the biomechanical principles governing octopus arm movements differ from those operating in arms with a rigid skeletal support.

The octopus nervous system is divided into a central and peripheral nervous systems. Axial nerve cords are projecting from the brain along the center of each arm, and the peripheral neurons located in the axial nerve cords are organized into an extensive nervous system comprising both sensory and motor circuits (Young, 1971). Behavioral studies suggest that the nerve cord circuitry and the peripheral components play a major role in the control of the complex actions performed by octopus arms (Altman, 1971; Wells, 1978).

Analyses of octopus reaching (Gutfreund et al., 1996, 1998; Sumbre et al., 2001; Yekutieli et al., 2005a,b) and fetching movements (Sumbre et al., 2001, 2005, 2006) have revealed some control principles that underlie movement generation. During reaching a bend point propagates along the arm following an invariant velocity profile. Fetching movements use a vertebrate-like strategy, reconfiguring the arm into a stiffened *quasi*-articulated structure. These movements were studied by analyzing the kinematics of the movements of specific points along the arm which display several stereotypical characteristics. Electromyographic recordings and detailed biomechanical simulations assisted in revealing common principles which reduce the complexity associated with the control of these movements. The travelling bend, used in arm extension movements, was found to be associated with a propagating wave of muscular activations, where simple adjustments of the excitation levels at the initial

stages of the movement can set the velocity profile of the whole movement. Recently, a soft robotic arm inspired by the octopus arm has been designed in order to reproduce the octopus tentacle motor performance and to examine the possibility for the implementation of motor control principles identified in the octopus as part of its control (Laschi et al., 2009; Calisti et al., 2011).

However, describing the movements of specific points along the arm is insufficient for analyzing the full complexity of octopus arm movements. To determine whether the kinematics of octopus arm movements can be described by a reduced set of motion primitives requires analysis of different types of arm movements and of the shape of the entire arm as it moves through space. Motion primitives can be regarded as a minimal set of movements, which can be combined in many different ways giving rise to the richness of vertebrate and invertebrate movement repertoires and allowing motor learning of new skills (Flash and Hochner, 2005; Bizzi et al., 2008). Motor primitives have been inferred at various levels of the motor control system. Submovements were shown to be combined at the kinematic level (Krebs et al., 1999; Rohrer et al., 2002), a reduced set of static force field underlie controlling arm posture (Mussa-Ivaldi and Bizzi, 2000; d'Avella et al., 2003, 2006), while movement dynamics can be learned through a flexible combination of dynamic primitives (Thoroughman and Shadmehr, 2000). Dynamical movement primitives were also used to model attractor behaviors of autonomous non-linear dynamical systems and rhythmic movements (Ijspeert et al., 2002, 2013), and discrete and rhythmic movement elements were used to investigate single-joint and multi-joint motor behaviors (Sternad et al., 2000; Sternad and Dean, 2003). Inferring motion primitives from octopus arm movements may help understand underlying principles and kinematic optimal measures, and provide new understanding of how the nervous system in muscle hydrostats handles the complexities associated with the control of hyper-redundant arms. This may also facilitate designing control systems for hyper-redundant robotic manipulators.

Here we refer to the behavioral level and aim at describing octopus arm behaviors as being composed of elementary kinematic units to which we also refer to as motion primitives (Flash and Hochner, 2005). We believe that identifying basic kinematic patterns is the first step in further investigating the existence of primitives also at the control, movement dynamics, and muscle activation levels as well as the neural control levels as was demonstrated in earlier studies of the octopus motor system (Gutfreund et al., 1996, 1998; Sumbre et al., 2001, 2005, 2006; Yekutieli et al., 2005a,b). As was discussed in Flash and Hochner (2005) elementary building blocks may exist at all the above levels of motor representation but the most immediate and direct way is to search for elementary units at the kinematic level. Movement strokes with specific spatial and temporal features and submovements were shown to successfully describe both periodic and discrete motions and were indicated as plausible building blocks of human and monkey movements (Sosnik et al., 2004; Polyakov et al., 2009). Furthermore, in robotics research locomotion trajectories for a humanoid robot were constructed based on kinematic motion primitives derived from humans' locomotion trajectories (Moro et al., 2011, 2012). Relations between behavioral and control levels were suggested in different earlier studies, for example: hand trajectories of stroke patients were shown to be composed of submovements with velocity primitives obeying the minimum jerk model (Flash and Hogan, 1985) whose number was found to decrease as the patients gained better control of their limb (Rohrer et al., 2004), simple curved two-dimensional trajectories that follow the two-third power law (Lacquaniti et al., 1983) were described by means of parabolic units and corresponded to neural activation states identified using a hidden Markov Model (Polyakov et al., 2009). Another example consists of grasping and object manipulation movements described as arising from well-coordinated combinations of basic motor actions-arm transfer and hand shaping (Jeannerod, 1994).

An algorithm for 3D tracking and analysis of octopus arm movements (Yekutieli et al., 2007; Zelman et al., 2009) enabled us to create a large database of many types of modeled octopus arm movements. Here we describe a new framework allowing the extraction of kinematic units from these reconstructions. The octopus arm movements were represented by a pair of surfaces describing the curvature and torsion values of the arm. 2D Gaussians for each surface were extracted such that each Gaussian represented the characteristic shape of the curvature or torsion along a section of the octopus arm during some time interval. We found that Gaussian functions generally fit quite well the continuous form of the configurations that the octopus arm can take with respect to both the time and the arm index dimensions: the curvature and torsion values were observed to change smoothly along the arm length for any quasi-static arm configuration, and the magnitude of curvature or of torsion at any specific point was gradually changing with time during the movement. Gaussian-like functions were previously used in composing hand velocity (Thoroughman and Shadmehr, 2000) and limb position profile (Hwang et al., 2003).

The resulting Gaussians were divided into clusters whose centroids defined kinematic units, and each movement was represented as a weighted combination of such units. These kinematic units can be used to form a language of motion primitives, allowing characterization and representation of a large repertoire of octopus arm movements. We show how these kinematic units can be used to classify octopus arm movements into meaningful groups. Understanding how kinematic primitives can be utilized and combined can greatly contribute not only to studies of motor control in octopus arms and other hyper-redundant appendages but can also provide a deeper understanding of motor control systems in general.

METHODS

The analyzed octopus arm movements in our study were performed by four specimens of *Octopus vulgaris*, weighing 200 (female), 200 (male), 450 (male), and 470 (female) g. The animals were maintained in 50 × 40 × 40 cm tanks containing artificial seawater. The water was circulated continuously in a closed system through a biological filter of Orlon, gravel and coral dust. Water temperature was held at 16°C in a 12 h light/dark cycle. Prior to the video recording sessions, the animals were moved to a bigger glass tank (80 × 80 × 60 cm) with a water temperature of 18°C.

SPATIO-TEMPORAL REPRESENTATION OF MOVEMENT AS A PAIR OF CURVATURE AND TORSION SURFACES

Since the octopus arm displays no well-defined landmarks, a skeletal representation can be naturally used to model the octopus arm using curves which prescribe its virtual backbone. The backbone was found using a "grass fire" algorithm that extracts the middle line of the arm: first the contour of the arm is separated into two sides, dorsal and ventral, from base to tip. Then two distinct waves are initiated from the two sides of the contour and are propagated at an equal speed inward. The set of points where the wave fronts collide is the midline (Yekutieli et al., 2007).

The reconstructions of octopus arm movements result in a sequence of 3D curves prescribing the virtual backbone of the octopus arm as its configuration changes during the movement. **Figure 1** presents an extension movement as a sequence of 60 3D curves that prescribe the virtual backbone during the movement. For each curve, green, and red points mark the base of the arm (that was aligned between sequential images using textural cues) and the tip, respectively. Given a sequence of m 3D curves as an input, we wished to construct a pair of surfaces describing the values of the curvature and torsion along these curves. Since arm configurations were reconstructed from video records whose sample rate was 50 frames/s, the smoothness of the motion between consecutive configurations of a movement was guaranteed, and a spline function was used to smooth noisy points as necessary (Yekutieli et al., 2007; Zelman et al., 2009).

Each 3D curve was first represented by $(n = 100)$ sample points uniformly distributed along the curve. This 3D curve was then approximated by a cubic smoothing spline constructed of piecewise third-order polynomials passing through the n sample points. Approximation was achieved, by considering both the smoothness of the spline and the distance between the spline and the sample points. Formally, given the data site $x(j)$ and the corresponding data values $y(j)$ for $j = 1, \ldots, n$, the cubic smoothing spline f minimizes:

$$p \sum_{j=1}^{n} \left| y(j) - f(x(j)) \right|^2 + (1-p) \int \left| D^2 f(t) \right|^2 dt,$$

where the integral over the second derivative of f is over the smallest interval containing all the entries of x. The smoothing parameter p defines the tradeoff between the success in approximating the data points and the smoothness terms.

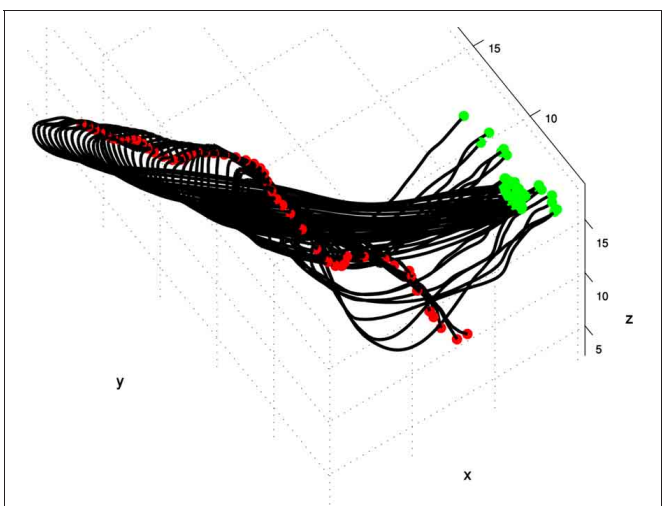

FIGURE 1 | A spatio-temporal profile of an extension movement shown as a sequence of the virtual backbone of quasi-static arm configurations. The presented 3D curves are the result of the reconstruction process in which the virtual backbone prescribing the octopus arm is detected (see section spatio-temporal representation of movement as a pair of curvature and torsion surfaces). The virtual backbone was found by a "grass-fire" algorithm, green and red points mark the base of the arm (that was aligned between sequential images using textural cues) and the tip respectively (Yekutieli et al., 2007).

We then calculated the curvature (κ) and torsion (τ) values for the n sample points along each of the 3D curves. The curvature was calculated using the circle passing through three successive points as an approximation of the osculating circle to the curve at the middle point. This is formally described by Calabi et al. (1998): Let A,B,C be three successive points on the curve C such that the Euclidean distances are $a = d(A,B)$, $b = d(B,C)$, $c = d(A,C)$. Let Δ denote the area of the triangle whose vertices are A,B,C, and let $s = \frac{1}{2}(a+b+c)$ denote its semi-perimeter, so that $\Delta = \sqrt{s(s-a)(s-b)(s-c)}$. Then the radius of the circle passing through the points A,B,C is computed leading to the formula for its curvature:

$$\kappa(A, B, C) = 4\frac{\sqrt{s(s-a)(s-b)(s-c)}}{abc}.$$

In this study we will use the word curvature as the inverse of the radius of curvature.

The torsion along a 3D curve, defined as $\tau = \frac{d\theta}{dt}$, was calculated for a pair of successive points as the angle between the normals to the planes defined by the successive triangles corresponding to these points, divided by the distance between the points (Boutin, 2000). Let A,B,C,D,E be five successive points on the curve such that $\hat{n}_{ABC}$ and $\hat{n}_{CDE}$ are the normals to the planes defined by A,B,C and C,D,E respectively, and the Euclidean distance between points B and D is $d(B,D)$. Then the torsion at point C is calculated as:

$$\tau(C) = \frac{\cos^{-1}(\hat{n}_{ABC} \cdot \hat{n}_{CDE})}{d(B, D)}.$$

Finally, the curvature and torsion values calculated for a sequence of 3D curves were represented on two surfaces that separately described the curvature and torsion as a function of time and arm index. The result was a pair of smooth and normalized curvature and torsion surfaces, such that a single arm movement was compactly represented by a pair of n by n matrices. This representation was invariant to rotation and translation in a Cartesian coordinate system, as curvature and torsion measures are intrinsic (i.e., they do not depend on the orientation and position of the arm in 3D space).

Figure 2 presents the curvature and torsion surfaces for the extension movement presented in **Figure 1**. The relatively high

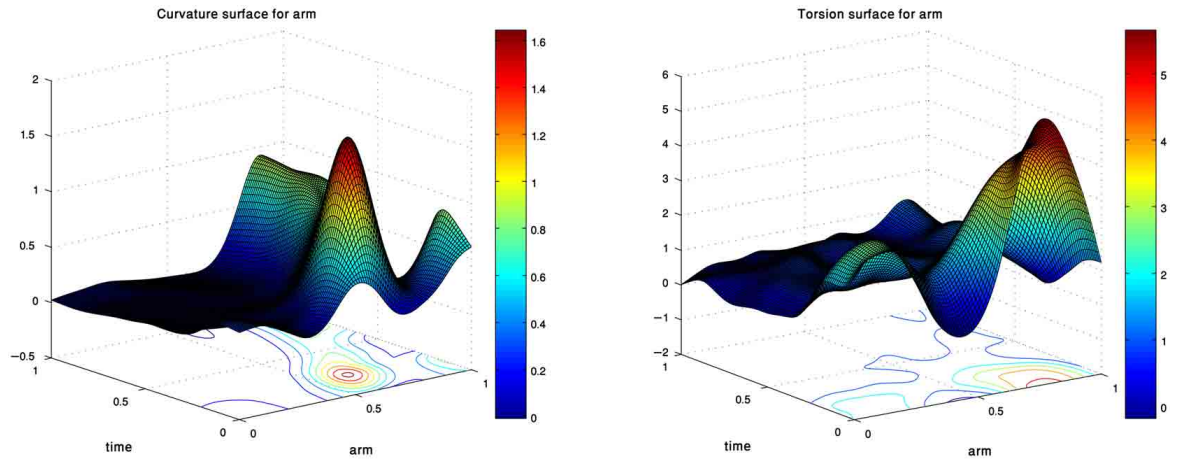

FIGURE 2 | Curvature and torsion surfaces extracted for the movement shown in Figure 1. The values are given as a function of the arm index and time.

values of the curvature surface generally describe propagation of a bending section from the middle of the arm toward the tip. The decrease in the torsion values as the movement proceeded means that the arm configuration became relatively planar.

SURFACE DECOMPOSITION USING GMM

Gaussian Mixture Model (GMM) is a statistical method for density estimation and data clustering (McLachlan and Peel, 2000). In this model a Gaussian fitting method can be used to approximate a function of one variable by a weighted sum of 1-dimensional Gaussians. As GMM is a generalized framework, it can approximate any multidimensional data by a set of multivariate Gaussians. The model uses an iterative process which optimizes the Gaussians' parameters by the Expectation Maximization (EM) algorithm (Xuan et al., 2001).

A function of one variable ($y = f(x)$) can usually be approximated by a mixture of 1D Gaussians, where each Gaussian is defined by its *mean* and *standard deviation*. In our case, we refer to a surface as a function of two variables $z = f(s,t)$, where z stands for either the curvature or torsion values, and s,t refer to the arm index and time dimensions, respectively. We therefore use 2D GMM to approximate a surface by a weighted combination of 2D Gaussians. Specifically, a surface is approximated as:

$$z(s,t) = \sum_i w_i \cdot g_{[\mu_i,\Sigma_i]}(s,t),$$

where g is a Gaussian defined by a 2×1 *mean* vector μ and 2×2 *covariance* matrix Σ, and w is the Gaussian weight. The Gaussian g is defined as:

$$g_{[\mu,\Sigma]}(\vec{x}) = \frac{1}{2\pi\,|\Sigma|^{1/2}} \exp\left(-\frac{(\vec{x}-\mu)^T\Sigma^{-1}(\vec{x}-\mu)}{2}\right),$$

where $\vec{x} = \left|\frac{s}{t}\right|$. The *mean* vector μ corresponds to the position of the Gaussian center on the surface, and the two eigenvalues of the *covariance* matrix Σ correspond to the *standard deviation* of the 2D Gaussian. Its two eigenvectors correspond to the axes of the Gaussian with respect to a fixed coordinate system, such that the *covariance* matrix defines the shape and orientation of the Gaussian.

We also added a criterion to choose the right number of Gaussians into which each surface should be optimally decomposed, based on the Minimum Description Length (MDL) principle. The MDL descriptor to be minimized here is the Bayesian Information Criterion (BIC), as developed by Andrews and Lu (2001):

$$\mathrm{BIC} = -2 \cdot L + d \cdot \log(n)$$

where L is the log likelihood of the mixture of Gaussians, d is the number of parameters in the model (number of degrees of freedom) and n is the number of observations in the sample. The BIC criterion allows choosing the most parsimonious model, i.e., the model which best describes the data with respect to the number of Gaussians it uses for the decomposition. [See also Bhat and Kumar (2010) for a more detailed derivation of the BIC formula].

Figure 3 shows the approximation of a curvature surface by a weighted combination of four Gaussians. Intuitively, each Gaussian can be illustrated as a hill, whose center, shape, orientation, and height are defined by the Gaussian parameters. The decomposition into 2D Gaussians allows us not only to explore Gaussians as possible units enabling to define the kinematics of octopus arm movements, but also to compactly represent a surface as a weighted sum of 2D Gaussians.

CLUSTERING ALGORITHM

The GMM allows us to decompose octopus arm movements into curvature and torsion 2D Gaussians which describe their kinematics. We refer to each of the resulting Gaussians as a data point, whose dimension corresponds to the number of parameters defining a Gaussian (section surface decomposition using GMM). To cluster these points (i.e., the 2D Gaussians)

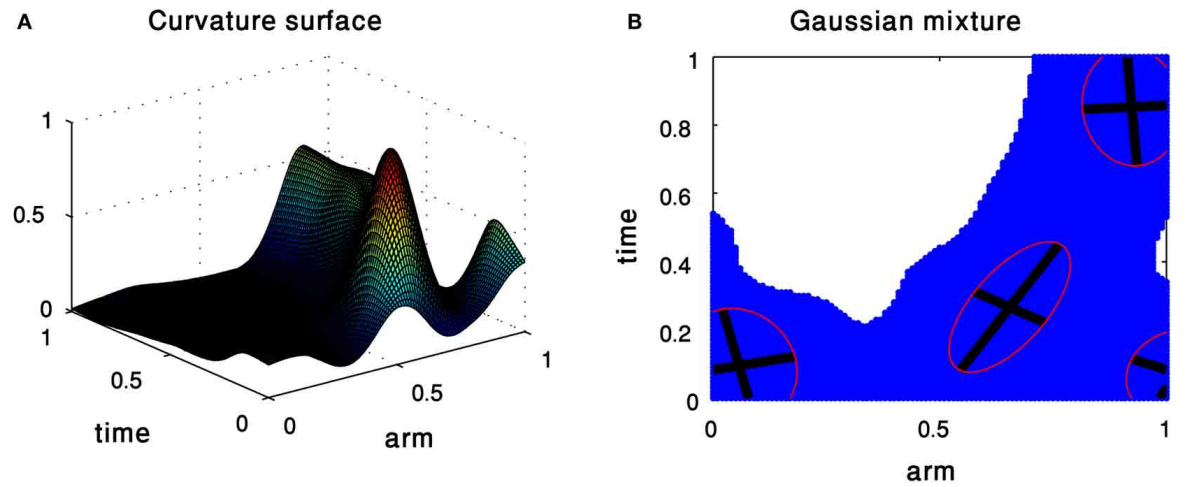

FIGURE 3 | Gaussian Mixture Model of the curvature surface of an extension movement. (A) The input surface. **(B)** The resulting mixture of Gaussians.

into meaningful groups we used the *kmeans* clustering algorithm which is an unsupervised clustering method. The output of the *kmeans* algorithm is k disjoint clusters, where each cluster includes a different number of points and is represented by a centroid that can be regarded as the average of all the points assigned to the cluster. *kmeans* uses a two-phase iterative algorithm to yield a clustering result which minimizes the point-to-centroid distances summed over all k clusters.

The distance usually employed for *kmeans* is the Euclidean distance (Hastie et al., 2009), but here we want to improve the clustering from two points of view. First, we designed a Weighted Euclidean Distance, i.e., for each of the parameters of the Gaussians—center, shape, area, and orientation, we separately computed the Euclidean distance among the different elements of the sample. We then got four distances, each being related to one of the four parameters. The quantity to be minimized in the *kmeans* algorithm at each step is then an average of these four distances. Second, we used the Gap-Statistics (Tibshirani et al., 2001) as a criterion of the optimal number of clusters to be used. Gap-Statistics compares the within-clusters distance of the distribution (given by *kmeans*) to the within-distance W^*_{kb} of a Monte–Carlo sample drawn within the range of the reference distribution. This criterion was used for example by Ben-Hur et al. (2002) and Pedersen and Kulkarni (2006). The idea of this approach is thus to compare the graph of $\log(W_k)$ (log of the within-cluster distance) with its expectation under an appropriate null distribution. The mathematical rationale of this approach is explained in greater detail by Tibshirani et al. (2001). Defining B as the number of generated data sets, the Gap-Statistics is expressed as:

$$\mathrm{Gap}\,(k) = 1/B \sum_{b=1}^{B} \log\left(W^*_{kb}\right) - \log(W_k)$$

The optimal number of clusters is the minimal k which gives a local maximum of the Gap.

RESULTS

Our data set consisted of 60 reconstructions of octopus arm movements that included *extension* movements. Extension in the octopus arm is generally characterized by a bend propagating along the arm (**Figure 11**). Some of these extension movements were preceded by initialization movements, referred to as *pre-extension* movements, in which the octopus arm moved from an initial random position to a configuration that seemed to be ideal for the extension (**Figure 12**).

Careful examination of the video sequences allowed us to define start- and end-points of the extension phase as characterized in earlier studies (Gutfreund et al., 1996, 1998). In an extension movement, a bend is created usually near the base of the arm and is propagated along the arm toward the tip where it vanishes, while the base of the arm points in the direction of propagation. A pre-extension movement is generally defined as a movement in which an arbitrary configuration of the arm is reconfigured to an initial extension configuration. Based on these observations we initially divided our data into 25 pre-extension and 60 extension movements. In order to characterize sets of kinematic units and determine synthetic rules allowing reconstruction of the observed movements, we next decomposed the movements into curvature and torsion Gaussian units (as defined in section surface decomposition using GMM) and analyzed these units as described below. Since each movement was defined by a specific combination of kinematic units, we could classify the movements into sub-groups, such that all the movements in a sub-group were defined by a combination of similar kinematic units. In order to explain the different phases of the movement analysis as clearly as possible we focus here mainly on the group of extension movements.

DECOMPOSITION AND CLUSTERING OF KINEMATIC UNITS

Curvature and torsion surfaces were extracted for all the octopus arm movements in our database (see section spatio-temporal representation of movement as a pair of curvature and torsion

surfaces). The curvature and torsion values at the tip of the arm could be very high (and sometimes noisy) relative to the values along the proximal and middle parts of the arm and were, therefore, analyzed separately. The resulting surfaces were approximated using the GMM, yielding decompositions of each curvature/torsion surface into 2D Gaussians units (see section surface decomposition using GMM). These units were found to naturally describe the surfaces, as each unit essentially described bending or torsion along a defined section of the arm and its movement along the arm as function of time.

A set of 2D Gaussians was assembled as a set of kinematic units separately for the pre-extension and extension movement groups. A set of Gaussians can be variously clustered by referring only to a subset of the parameters defining the 2D Gaussians, namely the center location, size, shape and orientation (see section clustering algorithm). These parameters were easily extracted from the *mean* and *covariance matrix* of a 2D Gaussian; the coordinates of the Gaussian center on the surface (i.e., the time point and the arm index at which the Gaussian reached its maximum) were directly defined by the Gaussian *mean*. The orientation of the Gaussian (the angle between the Gaussian axes and the axes of the fixed coordinate system) was defined by the eigenvectors of the Gaussian *covariance matrix*. The projection of the Gaussian on the plane was an ellipse whose size and eccentricity were defined by the eigenvalues of the *covariance matrix* and the ratio between them. Finally, the relative influence of the Gaussian in the decomposition in which it participated was defined by its weight. The clustering results presented here were obtained by referring to the Gaussian's center location (Gaussian *mean*), Gaussian's shape (ratio between the eigenvalues of the Gaussian's *covariance matrix*), and Gaussian's weight.

Figure 4 presents the clustering results obtained for the curvature and torsion Gaussians of the 60 extension movements. Gaussians marked by the same color belong to a single cluster. Executing *kmeans* with the Gap-Statistics method (section clustering algorithm) resulted in three clusters both for the curvature and torsion Gaussians. Coordinates of the centroids of the various clusters are presented in **Table 1**.

These results essentially suggest that all the Gaussians composing the curvature and torsion surfaces of the extension movements can be classified into three types according to the values of the Gaussian's center location and shape. Explicitly, the blue curvature cluster (**Figure 4** left) represents curvature Gaussians defining curvature along the proximal section of the arm during the movement. Examining the orientation of these Gaussians as defined by the eigenvectors of their *covariance* matrices shows that there was a relatively small angle between each of the Gaussian axes and the axes of the arm-index—time coordinate system (**Table 2**), that is, the internal Gaussian axes almost aligned with the direction of the arm-index and time axes. This characteristic means that the section of the arm to which these Gaussians relate did not change during the movement; we therefore term them "fixed" Gaussians. We suggest that these Gaussians correspond to movements used to aim the base of the arm toward a target point during the extension movement (see discussion below).

The green and magenta clusters represent curvature Gaussians that travel toward the tip of the arm during the extension and are probably associated with the main characteristics of the bend

propagation in extension movements. The mean orientation of each of these clusters is significantly larger compare with the blue cluster that refers to the base of the arm (**Table 2**). A similar interpretation is valid for the resulting clusters of the torsion Gaussians, where the green and magenta clusters refer to torsion Gaussians in the early stage of a movement, and the blue cluster refers to torsion Gaussians at the end of movement. **Table 2** presents the median, mean and standard deviation of the orientation values of the resulting clusters. These findings are supported by earlier analyses and simulations of the stereotypical characteristics of an extension movement (Gutfreund et al., 1998; Yekutieli et al., 2005b).

SYNTHESIZING ARM BEHAVIORS FROM KINEMATIC UNITS

The 2D Gaussians were clustered by the *kmeans* algorithm based on their mean vector and covariance matrix values. The centroid point of each cluster represented the center of the cluster, i.e., the point giving the minimum sum of distances from it to all the data points in that cluster. Since the *mean* vector and *covariance* matrix which define a Gaussian as a data point also apply to the centroid point, a centroid point essentially defines a representative Gaussian for its cluster. Each of these Gaussians has a unique position, size and orientation, thus uniquely defining the octopus arm movement in 3D space.

We therefore consider the curvature and torsion Gaussians defined by the resulting centroid points as kinematic units that can be used to generate a set of behaviors of the octopus arm. These are local time-dependent behaviors, since they refer to a specific section of the arm at a specific time during the movement. **Figure 5** presents the three curvature Gaussians (left) and the three torsion Gaussians (right) defined by the centroid points of the clusters found for the extension movements (**Figure 4**). A curvature unit alone defines a planar arm behavior, as it defines a change in the curvature level along a section of the arm as a function of time, with a zero value for the torsion associated with the arm. Coupling a curvature and a torsion unit, such that both of them refer to a common section of the arm, defines a 3D behavior. However, a torsion unit on its own is meaningless since applying torsion on a straight line representing the backbone of the arm has no effect on its configuration. A torsion unit has no significant effect also when it is coupled with a curvature unit that refers to a different section of the arm. In general, n_C curvature units and n_T torsion units can define $n_C \cdot n_T$ 3D behaviors, and since the n_C curvature units define n_C planar behaviors where they are not coupled with any torsion unit, they can overall define $n_C \cdot (n_T + 1)$ behaviors. **Figure 6** presents some of the behaviors that can be defined by the curvature and torsion kinematic units extracted for the extension group (**Figure 5**). They are shown as sequences of quasi-static configurations in 3D space, where the red, black and blue curves represent the initial, intermediate and final configurations in the sequence, respectively.

CLASSIFYING OCTOPUS ARM MOVEMENTS

The kinematic units (curvature/torsion Gaussians) extracted for the extension and pre-extension movement groups can be used further to classify movements in a given group into different sub-groups according to the mixture of Gaussians composing their curvature and torsion surfaces. Intuitively, movements that were decomposed into weighted combinations of similar kinematic units were classified into the same sub-group, as they were assumed to be characterized by a similar 3D behavior.

We represented each of the movements in our data set by a weighted combination of the curvature and torsion kinematic units defined for the group of movements to which the movement belonged. That is, a movement m which was approximated by a pair of curvature (C) and torsion (T) surfaces $C = \sum_i w_i^C \cdot g_i^C$ and $T = \sum_j w_j^T \cdot g_j^T$, was represented by a row vector of the weights: $\vec{w} = [\{w_i^C\}, \{w_j^T\}]$. We applied the *kmeans* algorithm (section clustering algorithm) to the set of vectors of weights corresponding to a group of movements, such that the input to the algorithm is a matrix of weights, where the rows correspond to the analyzed movements and the columns to the Gaussians that were previously identified as curvature and torsion units.

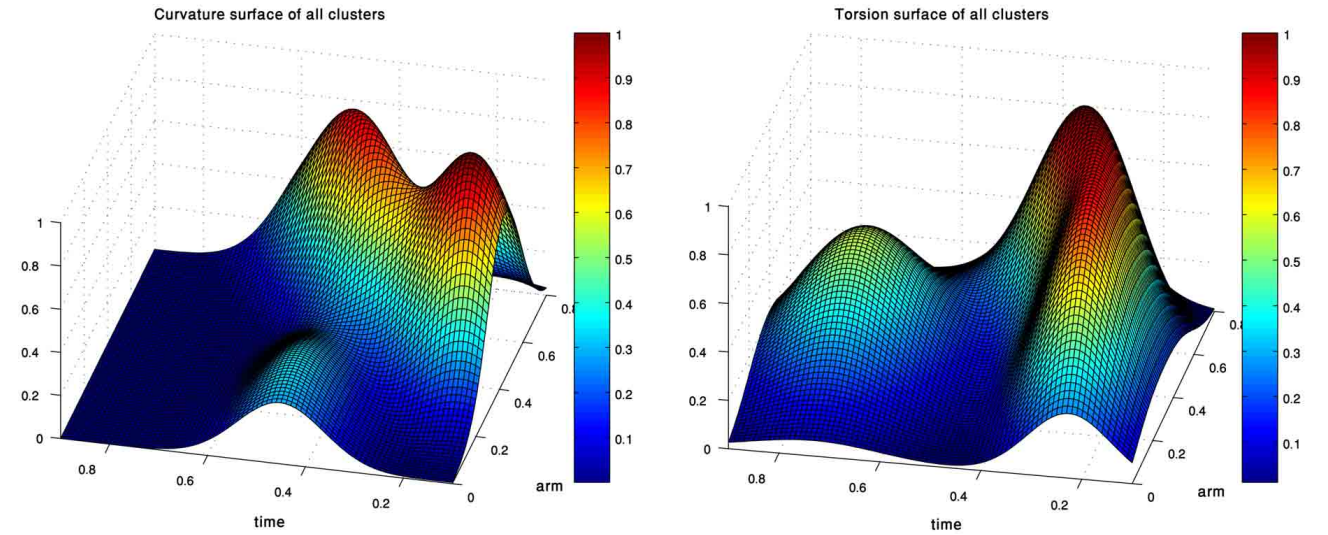

FIGURE 5 | The curvature (left) and torsion (right) centroid Gaussians of the extension group of movements. Each Gaussian is essentially the centroid of one of the clusters in **Figure 4**.

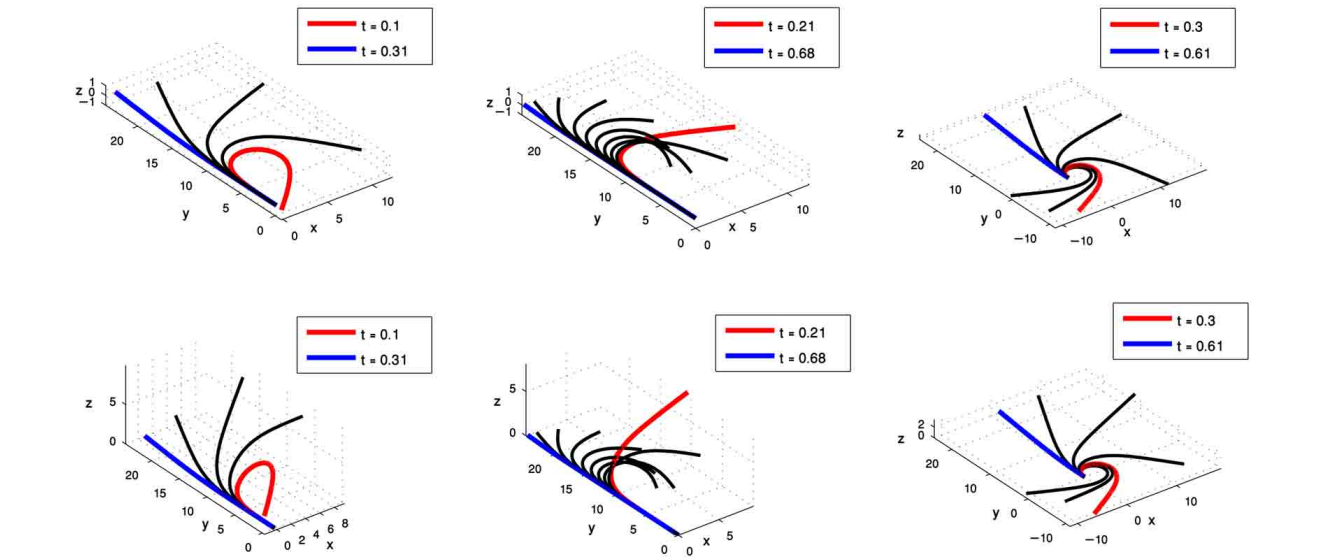

FIGURE 6 | Simulations of octopus arm behaviors in 3D space defined by the curvature and torsion kinematic units which were extracted for the extension movement group. These behaviors show the characteristics of extension movements—directing the base toward a target, initialization, and propagation of the bend.

Each row practically defines a movement as a weighted sum of the elementary Gaussian units (**Figure 7**). The *kmeans* algorithm separated the movements into clusters, such that movements belonging to the same cluster shared a similar pattern of weights. That is, a cluster consists of movements that can be spanned by a similar weighted sum of the available curvature and torsion units. We therefore refer to each of the resulting clusters as a sub-group of movements that share similar characteristics of their 3D behavior. The centroid point of each of the resulting clusters was considered a representative pattern of a weighted combination of kinematic units, which defined the behavior of the sub-group of movements in 3D space. We refer to these different behaviors as movement prototypes.

Each of the three pairs of curvature and torsion surfaces presented in **Figure 8** is defined by a weighted combination of kinematic units, corresponding to one of the extension sub-groups we found by the process just described. A pair of curvature and torsion surfaces defined a prototype which characterized one of the sub-groups by simulating a sequence of 3D curves whose curvature and torsion values corresponded to the values

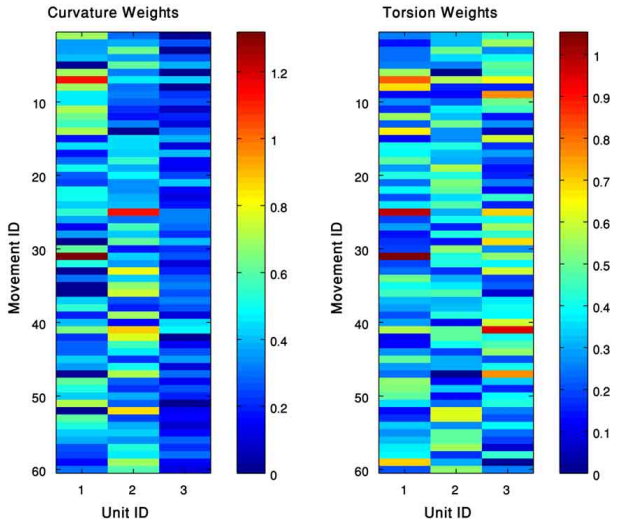

FIGURE 7 | The kinematic units can span the 60 extension movements. Each movement is expressed as a weighed sum of curvature (**left**) and torsion (**right**) units. Clustering these weights results with patterns of weights, such that each one defines a movement prototype in this group.

given by the curvature and torsion surfaces (**Figure 9**). Although the curvature surface of the first and third prototypes (**Figure 8** top, bottom) share a similar topographic structure, the difference between their curvature surfaces defines prototypes with different characteristics. Relative to the first prototype, the third prototype (**Figure 9** right) describes an extension movement in which a higher level of torsion is observed along with the propagating bend, causing the 3D configuration to deviate from the movement plane. Furthermore, the higher weight of the proximal curvature Gaussian results in a higher level of curvature along the base of the arm. The values presented by the torsion surface for the first prototype decrease during the second half of the movement, meaning that the configuration of the arm tends to become more planar as the movement progresses. For the first prototype (**Figure 9** left) the arm section around the propagating bend, which takes higher curvature values, creates a loop during the initial phase of the extension movement. Compared to the first and third prototypes, in the second prototype (**Figure 9** middle) the propagating bend starts with a higher curvature value and lower curvature values for the proximal section of the arm.

PRE-EXTENSION RESULTS

The analysis described above was also applied to the *pre-extension* movement group. The movements in this group refer to the actions that the octopus arm was observed to perform just before the extension phase has started. The well-defined time point in which the bend starts to propagate along the arm has been used to define the time at which a pre-extension movement ends. The kinematic units extracted for this group and the arm behaviors showed some similarities but also some unique characteristics. **Figure 10** presents the single prototype that was found for pre-extension movements. It appears to represent the initializing phase of the arm, in which the base is directed toward a target and the bend (which is propagated during the extension) is generated. The initialization of the bend is achieved by generating movements corresponding to the curvature and torsion kinematic units on the same mid-arm section. Such dynamics may be associated with a minimal loss of energy due to interactions with drag forces. Computer simulations of the movements using the dynamic model of the octopus arm (Yekutieli et al., 2005a,b) will help to further explore and characterize this prototype with respect to muscle activation and energy expenditure.

DISCUSSION

By carefully watching the octopus arm movements in video sequences and identifying the time points bounding the extension phase, we were able to divide our data set of reconstructed arm movements into two main groups, *pre-extension* and *extension* movements. The analysis described here was applied separately to each of these groups but we have presented results mainly related to the extension group. Equivalent results for the pre-extension group are also available.

Instead of the common representation of octopus arm movements in 3D Euclidean space, we modeled each arm movement using pairs of curvature and torsion surfaces. These surfaces essentially describe the curvature and torsion values at the sampled points along the virtual backbone of the octopus arm as a function of time and arm index. Such pairs of curvature and torsion surfaces provide a compact description of arm configuration which is independent of the arm location in 3D space and is invariant to rotation and translation. Most importantly, this approach can be used to demonstrate the existence of kinematic units or motor primitives in octopus arm movements.

The characteristics of the surfaces led us to examine whether they can be meaningfully decomposed. We applied the GMM, suggesting the use of 2D Gaussians as building blocks approximating the curvature and torsion surfaces of a movement. These 2D Gaussians provided a mathematically quantified representation whose hilly shapes fitted well to the topographic characteristic of the surface. We thus have demonstrated a meaningful representation for octopus arm movements and a method GMM for decomposing the movements into well-defined building blocks (2D Gaussians) allowing us to further examine them as possible kinematic units. We have also applied an alternative method which decomposes a surface to its fundamental surfaces by analyzing the principal curvature values at each point on the surface. These parameters allow defining eight fundamental surfaces (e.g., peak, pit, ridge) that correspond to the topography of a surface (Yilmaz and Shah, 2005). Interestingly, we found the results extracted by this method to be very similar to those achieved using the GMM—the positions of the peak fundamental surfaces were highly correlated with the mean values of the positions derived using the 2D Gaussians.

Intuitively, being able to represent the arm by a 2D curvature Gaussian corresponds to the propagation of a bend point along a defined section of the arm and during a defined time interval. All the kinematic properties—the affected section of the arm, the time interval, the maximal curvature value and the velocity of propagation—are simply defined by the center location of the Gaussian, by its covariance matrix and by the weight assigned

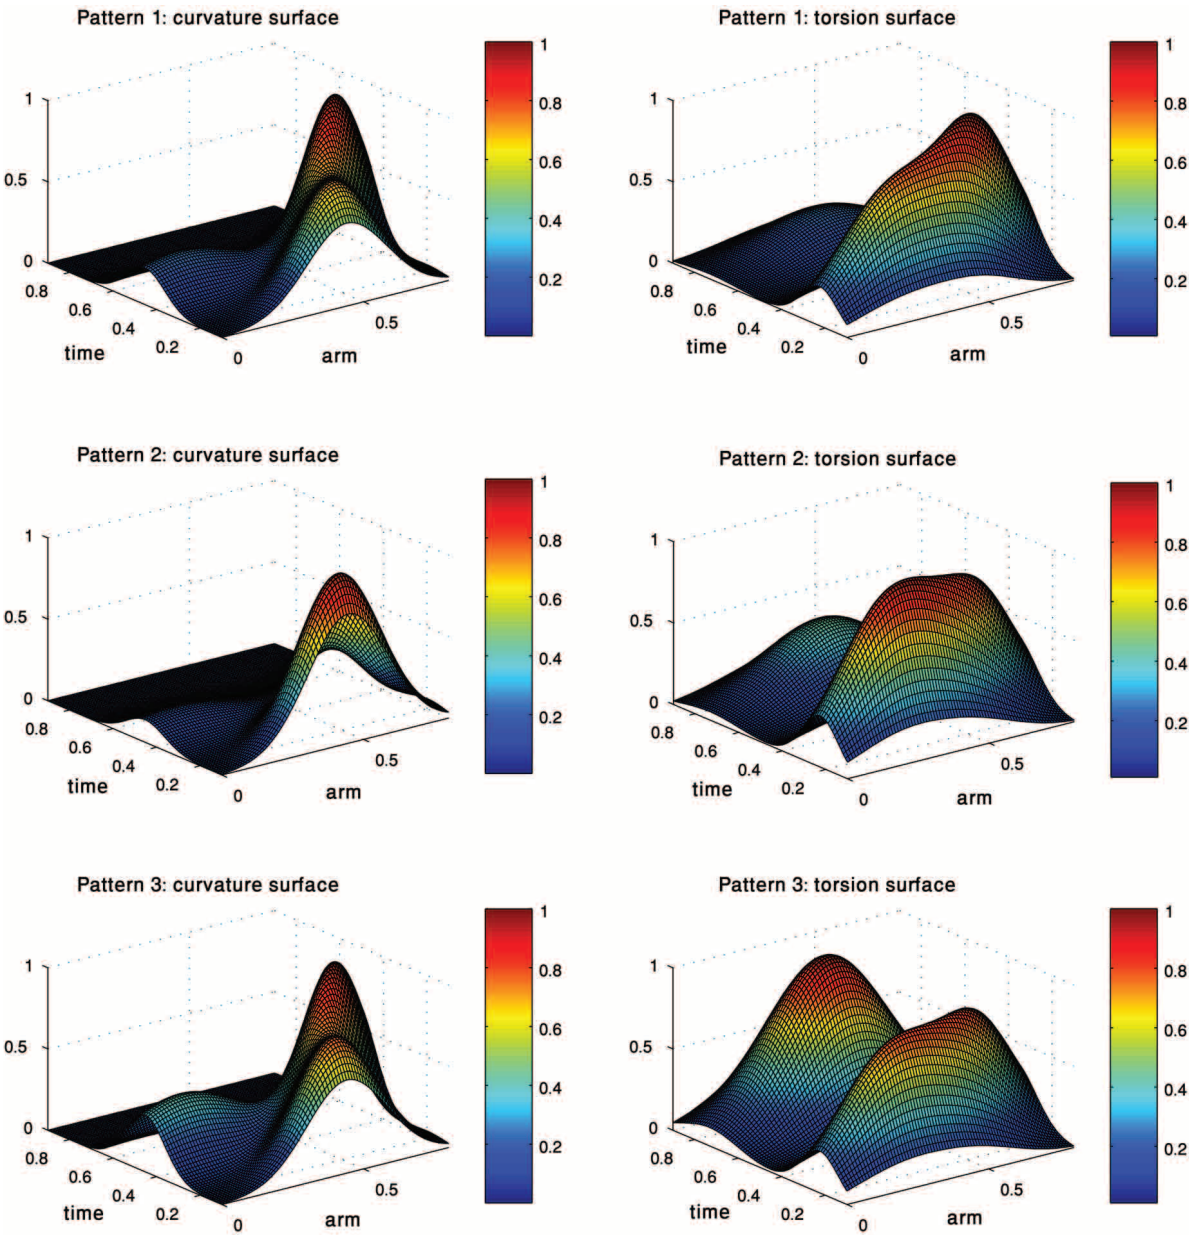

FIGURE 8 | Each pair of curvature and torsion surfaces defines one of the three prototypes of movements into which the extension movements were classified. Each surface is essentially a weighted combination of the curvature/torsion Gaussians extracted earlier.

to this Gaussian. By clustering Gaussians with similar characteristics, we were able to characterize each cluster by its centroid and use the Gaussian representing the entire cluster as a stereotypical kinematic unit. We obtained a set of such curvature and torsion units for each of the pre-extension and extension movement groups. Curvature and torsion units were then combined to simulate new movements in 3D space and to examine whether the entire observed repertoire of complex 3D octopus arm behaviors can be spanned using the derived basic set of kinematic units. We found that patterns of weighted combinations of the kinematic units can be clustered into prototypes of movements in the pre-extension and extension phases, allowing classification of the movements into sub-groups.

The combinations of kinematic units which define the prototypes needs further investigation to reveal the principles underlying the execution of the different arm movements. Sumbre et al. (2001) have suggested that a relation between kinematic features and basic motor programs (embedded within the neural circuitry of the arm itself) greatly simplify the motor control of the octopus arm. In addition, a simple command producing a wave of muscle activation in a dynamic model was sufficient to replicate the kinematic characteristics of natural reaching movements

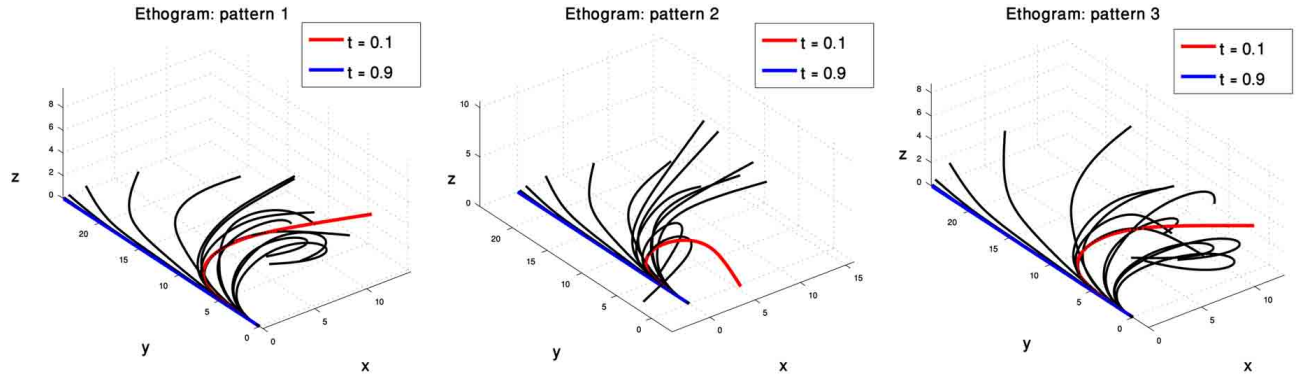

FIGURE 9 | Three prototypes represent the sub-groups into which the 60 extension movements were classified. These prototypes, defined by three pairs of curvature and torsion surfaces (**Figure 8**) show the differences in the various extension movements. See text for further explanation.

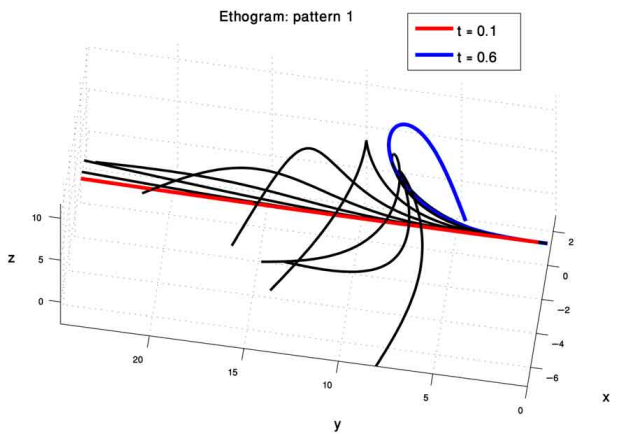

FIGURE 10 | One prototype was found to represent the pre-extension movements. Pre-extension movements are intuitively understood as an initialization phase, during which the bend propagating during the extension phase is generated and the base of the arm is directed toward the target. The form of this prototype suggests that the movement is initialized by generating a new bend at the appropriate position by propelling the mid-section of the arm.

(Yekutieli et al., 2005a). Specifically, it was found that natural extension movements can be generated by a dynamic model, in which a simple propagating neural activation signal is sent to contract muscles along the arm. In the model, the control of only two parameters fully specified the extension movement: the amplitude of the activation signal and the activation travelling time, such that different levels of activations can result in desired kinematics (Yekutieli et al., 2005b). We suggest that values of these two control parameters can be associated with the characteristics of the kinematic units extracted here. That is, the weight, shape, orientation, and size of a Gaussians can be related to the amplitude of the activation signal and the activation travelling time.

The relation between the kinematic units to the biomechanics of the octopus arm has to be examined (Feinstein et al., 2011). The arm morphology points to the dorsal group of the longitudinal muscles being much thicker than the ventral group, and both groups differ from the lateral groups. This anisotropy suggests that while bending movements to the left and right directions might be similar, this is not the case when comparing between upward, downward and sideward directions. The oblique muscles are composed of three pairs of helical bands, such that the handedness of the helix of one member of the pair is opposite to that of the other member of the same pair (Kier and Stella, 2007). This isotropy with respect to the arm axis supports that torsion toward the two different directions is applied in a similar manner.

The results from our analysis agree with our data on octopus arm movements. The extension movement shown in **Figure 11A** matched with prototype no. 2 of the extension group (**Figure 9** middle), as a movement in which a highly curved bend along a relative short section of the arm propagated rapidly toward a target. The lower movement **Figure 11B** matched with prototype no. 1 of the extension group (**Figure 9** left), as a movement in which the arm moved relatively slowly toward the target with relatively low curvature values for the propagating bend. The Gaussians referring to the main characteristic of extension movements strengthen the previous findings of Gutfreund et al. (1996) of a stereotypic profile of the position and velocity of the bend point. They suggested that the position of the bend in space and time is a controlled variable, which simplifies motor control. The travelling bend, associated with a propagating wave of muscle activation (Gutfreund et al., 1998), was simulated as a biomechanical mechanism in a dynamic model of the octopus arm (Yekutieli et al., 2005a).

Two pre-extension movements shown in **Figure 12** matched with the prototype of the pre-extension group (**Figure 10**). A substantial manipulation of the initial arm configuration was involved by creating a bend in the arm and directing it toward the target. In this movement, curvature and torsion kinematic units are both applied on the mid-section of the arm during the pre-extension phase. These results demonstrate that the Gaussian description of movement primitives allows us to describe a complex motor behavior. Clearly, additional types of octopus arm movements other than the pre-extension and extension movements analyzed here are part of the motor repertoire of octopus behavior. While reconstruction and analysis of these other movements will probably reveal additional kinematic building blocks, we can expect that the general characteristics of octopus

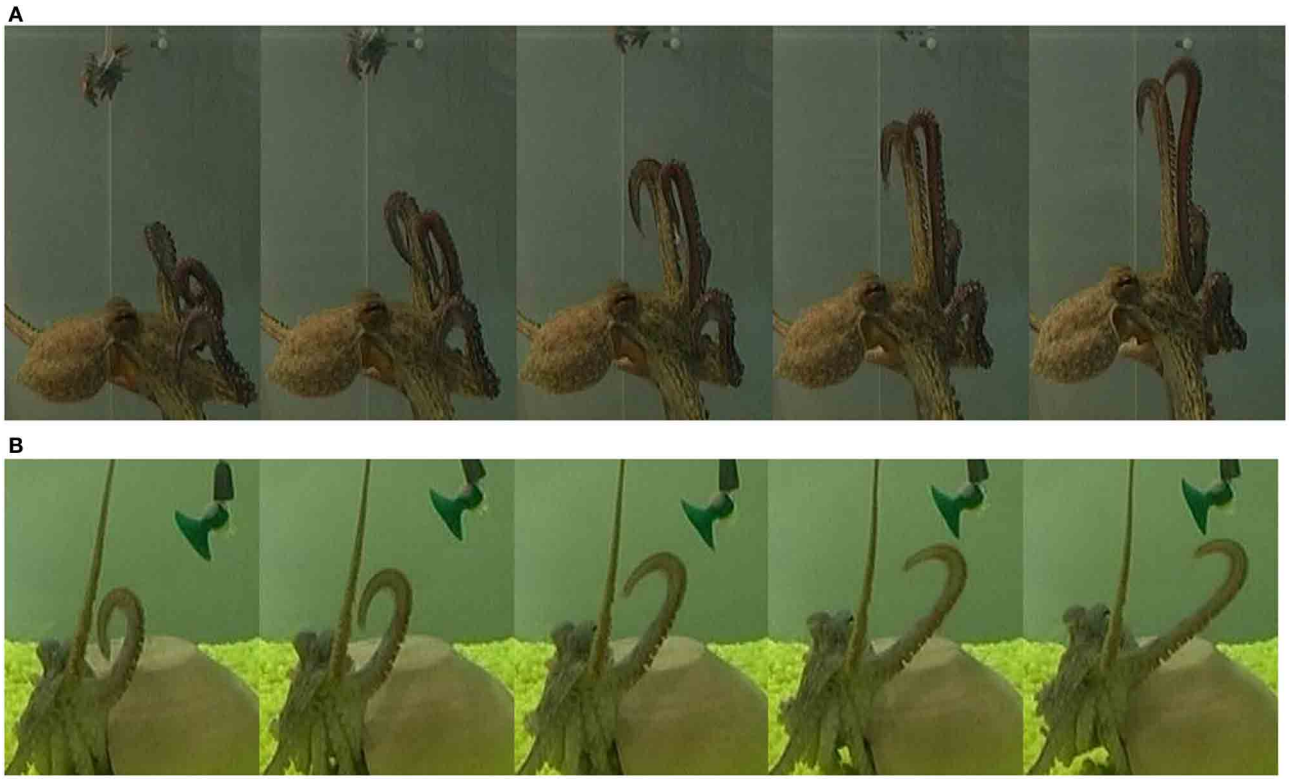

FIGURE 11 | Two extension movements. The upper movement **(A)** was classified as prototype no. 2 of the extension group (**Figure 9** middle), as a movement in which a highly curved bend was rapidly propagated toward a target, while the base of the arm stayed oriented with a fixed direction. The lower movement **(B)** was classified as prototype no. 1 of the extension group (**Figure 9** left), as a movement in which the bend showed lower curvature values and moved relatively slowly toward the target while the direction of the base of the arm was not preserved. The movements progress from left to right in each panel.

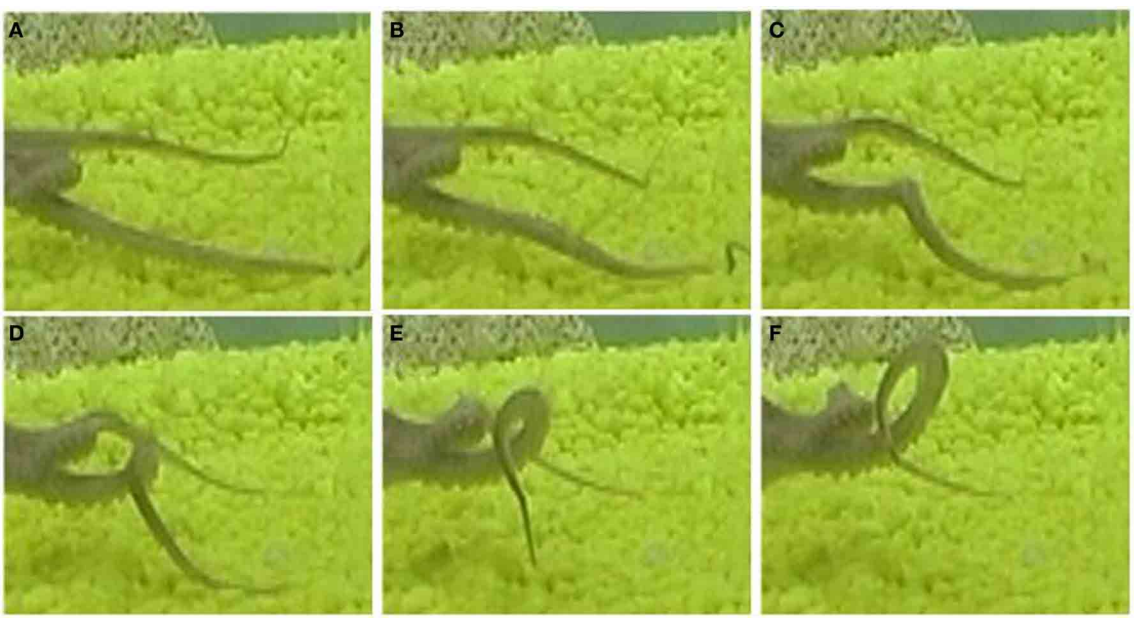

FIGURE 12 | A pre-extension movement as a sequence progressing from the upper left (A) to the lower right (F) frames. A substantial manipulation, creating a bend and directing it toward a target, was applied to the initial configuration (upper left). This movement is matched with the prototype of the pre-extension group (**Figure 10**). Frame **(F)** presents a temporal configuration that matches the beginning of an extension movement.

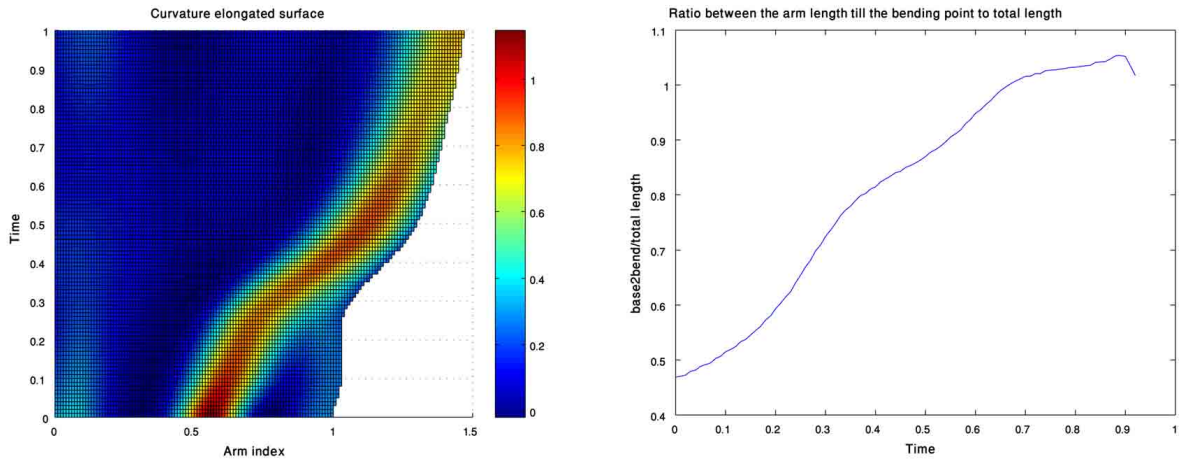

FIGURE 13 | A curvature surface which also refers to the elongation during an extension movement (left). The values of the ratio between the lengths of the proximal section of the arm (from base to bend point) and the length of the entire arm as a function of time **(right)**.

arm movements, mainly the smoothness in which curvature and torsion values vary along both the arm and the time dimensions will hold for other types of movements. Therefore, we believe that Gaussian functions could be efficiently used also in the decomposition and description of those movements.

Our results fit with Yekutieli et al.'s (2007) observations on the kinematic characteristics of the initiation of a reaching movement. The kinematic description is sufficiently rich for describing complex arm movements, although factors such as the biomechanics of the octopus arm (e.g., the different type of muscles and the constant volume constraint), water drag forces and energy expenditure also strongly influence the arm movement characteristics. For example, the perpendicular drag coefficient for an octopus arm is nearly 50 times larger than the tangential drag force coefficient. This most likely affects the preferred arm configuration during extension movements; only a small part of the arm is oriented perpendicularly to the direction of movement, minimizing drag (Yekutieli et al., 2005a). Yekutieli et al. (2005b) also found that the control of extension movements can be specified by the amplitude of the muscle activation signals and the activation travelling time. The primitives we suggest here can be used to further investigate the relation between the kinematic and muscle activation levels.

In our analysis the curvature and torsion surfaces were extracted for arm configurations whose length has been normalized. Replotting the curvature and torsion surfaces while showing the actual arm length values as analyzed from live data (**Figure 13** left) shows that the proximal section of the arm elongates during an extension (i.e., the section between the base and the bend point). This is demonstrated clearly in **Figure 13** (right) which shows the ratio between the length of the proximal section to the length of the entire arm during an extension movement. Arm elongation has recently been shown to play a key role in the biomechanics and control of octopus arm movements (Hanassy, 2008). Modeling the travelling bend along extension movements based on the propagation of muscle activation and stiffening wave (Gutfreund et al., 1998), where co-contraction of both the longitudinal and transverse muscles pushes the bends forward (Yekutieli et al., 2005b). Therefore, different ratios between the activation levels of longitudinal to transverse muscle can be used to control the elongation of the arm along the proximal section between the base and bending point. Gaussian units, which were found in this study to describe the travelling bend during extension movements, will be further examined in order to support recent findings related to the biomechanics and control of the octopus arm.

Our analysis presents a possible language of kinematic primitives—2D Gaussians of either curvature or torsion which define and classify octopus arm behaviors by their different combinations. Constructing a taxonomy of possible movements for a species is one approach to the study of its behavior. To construct a taxonomy of octopus arm movements and to reveal how combinations of components result in a variety of behaviors Mather (1998) used components which consist of movements of the arm itself, the ventral suckers and their stalks, as well as the relative position of the arms and the skin web between them. Comparing similar movement taxonomies and ethograms (catalog of body patterns and associated behaviors) in the squid and various octopus species (Hanlon et al., 1999; Huffard, 2007; Mather et al., 2010) suggests that behaviors may be conserved throughout the evolution of these species. Our results identify a number of kinematic units, possible time-dependent units and sub-groups (**Table 3**). As more reconstructed octopus arm movements become available (Yekutieli et al., 2007; Zelman et al., 2009), we will better be able to use our analytical tools to define a comprehensive language of motor primitives that incorporates the underlying kinematic principles, thus enriching the ethogram and taxonomy of octopus arm behavior.

Our analysis provides a new framework for research on the kinematics and control of any natural or mechanical flexible manipulator. Possible arm behaviors can be simulated by synthesizing new combinations of the extracted Gaussians. New primitives can be hypothesized and tested on dynamic models of the octopus arm and the resulting movements can

Table 3 | The analysis applied to each movement group yielded a number of kinematic units defining possible local-temporal 3D behaviors of the arm.

Group	Number of kinematic units		Number of possible behaviors	Number of sub-group prototypes
	Curvature	Torsion		
Pre-extension	1	3	3	1
Extension	3	3	6	3

Each group was divided into a number of sub-groups which were represented by different movement prototypes.

be compared with live movements. This, in turn, may allow future studies of activation commands at the neural control level, which may then enable operation of a real flexible manipulator to perform specified goal-oriented tasks (Laschi et al., 2009, 2012; Calisti et al., 2011).

† These authors have contributed equally to this work.

The endpoint trajectories of human movements fulfill characteristic power laws linking velocity and curvature. The parameters of these power laws typically vary between different segments of longer action sequences. These parameters might thus be exploited for the unsupervised segmentation of actions into movement primitives. For the example of sign language we investigate whether such segments can be identified by Bayesian binning (BB), using a Gaussian observation model whose mean has a polynomial time dependence. We show that this method yields good segmentation and correctly models ground truth kinematics composed of consecutive segments derived from wrist trajectories recorded from users of Israeli Sign Language (ISL). Importantly, polynomial orders between 3 and 5 yield an optimal trade-off between complexity and accuracy of the trajectory approximation, in accordance with the minimum acceleration and minimum jerk models. Comparing the orders of the polynomials best approximating natural kinematics against those needed to fit the power law ground truth data suggests that kinematic properties not compatible with power laws are also not adequately represented by low order polynomials and require higher order polynomials for a good approximation.

Keywords: motor primitives, two-thirds power law, differential invariants, Bayesian binning, sign language, minimum jerk model

1. INTRODUCTION

Complex motor behavior might be organized in terms of sequences of temporal movement primitives that follow each other sequentially in time. Determining such primitives from kinematic data is an important problem for many technical applications, e.g., in robotics, computer vision and computer graphics. At the same time, the characterization of possible temporal primitives that underlie the planning and execution of complex motor behavior remains a partially unresolved issue in motor control (Flash and Hochner, 2005). While the appropriate characterization of the temporal organization of complex motor behavior might require ultimately hierarchical multi-level representations (Flash and Hochner, 2005), many previous studies that investigated the nature of such primitives have focused on the analysis of movement kinematics. Specifically, it has been investigated how the temporal and kinematic properties of the movement are influenced by the path followed by the hand (see e.g., Polyakov et al., 2009b).

One approach to the definition of temporal segments is based on invariant properties that characterize movements within individual segments. It was already established at the end of the nineteenth century that for arm movements, curvature and speed are correlated variables, speed typically obeying an inverse relation to curvature (Jack, 1895). Almost a 100 years later, this rule was quantitatively formalized as the two-thirds power law. Specifically, this rule dictates that for figure drawing movements the speed along the motion path is proportional to the curvature of this path raised to the minus one-third power (Lacquaniti et al., 1983):

$$|v(t)| = \alpha\kappa^{-\frac{1}{3}}(t) \tag{1}$$

where v is the Euclidean velocity, κ is the Euclidean curvature (i.e. the reciprocal of the radius of osculating circle) and α is the so called velocity gain factor, which is constant within each individual segment.

Extensive research has investigated the conditions and origins of the two-thirds power law. Equation (1) was first developed for two-dimensional drawings but was also later applied to three-dimensional drawing under isometric force conditions (Massey et al., 1992) and to various movement modalities including eye pursuit (Viviani and deSperati, 1997) and speech movements (Tasko and Westbury, 2004; Perrier and Fuchs, 2008). Also, the exponent of the two-thirds power law varies in children and becomes more stable with age (Viviani and Schneider, 1991). This principle not only applies to motion production but also to motion perception as has been supported by studies of the perception of handwriting and drawing movements (Soechting et al., 1986; Viviani et al., 2000) and of the motion of abstract visual stimuli (Viviani and Stucchi, 1992; Levit-Binnun et al., 2006). Finally, a functional magnetic resonance imaging (fMRI) study has supported a central representation of the perception of this kinematic law (Dayan et al., 2007). Taken together, these studies show that the 2/3 power law is most likely not the expression of

bio-mechanical constraints but may reflect the involvement of the central nervous system (for a review see Flash et al., 2012).

A recent study (Meirovitch, 2008) has investigated the wrist trajectories in sign language with the goal of identifying the motor control strategies for such spatially constrained movements. Movement recordings from normal naive participants revealed that a generalized form of the 2/3 power law (Equation 1) predicts the velocity profiles of the wrist trajectories. The executed trajectories across a number of repetitions were fitted with the model:

$$|v(t)| = \alpha\kappa^{\beta}(t) \tag{2}$$

where v, κ and α are defined in the same way as for Equation (1) and the parameter $\beta \in [-1, 0]$ typically remains constant during individual trajectory segments. This suggests that this parameter might be used to segment longer action sequences into movement primitives, identifying the segments with an approximately constant β. The presence of the kinematic segments does not necessarily imply segmented control by the brain [see Schaal and Sternad (1999) and Flash and Hochner (2005)]. Therefore, an attempt to unravel kinematic primitives would require to be consistent with optimization models used in motor control such as the minimization of jerk (time derivative of acceleration), variance, etc. [see section 1.1]. Here, we employ the segment-wise constancy of β to generate ground-truth data for the testing of motion segmentation algorithms. We use sign language trajectories as a basis for our analysis and modify their velocity to match a possible power law segmentation with fixed values of the parameters α and β within each predefined segment. The timing of each segment in the ground-truth parameterization closely follows the timing of the natural sign language trajectories. Moreover, in simulating the discrete segmentation of the ground-truth data, the algorithm optimizes for a smooth transition between adjacent segments by choosing suitable power law parameters. The details of this procedure are described in section 2.4.

1.1. CONNECTION BETWEEN POLYNOMIALS AND POWER LAWS

In addition to these power laws (Equation 2), human movements were shown to be well-captured by optimization models that maximize the smoothness of the trajectories, mathematically expressed by the minimization of integrated jerk or by higher-order time derivatives of position, i.e., snap, crackle and so on (Flash and Hogan, 1985; Todorov and Jordan, 1998). Other types of movements (e.g. locomotion and arm reaching) were shown to be well captured by minimum acceleration models (Ben-Itzhak and Karniel, 2008; Mombaur et al., 2010). Mathematically, such models predict that the trajectories will be well captured by polynomials of orders 3, 5, and 7, corresponding to minimum acceleration, jerk and snap models, respectively. In Richardson and Flash (2002) it was mathematically shown that such polynomial trajectories, which optimize mean squared derivative cost functions

$$C_n = \int_0^T \left|\left|\frac{d^n r}{dt^n}\right|\right|^2 dt, \tag{3}$$

(where $n = 3,\ 4$ correspond to minimum jerk and snap, respectively) follow generalized power laws whose exponents depend on the cost function being optimized and on the geometrical shape of the trajectory being traced. In addition, such predicted power laws were shown to be consistent with the power law found empirically in the experimental data.

In another study Polyakov et al. identified parabolic strokes whose generation both obeys the 2/3 power law and yields minimum-jerk trajectories (Polyakov et al., 2009b). Parabolas are interesting because of their invariance with respect to affine transformations and additionally their special role as geodesics in equi-affine geometry which predicts the two-thirds power law (Flash and Handzel, 2007).

For 3-dimensional geometrically complex trajectories, a power law that depends on torsion which measures the rate of change of the osculating plane, was analyzed for 3D drawing movements (Maoz et al., 2009; Pollick et al., 2009) and although the link between power laws and variational optimization principles was studied for several figural forms (Polyakov et al., 2009b), such links have not been examined for natural complex trajectories. Here we provide the first detailed account for the computational equivalence between the generalized power law and variational models. To this end, we present a Bayesian approach for the temporal segmentation of complex end-effector trajectories based on a polynomial observation model and show that the resulting segments can be used to identify the power law structure of the kinematic profiles.

1.2. UNSUPERVISED SEGMENTATION OF COMPLEX END-EFFECTOR MOVEMENTS

Segmenting trajectories into power-law obeying pieces is difficult for three reasons: first, the number of segments and their temporal boundaries are *a-priori* unknown. Second, estimating higher derivatives from noisy trajectory data is prone to errors. Third, segments obeying power laws with different βs (Equation 2) are typically connected by short transition periods during which the trajectory is not well described by a power law (Viviani and Flash, 1995). We address the first two problems by choosing a Bayesian approach, based on Bayesian Binning (BB). Estimating the number of segments is a model complexity estimation problem, which we deal with using the "Occam's razor" inherent in Bayesian approaches: the larger parameter space of more complex models (e.g., having more segments) implies that every individual instantiation of such a model is *a-priori* less probable than a more parsimonious model (Bishop, 2007). Thus, simpler models are preferable, if they can explain the observable data equally well. To handle the (possibly large amounts of) noise in parameter estimates, Bayesian models infer a posterior distribution over parameters, instead of point estimates yielded by maximum-likelihood fitting procedures. This posterior distribution allows to assess not only the expected value, but also the uncertainty of the parameter of interest. We sidestep the third problem—transition periods which do not obey power laws—by using a dataset in which all transition periods are very short, almost instantaneous, and a segment model which can also well describe the point to point and transition movements (Flash and Hogan, 1985; Polyakov et al., 2009a). As detailed above, both

polynomials and power laws can be derived from the same optimization principles, and power law trajectories can be well fitted by time-dependent polynomials, but the kinematic profiles at the boundaries of segments are better explained by polynomials. Furthermore, the parameterization by polynomials avoids singularities that arise in Equation (2) for straight curve segments with zero curvature.

The rest of the paper is structured as follows. First we give a concise description of the data recordings and ground truth generation in section 2, since these data have not been published before. We develop BB for the segmentation of wrist trajectories recorded with motion capture in section 2.5. There, we show how to use BB with observations models having a polynomial time dependence of the mean and segment-wise constant coefficients. In section 3 we demonstrate the results achieved by BB and compare them with the ground truth. Finally, we give an outlook for further investigations in section 4.

2. MATERIALS AND METHODS

To generate a form of ground truth data that complies with the kinematic law (Equation 2), we corrected the speed parameterization of the original, recorded trajectories in a way that made them exactly compatible with the kinematic law.

Our experiments were based on data adapted from Meirovitch (2008). A short description of the experiments is given below. In section 2.4 we give a more detailed description of the segmentation mechanism which we used to synthesize the "ground truth" segmentation. While the employed synthesis method may appear complicated, we chose it to generate a ground truth with a high degree of biological realism.

2.1. SUBJECTS AND SIGNS

Subjects were two natural users of Israeli Sign Language (ISL): S00 (male, 45), a native signer who acquired ISL during his childhood through exposure to his parents, and S01 (male, 44) who acquired ISL in childhood.

Each subject was asked to sign two words, either "cake (baked)" or "chandelier." The English equivalents of these ISL signs were shown in English on a screen in front of the subject prior to execution. Each sign was repeated 20 times.

2.2. DATA RECORDING AND PREPROCESSING

Hand movements were recorded using the Polhemus LIBERTY 240/16 motion capture system which recorded the location of a sensor fixed to the subject's wrist at an accuracy of 0.08 cm at a frequency of 240 Hz.

The trajectories were preprocessed with a 50-samples 6 Hz low pass FIR filter (normalized gain of −6 dB at 6 Hz), and their velocity profiles and Euclidean curvature were calculated for each sample n (Calabi et al., 1998).

2.3. FITTING OF POWER LAW AND QUANTIFICATION OF COMPLIANCE

We used correlation coefficients to compare the actual trajectories with the predictions based on the best-fitting power law within individual trajectory segments. Within each segment, the law was fitted using non-linear regression (Coleman and Li, 1994, 1996; Maoz, 2007), where the predicted speed value is denoted as $\hat{v}(n)$ and where $\hat{\alpha}$ and $\hat{\beta}$ are the fitted parameter values for this segment. The predicted speed is given by the relationship:

$$\hat{v}(n) = \hat{\alpha}\kappa^{\hat{\beta}}(n) \tag{4}$$

A measure for the quality of the fit is given by the compliance

$$R_s^2(\hat{\alpha}, \hat{\beta}) = 1 - \frac{\sum_{i \le n \le j} \left(v(n) - \hat{v}(n)\right)^2}{\sum_{i \le n \le j} \left(v(n) - v_{\text{average}}\right)^2} \tag{5}$$

where s is the segment for which regression is carried out and v_{average} is the average speed within the segment.

2.4. POWER LAW SEGMENTATION

To generate a data set as ground truth that fully complies with the power law (Equation 2) the speed of the original trajectories was reparameterized (by time warping) to make the individual trajectory segments exactly compatible with the best fitting kinematic law. The purpose of the time-warping is the generation of a ground truth dataset that fully complies with the power law against which the automatic (polynomial) segmentation can be compared. Our paradigm enables the treatment of several minimization principles (e.g., acceleration, jerk, snap, crackle etc.) in parallel by choosing the model via Bayesian model comparison.

The idea employed in the ground truth synthesis is based on randomizing some parameters of the segmentation while optimizing others. At the first step the algorithm iterates through possible segmentations in which the temporal breakpoints and the exponents of the power laws are randomized. To respect the smoothness characteristic of natural movement, the gain-factors of the respective segments are then calculated from the curvatures at the boundaries of the segments, and the trajectory is then time-warped. The segments that comprise the ground truth dataset have durations comparable to the respective segments in the natural trajectories, comparable maximal speed, and their speed is continuous at the boundaries. An example of a synthesized ground truth trajectory is shown in **Figure 1**.

In the following, we give some additional technical details: To avoid singularities we excluded from the data basis the initial and terminal parts of the movement, where the speed was below a prescribed ratio of the maximal speed (<15% × maximal speed).

First, each trajectory was randomly partitioned into $N = 3$ consecutive time intervals, $[t_i, t_{i+1}]_{i=1}^{N}$, where the first interval begins at t_1, and the last interval terminates at the end of the recorded movement, at time t_{N+1}, such that the duration of each segment, $t_{i+1} - t_i$, was not too short (>300 ms). We proceeded to synthesize the power law parameters for each of the random partitions. At the first step, we uniformly randomized $\beta = \{\beta_1, \ldots, \beta_N\} \in [-1, 0]^N$ such that $|\beta_{i+1} - \beta_i| > 0.1$ and those β N-tuples that were biologically implausible were rejected according to criteria that are described below.

The α parameter, $\alpha = \{\alpha_1, \ldots, \alpha_N\}$, was determined based on the randomized β value and the empirical speed and curvature. The first value, α_1, was determined from the empirical speed using Equation (2) according to:

$$\alpha_1 = v(0)\kappa(0)^{-\beta_1},$$

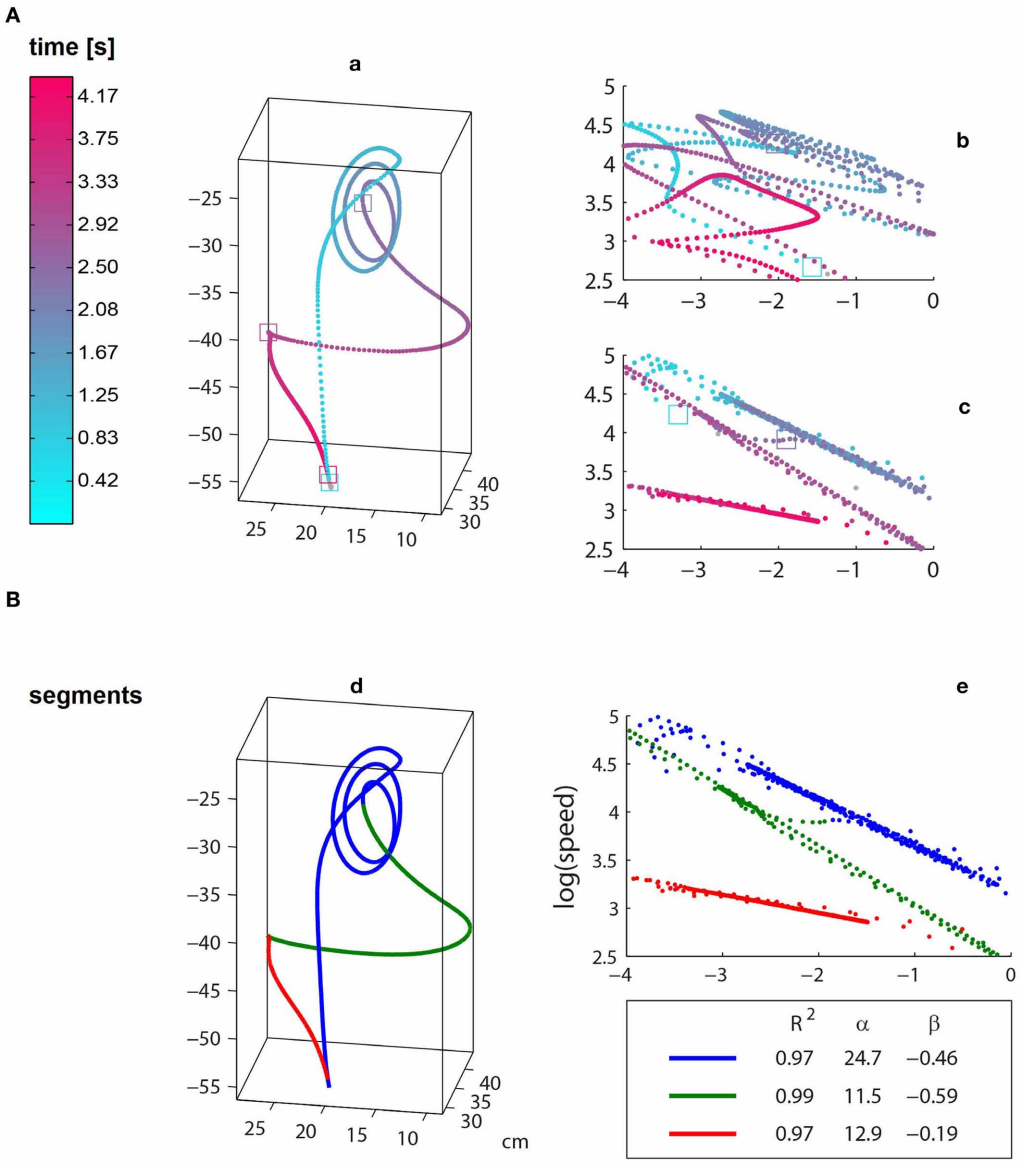

FIGURE 1 | The trajectories of an ISL "Cake" repetition before (a) and after (d) time-warping. (A) The samples of the raw data are colored according to time. **(B)** The time-warped trajectory, where the three colors designate power law segments. Log–Log plots of curvature and velocity are depicted on the right side: **(b)** raw data and **(c,e)** time-warping, colored according to time and segments, respectively. It can be seen that the spatial representation, i.e., path, of the raw and time-warped trajectories are identical. Also, although both raw and time-warped log–log curves are characterized by linear segments, the time warping is based on a simpler power law representation which is characterized by three highly fitting ($R^2 > 0.97$) segments with beta values ranging from about −0.19 to −0.6. The transitions between long straight segments in the log–log representation are made either by a very brief transitional period which does not comply with the power laws of the adjacent segments [e.g., the portion between the blue and green segments in **(e)**] or in the temporal point of intersection of the piecewise linear sections [e.g., green to red segment in **(e)**].

The α_{i+1} value was determined enforcing the constraint that the speed should be continuous at the segment boundaries, resulting in the relationship:

$$v(t_{i+1}) = \alpha_{i+1}\kappa(t_{i+1})^{\beta_{i+1}} = \alpha_i\kappa(t_{i+1})^{\beta_i}.$$

Using spline interpolation we reparameterized the trajectories within each time interval, $[t_i, t_{i+1}]$, defining a new effective time parameter, τ, that was defined up to a constant by:

$$ds = \alpha_i\kappa(t)^{\beta_i}d\tau$$

where ds is the Euclidean arc-length parameterization of the trajectory. This relationship results in the differential equation:

$$\frac{d\tau}{dt} = \frac{1}{\alpha_i}v(t)\kappa(t)^{-\beta_i}$$

that links the original and the warped time axis of the trajectory.

Finally, those trajectories that induced biologically improbable high speed ratios, were rejected. For those synthesized trajectories that were not rejected, we recalculated, using non-linear regression (see section 2.3), the actual $\hat{\alpha}$ and $\hat{\beta}$ N-tuples for the accepted $[t_i, t_{i+1}]$ time intervals and those were stored for further analyses. It is important to note that our reparameterization method did not change the durations of the original behavioral time intervals given by $\tau_{i+1} - \tau_i = t_{i+1} - t_i$.

2.5. BAYESIAN BINNING FOR SIGN LANGUAGE SEGMENTATION

In the following, we present an unsupervised segmentation algorithm that is based on BB. Briefly, BB is an approach to modeling data with a totally ordered structure, such as time series, by functions which are piecewise defined. The total order allows for an efficient iteration over all possible segment configurations in polynomial time.

BB was originally developed for modeling of (typically very noisy) neural spike train data (Endres et al., 2008; Endres and Oram, 2009) and their information-theoretic evaluation (Endres and Földiák, 2005). It was later generalized for regression of piecewise constant functions (Hutter, 2007). Concurrently, a closely related Bayesian formalism for dealing with multiple change point problems was introduced by Fearnhead (2006).

To apply BB to wrist trajectories we augment it by an observation model for the trajectory segments which is Gaussian with a full covariance matrix and a polynomial time dependence of the mean. This model was originally developed by two of the authors for segmenting joint angle trajectories of human actors in a "natural" fashion (i.e., in agreement with human intuition) (Endres et al., 2011a,b). To make this paper self-contained, the following sections describe the prior over bin boundaries (section 2.5.1) and the observation model (section 2.5.5). The algorithmic details of evaluating posterior expectations are only outlined schematically, they are elaborated in Endres and Földiák (2005). A full derivation of the polynomial observation model, including the exact posterior updates can be found in Endres et al. (2011a).

The results of this segmentation algorithm are validated using the ground-truth data basis from section 2.4 that consists of trajectories whose segments exactly comply with the previously described power law. We show (section 3) that BB results in good segmentation of data fulfilling this kinematic law. Furthermore, we argue that BB generalizes the segmentation approaches presented in Barbič et al. (2004) and Polyakov et al. (2009b) [see section 4].

2.5.1. The bin boundary prior

Our objective is to model a time series D in the time interval $[t_{\min} = t_1, t_{\max} = t_{N+1}]$. We discretize $[t_{\min}, t_{\max}]$ into T contiguous intervals of duration $\Delta t = (t_{\max} - t_{\min})/T$, such that interval j is $[j \cdot \Delta t, (j+1) \cdot \Delta t]$ (see **Figure 2**). Choose Δt small enough to capture all relevant features of the data[1]. We model the generative process of D by $M+1$ contiguous, non-overlapping segments, indexed by m and having *inclusive* upper boundaries $q_m \in \{q_m\}$. The segment m therefore contains the time interval $T_m = (\Delta t\, q_{m-1}, \Delta t\, q_m]$. Let D_m be that part of the data which falls into segment m. We assume that the probability of D given $\{q_m\}$ factorizes as

$$P(D|\{q_m\}, M) = \prod_{m=0}^{M} P(D_m|q_{m-1}, q_m, M) \tag{6}$$

with $q_{-1} = -1, q_M = T - 1$.

2.5.2. Prior on $\{q_m\}$

Since we have no preferences for any segment boundary configuration other than they be totally ordered, the segment configuration prior becomes

$$P(\{q_m\}|M) = \binom{T-1}{M}^{-1} \tag{7}$$

[1] E.g., choose Δt in the order of 1/sampling rate.

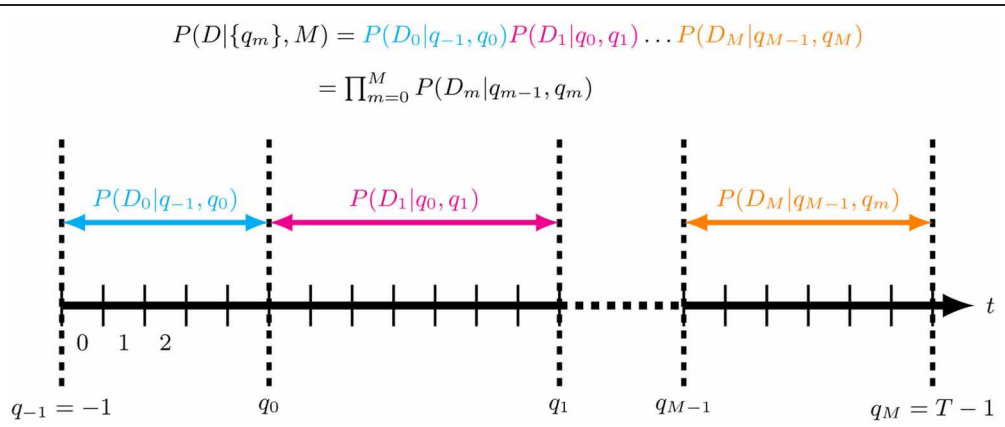

FIGURE 2 | Segmentation of a time series of length T into $M+1$ contiguous, non-overlapping segments with (inclusive) upper segment boundaries $q_m \in \{q_m\}$. The observation model in each segment m is given by $P(D_m|q_{m-1}, q_m)$, where D_m is that part of the data which is in segment m. Importantly, the model assumes that the data are independent across segments given the $\{q_m\}$and M.

where $\binom{T-1}{M}$ is the number of configurations in which M ordered segment boundaries can be distributed across $T-1$ places (segment boundary M always occupies position $T-1$, hence there are only $T-1$ positions left). While this prior expresses no preferences for boundary positions, it is important for complexity control: as long as $T \gg M$ (which is typically the case), this prior will decrease exponentially in M, thereby punishing models with larger number of segments.

2.5.3. Prior on M

We have no preference for any model complexity (i.e., number of segment boundaries), so we let

$$P(M) = \frac{1}{T} \tag{8}$$

since the number of segment boundaries M must be $0 \leq M \leq T-1$.

2.5.4. Posterior of $\{q_m\}$

For temporal segmentation, the most relevant posterior is that of the $\{q_m\}$ for a given M:

$$P(\{q_m\}|D, M) = \frac{P(D|\{q_m\})P(\{q_m\}|M)}{P(D|M)} \tag{9}$$

For the denominator, we need to compute $P(D|M)$:

$$P(D|M) = \sum_{q_0=0}^{q_1-1} \sum_{q_1=1}^{q_2-1} \cdots \sum_{q_{M-1}=M-1}^{T-1} P(D|\{q_m\}, M) \tag{10}$$

which appears to be $\mathcal{O}(T^M)$ since it involves M sums of length $\mathcal{O}(T)$. However, using the form of $P(D|\{q_m\}, M)$ (Equation 6) and distributivity of multiplication over addition allows us to "push sums" past all factors which do not depend on the summation variable:

$$\begin{aligned} P(D|M) &= \sum_{q_0=0}^{q_1-1} \sum_{q_1=1}^{q_2-1} \cdots \sum_{q_{M-1}=M-1}^{T-1} \prod_{m=0}^{M} P(D_m|q_{m-1}, q_m) \\ &= \sum_{q_0=0}^{q_1-1} P(D_0|q_{-1}, q_0) \sum_{q_1=1}^{q_2-1} P(D_1|q_0, q_1) \cdots \\ &\quad \cdots \sum_{q_{M-1}=M-1}^{T-1} P(D_M|q_{m-1}, q_M) \end{aligned} \tag{11}$$

Each sum of length $\mathcal{O}(T)$ needs to be evaluated $\mathcal{O}(T)$ times for the possible values of the upper summation boundary. As there are M sums, this calculation has complexity $\mathcal{O}(MT^2)$, rather than the naïve $\mathcal{O}(T^M)$. This is an instance of the **sum-product** algorithm (Kschischang et al., 2001). As explained in Endres and Földiák (2005), the expectations of functions of the model parameters (e.g., segment boundary position, segment width or probability of a segment boundary at a given point in time) can be evaluated similarly, if the function depends only on the parameters of one segment.

2.5.5. Observation models $P(D|\{q_m\})$ for wrist trajectories

For the wrist trajectories, we employed a multivariate Gaussian observation model with polynomial time-dependence of the mean, because we would like to explore the relationship between power-laws and polynomials. With this choice, we can specify a conjugate prior on the parameters, which allows for an evaluation of expectations and marginal probabilities within each segment in closed form. A prior is conjugate to an observation model, if the resulting posterior has the same functional form as the prior (Bishop, 2007). In that case, posterior updates reduce to parameter updates of the prior, instead of having to compute a (often intractable) multi-dimensional integral. Thus, we can efficiently compute the marginal probability of the data given the number of bin boundaries (Equation 11), as explained above.

The exponential family conjugate prior on the mean μ and the precision matrix $\mathbf{P}$ (inverse covariance) is given by an extended Gauss–Wishart density (see e.g., Bishop, 2007). Let $\vec{X}_t \in D$ be a $L = 3$-dimensional vector of wrist positions at time $t \in T_m$, and S be the chosen polynomial order. Let $t_m = \Delta t\, q_{m-1}$ be the start time of segment m. Then

$$p(\vec{X}_t|t \in T_m) = \mathcal{N}(\vec{X}(t); \vec{\mu}_m, \mathbf{P}_m^{-1}) \tag{12}$$

$$p(\mathbf{P}_m|\nu_m, \mathbf{V}_m) = \mathcal{W}(\mathbf{P}_m; \nu_m, \mathbf{V}_m) \tag{13}$$

$$\vec{\mu}_m = \sum_{i=0}^{S} \vec{a}_{i,m}(t - t_m)^i \tag{14}$$

The $\vec{a}_m = (\vec{a}_{i,m})$ are the polynomial coefficients in segment m. Note that this vector has $(S+1) \cdot L$ components. $\mathcal{N}(\vec{X}, \vec{\mu}, \Sigma = \mathbf{P}^{-1})$ is a multivariate Gaussian density in $\vec{X}$ with means $\vec{\mu}$ and covariance matrix Σ. $\mathcal{W}(\mathbf{P}; \nu, \mathbf{V})$ is a Wishart density in $\mathbf{P}$ with ν degrees of freedom and scale matrix $\mathbf{V}$. To construct a prior which is conjugate to the likelihood (Equation 12), we choose a vector $\vec{\alpha}_m = (\vec{\alpha}_{i,m})$ with $(S+1) \cdot L$ components, which are the biases on $\vec{a}_m$. Furthermore, we introduce a symmetric, positive (semi-)definite $(S+1) \times (S+1)$ matrix $\mathbf{B}_m$, which contains the concentration parameters on $\vec{a}_m$. The prior on $\vec{a}_m$ given $\mathbf{P}_m$ is then a multivariate Gaussian density

$$p(\vec{a}_m|\vec{\alpha}_m, \mathbf{B}_m, \mathbf{P}_m) = \mathcal{N}(\vec{a}_m; \vec{\alpha}_m, \mathbf{Q}_m^{-1}) \tag{15}$$

where the $(S+1)L \times (S+1)L$ matrix $\mathbf{Q}_m$ is given by the Kronecker-product of $\mathbf{B}_m$ and $\mathbf{P}_m$ (i.e., block-wise multiplication of the entries $\mathbf{B}_{m,i,j}$ of $\mathbf{B}_m$ with $\mathbf{P}_m$):

$$\mathbf{Q}_m = \mathbf{B}_m \otimes \mathbf{P}_m = \begin{pmatrix} \mathbf{B}_{m,0,0}\mathbf{P}_m & \cdots & \mathbf{B}_{m,0,S}\mathbf{P}_m \\ \vdots & \ddots & \vdots \\ \mathbf{B}_{m,S,0}\mathbf{P}_m & \cdots & \mathbf{B}_{m,S,S}\mathbf{P}_m \end{pmatrix} \tag{16}$$

It is shown in Endres et al. (2011a) that the product of the Gaussian (Equation 15) with the Wishart (Equation 13) does constitute a conjugate prior on the likelihood given by Equation (12). Since the prior is conjugate, we can evaluate the marginal likelihood of the data in each segment, and BB can be applied with this observation model.

3. RESULTS

3.1. TRAJECTORY FITTING AND POLYNOMIAL ORDER DETERMINATION

To illustrate that BB is a suitable tool for the computation of compact and accurate ISL trajectory representations, we generated ISL-like trajectories with a 3rd order polynomial segment structure and evaluated if BB was able to recover this polynomial order and the segment boundaries. These trajectories were computed by fitting the original data (black lines in **Figure 3A**) with 3rd order polynomials using BB and evaluating the posterior expected trajectories (red lines in **Figure 3A**), which we will refer to as "fitted trajectories." The dotted vertical lines in this plot are the most probable segmentation points determined by BB, of which it suggests $M = 7$ boundary points with almost certainty. We determined this number by finding the maximum of Equation (11) with respect to M.

We then tested whether BB would be able to recover the polynomial order of such fitted trajectories. To this end, we ran BB on the fitted trajectories and evaluated the posterior distribution of the segment order. The result, averaged across the whole dataset, is shown in **Figure 3B**. The correct polynomial order, here 3, is recovered with near certainty.

The fitted trajectories follow the original trajectories very accurately. **Figure 3D** shows the variance explained (EV) by polynomial orders between 0 and 7. Even for 0th order fits, EV > 0.95, obtained with on average $M = 13$ bin boundaries. EV > 0.99 for orders greater than 1, and it stays in that range for all tested orders up to 7, where an average $M = 2$ are needed to fit the data.

For a quantitative evaluation of the match between the segmentation points of the fitted trajectories, and the BB segmentation points computed on these fitted trajectories, we conducted a hit rate analysis similar to Endres et al. (2011a). The results are plotted in **Figure 3C**. We obtained this plot in the following way: after computing the most probable number of segmentation point with Equation (11), say M_{opt}, we found the M_{opt} maxima of the posterior distribution of the segmentation point locations. This yielded the "predicted segmentation points" (PSP). Denote with PSP_3 the segmentation points of the fitted trajectory, and with PSP'_k the segmentation points of a k-th order BB model computed from the fitted trajectory. A PSP'_k counted as a hit if it was within an accuracy window of 90 ms of a PSP_3, and if no other PSP'_k had been matched to that PSP_3 already. All remaining PSP'_k comprised the false positives. PSP_3s without a matching PSP'_k were counted as misses. The hit rate is then computed in the usual way:

$$\text{hit rate} = \frac{\text{hits}}{\text{hits} + \text{misses}}$$

which implies that the hit rate ≤ 1. Moreover, the miss rate (or false negative rate) is just given by miss rate $= 1 -$ hit rate. Computing a false positive rate for a standard ROC analysis

$$\text{false positive rate} = \frac{\text{false positives}}{\text{false positives} + \text{true negatives}}$$

is somewhat problematic, since it requires the evaluation of the "true negatives," i.e., the number of instances where neither BB model predicts a segmentation event. This number depends on the chosen discretization: the false positive rate can be reduced almost arbitrarily by increasing the temporal resolution, since both PSP'_k and PSP_3 are (almost) point events. We therefore chose to evaluate the false positives per second, which is

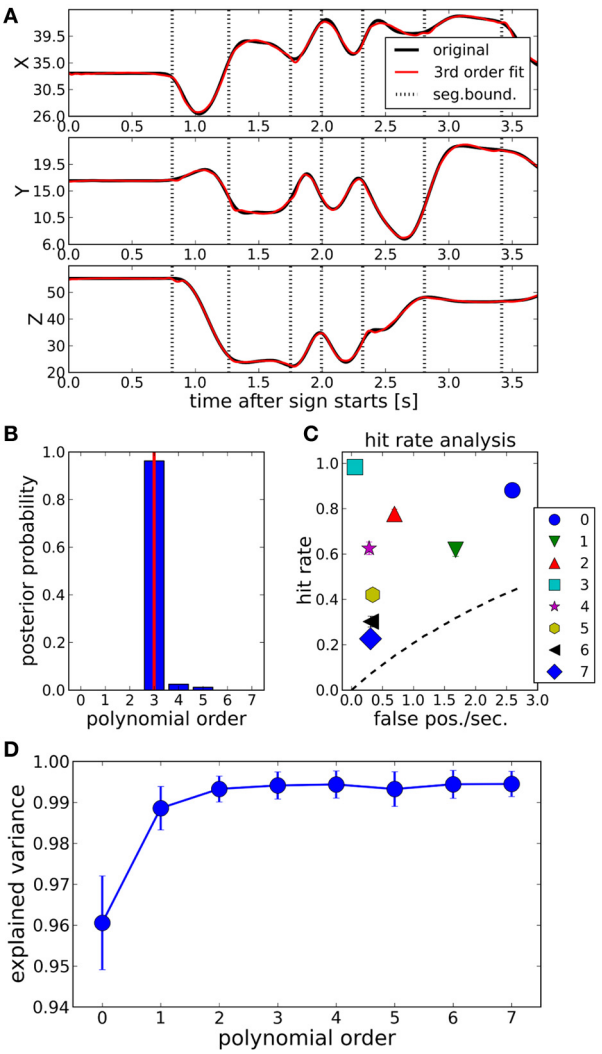

FIGURE 3 | (A) Fitting a sign language trajectory (black lines) with a 3rd order polynomial segment model (red lines). Dotted vertical lines: most probable segmentation points determined by Bayesian binning. The fit closely models the original trajectory. Explained variance averaged across the whole dataset is >99%, see **(D)**. **(B)** Posterior probability of segment order, computed by using the 3rd order fitted trajectories computed with BB [red lines in panel **(A)**] as data. The correct polynomial (3, indicated by red vertical line) order is recovered with near certainty. **(C)** Hit rate analysis for polynomial segment orders between 0 and 7, using the 3rd order fitted trajectories as data. Dashed line: line of no discrimination. At order 3, hit rate is maximal with no false positives. Error bars (standard errors of the means of hit rate and false positive rate) are smaller than the symbols. **(D)** Explained variance of the original trajectories as a function of the polynomial order of the BB fit. Error bars are ±1 standard deviation, computed across the whole dataset. All polynomial orders are able to fit the data well. For details, see text.

largely independent of the temporal resolution. As a reference, we computed a "line of no discrimination" (dashed line in **Figure 3C**) assuming a homogeneous Poisson process with rate parameter λ as a generator of uninformative segmentation events. Each setting of λ corresponds to one point on the line of no discrimination. If a given model's performance is above that line, then it can be said to provide an informative signal about the fitted trajectory segmentation points.

All polynomial orders provide an informative signal, with the 3rd order model performing optimally: it combines a very high hit rate with almost no false positives.

We performed the above analyses with fitted trajectories of orders between 1 and 7, see Appendix A1. The results are very similar to the 3rd order results presented here: the posterior distribution of the segment order peaks strongly at the order of the fitted trajectories. Moreover, the hit rates of the fitted order are near one, with almost no false positives.

3.2. POWER LAW GROUND TRUTH EVALUATION

We applied BB to the generated power law ground truth trajectories to determine whether the segments predicted by BB would match the imposed power law segments [see section 2.4]. Prior hyperparameters were $\vec{\alpha}_m = \vec{0}$, $\mathbf{B}_m = \delta(i,j) \times 0.1$, prior covariance was diagonal with the data variances as diagonal entries. We chose $T = 100$ time discretization points, and experimented with polynomial orders between 0 (constant trajectories per segment) and 7.

As shown in **Figure 4**, top panel, the posterior expectation of the trajectories follows the actual trajectory closely for all orders. However, the 0th order observation model requires a large number of segments to do so. With increasing order, the number of necessary segments decreases. Shown in **Figure 4**, lower panels, are the segmentation densities, i.e., the posterior probability densities of finding a segment boundary at a given point in time. Black dotted vertical lines indicate ground truth segmentation boundaries in all panels. The 0th order model generates many, uncertain segmentation boundaries, resulting in a large number of false positives with respect to the ground truth. The 6th order model generates too few segments, but its segment boundaries coincide with the ground truth. The 3rd order model puts boundaries close to the ground truth, without false positives in this example.

For a more quantitative performance evaluation, we conducted a hit rate analysis as described above. The results are plotted in **Figure 5**. Here, power law ground truth segmentation points (vertical dotted lines in **Figure 4**) are compared against segmentation points predicted by BB models of polynomial orders between 0 and 7. The BB segmentation points were obtained as described in section 3.1. As can be seen in **Figure 5**, most polynomial orders provide an informative signal about the ground truth. However, the lower orders generate significantly more false positives per second than the higher ones. For orders >3, the hit rate decreases without a matching decrease in the false positives. This can be seen more clearly in the hit rate per false positives per second (HPFPPS) plot in **Figure 6**, bottom panel. Let

$$\text{HPFPPS} = \frac{\text{hit rate}}{\text{false positives per second}} \tag{17}$$

The larger HPFPPS, the fewer false positives are incurred per hit, hence a large HPFPPS is desirable. In the ground truth data, it peaks at polynomial segment order 3. This peaking is

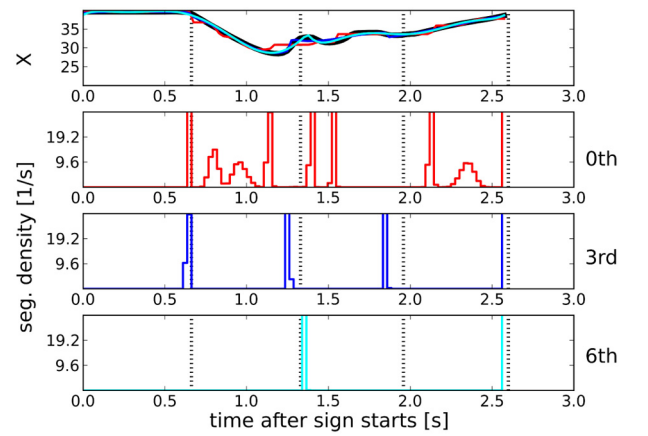

FIGURE 4 | Top panel: Trajectory of X coordinate (black line) and posterior expected trajectories for observation models of 0th (red), 3rd (blue), and 6th (cyan) order. All observation models provide a good fit. Vertical dotted black lines indicate ground truth segmentation points in all panels. **Lower panels**: Segmentation densities (i.e., probability density of segmentation boundaries) for these observation models. The 3rd order model puts boundaries close to the ground truth, with no false positives in this example.

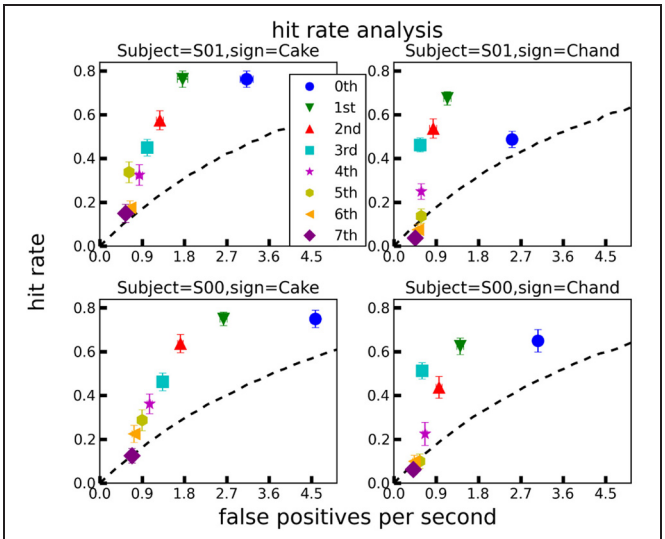

FIGURE 5 | Hit rate analyses for each sign ("cake" and "chandelier") and subject ("S00" and "S01"), for all polynomial orders between 0 and 7. A predicted segmentation point counted as a "hit" if it occurred within an accuracy window of 90 ms around a ground truth segmentation point. The lines of no discrimination (black dashed) were computed assuming a homogeneous Poisson process as a generator of uninformative segmentation events. Error bars are ±1 standard errors of the means. For details, see text.

significant (Kruskal–Wallis, $p < 10^{-7}$ for both testing order 3 vs. rest and testing all orders against each other). A polynomial order of ≈3 therefore seems a reasonable choice for these data. This observation is confirmed by the posterior distribution of the polynomial orders (**Figure 6**, top panel), which peaks at order 3 for the ground truth data.

3.3. POLYNOMIAL ORDER OF ISL TRAJECTORIES

Interestingly, the best polynomial order for the real ISL data peaks at 4, with $P(3 \leq \text{order} \leq 5) > 0.95$ (see **Figure 7**). The order of 5 corresponds to trajectories that comply with the minimum jerk principle (Flash and Hogan, 1985), which has been largely established as describing the structure of many types of natural movements (Todorov, 2004). This shows that the power law temporal structure in the real data requires higher order polynomials, suggesting that the co-articulation between consecutive power law segments is better represented by polynomial orders > 3. In other words, BB combined with a segment-wise polynomial trajectory model results in biologically reasonable segments that could be indicative of individual optimally controlled submovements. We elaborate this point further in the discussion (section 4).

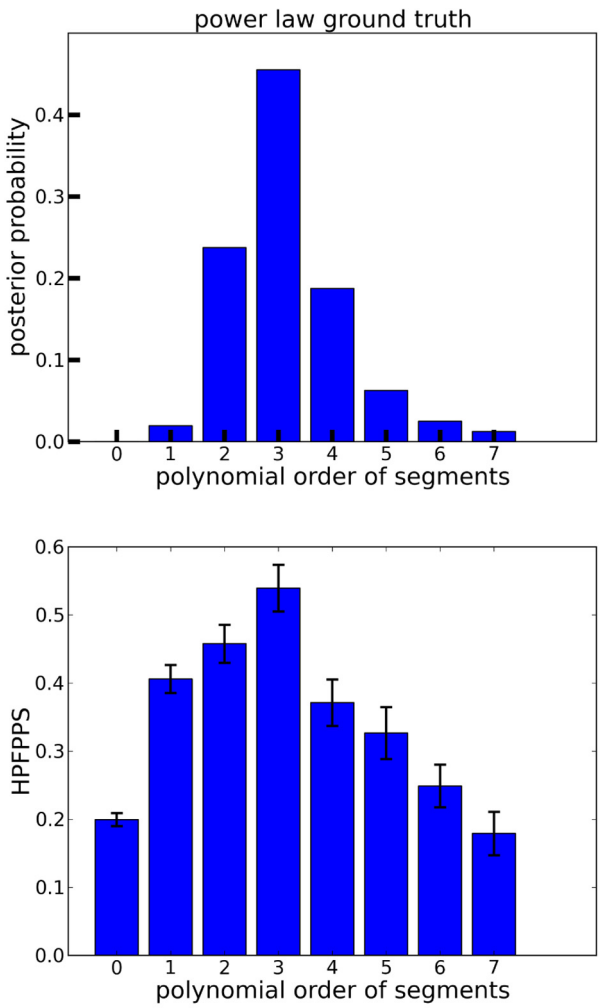

FIGURE 6 | Polynomial order evaluation of power law ground truth data. Top panel: Marginal posterior probabilities of observation models with polynomial orders between 0 and 7. Posteriors were averaged across signs and subjects. Order 3 is most probable. **Bottom panel**: Hit rate per false positives per second (HPFPPS) as a function of the polynomial order of the segments. The higher HPFPPS, the fewer false positives are incurred for each hit. Hence, a high HPFPPS is preferable. In the power law ground truth data of **Figure 5**, this quantity is maximized for order 3. Error bars are ±1 standard errors of the means.

3.4. INTERPRETATION OF SEGMENTS

We worked on single signs, so the segments discovered by BB are units on a sub-semantic level. Even within movements, like a drawing of a letter or an ellipse, there are often multiple segments that are described by different mixtures of several non-euclidian geometries (Bennequin et al., 2009; Polyakov et al., 2009a; Pham and Bennequin, 2012). Our approach aimed at estimating such invariants. Consequently, a hit rate analysis for the real data cannot be done meaningfully, because we segmented single signs and because there is no accepted method for the sequential decomposition of trajectories based on power laws. To find out the relevant segments is exactly the scientific problem in motor control research which is addressed by our Bayesian approach. We therefore created ground truth data with known segments against which the Bayesian decomposition was successfully compared. Whether these segments are related to the temporal aspects of "phonemes" of sign language (Sandler and Lillo-Martin, 2006) (phonemes are defined as the smallest, contrastive units in a spoken language) remains to be investigated.

4. DISCUSSION

We presented two novel contributions in this paper: firstly, we demonstrated the applicability of BB with piecewise polynomial observation models to motion capture data with a segment-wise

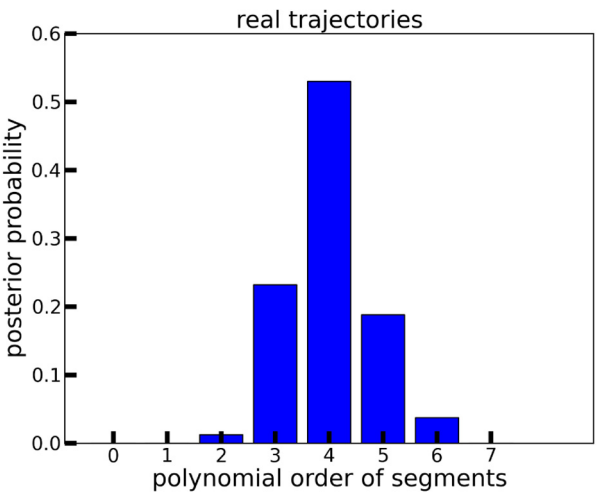

FIGURE 7 | Marginal posterior probabilities of observation models with polynomial orders between 0 and 7, computed on the real ISL trajectories. Posteriors were averaged across signs and subjects. 4th order is preferred.

power law structure. Secondly, we found that ISL wrist trajectories are best described by observation models with polynomial orders between 3 and 5.

This is compatible with established principles in motor control, like the minimum jerk and minimum acceleration principles. The study in Richardson and Flash (2002) suggested three main insights. First, among all optimization criteria whose mean squared derivative (MSD) cost functions are

$$C_n = \int_0^T \left|\left| \frac{d^n r}{dt^n} \right|\right|^2 dt,$$

the optimal trajectories that correspond to $n = 3$ (minimum jerk) provide the best kinematic fit to point-to-point reaching movements. Second, for periodic movements, the cost functions corresponding to $n = 3$ (minimum jerk—fifth order polynomials) and $n = 4$ (minimum snap—seventh order polynomials) provide reasonable predictions while optimal trajectories corresponding to the limit case $n \to \infty$ converge to the 2/3 power law. Third, earlier studies (e.g., Viviani and Cenzato, 1985) have suggested based on the two-thirds power law that complex movements should be segmented at inflection points, however, this segmentation criterion is also predicted by a path-constrained minimum jerk criterion and thus may not necessarily be a result of segmented control by the brain. It should be noted that inflection points are special cases in equi-affine geometry since at these points the equi-affine arclength vanishes faster than the Euclidean arclength [$\frac{d\sigma}{ds} \to 0$, see Flash and Handzel (2007); Bennequin et al. (2009)] from which one deduces that that the 2/3 power law breaks down at inflection points. Hence any kinematic model that is compatible with the 2/3 power law will give similar segments to those hypothesized according to the law and this explains the observations in Richardson and Flash (2002) and of Todorov and Jordan (Todorov and Jordan, 1998)—whereby both studies were using a constrained minimum jerk (as it was named by Todorov and Jordan). However, it was not *a-priori* clear whether this agreement will hold for different complex geometries and for different optimization principles. Our results indicate that the two approaches lead to compatible segmentations in a general sense. The unsupervised BB approach shows that for highly complex motor tasks, optimal MSD segments are temporally aligned with the generalized power law segments. It should be noted that MSD criteria are drawn from first principles and thus provide a predictive model while the two thirds power law was mainly studied as a descriptive model (Lacquaniti et al., 1983; Viviani and Cenzato, 1985). Nevertheless, it was found that the 2/3 power law is theoretically founded in equi-affine geometry (Pollick and Sapiro, 1996; Flash and Handzel, 2007; Bennequin et al., 2009). From this we hypothesize that the power law modulation is a possible outcome of an optimization procedure that takes into account different MSD criteria such as minimum acceleration, minimum jerk and minimum snap models.

Another implication is related to the distribution of polynomial orders found in the power law ground truth kinematics vs. that of the original kinematics. The kinematics in the ground truth dataset was implemented by introducing a perfect power law segmentation that respects the timing in the original data in a segment-wise manner and maintains continuity at the boundaries of segments. The original kinematics may differ from the ground truth in the parameters of the natural power law regularities and the transitions between segments which may be comprised of both co-articulatory movement and movement kinematics not adhering to the power law. The latter is more probably capturing the differences between the two datasets. We therefore hypothesize that the differences in the distribution of the polynomial orders found by BB for these two datasets is related to transitional movements that are less compatible with the generalized power law and require a description involving higher order polynomials. The interpretation of this result in terms of the MSD approach suggests that the minimum acceleration model (C_2) does not provide an equally good explanation for the complex co-articulatory movements in between and at the boundaries of power law segments for which jerk and snap minimizations are required.

Three methods for motion capture data segmentation are compared in Barbič et al. (2004): segment-wise PCA, probabilistic PCA (pPCA) and finite Gaussian mixture models. The pPCA methods is found to deliver the best performance compared to manual segmentation. Our 0th order polynomial segment model, due to its full covariance matrix, essentially describes each segment by a different (p)PCA decomposition. This decomposition could be extracted from the posterior covariance matrices. Hence, the 0th order model is approximately equivalent to the best method of Barbič et al. (2004). Segment positions are decided via a Mahalanobis distance criterion in Barbič et al. (2004), which is related, but not equivalent to the marginal log-likelihood of our Gaussian observation model used by BB[2]. As illustrated in **Figure 5**, our higher-order models offer a significant performance advantage over a pPCA model with constant means on the ISL data.

The authors of Polyakov et al. (2009a) found that monkey scribbling trajectories could be fitted well with parabolic pieces. Such pieces can be generated by our 2nd order segment model. We showed that higher polynomial orders are favored on both an ISL-inspired ground truth and real (human) ISL data. However, the segmentation criteria in that paper appears rather different from ours: while we use a marginal likelihood based criterion which follows from the polynomial observation model, the authors of Polyakov et al. (2009b) first extracted from the recorded data portions corresponding to active movement and others of rest. The extracted movement portions were segmented into strokes at curvature extrema. This is just one example of a wide range of segmentation approaches based on kinematic descriptors, another example is the work of Fod (2002) which uses speed features.

Hidden Markov Models (HMM) have been used extensively for both action segmentation and recognition, see e.g., Kulic et al. (2009) for a template based approach, or the switching HMM approach of Green (2003) where actions are segmented

[2]Due to the conjugate prior on the polynomial observation model, we can integrate over the likelihood before taking the logarithm, see Endres et al. (2011a) for details. The resulting marginal log-likelihood is monotonically related to a Mahalanobis distance.

into "dynemes," a kind of dynamical primitives. While dynamical primitives are in principle more invariant, and hence variation tolerant (e.g., against time-warping) than polynomial segments, they are also much harder to learn: in Green (2003), the dynemes had to be defined manually. For American Sign Language recognition, Vogler and Metaxas (1998) used a semi-supervised training scheme, which was extended to deal with two-hand signing using parallel HMMs in Vogler and Metaxas (1999, 2001). In that work, labeled and pre-segmented data were used to bootstrap the training process. In contrast, we segmented sign language based on kinematic regularities which, in order to be independent of representation or a linguistic formalism (Sandler and Lillo-Martin, 2006), must be unsupervised. Furthermore, unsupervised segmentation facilitates working with large datasets.

We conclude that BB combined with polynomial observation models represents a biologically well-inspired way for the unsupervised extraction of movement primitives from natural action streams. It remains to be investigated whether our approach is applicable to data obtained with other recording modalities, e.g., EMG, and if it yields interpretable results on forces/torques instead of positions. Instead of a polynomial observation model for (wrist) positions, one could also construct an observation model for velocities and curvatures. This would lead to a more direct power law segmentation than the approach presented here, and will be of interest for future work.

A. APPENDIX

A.1. Polynomial Order Determination for Ground Truth Orders ≠ 3

In response to a reviewer request, we repeated the analysis in section 3.1 for polynomial ground truth orders other than 3. The resulting order posteriors and hit rate analyses are depicted in **Figure A1**. For all tested ground truth orders, the BB order posterior peaks at the ground truth order, i.e., this order can be recovered with high probability. Furthermore, hit rate is near one with almost no false positives for the ground truth order only, i.e., correct segment boundaries can also be determined by BB.

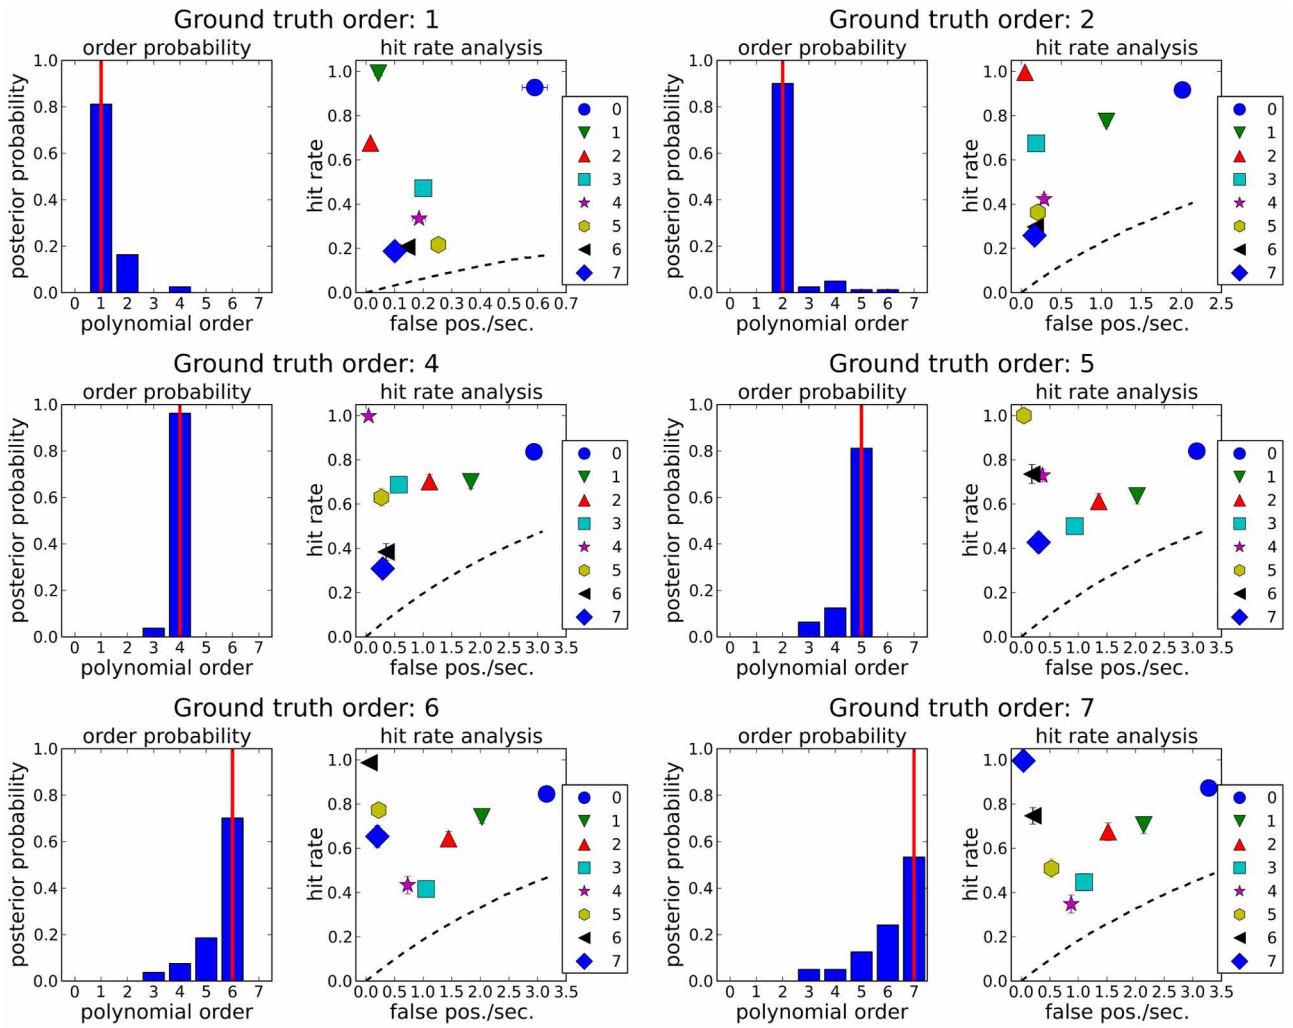

FIGURE A1 | Order posteriors and hit rate analyses for polynomial segment orders between 0 and 7, using fitted trajectories of several orders as ground truth. Vertical red lines in the order posteriors indicate ground truth order. Dashed lines in the hit rate analyses: line of no discrimination. Results for ground truth order 3 were depicted above in **Figure 3C**. Order posteriors are maximal at the respective ground truth orders, i.e., the correct order is recovered by BB with high probability. Hit rates are near one, with almost no false positives if and only if the ground truth order and BB order match. Error bars (standard errors of the means of hit rate and false positive rate) are mostly smaller than the symbols.

Given the vast complexity of human actions and interactions with objects, we proposed that control of sensorimotor behavior may utilize dynamic primitives. However, greater computational simplicity may come at the cost of reduced versatility. Evidence for primitives may be garnered by revealing such limitations. This study tested subjects performing a sequence of progressively faster discrete movements in order to "stress" the system. We hypothesized that the increasing pace would elicit a transition to rhythmic movements, assumed to be computationally and neurally more efficient. Abrupt transitions between the two types of movements would support the hypothesis that rhythmic and discrete movements are distinct primitives. Ten subjects performed planar point-to-point arm movements paced by a metronome: starting at 2 s, the metronome intervals decreased by 36 ms per cycle to 200 ms, stayed at 200 ms for several cycles, then increased by similar increments. Instructions emphasized to insert explicit stops between each movement with a duration that equaled the movement time. The experiment was performed with eyes open and closed, and with short and long metronome sounds, the latter explicitly specifying the dwell duration. Results showed that subjects matched instructed movement times but did not preserve the dwell times. Rather, they progressively reduced dwell time to zero, transitioning to continuous rhythmic movements before movement times reached their minimum. The acceleration profiles showed an abrupt change between discrete and rhythmic profiles. The loss of dwell time occurred earlier with long auditory specification, when subjects also showed evidence of predictive control. While evidence for hysteresis was weak, taken together, the results clearly indicated a transition between discrete and rhythmic movements, supporting the proposal that representation is based on primitives rather than on veridical internal models.

Keywords: discrete, rhythmic, internal models, primitives, arm movements

INTRODUCTION

E pur si muove (and yet it moves).
Galileo Galilei, June 22, 1633

One core question in motor neuroscience is how neural control interacts with the peripheral mechanics of the body: What aspects of skilled movements are controlled by the nervous system and what aspects are attributable to intrinsic limb mechanics? What does the central nervous system "know" about the dynamics of its body? Neural control of movements necessitates some internal knowledge of the limb dynamics to predict and integrate the consequences of its commands to the mechanical periphery. However, it appears unlikely that the brain can make real-time predictions based on a veridical model of detailed body dynamics, especially if that model must include the dynamics of objects to be manipulated. Neural information transmission is extremely slow, which leads to substantial communication delays. This is particularly important for fast movements, where there is no time to correct for errors, yet complicated non-linear mechanical effects such as Coriolis accelerations become prominent. Consider wielding a whip: using a veridical model to predict the mechanics of this flexible body interacting with a compressible gas (air) would tax even modern supercomputers. Using this model to find an "optimal" action to place the end of the whip at a desired location in space is vastly more challenging. Yet, humans solve this apparently intractable problem and can manipulate a whip with astonishing skill. But how? Observing the solution that humans adopt is revealing: it appears to consist of essentially two relatively simple movements, a large sweeping arm motion combined with an extremely fast (and precisely-timed) wrist "flick."

We propose that the nervous system generates complex actions by combining elements from a limited set of modules or primitives. In recent work (Hogan and Sternad, 2012, 2013) have outlined a theoretical framework proposing dynamic primitives for the control of sensorimotor behavior. Specifically, we argued that actions are composed of submovements, oscillations, and mechanical impedances, the latter to account for interaction with external objects. Note that these primitives are dynamic attractors giving rise to the observable movements. Submovements and oscillations in particular generate the observable discrete and rhythmic movements, respectively. This work extends previous experimental and modeling work by Sternad and colleagues that examined complex movements as a combination of discrete and rhythmic elements (Sternad et al., 2000; Sternad, 2008). Generating actions on the basis of primitives may afford more computational efficiency but, in turn, may also imply less versatility. The present experimental study probes into such limitations to test whether rhythmic and discrete movements indeed reflect distinct classes of behavior, i.e., primitives.

A few studies have provided support that discrete and rhythmic movements are mediated by different neural circuits. An fMRI study revealed significantly different cerebral activation for the two types of movements (Schaal et al., 2004). In continuous rhythmic wrist movements cerebral activation was largely confined to unilateral primary motor areas, whereas a sequence of discrete movements elicited strong additional activity in the bilateral parietal cortex and cerebellum. Subsequent behavioral results reinforced this difference. For example, Ikegami et al. (2010) showed that adaptation to altered visuomotor conditions was almost fully transferred from discrete to rhythmic performance, while there was minimal transfer in the reverse direction. Howard et al. (2011) reported that when learning reaching movements in force fields with different directions, interference between reaching in different force fields was reduced when each field was performed in either a rhythmic or discrete manner.

While these studies present intriguing differences between rhythmic and discrete performance, a stronger test for the existence of primitives would be to reveal limitations that arise when the two movements coexist. Previous experimental work by Sternad and colleagues examined movements that combined rhythmic and discrete elements in uni- and bimanual, single- and multi-joint tasks. Probing superposition of rhythmic and discrete movements at random phasing revealed that discrete displacements preferentially occurred in limited phase windows of the ongoing rhythmic movements (Sternad et al., 2000, 2002; Sternad and Dean, 2003; Wei et al., 2003). If control were based on a veridical internal model, it should be possible to superimpose or merge discrete and rhythmic movements in any task-specified way, subject only to the limitations of the musculo-skeletal system. Other evidence comes from slow movements, where the slow response of the musculo-skeletal system becomes less important. If control was based on a veridical internal model, it should be possible to perform rhythmic movements arbitrarily slowly. However, several studies indicated that repetitive movements, if performed sufficiently slowly, transition to a sequence of discrete movements (Doeringer and Hogan, 1995; Adam and Paas, 1996; Hogan et al., 1999; van der Wel et al., 2010). Further, evidence from stroke patients showed that their earliest recovered movements are "quantized," but become smoother and more continuous with recovery (Krebs et al., 1999; Rohrer et al., 2002, 2004).

The present study adopted another approach to expose limitations arising from a modular representation. Based on the reasonable assumption that fast movements have high computational and mechanical demands (more prominent velocity- and acceleration-dependent forces and time-stressed planning to compensate for them), we stressed the neuromechanical system by driving it fast. Performing a sequence of discrete point-to-point movements at an increasing frequency should challenge the central nervous system, leading to an eventual "break-down" of movement performance, either due to mechanical or computational limitations. We hypothesized that if the CNS operates on the basis of primitives, discrete movements with precisely timed starts and stops would become computationally more challenging with speed and give way to rhythmic movements as an easier way to satisfy the timing demands. Importantly, this transition should occur after the neuromuscular system had reached its mechanical limits and, ideally, within the course of a single cycle (*Hypothesis 1*).

In systems that have multiple stable states, transitions between them typically depend not only on the present state, but also on the history of states. Therefore, transitions in opposite directions may exhibit an asymmetry, usually termed hysteresis. This is particularly the case in systems that have a lag between input and output, as has been demonstrated in numerous physical systems. Importantly, this type of hysteresis has also been identified in biological systems and, specifically, in perceptual-motor systems. For example, the perception of motion direction shows hysteresis (Williams et al., 1986; Hock et al., 2005). In human locomotion the transition from walking to running typically happens at a speed greater than in the reverse direction (Thorstensson and Robertson, 1987; Hreljac, 1995; Li, 2000). We therefore hypothesized that if discrete and rhythmic movements are generated by dynamic primitives with attractor stability, then transitions between these two movements should exhibit hysteresis (*Hypothesis 2*).

To test these two hypotheses we required subjects to perform a sequence of precisely timed discrete movements in synchrony with a decreasing and, subsequently, increasing metronome interval. We used a chirp signal where, after initially constant intervals, each successive interval first decreased by a fixed amount per cycle, then was constant for several cycles, then increased again by a fixed amount per cycle, and finally remained constant. Discrete movements require explicit demarcation by a non-zero interval of dwell time (Hogan and Sternad, 2007). To emphasize starting and stopping as a task criterion, the instruction explicitly specified this dwell time to be half of the movement time. To make this instruction even more explicit, we presented not only a sequence of short auditory beeps, but also prolonged auditory stimuli that exactly specified the required dwell duration. In this way, any deviation from the instructed dwell time could not be attributed to ambiguous instruction. If movement control is based on primitives, we hypothesized that transitions from discrete to rhythmic movements would occur, even

if explicit temporal information about dwell time was available (*Hypothesis 3*).

A large body of research has examined control and adaptation of discrete reaching movements. The majority of these studies included visual control or examined visually evoked adaptations explicitly (Krakauer et al., 2000; Shabbott and Sainburg, 2009, 2010). As visual information typically predominates over proprioceptive and auditory information, visual information and visually-based error-correction processes may mask aspects of representation and may potentially bias neural or computational constraints due to primitive-based representation. To avoid such masking or biasing effects, the experiment tested performance with and without visual information. We hypothesized that the transition from discrete to rhythmic movements would occur for both visual conditions, but may be facilitated under no-vision conditions (*Hypothesis 4*).

METHODS

PARTICIPANTS

Ten volunteers participated in this experiment (31 ± 12 years old, 6 male and 4 female). Nine subjects were right-handed according to the Edinburgh handedness test, one subject was left-handed. Prior to data collection, the participants were informed about the experimental procedure and signed an informed consent form approved by MIT's Institutional Review Board.

EXPERIMENTAL APPARATUS AND DATA COLLECTION

The participant was seated in front of a table, with the sternum close to the table edge (**Figure 1**). To fixate the shoulder position, two belts tied the upper body to the back of the chair. A mark on the table was used to locate each subject in a comparable position. The marked spot was in the subject's mid-sagittal plane, 23 cm away from the edge of the table (in the anterior-posterior direction) and ∼26 cm distant from the subject's sternum. The height of the chair was adjusted to position the subject's upper arm to be ∼45° to horizontal; the forearm rested on the table. From this neutral position, the subject could perform a reaching movement forward and backward in the sagittal direction, involving both shoulder and elbow joints without reaching the limits of their workspace. The forearm was mounted on a low-friction skid that reduced the static and kinetic friction on the surface during the movements. A brace stabilized the wrist to discourage wrist joint rotation.

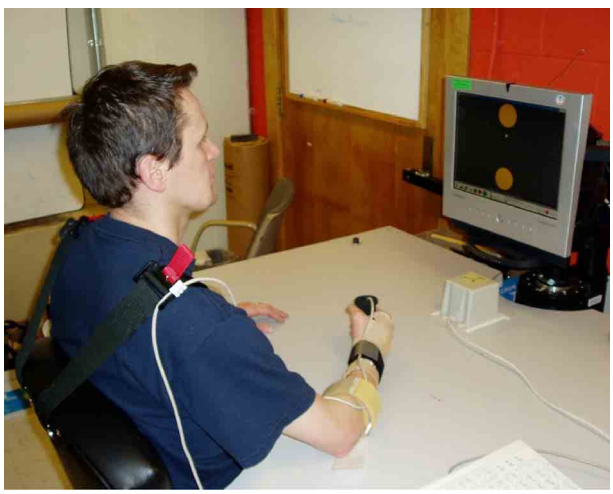

FIGURE 1 | Experimental set-up. Subject holds a handle with a magnetic sensor attached that measures and shows its position online on the monitor in front. Subject is instructed to perform discrete movements forward (away from his body) and backward (toward his body), sliding on the horizontal table surface. Movement amplitude is indicated by two large circles on the monitor.

Two circular targets were shown on a screen in a vertical arrangement to signal the amplitude of the movements (**Figure 1**). The two targets were at a distance of 14 cm from the neutral position, specifying a movement amplitude of 28 cm. The targets had a radius of 5 cm, which was relatively large so that accuracy requirements were minimal. The monitor was placed ∼65 cm in front of the subjects to display the targets and a cursor showing their movements. The display gain was 0.5, showing the targets and movement amplitude at half of their real size. The subjects were asked to move from target to target by moving the handle back and forth on the table in the sagittal direction. A computer-generated metronome signal prescribed the timing for the movements.

The subject grasped a handle onto which a magnetic Flock of Birds sensor was attached (Ascension Technologies, Burlington, VT). The static accuracy and resolution were 0.25 and 0.08 cm, respectively. The combined weight of the sensor and handle was ∼70 g, which is about 1/8 of the mass of the hand. The sampling frequency was 100 Hz. This frequency was sufficient as the frequency content of the motion was significantly below 50 Hz and anti-aliasing was not required. The position was zeroed with the handle in a neutral position shown by a mark on the tabletop. Data collection was controlled by a custom-made software routine written in Tcl on a computer running Linux Ubuntu operating system.

EXPERIMENTAL CONDITIONS AND PROCEDURE

At the beginning of each trial participants placed their hand in the neutral position. All participants used their dominant hand. They were then instructed to move between targets in synchrony with the metronome sounds. The metronome sequence took the following form for all trials: the trial began with 20 sounds separated by an interval of 2 s, presenting a constant-period signal for 40 s. Subsequently, 50 sounds were produced where each interval decreased by 36 ms, ending at an interval of 200 ms. This short period was sustained for 20 sounds, equivalent to a duration of 4 s. After this constant-period interval, another 50 sounds with an increasing interval of 36 ms followed. The trial ended with 20 sounds of 2 s duration. The total trial duration was 194 s for a sequence of 160 moves. **Figure 2** shows the sequence of periods as a function of time and also as a function of the number of metronome sounds. The figure also includes the change of inter-sound-interval as a percent of the previous inter-sound-interval to highlight that the changes were initially small, below 2%, but then grew to a maximum of 18%.

Subjects were instructed to perform point-to-point movements with an explicit dwell time to separate the movements

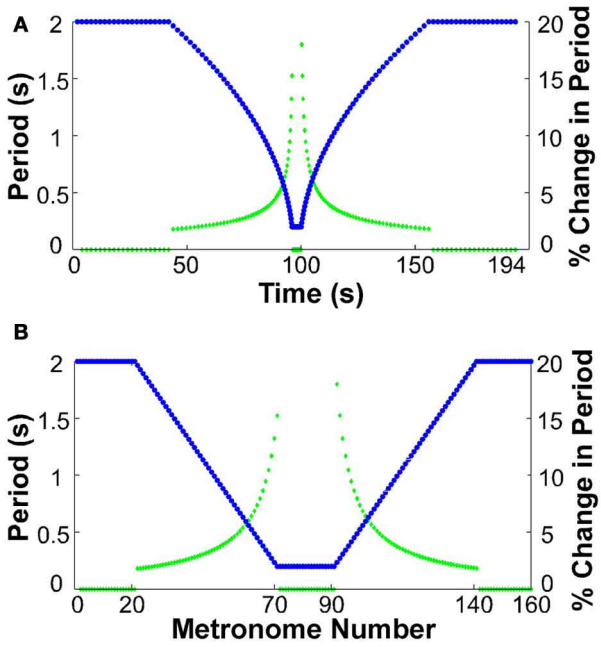

FIGURE 2 | Sequence of metronome intervals and their change in percent. (A) Intervals (blue) and their corresponding percent change (green) displayed as a function of real time. **(B)** Intervals (blue) and their corresponding percent change (green) as a function of metronome number.

into discrete movements. This dwell time should last for 50% of the metronome interval as accurately as possible. Subjects were instructed to maintain this discretization of movements for as long as possible, even when the pace increased and made the task more difficult.

This same timing sequence was presented under three different perceptual conditions. In the "vision" condition *V-short*, subjects had their eyes open and executed their movements to the displayed targets on the monitor. All metronome sounds had a duration of 50 ms, a short "beep." In the "no-vision" condition, *NV-short*, subjects were asked to close their eyes, which removed the amplitude specification; the metronome sounds were still short with a 50 ms duration. In a third condition, *NV-long*, the sound duration was longer and adjusted at each interval to last 50% of the period, giving exact auditory information about the instructed dwell duration. Subjects again kept their eyes closed to encourage focus on the auditory timing information. These three conditions were repeated twice, both times in the same sequence. Comparison of the two trials allowed a test whether the performance features changed with practice. The total duration of these six experimental trials was ∼25 min. Prior to data collection, each participant performed several moves with the metronome to familiarize him/herself with the task.

DATA REDUCTION AND ANALYSIS

Of the 3D signals from the Flock-of-Birds sensor only displacements in the sagittal direction were processed. **Figure 3** shows a complete time-series of one trial (condition *V-short*), divided into five segments due to the length of the trial. The time-series reveals the dwell times at the extreme positions in the initial and final slow-paced sections of the trial. As the pace increased, the dwell times steadily decreased and then disappeared. The dwell times reappeared with increasing metronome interval. The vertical lines denote the onset of the metronome sound; the circles mark the onset and offset of each movement.

To extract the changes of kinematics with the changing metronome pace and to identify whether a transition in control occurred, the kinematic signals were analyzed as follows. Before extracting quantitative markers, the position data were smoothed using a five-sample moving average filter, with centered filtering that did not introduce a lag (*smooth* function in Matlab®). Velocity was obtained numerically from the two-sample difference of the position signal, and was smoothed again with the same five-sample moving average filter. The acceleration signal was obtained by spline fitting and differentiation of the position signal (see below).

PARSING INTO SINGLE MOVEMENTS

For all analyses, the continuous kinematic data were parsed into single movements, delimited by t_{onset} and t_{end} (**Figure 4A**). Both onset and end of a movement were defined by the time when velocity crossed a threshold, defined as 3% of the peak velocity of the same movement. Given that all subsequent measures depended on this temporal demarcation, alternative thresholds of 1 and 5% were compared for their influence on subsequent analyses. As no significant differences were identified, we used 3% as the threshold for all subsequent analyses. Another option was to apply a fixed threshold, for example based on a threshold velocity. However, with decreasing interval and increasing velocity, a fixed threshold would favor earlier parsing. As this might have biased the calculations of dwell times (see below) in favor of our hypothesis, we chose the percent-based criterion.

This parsing analysis, however, faced a challenge when the movements merged to become approximately sinusoidal: the velocity decreased to zero but there was no longer any dwell time (**Figure 4B**). To eliminate false detections, a linear fit was applied to the velocity samples that were below the 3% threshold; the number of samples for this regression varied between 3 for fast movements up to 100 for slow movements (depending on the individual). t_{onset} and t_{end} were considered coincident when the R^2 of the linear fit was above 0.99. The sample with the lowest velocity defined the time separating adjacent movements. To test the robustness of the onset and end times, we also ran the algorithm with an R^2 cut-off of 0.95. The small differences that resulted did not have any effect on the subsequent analyses, most notably on onset and offset of dwell time.

MOVEMENT TIME, DWELL TIME, AND TOTAL MOVEMENT TIME

Movement time MT_i, dwell time DT_i, and total movement time TMT_i were defined as

$$MT_i = t_{\text{end},i} - t_{\text{onset},i}$$

$$DT_i = t_{\text{onset},i+1} - t_{\text{end},i}$$

$$TMT_i = t_{\text{onset},i+1} - t_{\text{onset},i}$$

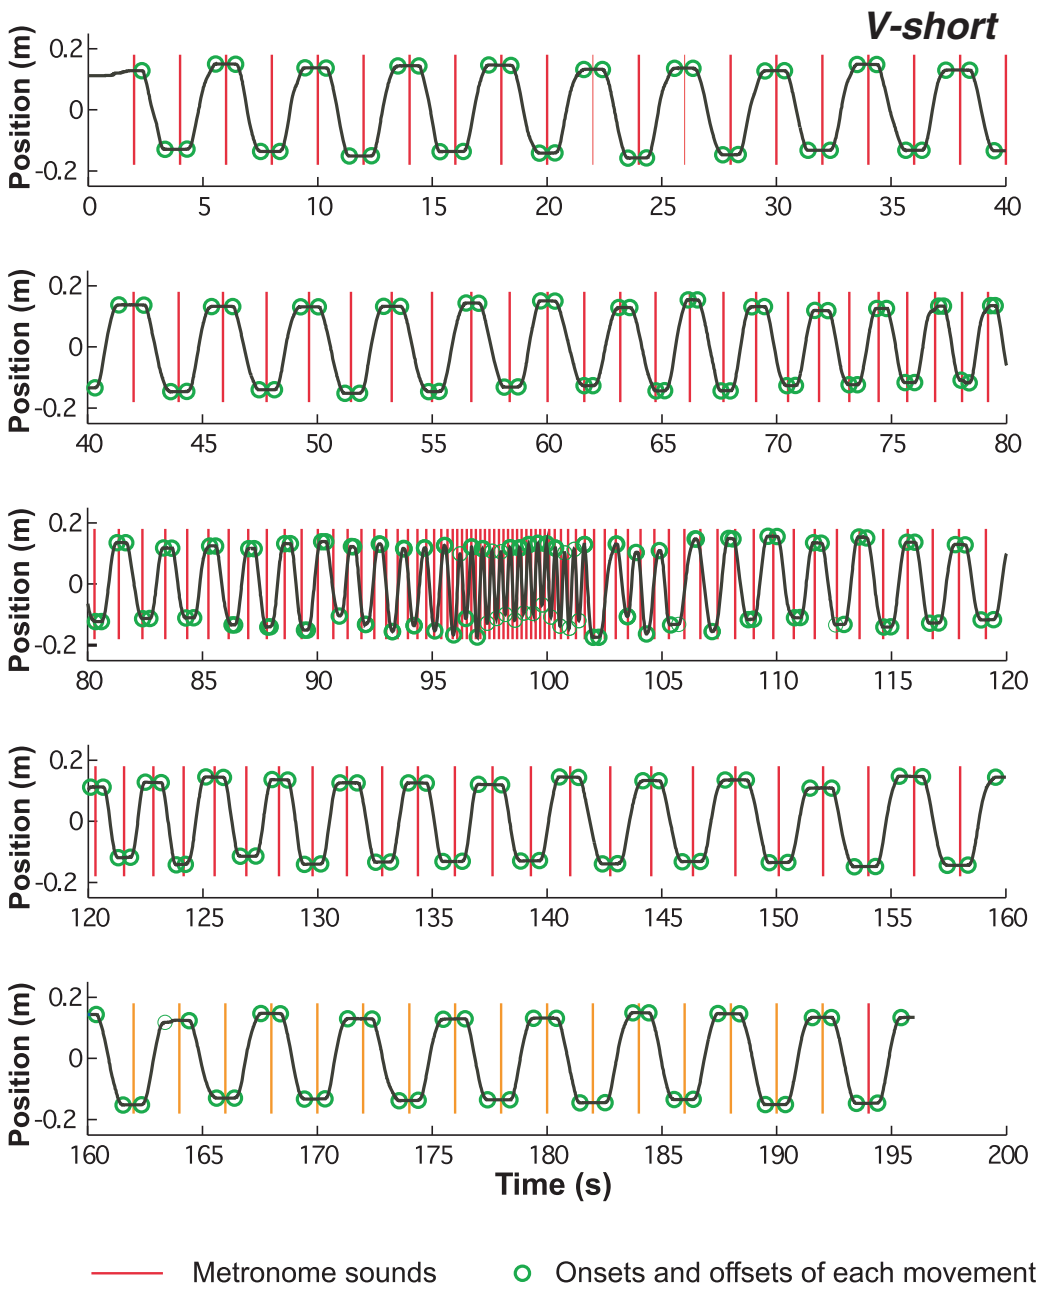

FIGURE 3 | Time series of continuous position over the entire trial of 194 s duration. Red vertical lines indicate the onset of the metronome sounds, the green circles mark the onset and offset of each movement (see methods).

where i and $i+1$ denote the movement index. The duty cycle DC_i for each movement was defined as:

$$DC_i = MT_i/(MT_i + DT_i)$$

By instruction, DC_i should be equal to 0.5; it became 1.0 when dwell time became zero.

TRANSITION BETWEEN DISCRETE AND RHYTHMIC MOVEMENTS

The criterion used to define a transition between discrete and continuous rhythmic movements was when dwell time became zero. In the accelerating portion of the trial, this time $DT = 0_{\text{Accel}}$ was defined by the movement i that had zero DT and was followed by at least two more movements with zero DT. Similarly, for the decelerating portion, where rhythmic movements transitioned to discrete movements, $DT = 0_{\text{Decel}}$ was defined as the

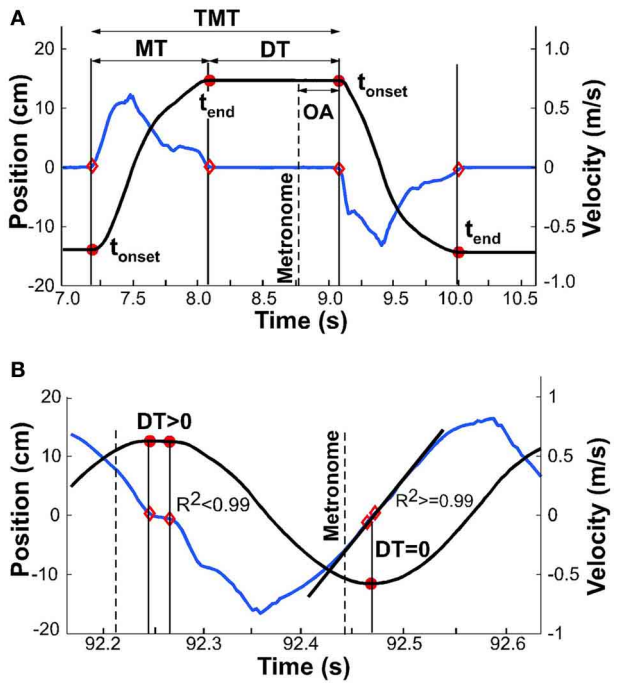

FIGURE 4 | Exemplary kinematic profiles to illustrate details of data analysis. The black line denotes position, the blue line denotes velocity. **(A)** Movement time, dwell time, and total movement time are demarcated by onset and offset times, shown by red dots. Onset asynchrony is the temporal difference between metronome onset and movement onset. **(B)** Exemplary profile where detected onset and offset are in close proximity and dwell time is greater than zero (first segment of profile); onset and offset are identical (second segment) and dwell time is zero. Linear regression at this point yields R^2 greater than 0.99.

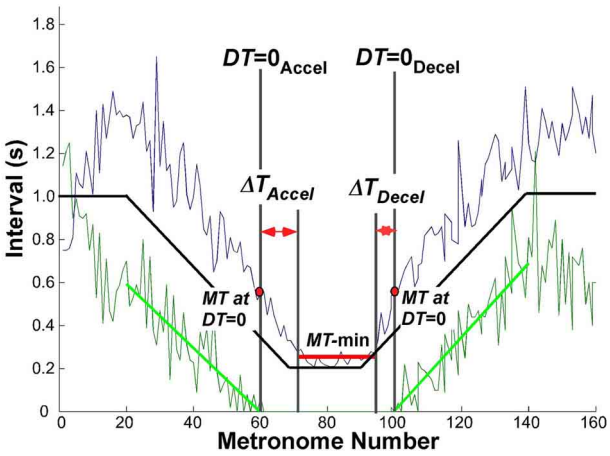

FIGURE 5 | Exemplary trial of one subject to illustrate the landmark events that were used to evaluate the transition from discrete to rhythmic movements. The black solid line represents the instructed movement time; the green data show the dwell time, the blue data denote the movement time. The green line is the linear regression of dwell time between movement number 20 (end of initial steady state interval) and $DT = 0_{\text{Accel}}$; in the decelerating portion between $DT = 0_{\text{Decel}}$ and movement number 140 (start of steady state interval).

last movement i with zero DT preceded by at least two movements with zero DT. This criterion proved to be very robust, as the onset and offset times remained unaffected by small changes in the parsing algorithm (see above). **Figure 5** shows an exemplary trial with MT and DT displayed as a function of metronome number. For statistical comparisons we examined the movement times MT and metronome numbers associated with $DT = 0$.

To evaluate the hypothesized transition from discrete to continuous rhythmic movements, it was also necessary to determine the minimum movement duration that subjects could perform, which was typically longer than the shortest metronome interval. Inspection of the data showed that the region of minimum movement duration was not coincident with the trial segment of the 200 ms metronome intervals. Hence, to obtain a robust estimate of this interval when subjects reached and left their minimum movement duration, a window was defined using the following threshold (**Figure 5**):

$$MT \leq MT_{\min} + 0.05 \times (MT_{\max} - MT_{\min})$$

where $MT_{\min}$ and $MT_{\max}$ was the absolute minimum and maximum in the same trial, respectively. Successive MTs below this threshold defined the window length, which was typically shorter than the 20 metronome sounds that defined the constant-period interval. This window is shown in **Figure 5** as a horizontal red line in the center of the trial. The mean MT in this interval was used as a robust estimate of MT-min.

These defined landmarks served to quantify the relation between $DT = 0$ and when minimum movement duration was reached. In particular, we defined ΔT_{Accel} as the interval between $DT = 0_{\text{Accel}}$ and the start of MT-min, and ΔT_{Decel} as the interval between the end of MT-min and $DT = 0_{\text{Decel}}$.

$$\Delta T_{\text{Accel}} = \text{start}(MT\text{-min}) - DT{=}0_{\text{Accel}}$$

$$\Delta T_{\text{Decel}} = DT{=}0_{\text{Decel}} - \text{end}(MT\text{-min})$$

DISCRETENESS INDEX

It was expected that with changing pace, the shape of the kinematic profile of each movement would change. To capture this modulation, a discreteness index DI was defined for each movement i based on the position and acceleration profiles (**Figure 6**). The DI was defined as the relative timing of the first peak in the acceleration profile t_{acc} with respect to the movement time:

$$DI_i = \left(t_{\text{acc},i} - t_{\text{onset},i}\right)/MT_i$$

Figures 6A,B illustrate this measure for discrete and rhythmic movements, using simulated profiles for clarity. A discrete movement DI had a non-zero value, while for the sinusoidal movement, DI was equal to zero. For reference, the DI for a cycloidal movement is 0.25. A movement that minimizes jerk has a DI of about 0.20 (Hogan, 1984). **Figures 6C,D** shows data.

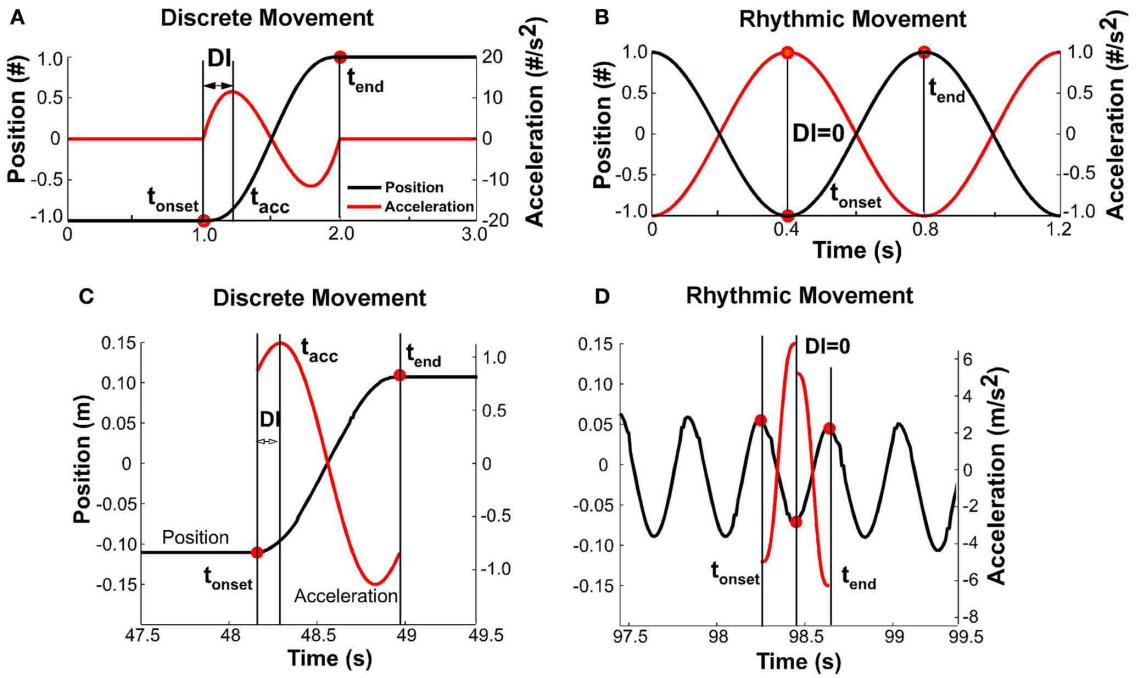

FIGURE 6 | (A) Simulated profile of a discrete movement to illustrate the definition of the discreteness index, *DI*: the interval between movement onset and time of first peak acceleration divided by the total movement time. **(B)** Simulated profile of a rhythmic movement; the discreteness index is zero as the interval between movement onset and peak acceleration is zero. **(C)** Data profile of a slow movement where the position signal was approximated by a quintic spline and the acceleration profile was the double-differentiated signal. The movement has clearly demarcated dwell times and is discrete. **(D)** Data profile for a fast movement that was determined to be continuously rhythmic.

As acceleration is notoriously noisy, the position signal of each movement (in the interval between onset and offset, not considering dwell time) was approximated via a quintic spline. The second derivative of the spline served as the acceleration profile needed for the calculation of the discreteness index. As the figure for the fast rhythmic movement shows, the quintic spline was different for the first and second half of the movement. Importantly, though, the DI was zero.

ONSET ASYNCHRONY

To quantify how movements were synchronized with the metronome sounds, a measure of onset asynchrony was defined as the temporal difference between each movement's onset and the corresponding metronome sound's onset (**Figure 4A**):

$$OA_i = t_{\text{onset},i} - t_{\text{metronome},i}$$

Positive numbers indicated that the movement onset lagged the onset of the metronome sound. Determining this difference needed care as in the faster portions of the trial subjects occasionally skipped cycles. To avoid erroneous matching yielding onset asynchronies longer than a cycle, the algorithm matched the metronome and movement times with increasing time for the first accelerating part of the trial; for the second decelerating part of the trial, the algorithm started at the end of the trial and worked backwards to determine correspondence between metronome and movement times.

STATISTICAL ANALYSES

Comparison of the different measures in the three conditions was performed using two-way analysis of variance, with condition and trial as fixed factors and subjects as random factor. If variables of the accelerating and decelerating portion were compared, a three-way 3 (condition) $\times$ 2 (Accel, Decel) $\times$ 2 (trial) ANOVA was conducted. If different segments of the same trial were compared, a 3 (condition) $\times$ 2 (segment) $\times$ 2 (trial) ANOVA was used. Student *t*-tests were used to compare time estimates with metronome times. The significance level was always set at $\alpha = 0.05$.

RESULTS

An exemplary time series of one subject in condition *V-short* is shown in **Figure 3**. The figure shows that in the first and last portion of the trial dwell times at the position extrema demarcating discrete movements were pronounced, but these plateaus decreased and eventually merged at ~90 s into the trial. They reappeared at approximately at 115 s in the trial. Movements appeared to be synchronized with the metronome, although strict synchronization between metronome sounds and movement peaks was lost during the short interval section in the center of the trial. In fact, almost all subjects skipped or even inserted cycles in the fast portion of the trial. In 22 out of 60 trials the number of cycles did not correspond to the metronome-specified number. However, the occurrence did not show any systematic dependency on the task condition. Supported by spontaneous

comments of the subjects following the experiment, the fast movements were very difficult to perform and synchronization with the metronome could no longer be sustained.

Movement amplitudes were relatively invariant in the slower portions of the trial following the visual targets but became more variable and smaller when the movements became fast. As is to be expected, the decrease in amplitude in the short-interval section was more significant in the no-vision conditions. This corroborated that maintaining synchrony with the metronome was indeed taxing as intended and subjects compromised amplitude to facilitate the increasingly faster timing.

SYNCHRONIZATION WITH METRONOME

To evaluate whether subjects followed the task instructions and produced the movement times as specified, **Figure 7** presents the total movement time, *TMT*, defined as the temporal difference between two consecutive movement onsets, plotted for each movement and for all subjects in condition *V-short*. The green band is an envelope around the instructed intervals with a width of ±350 ms that encompassed 99% of all values. The results are displayed as a function of metronome number. This convention avoided inconsistent plotting across individuals when movement cycles were skipped, which happened frequently during the short-interval section of the trial.

To test the subjects' synchronization to the instructed time, *TMT* was regressed against the metronome interval. For perfect synchronization, the slope of this regression should be the identity line. For all 10 subjects in all three conditions the mean slope was 0.98 ± 0.025 (one standard deviation), with R^2-values ranging between 0.89 and 0.99. There was no significant difference between the three conditions. Hence, it can be concluded that overall, subjects maintained synchronization with the metronome.

DISCRETE MOVEMENTS AND DWELL TIME

To assess whether subjects satisfied the task instructions and produced discrete movements separated by dwell times, the TMT was split into its component times, dwell time *DT*, and movement time *MT*. **Figure 8** shows one subject's data in the three conditions (first trial), with *DT* in green, *MT* in blue, and the duty cycle *DC* in red; the black line represents the metronome-specified movement interval. As is clear from the duty cycle, the instructed dwell time was not always achieved, neither in the steady state portions of the trial, nor in the accelerating and decelerating portions. This subject did not display a duty cycle of 1.0 in the beginning of conditions *NV-short* and *NV-long*. Other subjects showed similar deviations in this part of the trial but no systematic pattern or dependency on condition could be identified.

When the movement intervals changed after movement number 20, the duty cycle was not maintained for long. Following a steady decrease, dwell time *DT* vanished at about metronome number 60 in the decelerating portion of the trial. In the accelerating portion of the trial, *DT* re-appeared approximately at metronome number 100, followed by a declining duty cycle. **Figure 9** summarizes these observations for the condition *V-short*. The figure shows the average of all 10 subjects; the shaded error bands represent ± one standard deviation across subjects.

The important observation in **Figures 8**, **9** is that dwell times vanished before movement durations had reached their minimum in the center portion of the trial; in the accelerating portion of the trial, dwell times re-appeared after movement time had already increased. According to the task instructions, dwell times should have declined continuously proportional to movement duration until minimum movement time was reached. In contrast, *Hypothesis 1* predicted that discrete movements would be abandoned early in favor of computationally less demanding rhythmic movements.
