FIGURE 7 | Total movement time of all 10 subjects across trial 1 in condition *V-short*. The green band illustrates the instructed movement time with an envelope of ±350 ms that includes 99% of all data.

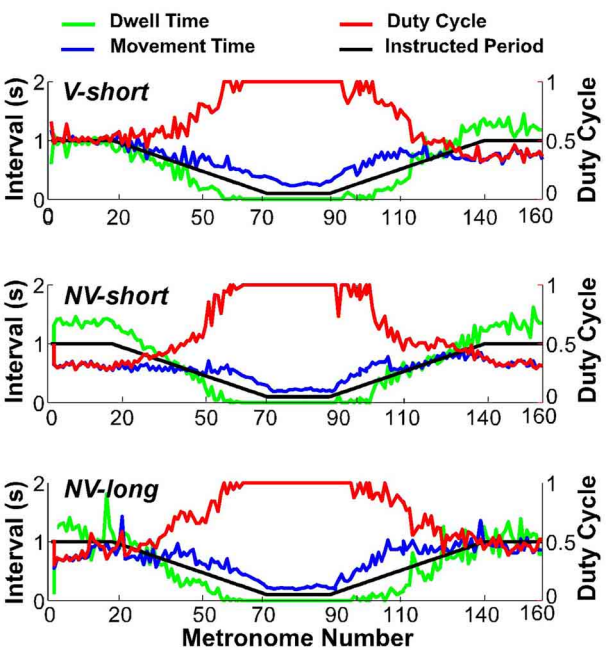

FIGURE 8 | Movement time (blue), dwell time (green), and duty cycle (red) of one representative subject in all three conditions. The black line serves as reference denoting the instructed interval.

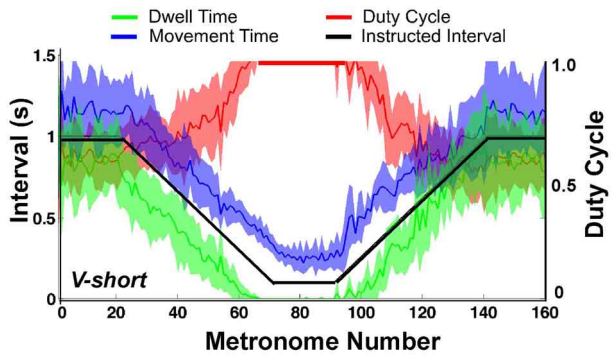

FIGURE 9 | Movement time (blue), dwell time (green), and duty cycle (red) averaged over all subjects. The black line represents the instructed interval. The shaded areas around movement time, dwell time, and duty cycle denote ± one standard deviation around the mean of 10 subjects.

MINIMUM MOVEMENT TIME

To test *Hypothesis 1*, we first determined minimum movement time, *MT*-min, as reached in the center of the trial (see **Figure 5** and methods). All subjects' values in the three perceptual conditions were submitted to a 3 (condition) × 2 (trial) ANOVA. Results revealed that the condition *V-short* showed a significantly longer *MT*-min of 248 ms, compared to 220 and 217 ms in the no-vision conditions *NV-short* and *NV-long*, $F_{(2,\ 47)} = 5.76$, $p < 0.001$. *Post-hoc* tests showed that the 248 ms in the *V-short* condition was significantly different from the other two conditions, which did not differ from each other ($p < 0.01$). The two trials showed no significant difference. Pair-wise student *t*-tests compared *MT*-min against the instructed movement interval of 200 ms and detected a significant difference for all subjects in all three conditions, $t_{(59)} = 4.82$, $p < 0.0001$. This result again corroborated that, as intended, subjects had reached their limit of movement duration in all conditions. This conclusion was further supported by the fact that this effect was not influenced by practice. The shorter times in the no-vision conditions correlated with a decrease in amplitudes. As expected from *Hypothesis 4*, subjects complied better with timing demands of the task when visual information was removed.

MOVEMENT TIME AT TRANSITION TO RHYTHMIC MOVEMENTS

We next determined the times when dwell time disappeared and reappeared in the decelerating and accelerating portions and the corresponding movement times, $MT_{DT=0}$ (see **Figure 5**). Subjecting $MT_{DT=0}$ to a 3 (condition) × 2 (Accel-Decel) × 2 (trial) ANOVA revealed a significant difference between conditions, $F_{(2,\ 80)} = 4.77$; $p < 0.01$, while there was no difference between the accelerating and decelerating segments, nor a significant difference across the two trials. Subjects performed with an average movement time of 463 and 457 ms for *V-short* and *NV-short*, respectively; for *NV-long* the average movement time was 536 ms, which was significantly longer than the other two conditions, which did not differ from each other ($p < 0.01$). These times were significantly longer than the minimum movement times ($p < 0.01$). This result supported *Hypothesis 1*. However, the symmetry in movement times between the accelerating and decelerating portions was not consistent with *Hypothesis 2*. Importantly, these results also revealed that zero dwell times started earlier in the condition with the explicit temporal information. This finding is consistent with *Hypothesis 3* predicting that explicit temporal information will not prevent a transition. In fact, the result shows that the transition occurred even earlier in the short beep conditions.

HYSTERESIS

Despite the symmetry in movement times at $DT = 0$, inspection of **Figures 8**, **9** shows that the first and second transition, i.e., start and end of the minimum movement time, *MT*-min, were slightly shifted relative to the instructed movement times or metronome indices, suggestive of hysteresis. To quantify this observation we defined the intervals between $DT = 0$ and *MT*-min in the accelerating and decelerating portions, ΔT_{Accel} and ΔT_{Decel}, for each subject (see methods and **Figure 5**). A first set of *t*-tests confirmed again that these intervals were significantly different from zero for all subjects and conditions ($p < 0.01$). Subsequently, ΔT_{Accel} and ΔT_{Decel} were subjected to a 3 (condition) × 2 (Accel-Decel) × 2 (trial) ANOVA. Results showed a significant difference between the two transitions, $F_{(1,\ 76)} = 24.77$, $p < 0.0001$, but no differences between the three perceptual conditions, nor between the two trials. Dwell time vanished on average 11 movements before the minimum movement time was reached; in the decelerating portion movement time *MT* increased on average 7 movements before dwell time *DT* re-appeared. This asymmetry is consistent with a hysteresis effect as predicted by *Hypothesis 2*. The persistence of fast rhythmic movements after metronome intervals had increased lasted ∼2.8 s, which is relatively long and makes a mechanical cause improbable.

DISCRETENESS INDEX

To further identify the hypothesized transition we examined changes in the continuous movement kinematics in terms of the discreteness index *DI*; this index quantified the shape in the bell-shaped velocity profile of each movement. **Figures 10A–C** shows the *DI* for all subjects in the three perceptual conditions. As can be seen, *DI* changed rapidly near movement number 60 and again at 100 in a similar fashion for all three conditions. **Figure 10D** shows an exemplary single subject's trial in the *V-short* condition to further illustrate the abrupt change in *DI*. For statistical analysis, the trial was parsed into three segments: before $DT = 0_{\text{Accel}}$, the center portion, and after $DT = 0_{\text{Decel}}$. This individual's *DI* values were 0.13 in first and last segments, with a drop to 0.05 in the middle segment. A 3 (segment) × 3 (condition) × 2 (trial) ANOVA on all subjects' data identified significant differences across segments, $F_{(2,\ 76)} = 431.42$, $p < 0.0001$. There was no main effect or interactions for the perceptual conditions and trials. The average *DI* across the three conditions was 0.13 before $DT = 0_{\text{Accel}}$, 0.04 in the center portion, and 0.14 after $DT = 0_{\text{Decel}}$, similar to the exemplary subject in **Figure 10D**. This measure captured changes in each trajectory and revealed a relatively abrupt transition from discrete to rhythmic movement control strategies, consistent with *Hypothesis 1*.

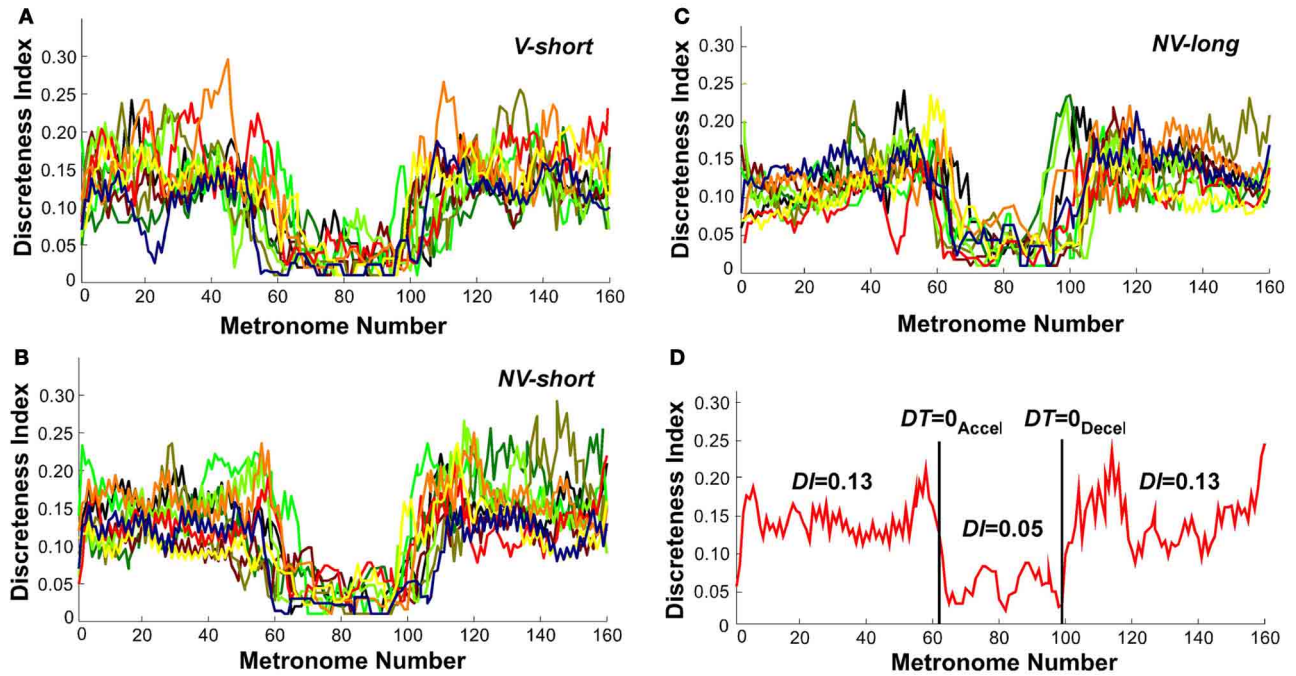

FIGURE 10 | Discreteness index values of all subjects across metronome number. (A–C) All subjects' values in the three perceptual conditions. **(D)** A single subject's trial; the vertical lines show the trial segmentation delineated by the time when dwell time is zero. The discreteness indices *DI* calculated for the three segments are shown.

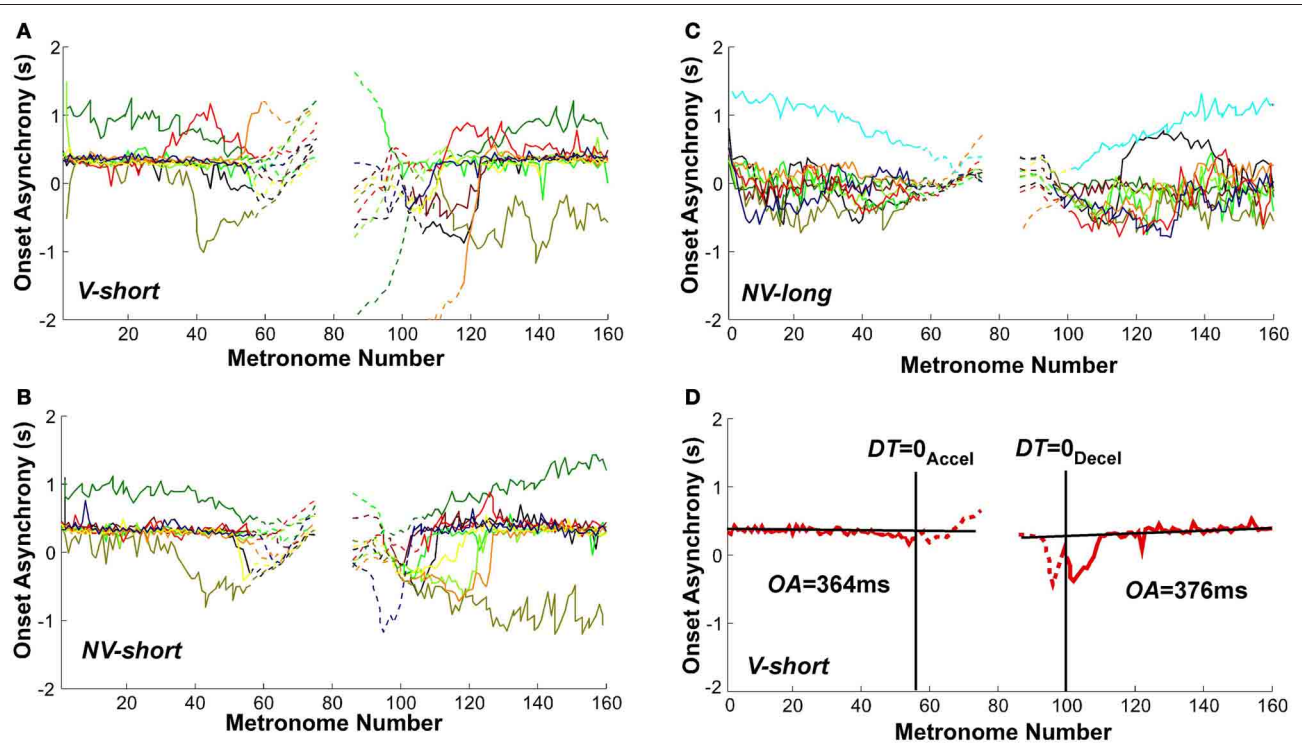

FIGURE 11 | Onset asynchrony values of all subjects across metronome number. (A–C) All subjects' values in the three perceptual conditions. **(D)** A single subject's trial with line fits. The linear regressions were performed over the intervals 0–40 and 120–160 of metronome numbers. The red lines are dashed after $DT = 0_{\text{Accel}}$ and before $DT = 0_{\text{Decel}}$.

ONSET ASYNCHRONY

Given that the task required synchronization with a metronome, the synchrony of movement onset with the auditory stimulus was analyzed to assess entrainment and predictive control. **Figures 11A–C** shows the sequence of onset asynchronies, the difference between movement and metronome onset. The data from all individual subjects in all three conditions showed that there was considerable variability across subjects. Despite this inter-individual variability, the majority of subjects exhibited a relatively constant onset asynchrony *OA* from the trial start until movement numbers 50–60, which lasted well beyond the initial long-interval section. Similarly, the second part of the trial showed relatively constant values of *OA* for the last 40–50 movements. The *OA* values after $DT = 0_{\mathrm{Accel}}$ and before $DT = 0_{\mathrm{Decel}}$ are shown as dashed lines. To highlight these observations, **Figure 11D** shows *OA* values in a single subject's trial in the *V-short* condition. The straight black lines were obtained from linear regression over the first 40 and last 40 *OA* estimates in each trial. As the slopes did not differ from zero in all conditions, we used the mean values to estimate representative onset asynchrony for the accelerating and decelerating segment and condition.

A 3 (condition) $\times$ 2 (segment) $\times$ 2 (trial) ANOVA identified a main effect for condition, $F_{(2,\ 106)} = 6.755$, $p < 0.002$, and a main effect for segment, $F_{(1,\ 91)} = 5.97$, $p < 0.05$. There were no other main effects or interactions. In the two conditions with the short metronome sound, *V-short* and *NV-short*, subjects showed an onset asynchrony of 536 and 399 ms; in *NV-long* it was only 129 ms, which was significantly different from the other two, as shown in *post-hoc* tests ($p < 0.01$). The delayed onset of the discrete movement in the two conditions with the short metronome sounds indicates reactive responses to the auditory stimulus, while the shorter onset asynchrony suggests some degree of predictive control. The long reaction times also suggest that the movements were complex and demanded substantial neural resources. The mean onset asynchronies in the first and second segment of the trials were 469 and 240 ms, respectively. Even though this difference between the two segments does not directly test hysteresis, it may still be consistent with the hysteresis effect shown above (*Hypothesis 2*). Summarizing, explicit auditory timing information apparently elicited predictive control.

DISCUSSION

This study attempted to test whether movement control is based on a small set of dynamic primitives, specifically submovements and oscillations that underlie observable discrete and rhythmic movements. We hypothesized that coordination based on primitives is computationally less demanding. However, representation in the form of dynamic primitives may also limit the versatility of coordinated movements that can be performed. One such limitation may be the speed with which a sequence of discrete movements can be executed. If rhythmic primitives are less demanding of neural resources then, when stressed by requiring rapid action, the system may merge a sequence of discrete movements into a continuous rhythmic movement.

TRANSITIONS ARE NOT DUE TO LIMITATIONS OF THE MOTOR PERIPHERY

The findings unambiguously demonstrated a switch from the instructed discrete movements to continuous rhythmic performance as TMT was reduced and another switch back to discrete movements as TMT increased again. This could not be attributed to limitations of the peripheral neuro-musculo-skeletal system. Despite the fact that subjects matched their TMTs to the metronome interval, they did not preserve the instructed dwell times, but progressively reduced them. The movement times at which dwell times disappeared were significantly longer than the minimum movement time achieved.

This alone might be attributed to a limited peripheral response speed or bandwidth, because, for a given metronome interval, a movement with dwell time has higher frequency components than a movement without dwell. Stated in the time domain, a movement with infinitesimal dwell time has larger accelerations than a smoothly rhythmic movement (Hogan and Sternad, 2007). However, changing the sensory condition significantly affected the movement duration at which dwell times disappeared—536 ms for *NV-long* vs. 463 and 457 ms for *V-short* and *NV-short*, respectively. In the *NV-long* condition, the passage to zero dwell time cannot be attributed to limited peripheral response speed, because subjects were demonstrably capable of faster movements with non-zero dwell times.

In addition, in all subjects and conditions, the discreteness index showed an abrupt change around metronome number 60 and 100. It dropped rapidly to zero approximately coincident with dwell time reaching zero as TMT decreased; it recovered rapidly from zero approximately coincident with dwell time increasing from zero as TMT increased again. Both of these observations are as predicted by *Hypothesis 1*. Discrete movements with precisely timed starts and stops require more neural resources than smoothly rhythmic movements (Schaal et al., 2004). As available movement time decreased, the increasing demand on neural resources evoked a switch to the neurally simpler rhythmic movements. Once available movement time increased again, the more challenging discrete movements were reinstated.

WEAK SIGNS OF HYSTERESIS

A common phenomenon in systems with more than one stable state is that transitions between these stable states may display hysteresis: transitions in one direction occur at different parameter values than in the reverse direction. To test *Hypothesis 2*, the experiment included accelerating and decelerating portions that induced transitions from discrete to rhythmic movements and back from rhythmic to discrete movements, respectively. However, the TMT when dwell time reached zero as metronome intervals decreased was not significantly different from the TMT when dwell time increased from zero as metronome intervals increased again. This result is not consistent with *Hypothesis 2*.

Nevertheless, some asymmetry in the transitions was evident. The fastest (rhythmic) movements persisted for several seconds (2.8 s on average) after the metronome intervals began

to increase again. This was followed by a faster rate of increase of movement time and dwell time with metronome number than their rate of decrease during the accelerating portion of the trial. The exact origin of this phenomenon requires further investigation.

EXPLICIT AUDITORY INFORMATION PROMOTED RHYTHMIC MOVEMENTS

One condition was included that presented explicit auditory information about the dwell duration in order to test whether this would guide subjects to produce the required dwell time. *Hypothesis 3* stated that explicit auditory information about dwell duration should not be able to prevent the transition between the two primitives: transitions should occur when the neural system was challenged and induced to resort to simpler solutions. Indeed, as predicted, auditory specification of dwell times did not facilitate the discrete movements and the weak hysteresis effect in the decelerating portion was unaffected by the different auditory conditions. However, there was one effect of prolonged auditory stimuli that was counter to expectations: when the metronome sounds were longer, subjects switched to rhythmic movements *earlier* and switched back to discrete movements *later* than in the short metronome conditions. This effect may be due to the fact that "filling" half of the time interval with sound made the auditory signal appear more periodic: sound and no-sound alternated periodically. The more rhythmic nature of the signal may have entrained the movement and induced rhythmic behavior.

The different auditory stimuli produced one additional effect. The two conditions with the short sound revealed a considerable delay between metronome to movement onset, 536 and 399 ms, that clearly indicated a reactive response. This is not surprising as the intervals of 2 s in the beginning and end of the trial were longer than humans can temporally integrate and perceive as rhythmic (Fraisse, 1984). In contrast, in the long-beep condition the delays from metronome onset to movement onset were considerably shorter (129 ms). In this condition the silent interval was at most 1 s, alternating with 1 s of sound. This sound pattern can easily be perceived as periodic. Human subjects readily predict periodic signals and have been shown to reduce the phase lag of their responses or even exhibit phase lead (Aschersleben, 2002). This distinctive feature of responses to periodic stimuli may also account for the transitions to and from rhythmic performance at longer metronome intervals. In effect, the auditory stimulus was more readily perceived as rhythmic and may have entrained a primitive rhythmic motor behavior (Mates et al., 1994). If so, this raises the intriguing possibility that *perception* as well as action may be based on dynamic primitives.

The substantially longer delays in the *V-short* and *NV-short* conditions suggest that subjects only reacted to the metronome trigger—without any prediction. Reactive behavior during the long inter-beep intervals of 2–1.5 s is not unexpected, although the reaction times were approximately 2–3 times longer than simple auditory reaction times. Moreover, the same reaction times persisted into much shorter intervals, even though the interval changes were systematic and predictable. These long reaction times may indicate the demands of movement planning (Henry and Rogers, 1960; Sternberg et al., 1978). It would appear that simple reaching movements with a timed dwell demanded considerable neural resources.

VISUAL INFORMATION HAS NEGLIGIBLE INFLUENCE ON TRANSITIONS

We speculated in *Hypothesis 4* that visual information may mask primitive-based transitions and performance with visual information excluded may better reveal transitions due to neural or computational constraints. However, none of the transition effects showed any dependency on the presence of visual information. One possible explanation for this lack of effect could be that in the no-vision conditions, where the spatial targets were not visible, subjects may have decreased their amplitudes to maintain discrete movements longer, which could have cancelled the hypothesized effect. The only effect that depended on vision was the minimum movement time reached. In the vision condition the minimum movement time was ∼25 ms longer compared to the no-vision conditions. This difference was probably due to the fact that subject tried harder to maintain the target amplitude while when their eyes were closed they traded amplitude for timing accuracy.

SUMMARY AND CONCLUSIONS

The results are consistent with the overall hypothesis that control is based on primitives. Transitions from discrete to rhythmic movements occurred before the neuro-mechanical system had reached its maximum performance and the kinematic profiles changed rather abruptly. On the other hand, the evidence for hysteresis was weak. Interestingly, the transition from discrete to rhythmic was facilitated by long auditory metronome sounds, counter to expectations, indicating that perceptual rather than biomechanical factors influenced the transition. These results complement findings that revealed how continuous movements, if performed sufficiently slowly, decompose into chunks or submovements. Evidence for this intermittent control has been seen in healthy subjects and patients with lesions (Doeringer and Hogan, 1998; Krebs et al., 1999). In particular, slow rhythmic movements may transition to a sequence of discrete movements (Adam and Paas, 1996; van der Wel et al., 2010). Our experimental results add one more piece of evidence supporting the hypothesis that control is based on dynamic primitives.

Studies of the nature of the neural mechanisms involved in goal-directed movements tend to concentrate on the role of vision. We present here an attempt to address the mechanisms whereby an auditory input is transformed into a motor command. The spatial and temporal organization of hand movements were studied in normal human subjects as they pointed toward unseen auditory targets located in a horizontal plane in front of them. Positions and movements of the hand were measured by a six infrared camera tracking system. In one condition, we assessed the role of auditory information about target position in correcting the trajectory of the hand. To accomplish this, the duration of the target presentation was varied. In another condition, subjects received continuous auditory feedback of their hand movement while pointing to the auditory targets. Online auditory control of the direction of pointing movements was assessed by evaluating how subjects reacted to shifts in heard hand position. Localization errors were exacerbated by short duration of target presentation but not modified by auditory feedback of hand position. Long duration of target presentation gave rise to a higher level of accuracy and was accompanied by early automatic head orienting movements consistently related to target direction. These results highlight the efficiency of auditory feedback processing in online motor control and suggest that the auditory system takes advantages of dynamic changes of the acoustic cues due to changes in head orientation in order to process online motor control. How to design an informative acoustic feedback needs to be carefully studied to demonstrate that auditory feedback of the hand could assist the monitoring of movements directed at objects in auditory space.

INTRODUCTION

Interactions between the auditory and motor systems are mainly studied in the context of musical rhythm or vocal sounds perception and production (e.g., Hickok et al., 2003; Chen et al., 2009). However, hand pointing to sounds is often used to study auditory localization. It is a complex task that relies on a precise representation of auditory space that can be used for the control of directional motor output. Just like pointing to visual targets, it involves different modular neural processes since spatial information about the target position and hand position have to be combined across different senses and reference frames.

In order to address the mechanisms whereby an auditory input is transformed into a motor command, we studied online auditory control of the direction of pointing movements toward auditory sources. We first investigated whether pointing movements were more accurate when the target was present throughout the entire pointing movement than when the target disappeared shortly after the hand movement had begun.

We then added an auditory feedback of the pointing hand's position during the entire hand movement to evaluate whether human subjects could use such a feedback. This additional auditory feedback named auditory avatar (by analogy with avatars used to represent visually a part of the body of a participant in a virtual environment) was used in order to evaluate whether it would constitute stable and relevant information to guide the motor action of the user, as already suggested by recent results indicating that auditory information is used to control motor adaptation (Oscari et al., 2012). With such an auditory feedback, the auditory modality conveys supplementary sensory information that is correlated with proprioception and set in modular processes in the same spatio-temporal reference frame as the target, hence facilitating precision in the pointing task. A well-designed auditory avatar, which corresponds to a sonification transforming relevant parameters of human movement patterns into appropriate sound, could be used to enhance perception accuracy and would be useful for sensory substitution and motor training technologies.

The first auditory avatar condition was contrasted to a shifted condition where the heard hand position did not correspond to the actual hand position thus resulting in a

discrepancy between auditory and proprioceptive information. Similar methodology can be found in Forma et al. (2011), where participants were asked to point to virtual targets in a spatialized audio environment using the openAL library (interaural time and level differences based audio environment). Studying online adaptation to this sensory conflict was expected to provide further information about the contribution of auditory inputs generated by arm movements to motor control.

MATERIALS AND METHODS

SUBJECTS

Twenty-four self-reported right-handed volunteers (12 females and 12 males; 25.6 ± 6.6 years old) participated in the experiment. All were healthy and had normal hearing. The study was carried out in accordance with the Declaration of Helsinki. All subjects gave written informed consent and were paid for their time.

EXPERIMENTAL SETUP

The experiment used real-time controlled virtual audio rendering for both representing sound sources at the target positions in space and attaching sounds to the subject's right hand during the pointing movement. Audio was played back over headphones and subjects were seated in front of a table from which the auditory targets virtually originated. To prevent any visual input interference during the experiment all subjects were blindfolded.

The stimuli for target sources and the auditory avatar were (mutually uncorrelated) white Gaussian noise signals. The virtual audio targets as well as the auditory feedback of the hand position were provided with the Head-Related Transfer Functions (HRTFs) binaural technique (Wightman and Kistler, 1989a,b). Spat~, IRCAM's software for real-time sound source spatialization, was used to create the binaural signals. Binaural rendering uses HRTFs to reproduce the sound pressure at the ear entrance that corresponds to a sound source at a given position in 3-dimensional space. Processing a monophonic audio signal with a set of HRTF filters and playing these signals back over headphones creates the illusion of a virtual sound source at the corresponding position in space. The spatialization of the sounds (stimuli and hand position) was calculated in real-time through the tracking of the head's and right hand's positions and orientations using a six-camera Optitrack (by Natural Point) 3-D infrared motion capture system. To this end, two rigid sets of markers were placed on the headphones and the right-hand's forefinger. They were, respectively, composed of seven and four reflective markers tracked by the cameras. The coordinates of the hand and head's locations in space were measured and recorded with the tracking system at a sampling frequency of 100 Hz. The minimal latency of the overall system is then 10 ms, with an audio latency of 0.6 ms, which is fast enough to ensure perceptive coherence when localizing virtual sound sources (Brungart et al., 2004). The orientation of the 7-marker rigid body fixed to the headphones allowed for computing the heading direction (0° is forward, positive is to the right, see **Figure 1**). The endpoint used to measure the kinematics of the hand corresponded to the tip of the index finger.

EXPERIMENTAL PROCEDURE

The experiment lasted 1 h and was composed of pre-trials and 4 sessions. The pre-trials aimed at selecting the best-fitting HRTF from a set of several HRTFs. This best-fitting HRTF was then used to convolve the stimuli of the main experiment. Subject tested HRTFs previously selected in HRTFs fitting past experiments [see Sarlat et al. (2006) for a description of the method] plus their individual HRTFs when available, while hearing the spatialized targets. Up to four functions were tested. Approximately 10 practice trials per tested HRTF were performed in a pseudo-random order using the five targets of the experiment. Subjects were asked if they heard a spatialized sound and if so were asked to point toward its direction. The HRTFs were selected if in at least 8 trials the subjects pointed toward the correct direction (±10° approximately). The five subjects who did the pre-trials with their own HRTFs used them. The other subjects did not have individual HRTFs and used the non-individual HRTFs they selected during the pre-test.

Each session tested a different condition. In the short sound condition (named A) the auditory target was played for 250 ms before subjects pointed toward it. In the long sound condition (B) the auditory target was played for 2000 ms and subjects pointed toward it whilst hearing the auditory stimulus. Two other sessions included the auditory avatar that provided auditory feedback of the position of the hand in space. The fingertip position was dynamically tracked in real-time with the motion capture system and controlled the sound spatialization. Thus the white Gaussian noise stimulus was perceived as coming from the hand position. In these sessions the target was displayed during 250 ms and the avatar was heard constantly. In the "avatar condition" the actual hand position was heard (C), and in the "conflicting avatar condition" (D) the audio rendered hand position was shifted 18.5° left from the real hand position. Before each session, the subjects did a few trials to get used to the task demands and to the auditory feedback. The

subjects were divided into 2 groups: group 1 performed the sessions in the regular order (A-B-C-D) and group 2 in the reverse order (D-C-B-A).

At the beginning of a trial, subjects were told to put their right hand on the table in front of them near their abdomen, with the palm at a position indicated by a tactile marker, and to hold their head up right facing ahead during the experiment. The auditory sources originated from a virtual distance of 60 cm in the horizontal plane of the table centered by the tactile marker. The targets originated from five directions with azimuth angles of −35°, −20°, 0° (ahead of the subject), 20°, and 35° (right is positive). Each session contained 32 trials presented in the same pseudo-random order for each subject. Moreover, the table on which the subjects pointed was covered with a semi-circular protractor of which origin was located at the starting hand position. It enabled a measure in degrees of the pointing as subjects were asked to keep their hand still for a few seconds after pointing. After each trial the subjects put their hand back to the tactile marker. The experimental setup from the subject's viewpoint is shown in **Figure 1**.

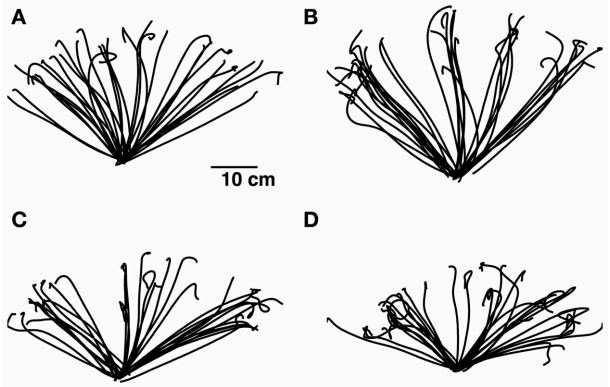

FIGURE 2 | Typical trajectories of the tracked hand for a single subject for each of the four conditions tested: short sound condition (A), long sound condition (B), avatar condition (C), and conflicting avatar condition (D). Better pointing precision and reduced overshooting is noticeable in condition **(B)**.

DATA ANALYSIS

LEVEL OF PERFORMANCE

The pointing direction was directly measured on the protractor. The level of performance is evaluated by the signed angular error, which is the difference between the target direction and the final direction pointed by the subjects. If the subject pointed to the left of the target, the error was negative, and conversely it was positive if the subject pointed to the right of the target.

MOVEMENT ANALYSIS

The raw data of hand and head positions was recorded and processed off-line for the analysis of the kinematics of hand and head movements. A semi-automatic method was designed to detect and segment each pointing gesture and eliminate the way back to the start tactile marker. A primary segmentation was performed by applying thresholds on the hand displacement along the horizontal plane (x, y). The typical trajectories projected on the horizontal plane are shown in **Figure 2** for each condition.

The second segmentation process was based on systematic movement kinetics analysis. To compute velocity, acceleration and jerk, position data was filtered with a Gaussian low-pass filter, with a cut-off frequency of 5 Hz. As the movement is captured along the 3-dimensions of space the computed values are 3-dimensional energy-related vectors: v_{3D}, a_{3D}, and j_{3D} are, respectively, the norms of the tangential velocity, acceleration and jerk vectors. The beginning and the end of movement were defined as the crossing of a threshold on v_{3D} corresponding to 3% of the peak velocity calculated on the trajectory. The "beginning" of the gesture is thus related to the energy of the movement. The typical velocity and acceleration profiles obtained for one pointing gesture are plotted on **Figure 3**.

Additionally, kinematic analysis included the following measures for hand and head movement: movement duration, peak velocity value, average velocity, acceleration peaks analysis (occurrence and position), and trajectory length in space. We counted the total number of acceleration peaks occurring before and after the maximum velocity peak of the movement (peak velocity point PVP).

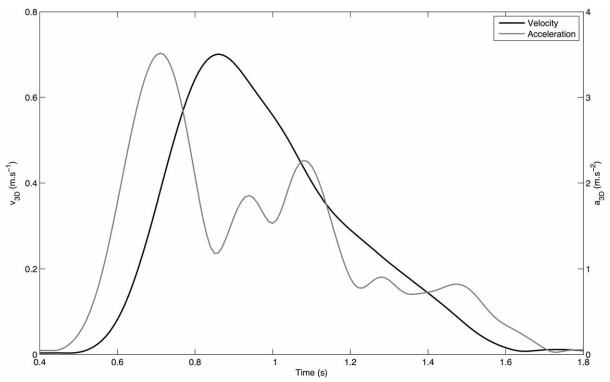

FIGURE 3 | Typical tangent velocity v3D (bold line) and a3D (gray line) profiles of a pointing movement.

In order to investigate the possible role of the head in sound localization before and during pointing to the estimated location of the source, we also measured the heading angle around the vertical axis and computed its maximum values and range of motion (ROM).

RESULTS

STATISTICAL ANALYSIS

The results of six participants were removed from the analysis based on three criteria: subjects who did not follow the instruction to point directly toward the target (the trajectory duration is more than twice the average and longer than the longer stimulus duration in the long condition), three subjects; trajectories showing no dependence on the target direction (with only two ±90° endpoints), two subjects; short trajectories (less than 10 cm) that lead to unstable angular calculations, one subject.

The dependent variables considered in our statistical analysis (ANOVA) are the averaged measures (duration, maximum velocity, average velocity etc.) over each target direction and each condition. In the statistical analysis, we considered two grouping factors. The first is the two-level HRTF factor that indicates if the subject used his own HRTF or not. The second factor is the two-level group factor that indicates the order of the presentation of the experimental conditions. We also considered two repeated-measure factors. The first one, the five-level target direction factor, corresponds to the direction of the target. The second one is the four-level condition factor indicating the experimental condition of each trial (A-B-C-D).

Statistical data analysis showed no main effect of the group factor. There was thus no effect of the order of the conditions either on the pointing performance or on the dynamical control of the gestures. There was a main effect of the individualized HRTF only on the proportion of acceleration peaks of the head after the PVP [$F_{(1,\ 16)} = 5.8$, $p < 0.05$]. However the average peak number was not significantly different between the two-levels of the HRTF factor (*post-hoc* Bonferroni test). It is important to note that the individualized HRTF factor had no effect on the measures related to hand movement. The group factor and the individualized HRTF factor will not be used further in the analysis and data will be averaged per factor.

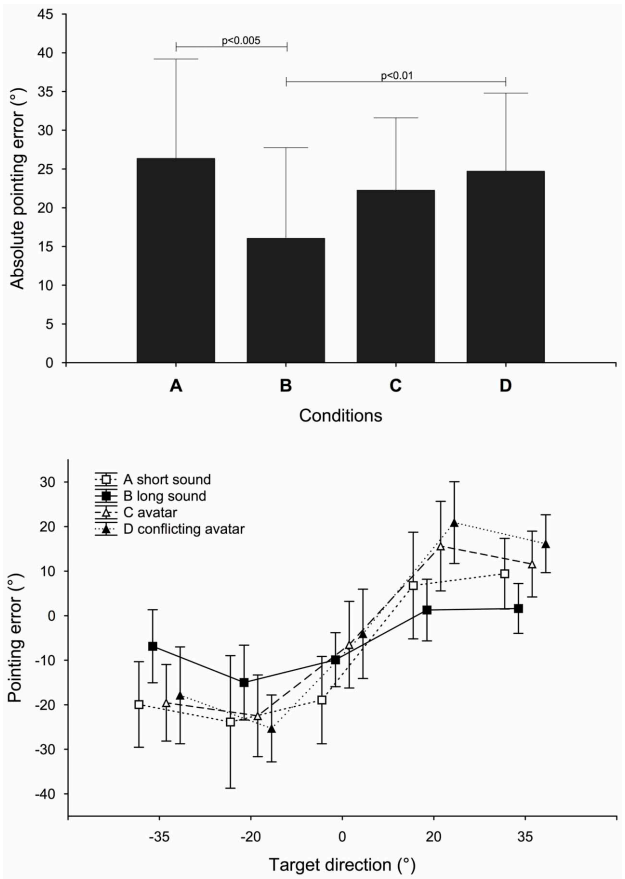

FIGURE 4 | Absolute pointing error in degrees (absolute difference between pointed direction and target direction) for each condition and signed pointing error in degrees (difference between pointed direction and target direction) for each target direction and each condition. Target direction goes from left (negative) to right (positive). A positive error indicates a pointing to the right of a target. Bars indicate 95% confidence interval.

LEVEL OF PERFORMANCE

There was a main effect of the condition factor but also of the target factor on the absolute value of the angular error [$F_{(3,\ 51)} = 6.23, p < 0.005$ and $F_{(4,\ 68)} = 5.80, p < 0.001$, respectively]. Subjects were significantly more accurate in the long sound condition B (see **Figure 4** top which shows the absolute pointing error for the different conditions and the results of the *post-hoc* Bonferroni test; error bars indicate 95% confidence interval). Furthermore, there was a significant interaction between the two factors [$F_{(12,\ 204)} = 1.91, p < 0.05$].

We also analysed the signed angular error as the sign indicates if the subjects pointed more to the left or more to the right of the target direction. There was a main effect of the condition [$F_{(3,\ 51)} = 2.84$, $p < 0.05$] and the target direction factor [$F_{(4,\ 68)} = 20.34, p < 0.0001$], and there was a significant interaction between condition and target direction factors [$F_{(12,\ 204)} = 6.13$, $p < 0.0001$]. Targets' azimuths were over-estimated by the subjects (see **Figure 4** bottom which shows the signed pointing error for target directions and among conditions tested). Left targets were pointed with negative errors, and right targets with positive errors. This overshooting was reduced in the B condition: −66%, −40%, −48%, −94%, and −90% for targets from left to right compared to the maximum errors in the other conditions. However, it is important to note that the subjects still presented a 9.8° average bias on the left when the target was presented straight ahead in the B condition.

GLOBAL KINEMATICS

The parameters associated with movement velocity were significantly influenced only by the target direction [$F_{(4,\ 68)} = 8.66, p = 0.00001$ for the duration; $F_{(4,\ 68)} = 81.59$, $p < 0.00001$ for the peak velocity and $F_{(4,\ 68)} = 72.31$, $p < 0.00001$ for the average velocity]. Peak and average velocities were significantly higher for target sounds coming from the right (i.e. for +20° and +35°): +37% for peak velocity and +31% for average velocity, *post-hoc* Bonferroni test $p < 0.0001$. The same test revealed no exploitable difference between the five target directions regarding movement duration.

The condition factor, the target direction factor and their interaction had a significant effect on the trajectory length [$F_{(3,\ 51)} = 5.47$, $p < 0.005$; $F_{(4,\ 68)} = 47.03$, $p < 0.0001$ and $F_{(12,\ 204)} = 2.58, p < 0.005$, respectively]. The analysis showed a significantly longer distance covered for targets on the right (0.473 m at +20°, 0.510 m at +35° against 0.414 for the three other targets averaged, $p < 0.005$), but also in the B condition (0.482 m against 0.432 m on average, *post-hoc* Bonferroni test $p < 0.05$; see **Figure 5**).

MOVEMENT DYNAMICS AND SEGMENTATION

The counting of acceleration peaks revealed a significant effect of condition factors [$F_{(3,\ 51)} = 3.04$, $p < 0.05$] and target direction [$F_{(4,\ 68)} = 30.93, p < 0.00001$] on the total number of peaks and

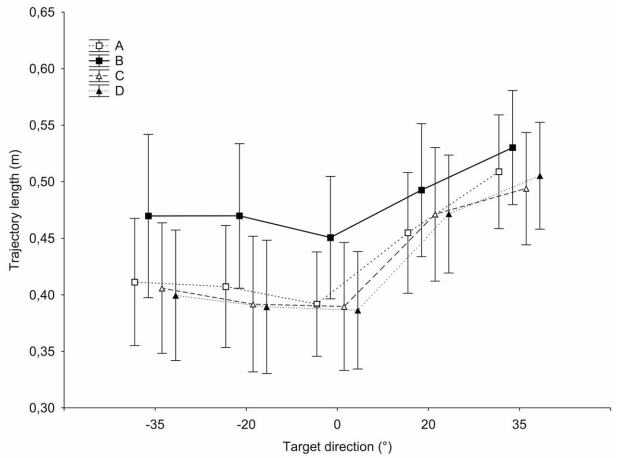

FIGURE 5 | Trajectory length in space (in meters) for each target direction and each condition. Bars indicate 95% confidence interval.

on the proportion of peaks before reaching the PVP [$F_{(3,\ 51)} = 3.34$, $p < 0.05$ and $F_{(4,\ 68)} = 36.97$, $p < 0.00001$].

In the B condition, subjects' movements presented larger total number of acceleration peaks, however, not significantly different from the other conditions (4.85 against 4.20 on average).

The number of peaks decreased as the target direction shifted to the right of the subjects (significantly for the two targets on the right, *post-hoc* Bonferroni test $p < 0.0005$: 3.89 and 3.70 against 4.73 on average). Only the target direction factor had an effect on the proportion of peaks after PVP [$F_{(4,\ 68)} = 10.68$, $p < 0.00001$] significantly different for $+20°$ and $+35°$ targets (-18% at $+20°$ and -22% at $+35°$ on average), while there was a marginally significant effect of the condition factor [$F_{(3,\ 51)} = 2.47$, $p = 0.07$].

It is noticeable that subjects produced movements with more acceleration peaks on the second "half" of the trajectory, during the deceleration phase: 1.52 before the PVP, 2.84 after on average. If taken as a factor, the proportion of peaks before or after PVP together with the condition factor shows a significantly higher increase of peaks after PVP for condition B than conditions A and C (*post-hoc* Bonferroni test $p < 0.01$).

HEAD MOVEMENT ANALYSIS

The same analysis was conducted on the head movement data. The target direction factor had a significant effect on the total number of acceleration peaks in the head movement [$F_{(4,\ 68)} = 5.75$, $p < 0.005$] with the same tendency toward right directions as for the hand (7.14 peaks for $-35°$, 6.53 for $+35°$). No significant effect was found on the proportion of acceleration peaks before PVP. After this point, both target direction and condition factors have significant effects [$F_{(4,\ 68)} = 4.97$, $p < 0.005$ and $F_{(3,\ 51)} = 6.93$, $p < 0.001$, respectively], again with the same behavior as for the hand. The B condition exhibited a significantly larger numbers of peaks after PVP ($+50\%$ for B on average, *post-hoc* Bonferroni test $p < 0.05$) than in the other conditions and the center and right targets exhibited fewer acceleration peaks (-17% on average).

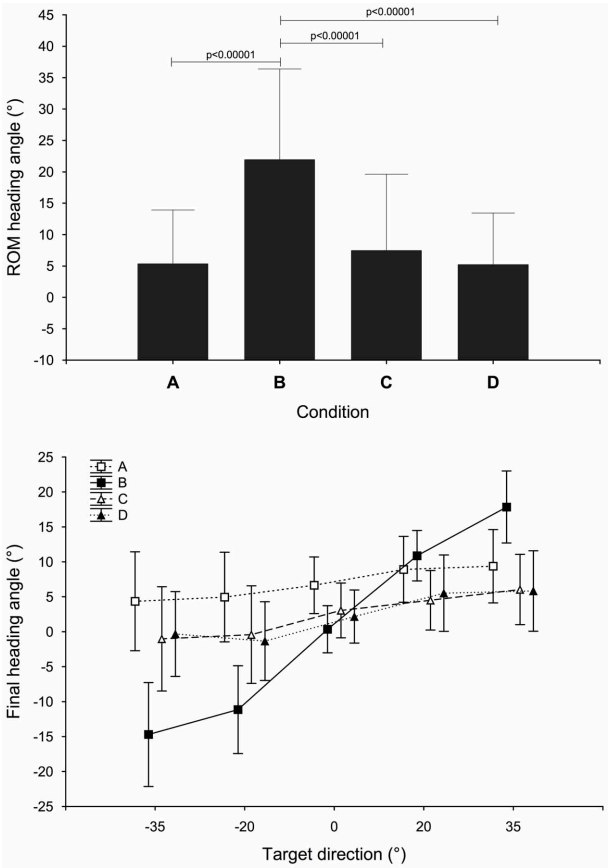

FIGURE 6 | Range of motion of the heading angle (in degrees) for each condition. Effect significance: [$F = 20.2$, $p < 0.0001$]; *post-hoc* Bonferroni test; Final heading angle (in degrees) for each target direction and each condition. Interaction effect significance: $F = 14.9$, $p < 0.00001$. Bars indicate 95% confidence interval.

Both condition and target direction factors had a significant effect on the ROM of the heading angle [$F_{(3,\ 51)} = 20.2$, $p < 0.0001$; $F_{(4,\ 68)} = 3.93$, $p < 0.01$ respectively] and there is a significant interaction between the two factors [$F_{(12,\ 204)} = 2.40$, $p < 0.01$]. The ROM of the heading angle was significantly higher in the B condition than in the other conditions (21.9° against 5.31°, 7.42° and 5.17° for A, C, and D conditions, *post-hoc* Bonferroni test), as shown in top **Figure 6**. No significant difference was found among the target directions but the ROM increased with the target eccentricity ($+45\%$ on the left, $+23\%$ on the right on average compared to 0° target).

In order to investigate the potential link between target direction and head rotation for localization when pointing we analysed the distribution of the heading angles at the end of the movement. As for the ROM, the condition factor, target factor and their interaction had an effect on the angle [$F_{(3,\ 51)} = 5.07$, $p < 0.005$; $F_{(4,\ 68)} = 9.17$, $p = 0.00001$ and $F_{(12,\ 204)} = 14.9$, $p < 0.00001$ respectively]. Significant differences were found for the two right targets compared to left targets ($p < 0.01$); the subjects turned their head toward the correct hemisphere corresponding to the target direction. When coupling the effect of the condition and

the target direction, we found that this behavior was prevailing under condition B (see **Figure 6** bottom). The two graphs on **Figure 6** show that subjects moved their head more under condition B and in the direction of the target. The bias for 0° target is also reduced under this condition: 0.30° compared to 6.66° for A, 3.06° for C, and 2.18 for D.

The analysis of the relative position of the PVP along the movement of the hand and the heading angle shows that subjects tended to initiate the movement of their head before the pointing movement. The distribution of these relative positions is shown in **Figure 7** for every trial over every subject in each condition. On average, 43% of the gestures exhibited heading peak velocity between the beginning and the first third of the movement completion against 12% only for the hand. The tendency is observed in all the conditions and in spite of the large differences in ROM of heading and final angle between conditions.

DISCUSSION AND CONCLUSION

In this study, we attempted to address the mechanisms whereby an auditory input is transformed into a motor command. First, we aimed at assessing the role of auditory information about target position in correcting the trajectory of the hand by varying the duration of the target presentation. Second, we attempted to evaluate whether human subjects could use an auditory feedback about their hand position and how they would react to shifts in this avatar of their heard hand position.

Only the long sound target condition exhibited a higher level of performance of the subjects. This strong effect is comparable to the one obtained during pointing movements toward visual targets present throughout the entire pointing movement (Prablanc et al., 1986). In the present study, the target is presented during the whole movement only in the long sound duration condition (B). In the short sound duration condition, the location of the target needs to be memorized and it is possible that a shorter sound would lead to a less precise or reliable representation of the target. Errors in pointing to remembered targets presented visually have been shown to depend on delay between target offset and pointing (McIntyre et al., 1998). Therefore, the neural processes involved in coding the target in a motor-related or body-related reference frame from its auditory spatial trace seem to require

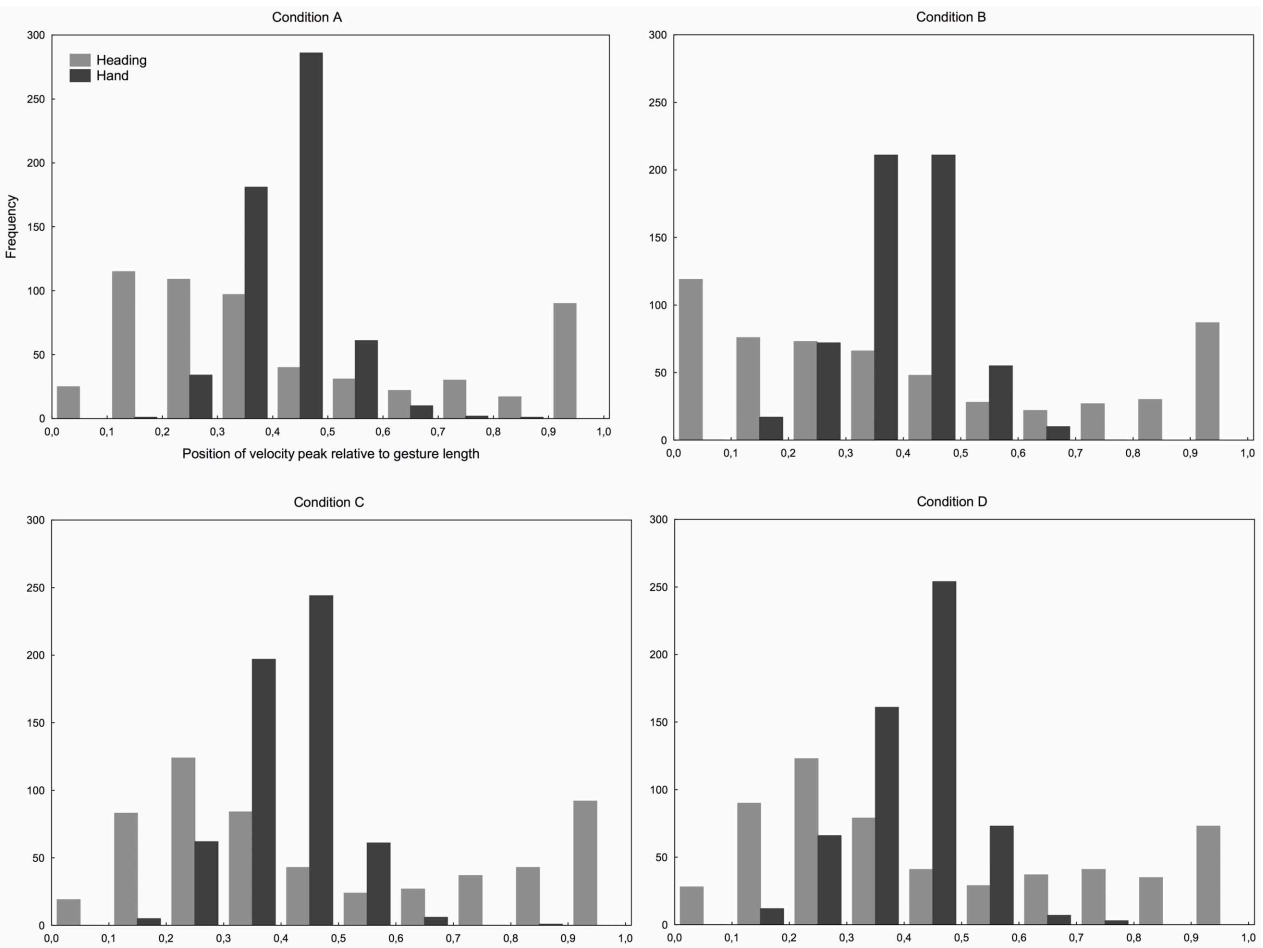

FIGURE 7 | Distribution of the position of the peak velocity point of heading angle and hand relatively to gestures length for every trial over every subject in each condition: short sound condition (A), long sound condition (B), avatar condition (C), and conflicting avatar condition (D). It indicates that head maximum velocity is reached sooner than for the hand.

a sufficiently long auditory stimulation. On the other hand, one can assume that comparison of auditory information about target position with proprioceptive information is required to update or refresh an internal representation of the goal to drive optimally the pointing hand.

In addition to better performance and precision (reduced bias for 0° target), subjects presented longer trajectories in the longer sound condition and slightly more acceleration peaks. The proportion of acceleration peaks in the deceleration part of the movement also increased in this condition. These results show that the improvement of precision in this condition may not only be due to better memorization of the target but also to the possibility to make online corrections of the hand trajectory. The use of auditory information about target direction as a feedback for guiding the reaching movement is likely since the kinematics showed indices of iterative corrections in condition B (in particular, increased length of the trajectory and increased number of peaks after PVP). These online corrections can be produced only if a neural process is able to use the auditory estimation of the target position and to make it available continuously to the sensorimotor process that drives the hand. Therefore, a sound still heard at the end of the pointing movement as in condition B would allow a more efficient updating of the goal representation in relation to the hand's position and thus a more accurate movement.

CONTRIBUTION OF THE AUDITORY AVATAR

As demonstrated in Oscari et al. (2012), hand trajectory can be controlled and optimized with an auditory feedback. Here, the directional accuracy of pointing movement was not greater with auditory feedback of the hand position than without this information available (comparison of conditions A and C). Furthermore, in condition D auditory feedback of hand position was shifted by 18.5° perpendicularly to the main movement direction. Following the shift, the hand trajectory was expected to deviate from those produced in the condition without the shift. The analysis showed no significant effect of the resulting discrepancy between auditory and proprioceptive information about hand position on the pointing accuracy. It is possible that the levels of performance in all conditions but the long target condition were impeded by an inaccurate representation of the target relative to the body and that this important inaccuracy masks a small effect of the hand auditory feedback. Indeed, in the short sound condition with no avatar (A), the mean absolute pointing error was of 26°, higher than the shift used with the avatar in condition D.

In the avatar conditions, the proprioceptive modality also might have overtaken or dominated the overflowed auditory modality, hence the importance of the design of such feedback, as showed in Rosati et al. (2012). In their study, the authors compare the contribution of different sound feedbacks on the performance in a manual tracking task and their interaction with visual feedback. They have observed that sound feedback can be counterproductive depending on the task and mapping between gesture and sound. In our experiment the same sound was used for the targets and the hand feedback. This might have confused the subjects when localizing the target and addresses the question whether spatial auditory information about limb position is enough to provide an efficient feedback to a motor action. Different parameters of the motor action might indeed need to be sonified (for instance kinematics rather than position in space). It is therefore important to study the appropriate parameters for auditory-motor mapping before being able to provide useful information for rehabilitation and sensory substitution devices.

HEAD MOVEMENTS

The analysis of final head orientation showed that in B condition heading automatically accompanied the auditory-manual pointing task despite the explicit instruction to avoid head movements. Thus, head rotations were only present when sufficient localization cues were available and the heading direction was consistently related to target direction and eccentricity. The first hypothesis than can be proposed is that this result indicates that in all the other conditions tested, the auditory target was too short to provide enough information to elicit head movements. However, since the heading direction and the direction of the pointing are clearly related in condition B (see **Figure 6**), one can propose also that the long sound allows an orienting movement of the head toward the auditory target and that the final angle of this orienting movement could guide the pointing movement of the hand. The fact that the head tends to achieve its maximum heading velocity before the hand PVP in all the conditions (see **Figure 7**) shows that early movement of the head alone did not lead to improved performance in condition B, but did along with a larger ROM and heading toward the target.

In general, heading movements belong to automatic orienting reactions that have been mainly studied in the framework of gaze orienting behavior (Guitton, 1992). Here in blindfolded subjects, we can assume that heading also aims at optimizing the binaural perception of the acoustic stimulation direction. The auditory system certainly relies on head motor information to build representations of the location of auditory targets. However and unfortunately, sound localization is mainly studied with the head fixed. Nevertheless several studies have used head orientation to quantify the ability of participants to indicate the perceived direction of a natural acoustic stimulation (Perrott et al., 1987; Makous and Middlebrooks, 1990; Pinek and Brouchon, 1992). These studies demonstrated that the direction indicated by the head was underestimated (∼10°). We obtained similar results despite different experimental conditions (voluntary head pointing vs. automatic orienting reaction). Orienting reaction and voluntary heading to natural acoustic stimulation were observed with relatively short stimuli (500 ms) in Goossens and Van Opstal (1999). In contrast, in our experiment with HRTF spatial rendering, heading toward the target was little observed with short sound stimuli. However, Goosens and Van Opstal authors suggested that head movements could provide spatial information about rich and long enough sounds that would be used by the auditory system to update the internal representation of the target. Our results suggest indeed that the accuracy of pointing to long stimuli could be due to the contribution of heading toward the target providing a more accurate frame of reference for the anticipated control of pointing. However, this does not exclude a direct role of the on-going presentation of the acoustic target.

TARGET DIRECTIONS AND CHARACTERISTICS OF MOVEMENTS

The estimated direction of targets are characterized by a perceived space wider than the real one. This was also observed with hand pointing toward "natural" sounds produced by loudspeakers (Pinek and Brouchon, 1992). However, it was much larger in our study than that observed with natural sounds (less than 10° for Pinek and Brouchon) and this could originate in the use of non-individual HRTF in which interaural differences are not adapted to the geometry of the head. The observed left bias in direction for straight ahead targets could result from a pseudo-neglect effect favoring the left hemispace similar to the pseudo-neglect effect observed with vision (Sosa et al., 2010).

The left/right asymmetry observed in the trajectories kinematics can be explained by this effect as well. Indeed, average and peak velocities increased for targets on the right without effect of the conditions. Along with longer distances covered and fewer number of acceleration peaks, this effect might have caused variations in the control parameters of the movements between the two hemispaces. The left bias observed for the 0° target sound supports this hypothesis. Nevertheless, considering the starting position of the task with the palm put at the center of the set-up, these results could also be accounted for subject's ease to point on the right with their right hand.

MODULARITY

This study addresses also the question of the cooperation between different modular neural processes involved in the multisensory and motor representations of targets in goal-directed movements. Do these different processes share a global amodal spatial representation (e.g., Pouget et al., 2002) or do they have their own dedicated spatial representation? Visual and auditory modules use certainly very different reference frames. Sounds are localized thanks to spectral and binaural cues naturally linked to a head-centered frame of reference when visual positions are primarily coded in an eye-centered reference frame. In addition, the visual system is retinotopic whereas the auditory system is characterized by broad tuning and lack of topographical organization (Maier and Groh, 2009).

The question of modularity in motor control arises when we consider the coordination between head orienting movements and hand movements. In the longer sound condition, the auditory stimulation is long enough to allow the triggering of head rotations. Since the amount of rotation of the head is related to the response of participants, there should certainly be a way for the two processes to share common information. This suggests that the heading direction is coded in a body-centered reference frame and can be used directly by the reaching motor command that shares the same reference frame.

To conclude, it is known that sound localization requires the integration of multisensory information and processing of self-generated movements: a stable representation of an auditory source has to be based on acoustic inputs and their relation to motor states (Aytekin et al., 2008). Our results highlight that auditory representations extracted from a sound signal can be transformed online into a sequence of motor commands for coordinated action, underlying the role of the auditory-motor loop in spatial processing.

The Uncontrolled Manifold (UCM) hypothesis and Minimal Intervention principle propose that the observed differential variability across task relevant (i.e., task goals) vs. irrelevant (i.e., in the null space of those goals) variables is evidence of a separation of task variables for efficient neural control, ranked by their respective variabilities (sometimes referred to as hierarchy of control). Support for this comes from spatial domain analyses (i.e., structure of) of kinematic, kinetic, and EMG variability. While proponents admit the possibility of *preferential* as opposed to strictly *uncontrolled* variables, such distinctions have only begun to be quantified or considered in the temporal domain when inferring control action. Here we extend the study of task variability during tripod static grasp to the temporal domain by applying diffusion analysis. We show that both task-relevant and task-irrelevant parameters show corrective action at some time scales; and conversely, that task-relevant parameters do not show corrective action at other time scales. That is, the spatial fluctuations of fingertip forces show, as expected, greater ranges of variability in task-irrelevant variables (>98% associated with changes in total grasp force; vs. only <2% in task-relevant changes associated with acceleration of the object). But at some time scales, however, temporal fluctuations of task-irrelevant variables exhibit negative correlations clearly indicative of corrective action (scaling exponents <0.5); and temporal fluctuations of task-relevant variables exhibit neutral and positive correlations clearly indicative of absence of corrective action (scaling exponents ≥0.5). In agreement with recent work in other behavioral contexts, these results propose we revise our understanding of variability vis-á-vis task relevance by considering both spatial and temporal features of all task variables when inferring control action and understanding how the CNS confronts task redundancy. Instead of a dichotomy of presence vs. absence of control, we should speak of a continuum of weaker to stronger—and potentially different—control strategies in specific spatiotemporal domains, indicated here by the magnitude of deviation from the 0.5 scaling exponent. Moreover, these results are counter examples to the UCM hypothesis and the Minimal Intervention principle, and the similar nature of control actions across time scales in both task-relevant and task-irrelevant spaces points to a level of modularity not previously recognized.

Keywords: motor control theory, redundancy, manipulation, dimensionality reduction, spatiotemporal dynamics

INTRODUCTION

Redundancy, and the variability it allows, has traditionally been viewed as the central problem of motor control research (Bernstein, 1967), which can be studied at a variety of levels (e.g., task, muscle, or goal redundancy). Here, we understand the term *task redundancy* to be the availability of infinitely many different *mechanical actions* by the neuromuscular system that can accomplish a given motor task. The totality of these mechanical actions form the goal equivalent manifold, a term coined in John and Cusumano (2007). This differs from *muscle redundancy*, which refers to the multitude of *muscle coordination patterns* producing a same mechanical action (Kutch and Valero-Cuevas, 2011). Multifinger static grasp has been studied extensively because it is a good example of task redundancy (Santello and Soechting, 2000; Latash and Zatsiorsky, 2009; Park et al., 2010; Rácz et al., 2012) since using n fingertips to satisfy static force and torque equilibrium of the object grasped is underconstrained (i.e., one can, for instance, squeeze an object harder without translating or rotating it). For multifinger grasp, the redundant task space of all applicable forces for static grasp can be mathematically separated into the mutually orthogonal subspaces of force variability that have no effect on static equilibrium (e.g., squeezing the object in static grasp) on the one hand, and on the other hand, force variability that disrupts static equilibrium (i.e., violates the task constraints). Others and we refer to the former and latter subspaces as task-irrelevant (or null space) and task-relevant, respectively, as they indicate a distinction about where the controller is thought to place emphasis.

Proponents of the Uncontrolled Manifold (UCM) and Principle of Minimal Intervention hypotheses have suggested

that, to simplify the control task, the nervous system only needs to identify and control the task-relevant subspace, and can disregard the task-irrelevant subspace (Scholz and Schoener, 1999; Scholz et al., 2002; Jordan, 2003; Valero-Cuevas et al., 2009; Latash et al., 2010). Compelling evidence for this comes from spatial domain analyses showing clear structure in the spatial variability of task variables. By *spatial variability* we mean the amplitude and range of the multidimensional task variables of fingertip or resultant forces. Researchers, including our group, have repeatedly shown that the spatial variability in task-irrelevant dimensions is relatively larger than in task-relevant dimensions (Scholz and Schoener, 1999) in analyses of kinematic (Tseng and Scholz, 2005), kinetic (Santello and Soechting, 2000), and EMG variability (Valero-Cuevas et al., 2009). In this context, larger spatial variability in a task dimension is assumed to imply less control effort (i.e., intervention) of those task variables that do not affect the successful performance of the task. In practice, however, even task-relevant dimensions will exhibit some variability because a certain amount is acceptable given, say, high contact friction, or unavoidable, given, say, sensory or motor noise, or neural delays. Conversely, task-irrelevant dimensions will also show some control action when, for instance, noise, delays or stochasticity drive the system across some boundary that requires intervention (e.g., Insperger, 2006; Milton et al., 2009b). Therefore, the relative magnitude of variability across task variables is not necessarily a robust predictor of task-relevance, control action or strategy (Valero-Cuevas et al., 2009; Dingwell et al., 2010). In fact, even proponents of the UCM hypothesis admit the possibility of *preferential* as opposed to a strict separation into clearly controlled and uncontrolled variables (Latash et al., 2010). Despite this qualification, we lack specific quantification and description of controlled intervention in both task-relevant and task-irrelevant spaces that would allow us to understand neural control strategies better.

SPATIAL VERSUS TEMPORAL VARIABILITY

There is a growing emphasis to infer neural control strategies by supplementing spatial quantification of variance with temporal analyses. As described above, much more attention has been given to spatial variability. However, relatively little attention has been directed at the temporal structure of variability in task variables in the context of task redundancy (Valero-Cuevas et al., 2009; Dingwell et al., 2010; van Beers et al., 2013). By *temporal variability* we mean the time-varying features of the multidimensional task variables, e.g., fingertip or resultant forces in this case. Lest the reader think that time-varying actions during static force production or grasp is an oxymoron, others and we have shown that finger muscles and fingertip forces exhibit rich dynamics during static grasp (Santello and Soechting, 2000; Valero-Cuevas et al., 2009; Rácz et al., 2012). Being considered and called uncontrolled, the implicit and explicit assumption is that task-irrelevant variability exhibits the spatial and temporal properties of uncontrolled dynamical processes. In the anomalous diffusion literature, this is considered either a white noise process, consisting of uncorrelated samples, or Brownian motion, formed by the integration of the former (Ben-Avraham and Havlin, 2000; Kantz and Schreiber, 2004). In the context of neural control, we take it to mean the state of least control (i.e., truly uncontrolled where the dynamics of the plant is not influenced by the controller). Conversely, a controlled process, continuously or intermittently (Collins and De Luca, 1994; Guckenheimer, 1995; Milton et al., 2009a; Suzuki et al., 2012), will exhibit the temporal properties of controlled dynamical processes such as negative correlations between time samples (i.e., if a task variable moves in one direction, at some future time it will require a corrective action in the opposite direction). Please also note that the mechanical properties of the musculoskeletal plant act as filters on the neural input, and can give to correlations in the output. This is a limitation common to all studies of neural commands. Therefore, studying the force variability that naturally occurs in static grasp provides unique opportunities to reveal the time-varying nature of control actions without having the confounding, or at least superimposed, effects of additional dynamics coming from other features of more dynamical tasks such as gait (Dingwell et al., 2010). By applying a combination of temporal and spatial analysis techniques to multifinger static grasp, we find that task-relevant and task-irrelevant variables are both subject to strong and weak control actions at different time scales. Therefore, these results provide evidence against the UCM hypothesis and the Minimal Intervention principle. We conclude that it is necessary to revisit and revise our understanding of variability vis-á-vis task relevance when inferring control action and understanding how the CNS confronts task redundancy.

METHODS

We combine linear spatial approaches and non-linear temporal approaches to (1) quantify the spatio-temporal nature of the variability in both the task-relevant and task-irrelevant subspaces; (2) compare them to the mechanical predictions of necessary control actions for the task; and (3) evaluate them in light of the UCM hypothesis and Minimal Intervention principle. We selected the task of static tripod grasp because it is a common and useful redundant motor task, and a fundamental aspect of human manipulation (Yoshikawa and Nagai, 1991; Flanagan et al., 1999; Rácz et al., 2012).

DATA COLLECTION

We asked 12 young, healthy and consenting subjects (ages 20–36, 6 males, 9 right-handed) to perform a static tripod grasp of an instrumented rigid object designed and built in our lab (**Figure 1**), whose use has been reported in Rácz et al. (2012). While performing the grasp, the thumb, index and middle finger were in contact with three ATI Nano17 6-axis force transducers (Apex, NC, USA) locked in a configuration comfortable for each subject. The angle between index and middle finger was approximately 30°, while the angles formed with the thumb by each finger were approximately 165°. Each force transducer was coated with a Teflon surface to reduce reliance on friction by the subjects to achieve a stable grasp. The force transducers were connected to a 16-bit National Instruments 6225 M-series data acquisition card (National Instruments, Austin, TX, USA). Attached to the object were three markers for motion capture, forming an equilateral triangle, whose plane was parallel to the grasp plane of the three fingertips. Seven motion capture cameras (Vicon, Oxford, UK) allowed us to measure the object's position and orientation

to quantify how well the subject met the task goal of maintaining a simple static grasp.

Furthermore, three different weights (50, 100, and 200 g) were attached from below to the object (**Figure 1C**). Additionally, the latter half the trials were performed with visual feedback presented to the subjects approximately 1 m away on a 23 inch computer screen. The visual feedback consisted of a horizontal target line representing the target sum of normal forces (in Newtons) applied by three fingers, and a crosshair representing the actually applied sum of normal forces (**Figure 1D**). The goal in those trials with visual feedback was to align the horizontal component of the crosshair with the target line and keep the variability of force application minimal. The target force was the average sum of normal forces applied by subjects across all trials without visual feedback. In effect, the visual feedback added another task-relevant dimension to the task, besides keeping the grasp as static as possible.

Subjects performed all trials with their dominant hand determined as per Oldfield (1971), as shown in Rácz et al. (2012). Subjects were seated in a chair, with the grasping hand resting on the chair's armrest (**Figure 1**). Moreover, we asked subjects to immobilize the wrist of their grasping hand by gripping the wrist with their non-dominant hand to minimize wrist rotation and hand translation, since we were interested in the coordination of fingertip forces for steady-state static grasp with as little motion as possible.

Subjects performed three repetitions of static grasp trials of 68 s duration for each weight and each visual condition, for a total of 18 trials per subject ($3 \times 3 \times 2$). The instructions to the subjects were to simply hold the object in a static tripod grasp with as little motion as possible, as in **Figure 1**. Even though the object was light (max. 260 g), we provided subjects with 1 min of rest to avoid fatigue or discomfort. Trials were block randomized: the different weights were attached in random order for each condition, but the nine trials with visual feedback were always performed after the ones without. This was because the target total grasp force line height was based on the self-selected average sum of normal forces for each weight in the non-visual condition. The individual experimental conditions are described in **Table 1**.

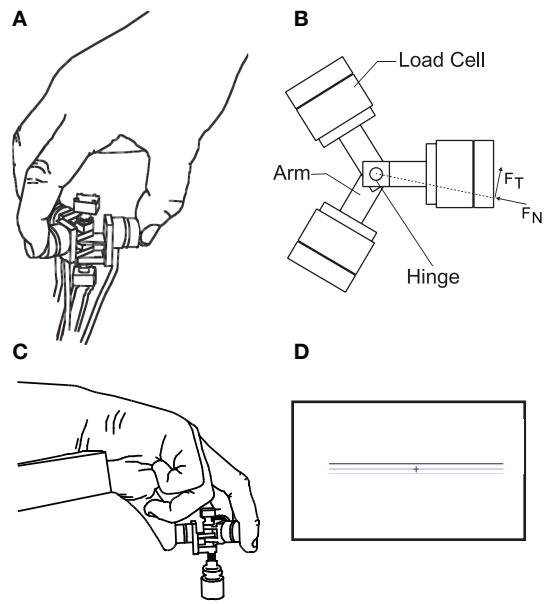

FIGURE 1 | The apparatus for tripod grasp designed and built in our lab. It consists of three arms rotating about a common hinge to adjust to the most comfortable configuration for each subject. The arms are then fixed to create a rigid object. Each arm is instrumented with a 6-axis force transducer that forms the contact surfaces for tripod grasp. **(A)** Representative illustration of the instrumented device being held. **(B)** View from above onto the instrumented device, showing the three load cells mounted on arms that rotate about a common hinge, and the forces used in the analysis, computed from the load cell surface measured forces. **(C)** The holding posture during the trials, also showing a weight attached from below to the instrumented device. **(D)** Visual feedback presented to the subjects: a crosshair representing the instantaneous sum of normal forces, to be aligned with a target line.

DATA PREPROCESSING

The three-dimensional force data recorded by each transducer were sampled at 400 Hz, while the motion-capture marker positions were sampled at 200 Hz (both force and motion data collection were triggered synchronously). We removed the first seven and last 1 second(s) from each trial's time series to avoid transients. Next, we downsampled both the force and motion capture time series to 100 Hz, to balance the need for temporal resolution and computational cost. Having performed the same analysis on a subset of the trial at the original sample rate, we subsequently found that results were unaffected, when repeating the analysis at lower sample rates. Hence, 100 Hz was found to be a useful compromise as it still allows for a physiologically meaningful temporal resolution on the order of 10^{-1} s.

As is required by our temporal analysis, see below, we did not filter the data to avoid creating artifactual correlations.

DATA ANALYSIS—SPATIAL

To analyze the spatial coordinated action among the three fingertip forces, we first performed principal component analysis (PCA) on the time series of each sensor's normal forces for each trial. PCA is a popular linear method for the estimation of spatial correlation structures in data (Clewley et al., 2008). Specifically, we computed the three principal components (PCs) of the 3×3

Table 1 | Overview of the experimental conditions (number of trials in parentheses).

Presented on screen (50 Hz, 1.5 m away)	Weight attached to object from below
No visual feedback (9)	50 g (3)
	100 g (3)
	200 g (3)
Force target tracked by crosshair (9)	50 g (3)
	100 g (3)
	200 g (3)

*The instructions to the subjects were to simply hold the object in a static tripod grasp with as little motion as possible, as in **Figure 1***

normal force covariance matrix (q-PCA). Each PC is a unit vector whose elements, called loadings, specify the multidimensional correlation among variables; and a combination of PCs forms a basis defining a vector subspace that is a linear approximation to the spatial correlation structure in the data (Clewley et al., 2008). PCA has been commonly used to estimate effective degrees of freedom in motor systems, and in the context of the UCM hypothesis to compute task-relevant and -irrelevant latent variable spaces, which are represented by the orthogonal PC vectors (e.g., Santello and Soechting, 2000). We then projected the 3-dimensional normal forces (one normal force per force sensor) time series data onto the three principal components. Following Rácz et al. (2012), we call the first, second, and third principal components the Grasp, Compensation and Hinge Modes of this task (**Figure 2**), respectively. We also tested doing this same analysis on the full 3D force data (normal and two tangential force components per force sensor, see Discussion and **Figures 10–13**) but the results are unchanged from when using only the normal force component from each sensor, in particular since the magnitude of the tangential force fluctuations were several orders of magnitude smaller than those of the normal forces, but not their mean levels, since vertical tangential components are required to sustain the weight of the object against gravity. Importantly, adding tangential forces to the analysis adds several task-relevant or task-irrelevant dimensions, which however, does not affect the fundamental question or findings of this study, i.e., the implications of certain temporal dynamics for the study of control of task-relevant and -irrelevant dimensions.

DATA ANALYSIS—TEMPORAL

Next, we applied Detrended Fluctuation Analysis (DFA) to each projected time series (Kantelhardt et al., 2001) to detect *temporal correlations in non-stationary time series*. It has the advantage, in particular over the classical time-lagged autocorrelation function, that it can distinguish unwanted trends of arbitrary order that can give rise to spurious non-zero correlations, from

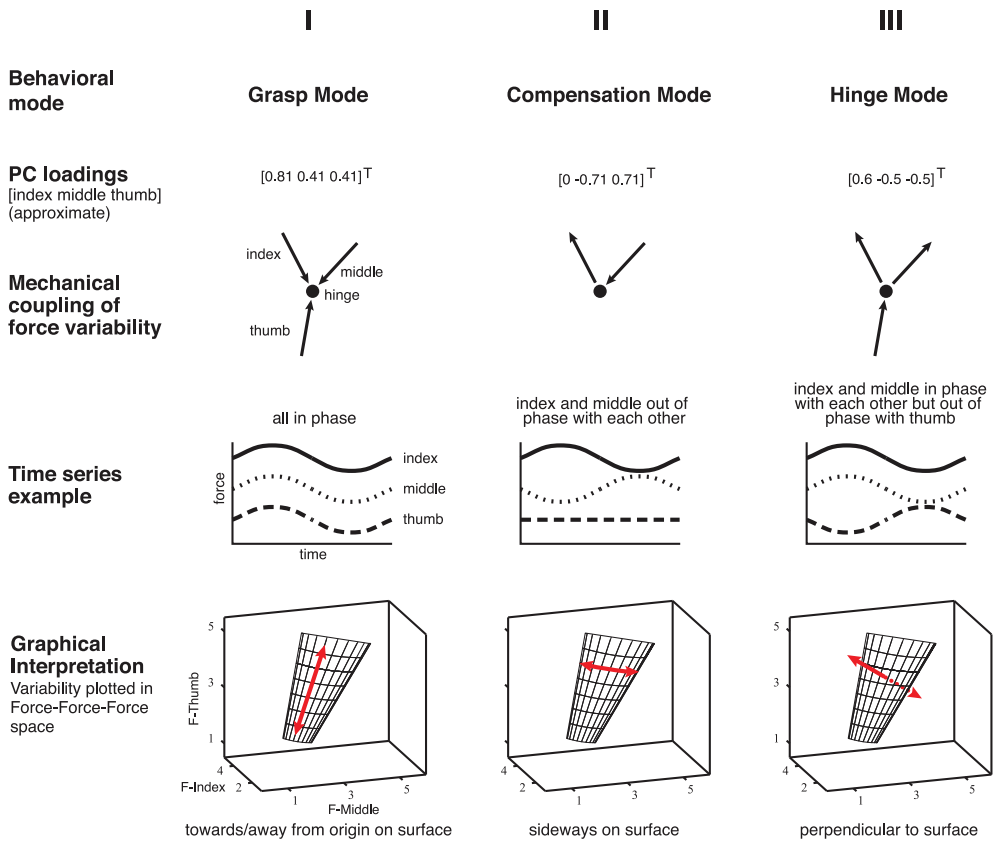

FIGURE 2 | Illustration of the three Modes of normal forces associated with the principal components computed from the data and the simulations, across all subjects, and conditions [adapted from Rácz et al. (2012)]. Please note that the loadings are the unit vectors describing the multidimensional correlation defining each PC. Therefore the loadings for this PC show that the thumb, index and middle finger forces all co-vary in this Mode. We refer to these three PCs as: (i) the task-irrelevant *Grasp Mode*, along $[0.81\ 0.41\ 0.41]^T$, as it reflects synchronous increases and decreases in the three normal forces, which are also known as grasp forces, (ii) the *Compensation Mode*, along $[0.0\ -0.71\ 0.71]^T$, reflecting the out-of-phase opposition, or compensation, of thumb normal force by either the index or middle finger normal force, and (iii) the task-relevant *Hinge Mode*, along $[0.6\ -0.5\ -0.5]^T$, reflecting an increase (decrease) in thumb normal force accompanied by a simultaneous decrease (increase) in the index and middle finger normal forces, which would typically occur if the object was accelerated by the thumb, thus violating the mechanical task requirements of static grasp (without loss of generality, the violation of static grasp by purely rotating the object using tangential forces is not considered here, see Discussion).

actual long-range correlations in non-stationary data. Examples of non-stationary data are time-series with trends that are long relative to the length of the time series or which exhibit clustering—mathematically speaking, data whose two-point autocorrelation is time-variant. DFA has been used extensively for the analysis of behavioral and physiological data (Hausdorff et al., 1996; Peng et al., 1998; Penzel et al., 2003). Mathematically, it quantifies the power-law increase of the root-mean square deviations from a trend in the time series fluctuations, once segments of increasing length n have been subtracted from it to remove trends of that length:

$$F(n) = \left[\frac{1}{L} \sum_{j=1}^{L} \left(X_j - (a_j + b) \right)^2 \right]^{\frac{1}{2}}$$

Where $X_j - (a_j + b)$ represents the residuals of the linear fit $a_j + b$ to the time series segments X_j of length n. For a given segment length n, there are L overlapping segments in the process. The complete expression for $F(n)$ represents the average root mean square deviation at segment length, or time scale, n. In a non-stationary process, this time scale is related to $F(n)$ by the relationship

$$F(n) \propto n^{\alpha}$$

This power-law increase in root-mean square deviation is mathematically linked to long-range temporal correlations in the data: negative correlations will, over time, lead to a smaller rate of increase than positive correlations. The scaling exponent α indicates the type of correlation, as well as the strength of the relationship between data increments separated by a time scale n. DFA reveals empirically (i.e., in a model-free way with minimal assumptions) the inherent time scales for which different temporal correlations exist in the data by showing if the scaling exponent α [i.e., the slope of the logarithmic plots of n vs. $F(n)$] differs at different time scales. These time scales are found based on regions of slope linearity in the logarithmic plots of n vs. $F(n)$, and thus regions of actual power-law scaling.

In particular, the scaling exponents α can be fit to the logarithmic plots of the time scales n vs. the $F(n)$ (for an interpretation of these scaling exponents, see **Table 2**).

Because long-range negative correlations reflect corrective actions that prevent dissipation, they are interpreted as evidence for the workings of corrective and stabilizing (i.e., negative feedback) control, while positive correlations can be interpreted as evidence of lack of corrections and thus lack of stabilizing control actions (Collins and Luca, 1993; Collins and De Luca, 1994). (Please note that these notions are related, but not equivalent to notions of stability, which are beyond the scope of this work because our static grasp task is stable). Recent work also supports the idea of interpreting scaling exponents in terms of indicating the degree of control effort (Dingwell and Cusumano, 2010; Dingwell et al., 2010).

To further confirm the reliability of our results, we repeated the DFA on the first and second half of each trial to test if the structure of the variability in normal forces is sensitive to the level of total grasp force. We felt this to be necessary because, as is commonly reported in studies of static grasp (e.g., Johansson and Westling, 1987), we noticed that some trials exhibited a relaxation of the total grasp force, likely an adaptation to reduce fingertip forces over time to mitigate fatigue (see Results).

MODELING OF TRIPOD GRASP

As in Rácz et al. (2012), we applied the same analysis methods to synthetic data generated by a simulation of the task. For a description of the model, see Appendix. In that model the variability in the simulated normal forces comes from our implementation of a standard Brownian random walk [see Appendix and Rácz et al. (2012) for details]. Analyzing data from a strictly mechanical simulation allows us to disambiguate features of mechanical origin from features of the control that cannot be explained by mechanics, and are therefore of likely neural origin [for other examples of this approach see Kutch and Valero-Cuevas (2012), Rácz et al. (2012), and Ristroph et al. (2010)].

RESULTS

PRINCIPAL COMPONENT ANALYSIS OF SIMULATED NORMAL FORCES

Figure 3 shows the simulated normal forces plotted against each other, which shows that, by construction, the valid solutions populate a plane representing the constraints of the task. In agreement with our mechanical analysis (Rácz et al., 2012), PCA of the simulated data finds the two basis vectors (principal components, or PCs) describing that plane: the Grasp Mode $[0.81\ 0.41\ 0.41]^T$ and the Compensation Mode $[0.0\ -0.71\ 0.71]^T$, **Figure 2**.

Mechanically, the dynamics associated with the Compensation Mode reflects movement of the intersection point of the three force vectors, as shown in Yoshikawa and Nagai (1991) and Flanagan et al. (1999): as long as the force vectors, extended from their respective application points, intersect in one common point inside the object, there will be no moment exerted on the object. The only physical limitation is that the force vector extended from each fingertip stay within its friction cone. The Grasp Mode, in turn, quantifies changes in the total grasp force, which is equivalent to the intersection point not moving side-to-side on the manifold in **Figure 2**, but rather up-and-down as the distance to the origin quantifies the total grasp force.

Table 2 | Different scaling exponents found by linear fitting in the logarithmic displacement vs. time scale plot.

Value of α at n	Type of correlation	Nature of correlation	Effect on data
>0.5	Persistence	Positive (negative) increment followed by positive (negative) increment	Expansion
<0.5	Anti-persistence	Positive (negative) increment followed by negative (positive) increment	Contraction (stabilization)
=0.5	Brownian motion	No correlation between increments	(No control)

These two PCs together explain all the normal force variance in the simulated data. In this idealized case, by construction once again, if the variability of normal fingertip forces exhibits this structure in steady-state static tripod grasp, then such variability will not give rise to accelerations or rotations of the grasped object and exists entirely in the null space of the task. Actual acceleration of the object is associated with variability of normal forces perpendicular to this plane, along the PC vector of the Hinge Mode $[0.6\ -0.5\ -0.5]^T$.

PRINCIPAL COMPONENT ANALYSIS OF EXPERIMENTAL FORCES

As expected, subjects met the task requirements of not dropping the object and holding it still, but still showing some variability in their normal forces and object movement. The object markers (for motion capture) stayed well within 5 mm in all directions, and object motion was significantly affected by the presence of visual feedback, but not weight ($p < 0.01$, Mann–Whitney U test). Given the mechanics of the task and instructions to the subjects, the small but measurable linear accelerations of the object must be due to dynamics along the Hinge Mode (or to a lesser extent to the unmodeled vertical motion and $3D$ rotation modes given that the wrist was held fixed).

We applied PCA to the time series of experimental normal forces (see **Figures 4**, **5** for representative trials for two different conditions) and, as expected from the mechanical requirements of the task (Rácz et al., 2012), we found that the variability of

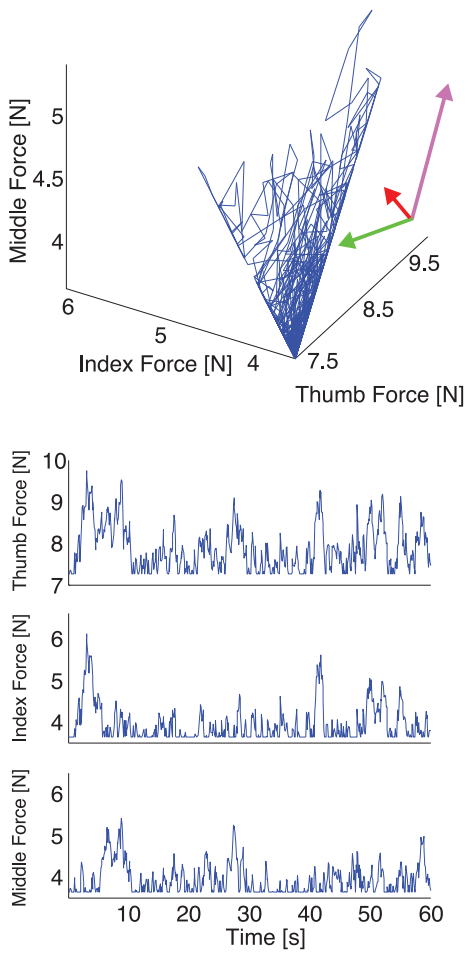

FIGURE 3 | Representative plot of the simulated thumb, index, and middle finger normal forces *without* visual feedback. Top: The three simulated normal forces plotted against each other. Note that the force fluctuations come to lie on a plane, whose orientation we compute using PCA. The rotated coordinate system indicates the directions of normal force variability, and the lengths of the arrows indicate the variance explained along that direction. Note that since in the simulation the motor task is executed perfectly, two directions, which span a manifold of solutions, explain all variability. **Bottom:** The three simulated normal forces during a trial plotted individually. Note that the floor effect results from the hard constraint of minimum normal force in the simulation, which for the subjects is more flexible and can result in a downward trend in total grasp force in trials without visual feedback.

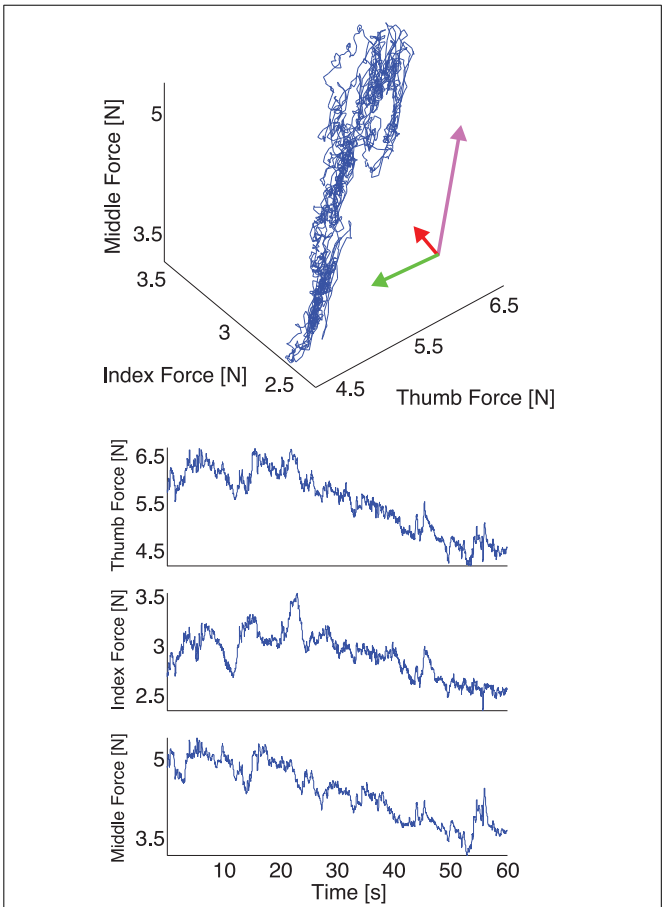

FIGURE 4 | Representative plot of experimental thumb, index, and middle finger normal forces recorded during one trial with a 200 g weight *without* visual feedback. Top: The three normal forces plotted against each other. Note that the force fluctuations come to lie on a plane defining the mechanical requirements of the task (see Appendix and **Figure 2**), whose orientation we calculate using PCA (directions and variances explained shown by the rotated and scaled coordinate system—note that most of the variability is explained by two components and the data come to lie on a plane). Note the elongated distribution of the data, due to a gradual reduction of total grasp force in the absence of visual feedback. **Bottom:** The three normal forces during a trial plotted individually. Note the elongated distribution of the data is here seen as a downward trend in the three fingers.

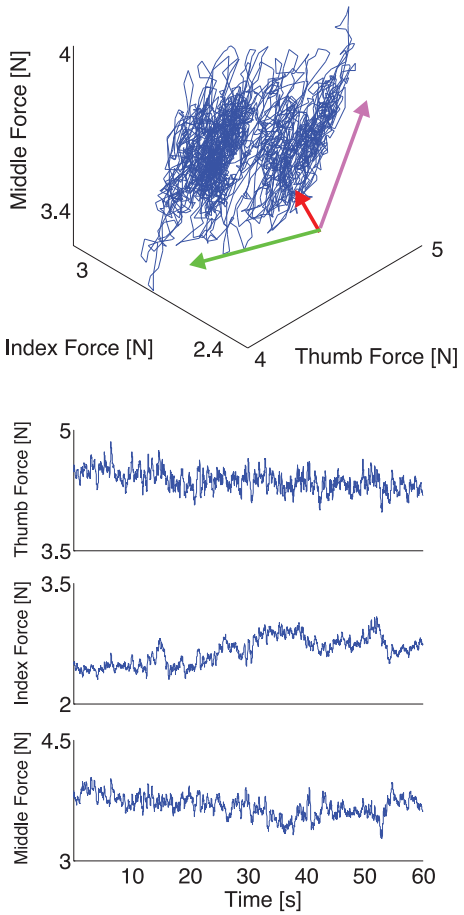

FIGURE 5 | Representative plot of experimental thumb, index, and middle finger normal forces recorded during one trial with a 200 g weight, *with* visual feedback. Top: The three normal forces plotted against each other. Note that the force fluctuations come to lie on a plane, as is expected if the task constraints are met (see Appendix and **Figure 2**, note the rotated and scaled coordinate system), but the variability in normal forces populates the plane in a tighter cluster given that a constant total grasp force is now a task constraint the subjects enforces. **Bottom:** The three normal forces during a trial plotted individually. Note the absence of a downward trend across the three fingers, due to the enforcement of the visual constraint on the sum of normal forces.

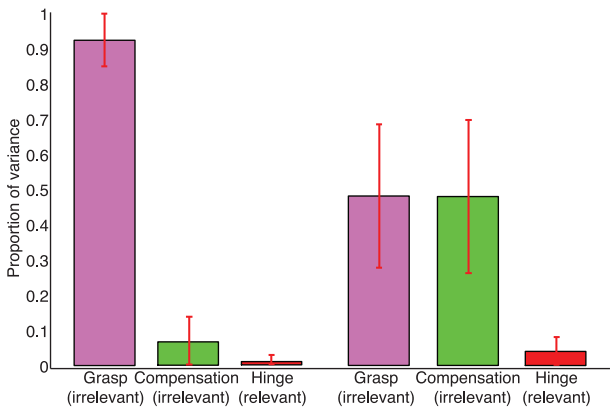

FIGURE 6 | Mean proportions of variance explained by the Grasp, Compensation, and Hinge Modes, respectively, in the sample trials *with* (*right*) and *without* (*left*) visual feedback. In trials without visual feedback, PCA indicates that most variance occurs along the Grasp Mode—which is true given that subjects gradually reduce the total grasp force and the data are distributed in an elongates fashion compared to the tighter cluster in the case where visual feedback is provided (cf. **Figures 2**, **3**) The overwhelming majority of the variance in trials with and without visual feedback is explained by the Grasp and Compensation modes, and hence the normal force variability occurs on a planar manifold.

normal forces consistently exhibited a structure described by the three principal components found in the simulation.

In the case of no visual feedback, the Grasp Mode obtained from PCA explains approximately 90% of the normal force variance, while the Compensation Mode approximately 5–10% and the Hinge Mode 1–3% (**Figure 6**). In contrast, in trials with visual feedback the Grasp and Compensation Modes contribute roughly equally to the normal force variance, slightly less than 50% each (**Figure 6**) with 1–3% accounted for by the Hinge Mode. The low percentage of variance explained by the Hinge Mode in both cases shows that subjects were mindful of the request to perform static grasp, and satisfied the task requirements of not accelerating the object. Lastly and not surprisingly, the Hinge Mode shows almost no variation over time given that the object was held relatively still, as confirmed by motion capture. **Figure 10** further shows that the variance explained by three Modes remains unaffected even if we consider all three force components for each digit.

DETRENDED FLUCTUATION ANALYSIS OF TIME SERIES PROJECTED ONTO PRINCIPAL COMPONENTS

Our first finding is that the Grasp, Compensation and Hinge Modes all naturally exhibit three distinct scaling regions, representing temporal correlations at three different time scales (**Figure 8**). In particular, the distinct time scales are at 10, 100, and 1000 s of milliseconds, subject to some fluctuation. Due to this fluctuation, we calculated the scaling exponent only for a conservative subrange of these time scales that was common to all trials and subjects, i.e., 1–50, 250–500, and 3500–7000 ms.

In the following, all reported changes in scaling exponents α (i.e., slopes of the log–log plots) are statistically significant at the $p < 0.01$ level, based on Kruskal–Wallis (across the three weight conditions) and Mann–Whitney U statistical tests (across the two visual feedback conditions). We used these non-parametric test (equivalents of ANOVA and t-test, respectively), because inspection of deviations from normality revealed a clear absence of a normal distribution of α required for parametric tests.

DETRENDED FLUCTUATION ANALYSIS: GENERAL SCALING EXPONENT RESULTS

Consider **Figure 9**, which shows the mean scaling exponents across all trials, respectively. At short time scales (1–50 ms), the slopes associated with both the Compensation and Hinge Mode time series are close to 0.5, indicating lack of positive or negative correlation (approximating a random walk) between increments and thus absence of a corrective control effort, while the Grasp

Mode has a mean slope of 0.7, reflective of positive correlations (i.e., diffusive growth) in the time series.

At medium time scales (200–500 ms), the slope of the Grasp Mode decreases to 0.5, indicating lack of corrective control effort along this dimension, while the Compensation Mode now indicates the activity of a stabilizing or correcting effort, with the scaling exponents α having decreased to a value of 0.3, and the Hinge Mode shows a very strong negative correlation (indicative of strong corrective action) of RMS deviation scaling with exponent $\alpha = 0.1$, indicating a strong tendency to enforce a constant mean level. Importantly, the 200–500 ms time delays include the shortest voluntary time scales of the sensorimotor system (Kawato, 1999).

The long time scale (3500–7000 ms) is not particularly different from the 200–500 ms time scale in terms of DFA slopes, except that the Grasp Mode now becomes corrective as well, with a slope having decreased from 0.5 to 0.3.

Importantly, DFA scaling exponents did not significantly differ between the first and the second half of the trials.

EFFECT OF ADDING VISUAL FEEDBACK

Solid arrows in **Figure 9** show the effect of adding visual feedback. Note that these arrows indicate only those statistically significant changes found based on our Mann–Whitney U statistical tests. Visual feedback had the predictable effect of decreasing the scaling exponent α for the Grasp Mode at the long time scales of 3500–7000 ms; indicating the success of the long visuomotor loop in keeping the total grasp constant. However, and somewhat counter-intuitively, it also increased the slope of the Grasp Mode at short time scales (1–50 ms), indicating greater positive correlations (i.e., diffusive growth) in the short latencies not affected by the visuomotor loop. This may reflect increased signal-dependent noise and spurious corrections known to result from higher gains in the motor and sensory components of a feedback loop—in this case the visuomotor loop. The Hinge Mode was the only other Mode affected by visual feedback; where its slope in the long time scales became slightly, but statistically significantly, more corrective as it is changing from 0.13 to 0.1.

DETRENDED FLUCTUATION ANALYSIS: EFFECT OF INCREASING WEIGHT

Dashed arrows in **Figure 9** show the effect of adding weight to the object. Note that these arrows indicate only those statistically significant changes found based on our Kruskal–Wallis statistical tests. The α slope of the Grasp Mode at scales (1–50 ms) increased toward to 1.0, as in the case of adding visual feedback. Again, this perhaps reflects the increase in signal-dependent noise with the need for greater grasp forces. Signal-dependent noise scales linearly with force and is observed in the 8–12 Hz frequency band of force measurements (Jones et al. (2002), i.e., time scales of $<$125 ms) and induces positive mechanical correlations across fingers due to reaction forces. The only other significant effect of weight was a slight increase of the Hinge Mode slope in the medium time scales, possibly reflecting the increased difficulty of maintaining immobile the more massive objects, which would show less effective corrections in this time-scale (see **Figure 9**).

DISCUSSION

Our spatio-temporal analysis of static grasp demonstrates that fingertip forces exhibit evidence of corrective actions and absence of corrective actions in both the task-relevant and task-irrelevant task subspaces. Our main message is that, during a static tripod grasp, we find examples at different time scales of how task-irrelevant parameters, which are commonly associated with the UCM, are actively controlled, and how task-relevant parameters (i.e., performance variables) are not actively controlled. This evidence critically extends our approach to task relevance, and compels us to revise our understanding of neural control of task redundancy. In particular, our results challenge the currently dominant approaches to redundancy of the UCM Hypothesis and the Minimal Intervention principle that advocate a separation of control strategies between task-relevant and task-irrelevant variables. Rather, we demonstrate that there exist corrective actions common to all task variables that supports the notion of a continuum, rather than a separation, of neural control strategies common to both task-relevant vs. task-irrelevant variables. Moreover, the similarity of control actions across time scales seen in both task-relevant and task-irrelevant spaces points to a level of modularity in corrective action not previously recognized. After explaining how methodological considerations do not challenge our main findings, we discuss the implications of our results to our understanding of neural control of task redundancy.

METHODOLOGICAL CONSIDERATIONS

We find that variability of the normal forces of the fingertips on the object during static grasp suffices to show a counter example to current thinking about neural control of task redundancy. We designed our experimental paradigm of static equilibrium to sidestep methodological and theoretical difficulties encountered by prior studies of more complex tasks, e.g., (Dingwell et al., 2008, 2010; van Beers et al., 2013). Studies investigating the UCM hypothesis and Minimal Intervention principle must restrict themselves to a measurable subset of performance variables (it is not practical to record EMG from all muscles, angles from all joints, etc.) during well-defined tasks (like planar limb motion or body motion in the sagittal plane). We used a mechanical model developed in Rácz et al. (2012) to interpret our normal force data, and were careful to only analyze trials for which the linear and angular accelerations were measured as negligible based on motion capture data, and thus considered as static grasp. We initially analyzed the 9-dimensional system that included tangential forces of all three fingertips, but found that the only significant tangential forces were those counteracting gravity. They were relatively constant, which is not surprising given the trials we considered as valid examples of static grasp. The magnitudes of the fluctuations of the other tangential forces (those in the horizontal plane) were several orders of magnitude smaller than the normal forces, and therefore considered negligible for the purposes of making our main point. Namely, showing a counter example of task-irrelevant task variables (those associated with the UCM) being actively controlled during a static tripod grasp. Tangential forces add to the dimensionality of the motor control task—some of the performance variables associated with these dimensions could be identified as task-relevant, others as

being part of the UCM. However, any additional task variability dimension is, mathematically and in the context of the UCM hypothesis, perpendicular to existing dimensions (e.g., moment cancelation efforts do not necessitate normal force variability, from a purely mechanical point of view). Therefore, whether or not these additional dimensions are subject to control (i.e., constitute additional performance variables) has no bearing on our main finding that there exist at least two task-irrelevant (from a UCM point of view) dimensions of variability (i.e., Grasp and Compensation Modes) that are being continuously controlled in the task of static tripod grasp, while simultaneously, there exists a task-relevant direction, or performance variable (i.e., Hinge Mode), that is not controlled at short time scales. Nevertheless, studying potential coupling between mechanically independent task dimensions is a worthwhile problem. In fact, we have looked at this problem for a similar (but dynamic) task in a previous paper (Rácz et al., 2012), but that analysis and discussion is beyond the scope of this work.

Our methodology has some important strengths and differences compared to prior work that uses a temporal analysis. Our work on multifinger manipulation differs from that of locomotion (Dingwell et al., 2008, 2010), reaching and gaze shifting (van Beers et al., 2013) in that: (1) it is substantially simpler problem than locomotion and therefore easier to identify performance variables; (2) it is equally important to activities of daily living; and (3) particularly relevant to human evolution. In particular, Dingwell et al. (2010) recently showed that gait, a non-linear dynamical task, exhibits the expected greater variability along goal-irrelevant directions as per the UCM and Minimal Intervention principle. In agreement with our findings, they find corrections for deviations in both goal-relevant and -irrelevant directions; but prefer to say that the nervous system largely "ignores non-essential variations." While they use DFA to study the correlation structure along each projected time series, they interpret the scaling exponents as continuous variables that indicate different levels of control action at different time scales in different subspaces. Given the complexity and non-linearity of their task, they explore variations in model structure to alter what was being controlled, but not the task variables, to further strengthen their conclusions. We did not need to do that because we chose a simpler task where the analytical solution to the mechanics of the system and task allows us to define our Modes, and interpret the scaling exponents. Importantly, they cite us (Valero-Cuevas et al., 2009)—when stating that quantification of variances along spatial dimensions alone can lead to incorrect conclusions about control—as motivation for their use of temporal analyses as a necessary next step. This is the point we also now make by emphasizing spatio-temporal analyses for static grasp. In fact, it is perhaps a testament to the utility of these spatio-temporal analyses that, even when done at multiple levels of observation and across multiple tasks, different studies agree that temporal dynamics is critical to proper interpretation of neural control. Lastly, van Beers et al. (2013) study two simultaneous discrete movement tasks: reaching and gaze shifts between visual targets that are not related to our work in multifinger grasp. However, their autocorrelation analysis of task-relevant and task-irrelevant variables shows that task-irrelevant variability is corrected less intensively. Because their tasks are dynamical target-driven tasks, their interpretation of the temporal structure of variability in the task-irrelevant variables is motor exploration, learning and performance optimization. Given that our static grasp task is simpler and has clear goals that can be modeled mechanically, we can make stronger claims as to the nature and structure of the variability. Our approach is, however, necessarily silent about methodological issues in those other non-linear dynamical experimental and analytical paradigms. However, we agree with them in that active exploration for fatigue mitigation is a potential benefit of variability in these task-irrelevant variables (see below).

Furthermore, it is important to consider prior studies that have identified voluntary and involuntary collaborative force interactions among fingertips when pressing or grasping rigid objects [e.g., Baud-Bovy and Soechting (2001); Scholz et al. (2002); Shim et al. (2005); Latash and Zatsiorsky (2009); see for review Schieber and Santello (2004)]. From the mechanical perspective, many extrinsic flexor and extensor muscles are multitendoned or have multiple compartments subject to a certain level of common neural inputs [but the thumb and index finger are largely independent (Brand and Hollister, 1999)]. This provides a level of mechanical coupling across fingers—which is mostly known to prevent large, individuated or disparate finger motions [Agee et al. (1991); Brand and Hollister (1999); Zilber and Oberlin (2004); as reviewed by Schieber and Santello (2004)]. Our task was designed to consider these potential confounds by requiring a low-magnitude static grasp in postures where all fingers are similarly flexed so that tendinous interconnections do not play a dominant role. Common neural inputs to muscles across fingers are also not a confound because, as reported by Latash and Zatsiorsky (2009), those common drives do not produce the kind of variability that leads to a pervasive dynamic Grasp Mode in the low frequency range during non-grasp force production tasks. Common neural input, by definition, is composed of highly correlated short-latency (i.e., high frequency) discharge of motor units. As reported by Bremner et al. (1991) the duration of the synchronization ranged from 5 to 31 ms (mode = 13 ms). These latencies are only applicable to the shortest (i.e., 1–50 ms) time scales in **Figure 9**. Moreover, the Grasp Mode captures such effects of common neural drive because it is defined as synchronous increase or decrease of finger forces. Common neural drive would not enter the other Modes because they require opposing (i.e., synchronous increases and decreases) in finger forces. Thus, common neural drive cannot explain our findings of evidence of control action in task-irrelevant variables, and lack of it in task-relevant variables, that are spread across Modes and time scales.

Lastly, Bryce and Sprague (2012) have urged caution when analyzing non-linear or non-stationary signals with DFA. However, our goal is not to estimate exact or specific Hurst exponents, but rather show that a clear deviation from the 0.5 line exists, much like in the recent work by Dingwell. We did consider the potential confound of non-stationary time series, but our results are robust with respect to analyzing first and second halves of each trial. Furthermore, we do not observe an initial curvature mentioned by Bryce and colleagues, among other things because

we do not allow for estimation of very small time scales, as mentioned in our methods. Instead, we see an initial linear region, with scaling different for each Mode. This finding is robust across subjects and trial halves. This underscores the stability of our conclusion: that task-irrelevant dimensions are indeed subject to control intervention, and vice versa, and that this observation is time-invariant.

SPATIAL ANALYSIS

Our simulation results clearly show that the first two principal components, the Grasp and Compensation Modes, span the null space of force dynamics associated with successful static grasp: variation of force inside this manifold does not violate the constraints of static grasp (i.e., zero net force and moment). Given however, that noise and variability are inevitable elements of neuromuscular systems, successful task completion naturally leads to the population of the null space manifold, and task-relevant variability in the Hinge Mode orthogonal to the solution manifold (i.e., modulating linear motion of the object in violation of the static task requirement) will be minimal, but not necessarily zero.

In the case of static grasp, the fingertips are coplanar in the horizontal plane, and their vertical tangential components serve to cancel gravity. Therefore, the point of intersection of 3D force vectors in the horizontal plane can either:

Remain stationary. In this case the only possible changes in the fingertip force vectors are to increase or decrease their magnitudes simultaneously and proportionally, i.e., change the total grasp force. Mind the fact that these magnitudes are bounded above by finger strength and the possibility of crushing the object; and below by the need to support the object against gravity. Regardless of the location of the point of intersection within the object, such simultaneous and proportional increases or decreases in 3D fingertip force vector magnitudes will induce identically simultaneous and proportional changes in the normal component of the normal forces. This is captured by the Grasp Mode where all normal forces are positively correlated and therefore having PC loadings of the same sign, as in $[0.81\ 0.41\ 0.41]^T$ in **Figure 2**. Please note that the loadings are the unit vectors describing the multidimensional correlation defining each PC. Therefore the loadings for this PC show that the thumb, index and middle finger forces all co-vary in this Mode. This analytical argument shows that the normal forces suffice to detect the spatial correlation structure defining the Grasp Mode. To confirm this, **Figure 11** plots the loadings of the 1st PC of the 3D force analysis case (i.e., normal and two tangential forces for each digit) for all subjects and trials. This 9D equivalent to the Grasp Mode shows that positive correlation of all three normal forces dominates, and that the loadings of the tangential forces straddle the zero line (i.e., do not show strong covariation with the normal forces) to create a vector roughly $[0\ 0\ 0.8\ 0\ 0\ 0.4\ 0\ 0\ 0.4]^T$.

Move within the object. If, say, the thumb force vector maintained its magnitude but changed its direction along an arc to the right by increasing its the tangential component and decreasing its normal component, then maintaining static equilibrium (as it was in the experiments we analyzed) would require the other two fingertip force vectors to track the 3D thumb force vector. In so doing, the magnitude of one fingertip force vector must increase, and the other decrease. This lengthening and shortening of the vectors must again be simultaneous and proportional. Once again, this will also induce identically simultaneous and proportional changes in the normal component of the normal forces. This is captured by the Compensation Mode, where one normal force is positively correlated with the thumb force and the other negatively. Thus the fingers have PC loadings of opposite signs, as in $[0\ -0.71\ 0.71]^T$ in **Figure 2**. That is, the full 3-component force vectors are not required to detect these changes. The normal forces suffice to detect these changes and their associated structure as the Compensation Mode. To confirm this, **Figure 12** plots the loadings 2nd PC of the 3D force analysis case for all subjects and trials. This 9D equivalent to the Compensation Mode shows a dominant anti-correlation between the loadings of the normal forces of the index and middle finger, and that the loadings of the normal force of the thumb and all tangential forces straddle the zero line to create a vector roughly $[0\ 0\ 0\ 0\ 0\ -0.7\ 0\ 0\ 0.7]^T$.

A different combination of normal forces is the one perpendicular to the manifold. This is the "Hinge Mode" that would induce linear motion, with PC loadings $[0.6\ -0.5\ -0.5]^T$ (thumb normal force increasing and simultaneous and proportional decreases in the fingers' normal forces). Our results show that dynamics along this task-relevant Mode was minimal because, by construction, we only analyzed cases where the object was in static equilibrium, in agreement with the UCM hypothesis that this Mode exhibits less variability. The normal forces suffice to detect these changes and their associated structure as the Hinge Mode, as also shown for the 3D force analysis case in **Figure 13**.

Very critically, we did not need PCA to identify our three Modes empirically. Rather, these were prescribed by the analytical solution to the mechanics of the system and task. PCA was only applied to the experimental data to identify for each subject the directions of normal force variability that maximally corresponded to the known directions inferred from mechanical analysis. For all subjects, these agreed well, by construction, with the closed-form analytical solution as mentioned in the results.

Our experimental spatial results, as expected, are in agreement with our simulations and the prior evidence for the UCM Hypothesis and the Minimal Intervention principle (Scholz and Schoener, 1999; Jordan, 2003): the variance in task-relevant variables is smaller than in the task-irrelevant spaces. The difference in variance explained by the Grasp and Hinge Modes in each case is explained by comparing **Figures 4**, **5** where, in the absence of visual feedback, the total grasp force (Grasp Mode) shows large variability that is absent when visual feedback is provided to avoid such drift. More specifically, the projection of the fingertip force time series data recorded without visual feedback onto the Grasp Mode shows a very slow monotonic downward trend (**Figure 7** for a representative trial). We interpret this slow trend to be the major contributor to large spatial variability explained by this mode: it is caused by the three fingers reducing their normal forces simultaneously. This underscores an important shortcoming of PCA when applied to non-stationary signals (for a detailed discussion see Clewley et al., 2008). On the other hand, in trials *including* visual feedback, the Grasp Mode does not exhibit such a trend (**Figure 5** for a representative trial). This is not surprising, since holding a constant total force is now an explicit

Table 3 | Summary of findings, highlighting in bold discrepancy among UCM and Minimal Intervention (MI) predictions and temporal Detrended Fluctuation Analysis (DFA) results.

Mode	Experimental condition	Task relevance	UCM and MI predictions	Spatial PCA results	Temporal DFA results at different time scales
Grasp mode	No visual feedback	Irrelevant	No control	High variance	Controlled and uncontrolled
	With visual feedback	Relevant	Control	Low variance	Controlled and uncontrolled
Compensation mode	No visual feedback	Irrelevant	No control	High variance	Controlled and uncontrolled
	With visual feedback	Irrelevant	No control	Low variance	Controlled and uncontrolled
Hinge mode	No visual feedback	Relevant	Control	High variance	Controlled and uncontrolled
	With visual feedback	Relevant	Control	Low variance	Controlled and uncontrolled

*As per **Figures 8** and **9**, by **uncontrolled** we mean evidence of unstable and Brownian growth (scaling exponents $\geqslant 0.5$), and by **controlled** we mean evidence of corrective action (scaling exponents <0.5). In particular, both the Grasp and Compensation Modes are task-irrelevant but show temporal features of corrective action at some time scales. Similarly, the Hinge Mode is task-relevant but shows temporal features of lack of corrective action at some time scales.*

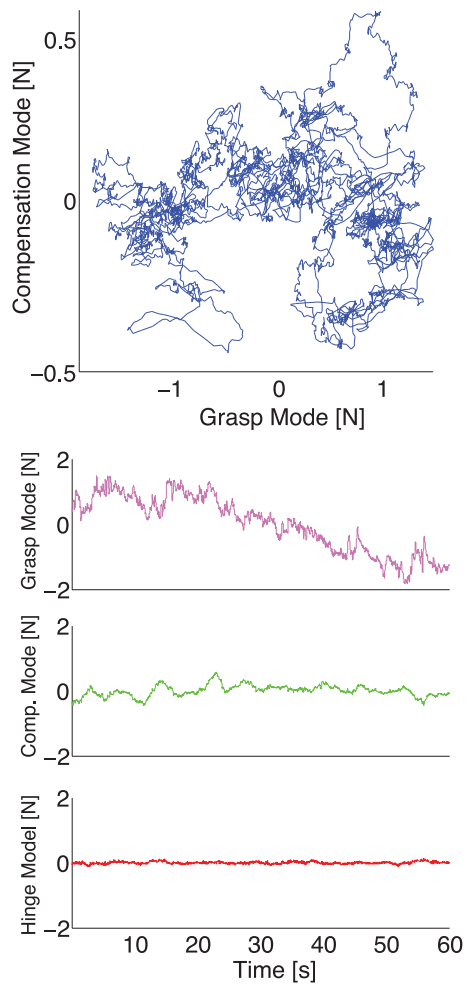

FIGURE 7 | Representative plot of the experimental normal forces now *projected onto the principal components* for the same representative trial as in Figure 4 *without* visual feedback. Top: The force fluctuations on the plane spanned by the Grasp and Compensation Modes. **Bottom:** The three principal component time series during a trial plotted individually. Note how the Grasp Mode captures the common downward trend, while the Compensation and Hinge Modes have relatively lower variability.

task constraint, converting the Grasp Mode into a task-relevant Mode (see **Table 3**). As a consequence, the Compensation Mode (the other task-irrelevant dimension) now contributes a larger proportion of the overall variability (**Figure 6**). The fact that variability in the Grasp Mode does not disappear with visual feedback is well known and can be attributed to unavoidable motor noise, and other central and peripheral sources of correlated finger forces (Santello and Soechting, 2000; Poston et al., 2010; Rácz et al., 2012). The Compensation Mode also exhibits a slow non-monotonic modulation both increasing and decreasing over time (**Figure 7**). This indicates that index and middle finger normal forces are slowly and continuously modulated, out of phase, during static grasp.

As we have argued before (Clewley et al., 2008; Kutch and Valero-Cuevas, 2011; Kutch and Valero-Cuevas, 2012), PCA of analytical solutions and experimental data alike naturally show a reduction in the dimensionality of task variables, which is a necessary result of meeting task constraints with a biomechanical plant. But this does not imply that the CNS is itself using a low-dimensional controller to simplify or optimize the redundancy problem. Rather, this simply reflects the structure of the solution space. Therefore, the question in not only whether the CNS *can* meet the requirements of the task (by definition it did if the task was accomplished), but also *how* it continues to meet them as time goes by. This makes temporal analysis of task variable dynamics critical to understanding the neural control actions in both the task-relevant and task-irrelevant spaces.

TEMPORAL ANALYSIS

Our DFA results, on the other hand, demonstrate the presence and absence of corrective actions by the CNS at different time scales in both the task-relevant and task-irrelevant task subspaces. Both linear and non-linear time series analysis has been commonly employed to reveal temporal correlation structures (positive or negative) indicative of control strategies (destabilizing or stabilizing, respectively), primarily in postural control research (Collins and De Luca, 1994; Jeka et al., 2004). For instance, in a seminal paper by Collins and De Luca (1994) the authors demonstrated a complex correlation structure in the center-of-pressure time series recorded during quiet stance, a highly redundant task. However, this perspective has not been

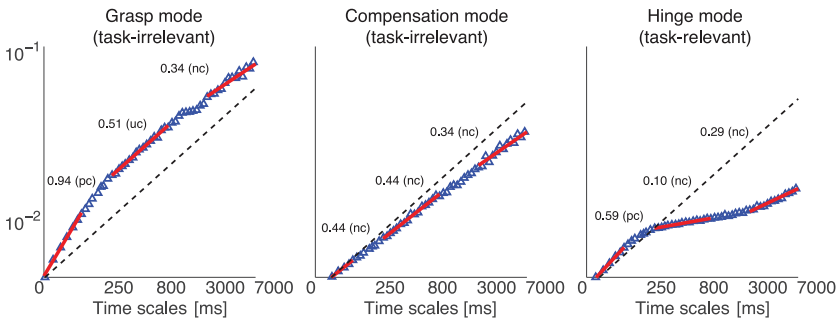

FIGURE 8 | Representative DFA of projected normal force time series from one subject, where the data were collected in a 200 g weight trial, *without* visual feedback. The plot shows the three scaling regions (1–50, 250–500, and 3500–7000 ms) which we used to fit the scaling exponent, for each normal force correlation Mode (Grasp, Compensation, and Hinge Modes). The red lines show the linear fits to the behavior of diffusion vs. time scale—their slopes can either be greater than, equal or less than 0.5 (dashed line), indicating the diffusive process is positively correlated (pc or uncorrected divergence), uncorrelated (uc or Brownian motion), or negatively correlated (nc or corrective action), respectively, at those time scales.

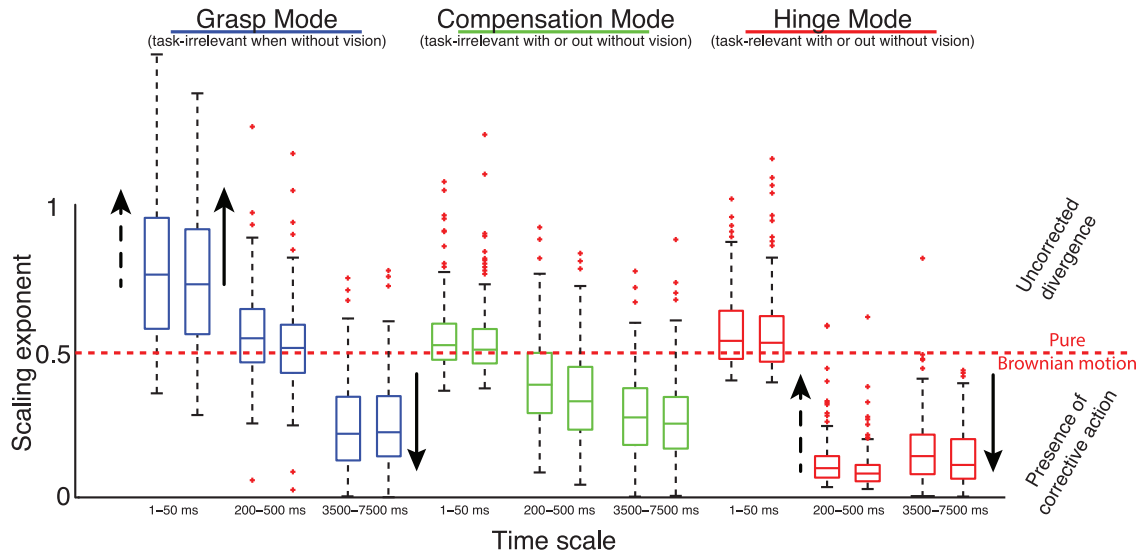

FIGURE 9 | Summary of temporal analysis. Distribution of DFA scaling exponents of the normal forces projected onto the three Modes at three time scales—during the first (left box plots) and the second half (right box plots) of the trials, in trials *without* visual feedback. Solid arrows indicate the effect, if any, of adding visual feedback; and dashed arrows indicate the effect, if any, of increasing the weight. Note that these arrows indicate any statistically significant changes found based on the non-parametric statistical tests described in the text. We find that, contrary to the suppositions of the UCM hypothesis and Minimal Intervention principle borne by spatial analysis, at different time scales we see evidence of control effort (i.e., negatively correlated time histories with scaling exponents <0.5) in the task-irrelevant Modes (i.e., Grasp and Compensation); and evidence of uncorrected divergence in the Grasp Mode—which becomes task-relevant when visual feedback is provided—, and Brownian-like dynamics and unstable growth in the task-relevant Hinge Mode (i.e., non-correlated and positively correlated time histories, respectively, with scaling exponents $\geqslant 0.5$).

brought to bear to the study of task redundancy. Once again, one can argue that the available literature endorses *preferential* as opposed to a strict separation into clearly controlled and uncontrolled variables, but we lacked a specific quantification of the temporal nature of the dynamics of task-relevant and task-irrelevant that would allow us to infer the neural control strategies in each space.

As per **Figures 8**, **9**, we find that both task-relevant and task-irrelevant variables exhibit the features of uncorrected divergence, Brownian motion and corrective action, depending on the time scale considered—as evidenced by positive, neutral, and negative correlations between force increments separated by different time periods (i.e., scaling exponents >0.5, $= 0.5$, and <0.5, respectively). As per **Table 3**, the UCM and Minimal Intervention approaches would predict a clearer separation of corrective actions (i.e., control strategies) across task-relevant and task-irrelevant variables.

The temporal features of the task-irrelevant Grasp Mode challenge the UCM Hypothesis and the Minimal Intervention principle. The Grasp Mode (when no visual feedback is given) exhibits all three control strategies as the time scales lengthen, and goes from uncorrected divergence, to Brownian motion to

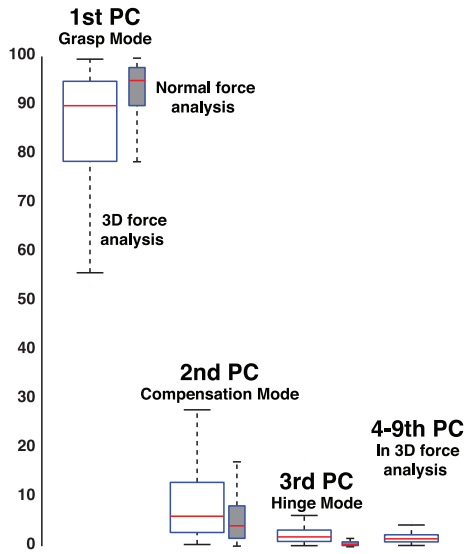

FIGURE 10 | Percent variance explained when considering three-dimensional forces for each digit (3D force analysis that is 9-dimensional given three forces for each of three digits, empty box plots) vs. when considering only the normal force at each digit (normal force analysis, gray box plots). The box plots show the variance explained by each PC from all subjects and trials, where the 1st PC explains the majority of the variance, the 2nd PC a modest amount, and the third PC less than 10%. The remaining variance explained by PCs four to nine is shown for the 3D force analysis. The structure of each PC is given by its loadings (as shown in **Figures 11**–**13**). Those figures shows that, even in the 3D force analysis case, the 1st, 2nd, and 3rd PC's represent the Grasp, Compensation and Hinge Modes seen in the normal force analysis. This consistency across percent variances explained demonstrates that the reduced normal force analysis is valid and equivalent to the full 3D force analysis.

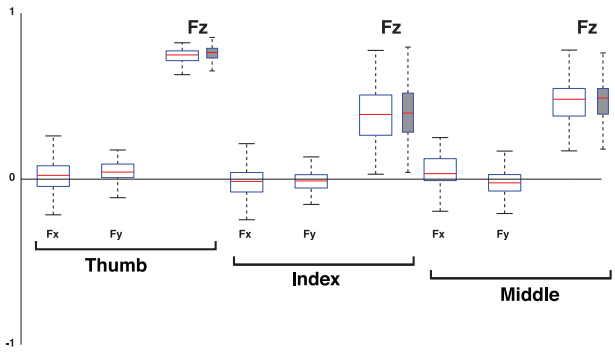

FIGURE 11 | Loadings of the 1st PC, the Grasp Mode, when considering the 3D force analysis case (normal plus two tangential force components, empty box plots) for each digit vs. when considering only its normal force (normal force analysis, gray box plots). Box plots show loadings from all subjects and trials. Note that the loadings of all tangential forces (Fx and Fy) straddle the zero line, demonstrating that they are not relevant to the correlation structure of the 1st PC. The normal force components (Fz) of all digits have positive and non-zero loadings, indicating that the structure of this PC using normal forces is equivalent to that of the full 3D force analysis. The dispersion or exact median values in the box plots are not the means to establish the task-relevance or task-irrelevance of the PC. That dispersion is a consequence of natural variability and inaccuracies in motor performance, and unavoidable sensor noise. It is the goals of the task and mechanical analysis that determine how to identify the task-relevant and task-irrelevant Modes.

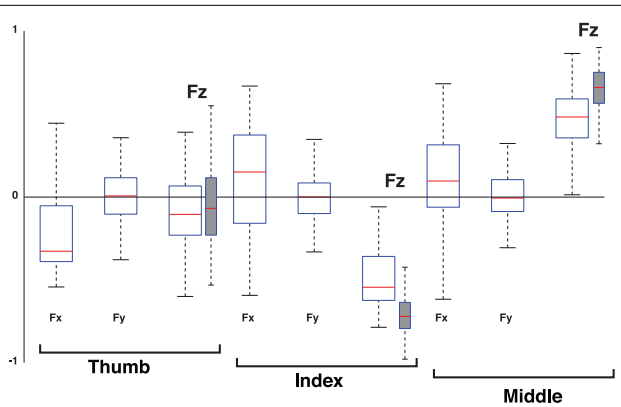

FIGURE 12 | Loadings of the 2nd PC, the Compensation Mode, when considering the 3D force analysis case for each digit (empty box plots) vs. when considering only its normal force (gray box plots). Box plots show loadings from all subjects and trials. Note that the loadings of the normal force components (Fz) of the thumb, and all tangential force components (Fx and Fy), straddle the zero line, demonstrating that they are not relevant to the correlation structure of the 2rd PC. The normal force components (Fz) of the index and middle finger exhibit anti-correlation, indicating that the structure of this PC using normal forces is equivalent to that of the full 3D force analysis. The increase in dispersion in the full 3D force analysis compared to the Grasp Mode in **Figure 11** is naturally associated with the increased susceptibility to measurement noise as this Mode explains much less of the variance in the data, see **Figure 10**.

corrective action. The slow downward trend in total grasp force in trials when without visual feedback happens at medium to long time scales—so it does not explain the uncorrected divergence seen at the short time scales. Such divergence, which was also present and even accentuated with visual feedback, is more likely a consequence of positive correlations that can be shown to be a result of the interplay between purely random signal-dependent noise (Jones et al., 2002), motor unit synchronization (Schieber and Santello, 2004), and instantaneous (but low-pass filtered by skin compliance) mechanical reaction forces. This variability in what are both task-irrelevant and task-relevant variables is nevertheless left uncorrected by the CNS either as part of the neural control strategy or because of inability to do so at such short latencies. Alternatively, we can argue that task-irrelevance is not only a spatial consideration but also a temporal one, where low-magnitude or short term variability is accepted and only corrected upon crossing a certain spatial or temporal threshold. But such interpretation is not really compatible with the UCM Hypothesis and the Minimal Intervention principle, but rather with other theories specifically phrased to advocate intermittent or drift-and-act control as an optimal strategy (Collins and De Luca, 1994; Guckenheimer, 1995; Milton et al., 2009a; Suzuki et al., 2012).

The neutral and negative correlations in the Grasp Mode at medium and long latencies, respectively, cannot be attributed to control intervention to avoid dropping the object due to a critical reduction in Grasp Mode force. The total grasp force level

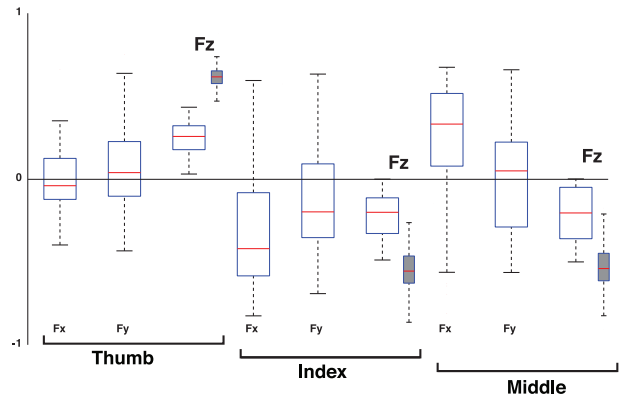

FIGURE 13 | Loadings of the 3rd PC, the Hinge Mode, when considering the 3D force analysis case for each digit (empty box plots) vs. when considering only its normal force (gray box plots). Box plots show loadings from all subjects and trials. Note that the loadings of the tangential forces (Fx and Fy) of the thumb, index and middle fingers straddle the zero line, demonstrating that they are not relevant to the correlation structure of the 3rd PC. The normal force components (Fz) of the thumb exhibits anti-correlation to those of the index and middle fingers, indicating that the structure of this PC using normal forces is equivalent to that of the full 3D force analysis. The increase in dispersion in the full 3D force analysis compared to the Grasp Mode in **Figure 11** is naturally associated with the increased susceptibility to measurement noise as this Mode explains much less of the variance in the data, see **Figure 10**.

always remained well above the weight of the object, the hand was held still, and the scaling exponents were unchanged between the first and second half of the trials (**Figure 9**)—and slip-grip responses happen at latencies well below 200 ms (Cole and Abbs, 1988; Gysin et al., 2003; Rácz et al., 2012). Thus we conclude that corrective control intervention depends on factors other than safety boundaries or automatic grasp tendencies seen only during dynamic manipulation (Rácz et al., 2012). Moreover, such corrective control intervention occurs regardless of whether the Grasp Mode is task-irrelevant or task-relevant (when without or with visual feedback, respectively). Further challenging the UCM Hypothesis and the Minimal Intervention principle, the task-irrelevant Compensation Mode also exhibits corrective control intervention at medium and long time scales.

DFA exposes an absence of correlation at very short time scales in the task-relevant Hinge Mode. This indicates an absence of corrective actions (i.e., control). This lack of control may, however, simply be due to the inability of the neuromuscular system to do so at such short latencies; or may be evidence of an intermittent or drift-and-act strategy. While finding the reasons for this requires further investigation, it is nevertheless important to point out this important temporal feature not previously addressed by the UCM Hypothesis and the Minimal Intervention principle, to the best of our knowledge. That is, the fact remains that, due to physiological limitations or control strategy, even highly task-relevant variables are left uncontrolled at some time scales.

The fact that the results are so similar between the first and the second halves of the trials indicates that the observed dynamics and the associated correlation structure depend neither on time nor the total grasp force (which can be interpreted as location in the force space; or in control terms our findings are not state-dependent). This in turn suggests a temporal control strategy that is state-independent (except potentially *at* the boundaries; which we have no reason to believe our subjects approached, but could be an important next research step).

One possible explanation for the observed negative correlations along the Grasp and Compensation Modes could be that traversing the solution manifold is an active process, through which the CNS actually takes advantage of redundancy. Specifically, controlled dynamics along the Compensation Mode corresponds to the regulation of the index and middle finger contributions to the opposition of thumb normal force. In agreement with others, we speculate that the may be actively trying to shift the demands between the two fingers over time, which in turn might mitigate effects of fatigue at the muscle level (e.g., Cote et al., 2002; Dingwell et al., 2008; van Beers et al., 2013). By gradually varying fingertip forces, the CNS can achieve a change in the underlying muscle coordination pattern, which in turn will change the rates of fatiguing of individual muscles, thus allowing for improved use of available resources. The slow downward trend along the Grasp Mode direction of normal forces agrees with this fatigue reduction strategy: a general reduction of forces generated by the muscles leads to a reduction in the fatigue rate. But at these low levels of grasp force magnitude, the redundancy of solutions for a given set of fingertip force vectors would also allow changes in coordination patters that would not be detectable as changes in the magnitude or direction of fingertip force vectors. This issue, therefore, deserves further investigation.

Lastly, note that here we do not employ DFA to determine self-similarity or fractional dimensionality in the data, as has been done in some studies (Hausdorff et al., 1996). In those studies, the linearity in the logarithmic plots needs to extend over at least one order of magnitude to count as strong evidence of fractionality (Kantz and Schreiber, 2004). In our case the requirements for the linearity of the logarithmic plots are not as rigid because the quantification of long-range correlations applies to data where the linearity extends over shorter ranges of time scales. Moreover, challenging the preferential separation of control action across task variables as in the UCM Hypothesis and the Minimal Intervention principle only requires evidence of similar corrective actions (or their absence) in both task-relevant and task-irrelevant-which our results clearly show. These results expose a fundamental limitation of the UCM hypothesis and the Minimum Intervention Principle: their focus on spatial aspects of motor variability and disregard for temporal aspects.

CONCLUSIONS AND MODULARITY

We show that both task-relevant and task-irrelevant parameters show corrective action at some time scales; and conversely, that task-relevant parameters do not show corrective action at other time scales. In agreement with recent work in other behavioral contexts, these results propose we revise our understanding of variability vis-á-vis task relevance by considering both spatial and temporal features of all task variables when inferring control action and understanding how the CNS confronts task redundancy. Moreover, these results are counter examples to the UCM hypothesis and the Minimal Intervention principle, as they assume a separation of task variables into relevant and irrelevant ones, indicated by their respective variabilities.

As mentioned above, proponents of UCM hypothesis and the Minimal Intervention principle admit the possibility of *preferential* as opposed to strictly *uncontrolled* variables (Latash et al., 2010), or that the nervous system largely "ignores non-essential variations" (Dingwell et al., 2010), but such qualitative distinctions have only begun to be quantified or considered in the spatio-temporal domain when inferring control action. Following up on those qualifications, we present specific spatio-temporal quantitative examples of controlled intervention (or lack thereof) in both task-relevant and task-irrelevant spaces (based on mechanical/mathematical definition of the task and its possible modes of variability) to expand our understanding of neural control strategies. Additional work is needed to revise our view of neural control that takes into considerations both spatial and temporal aspects of neuromuscular function and variability, and the structure and nature of the solution space of the task.

The similar nature of control actions across time scales in both task-relevant and task-irrelevant spaces that we find point to a level of modularity not previously recognized. The spatio-temporal results presented here instead suggest that neural control uses a continuum of control strategies going from uncorrected divergence to strong corrective actions that are not defined by the level of task-relevance of the controlled variables; and which may also involve intermittent and drift-and-act characteristics. Importantly, while the increase in weight and the addition of visual feedback does seem to modulate the dynamics on the individual dimensions, it does not lead to a crossing of the 0.5 line and therefore not to a fundamental change in the control strategy. Our methodological consideration and spatio-temporal analysis allow us to present clear examples of how the task-irrelevant parameters (i.e., elemental variables that are organized to constitute the UCM) are actively and continuously controlled during a tripod grasp at certain time scales, while the task-relevant parameter (or performance variable) is not actively controlled during a tripod grasp at certain time scales. Therefore, we show that estimating the different extents of control based on task variable variances alone (a purely spatial approach) is insufficient, as Dingwell and we had proposed before (Valero-Cuevas et al., 2009; Dingwell et al., 2010). Rather, those variables constituting the UCM (which are again, mathematically defined by the unambiguous mechanics of the task, see **Figure 2**) may have different temporal dynamics, but are not controlled in a fundamentally different way.

This spatio-temporal approach to variability provides a tool to quantify the nature and degree of neural control action, extending the traditional spatial variance magnitude approach by quantifying the temporal nature of variability. For example, traversing the solution manifold is an active process by which the controller *enforces* the constraints of the task. The CNS does not *create* the solution manifold [1], but rather seeks to inhabit it as has been discussed earlier (Keenan et al., 2009; Kutch and Valero-Cuevas, 2012; Suzuki et al., 2012). As such, the means by which the CNS enters and continually inhabits the solution manifold can be thought of as the implementation of a dynamical attractor on the task variables. In the context of time-varying stochastic behavior of differential and discrete-time distributed systems like the neuromuscular system, the implementation of such a controller enforcing an attractor can be thought of as the implementation of a specific probability density of the state (for a presentation of this view see Sanger (2011), which is different from Bayesian estimation and discrete-time Markov processes).

This emerging view of the nervous system as functioning at the level of affecting probability density functions (Sanger, 2011) is compatible with a modular interpretation of our spatio-temporal results. DFA estimates the statistical self-affinity of stochastic processes with memory whose underlying statistics (mean, standard deviation and higher-order moments) or dynamics are non-stationary (Kantelhardt et al., 2001). That is, DFA quantifies how well a probability density function is implemented. Thus the continuum of control strategies seen across all Modes and time scales can be thought of as essentially differently tuned versions of the same modular control process that can let drift (i.e., uncorrected divergence), be indifferent, or enforce (i.e., corrective action) the statistics of the time-varying probability density of the state so that it populates the solution space. Hence the level of modularity in the controller rests on the ability of the system to work with probability density functions in the task-relevant and task-irrelevant spaces at different time scales—and not with distinct basis functions or synergies implementing a separation of task variables.

[1]To be clear, the solution manifold arises independently of the controller as it depends only on the characteristics of the plant and the constraints of the tasks. A controller can then choose to inhabit a particular region or subset of the solution manifold to meet the requirements of the task (Kutch and Valero-Cuevas, 2012; Suzuki et al., 2012).

APPENDIX

IDENTIFICATION AND MODELING OF THE MECHANICAL REQUIREMENTS OF THE TASK AND ITS NULL SPACE

Each fingertip applies a three-dimensional force $\tilde{f}$ to the object. Computing the cross product of the moment arm, i.e., the vector between the point of force application and the object's center of mass, with the fingertip force vector yields the moment applied to the object. The total 6-dimensional force and moment applied to the object can be computed with the following mapping **W**:

$$\begin{bmatrix} \sum \mathbf{f} \\ \sum \mathbf{m} \end{bmatrix}_{6\times 1} = \begin{bmatrix} \mathbf{I}_{3\times 3} & \mathbf{I}_{3\times 3} & \mathbf{I}_{3\times 3} \\ \mathbf{M}_{\text{th}} & \mathbf{M}_{\text{ind}} & \mathbf{M}_{\text{mid}} \end{bmatrix}_{6\times 9} \begin{bmatrix} \tilde{f}_{\text{th}} \\ \tilde{f}_{\text{ind}} \\ \tilde{f}_{\text{mid}} \end{bmatrix}_{9\times 1} = \mathbf{W}\tilde{f}$$

where $\mathbf{I}_{3\times 3}$ is the unit matrix and $\mathbf{M}_{\{\text{th, ind, mid}\}}$ is the skew-symmetric matrix representing the cross-product between the moment arm of the finger and its force vector $\mathbf{f}_{\{\text{th, ind, mid}\}}$. Since **W** is a mapping from 9-dimensional (three 3-D finger forces) to 6-dimensional (six degrees of freedom for the object grasped) space, the associated null space, i.e., the space of vectors for which $\tilde{\mathbf{0}} = \mathbf{W}\tilde{\boldsymbol{x}}$ has 3 dimensions. Any vector $\tilde{\boldsymbol{x}}$ in this null space represents a solution to the static grasp requirement $\begin{bmatrix} \sum \mathbf{f} \\ \sum \mathbf{m} \end{bmatrix} = \begin{bmatrix} \tilde{\mathbf{0}} \\ \tilde{\mathbf{0}} \end{bmatrix}$, i.e., that both the sum of forces and the sum of moments should be zero. This is the mathematical description of the task-irrelevant subspace because fingertip forces can change inside this space but the object will remain static.

However, this is a necessary, but not sufficient, requirement. Additionally, we require that the finger tips do not slip, so the tangential forces are upper-bounded through the friction relationship $f_{\text{tangential}} \leq \mu f_{\text{normal}}$, i.e., the tangential force cannot exceed the normal force, multiplied with the friction coefficient μ, which we have set to 0.04, the approximate friction coefficient of Teflon on Teflon. This represents a lower bound on the coefficient of friction, since this coefficient is certainly greater whenfingertip and Teflon surface interact. That is, the grasp under experimental conditions is actually less constrained and tangential components can be greater. In addition, the sum of tangential forces directed vertically needs to oppose the force applied to the object by gravity. A nominal object had a weight of 100 g, hence the sum of tangential forces had to equal 0.981N, which in turn determined the sign (positive, i.e., into the object) and the minimum magnitude of the normal forces. This requirement changes with the weight condition, of course. For a complete list of static grasp model constraints, see **Table A1**.

Given that the task null space is well described, it was important to simulate the properties of expected solutions to compare against the experimental results to properly disambiguate the spatio-temporal features of the fingertip forces that can be explained by mechanics from those of neural origin; as in Rácz et al. (2012) and Kutch and Valero-Cuevas (2012). Enforcing all constraints gives us mathematical description of the null space of the task. To simulate instances of these fingertip forces, we numerically sampled vectors $\tilde{f}_{t_{\text{null}}}$ from the null space of the above linear matrix by multiplying the three null space basis vectors $\tilde{\boldsymbol{n}}_i$ with random values a, b, c, drawn from a standard Brownian random walk: $\tilde{f}_{t_{\text{null}}} = a \cdot \tilde{\boldsymbol{n}}_1 + b \cdot \tilde{\boldsymbol{n}}_2 + c \cdot \tilde{\boldsymbol{n}}_3$. We then added these null space vectors $\tilde{f}_{\text{null}}$ to the minimum sum-of-squared-forces solution $\tilde{f}_{\text{min sq}}$ of force vectors that met all the above described static grasp constraints: $\tilde{f}_t = \tilde{f}_{\text{min sq}} + \tilde{f}_{t_{\text{null}}}$, using MATLAB's (Natick, MA) `quadprog()` function to determine the actual solution with minimum Euclidean distance to $\tilde{f}_{\text{min sq}} + \tilde{f}_{t_{\text{null}}}$.

Table A1 | List of relevant constraints in static grasp.

Constraint	Magnitude	Interpretation
$\sum \mathbf{F}$	$[0, 0, mg]^T$	Sum of forces equal and opposite to gravity force, i.e., no net force
$\sum \mathbf{M}$	**0**	Sum of moments equals zero, i.e., no net moment
F_{i_T}	$\leq \mu \cdot F_{i_N}$	Tangential force at the i-th finger cannot exceed normal force

Humans achieve locomotor dexterity that far exceeds the capability of modern robots, yet this is achieved despite slower actuators, imprecise sensors, and vastly slower communication. We propose that this spectacular performance arises from encoding motor commands in terms of *dynamic* primitives. We propose three primitives as a foundation for a comprehensive theoretical framework that can embrace a wide range of upper- and lower-limb behaviors. Building on previous work that suggested discrete and rhythmic movements as elementary dynamic behaviors, we define submovements and oscillations: as discrete movements cannot be combined with sufficient flexibility, we argue that suitably-defined submovements are primitives. As the term "rhythmic" may be ambiguous, we define oscillations as the corresponding class of primitives. We further propose mechanical impedances as a third class of dynamic primitives, necessary for interaction with the physical environment. Combination of these three classes of primitive requires care. One approach is through a generalized *equivalent network*: a virtual trajectory composed of simultaneous and/or sequential submovements and/or oscillations that interacts with mechanical impedances to produce observable forces and motions. Reliable experimental identification of these dynamic primitives presents challenges: identification of mechanical impedances is exquisitely sensitive to assumptions about their dynamic structure; identification of submovements and oscillations is sensitive to their assumed form and to details of the algorithm used to extract them. Some methods to address these challenges are presented. Some implications of this theoretical framework for locomotor rehabilitation are considered.

Keywords: discrete, submovement, rhythmic, oscillation, impedance, primitive, locomotion, rehabilitation

INTRODUCTION

In a recent publication, we asserted a pressing need for a fundamental mathematical theory to help organize and structure the prodigious volume of knowledge about sensorimotor control (Hogan and Sternad, 2012). We contend that such a theory has come within reach, though we anticipate that its development will require a process of continuous and incremental revision. While it is common practice to develop mathematical models for narrowly-specified sensorimotor tasks, to establish a reliable theoretical foundation it is necessary to take a broader perspective and consider the widest feasible range of behaviors—even if for no other reason than to uncover and confront facts that might prove embarrassing to a narrowly-formulated theory. Previously we outlined a theoretical framework for upper-extremity motor control that could encompass those quintessentially human behaviors, object manipulation and the use of tools. The goal of this essay is to extend this framework to lower-extremity motor control. To illustrate the potential value of such a theory we consider some of its possible implications for locomotor rehabilitation.

Of course, we acknowledge that an integrated theory of upper- and lower-extremity motor control is ambitious, but it ought to be possible—after all, there is only one central nervous system (CNS). Moreover, many commonplace actions require integrated control and coordination of upper and lower extremities, indeed of the entire body. For example, drilling a horizontal hole in a vertical wall using a hand-held drill is commonly performed in a standing position. Therefore, the force exerted by the hand on the drill and wall necessitates tangential force on the ground at the feet. In fact, almost all of the body's degrees of freedom must be coordinated—essentially everything between the hands and feet. The horizontal force results in an overturning moment that must be offset by displacing the center of gravity from the center of pressure below the feet, and a sufficiently strong hand force is typically accomplished by moving the center of gravity far beyond the base of support—i.e., by leaning hard into the push or pull (Dempster, 1958; Rancourt and Hogan, 2001). That is a common cause of falls if the horizontal force exceeds the frictional force between feet and ground and the feet slip (Grieve, 1983). Moreover, with feet together in this leaning posture, an unstable dynamic zero is introduced such that the hand force cannot *decrease* without transiently *increasing*, and vice-versa (Rancourt and Hogan, 2001). With feet far apart, that dynamic zero can be eliminated. The essential point is that the configuration of the *feet* dictates the dynamics of force exertion by the *hands*.

Even aside from the need to integrate upper- and lower-extremity motor control, the spectacular agility of human locomotion demands explanation. Even walking, that most mundane of behaviors, is a subtle and complex dynamic process. Despite intensive and ongoing research, the dynamics of human walking have yet to be reproduced by robots, even though they have actuators faster than muscle by factors of tens to thousands, and communication faster than neurons by a factor of a million or more (Kandel et al., 2000; Hogan and Sternad, 2012). But locomotor behavior is far more versatile than walking. For example, soccer, arguably the world's most popular sport, not only requires agile high-speed maneuvering to avoid equally agile opponents, but controlling the ball requires dexterity with the legs and feet comparable to that of the hands and fingers. In comparison, robot soccer—though fun, highly motivating, and a superb enticement to study science and engineering—is a pale shadow of the "beautiful game."

DYNAMIC PRIMITIVES

Why is human locomotion so agile despite the limitations of our neuro-mechanical system? We believe that the answer lies in the distinctive character of human motor control. Mounting evidence indicates that sensorimotor control relies on a composition of primitive dynamic actions (Sternad et al., 2000; Thoroughman and Shadmehr, 2000; Flash and Hochner, 2005; Kargo and Giszter, 2008; Sternad, 2008; Sing et al., 2009; Degallier and Ijspeert, 2010; Dominici et al., 2011). We propose that *human motor control is encoded solely in terms of these primitive dynamic actions*.

Part of the challenge of controlling locomotor behavior is the high-dimensional, strongly nonlinear, hybrid character of the mechanical dynamics. "Hybrid" in this context refers to a mixture of discrete-event dynamics (each foot making or breaking contact with the ground changes the structure of the dynamic equations) and continuous dynamics (the motion of the skeleton in response to muscular action). With one foot on the ground, the human skeleton has on the order of 200 degrees of freedom; with two feet on the ground, a closed-chain kinematic constraint adds to the complexity. Moreover, kinematically-constrained rigid-body mechanics as described by Lagrange's equations is at best an approximation. Soft tissues contribute significantly to musculo-skeletal dynamics and add more degrees of freedom, e.g., via the deformation of muscles or body fat. For example, the impact due to heel strike can cause the mass of the calf muscles to resonate with the elasticity of passive tissues such as the Achilles tendon (Wakeling and Nigg, 2001; Wakeling et al., 2003). That phenomenon cannot be described by a model with only kinematically-constrained rigid bodies. The human body is a forbiddingly complex dynamic object. As we outline below, control via primitive dynamic actions may provide a way to manage this complexity.

The idea that motor control is accomplished by combining primitive elements is not at all new but the full extent of its ramifications for motor control may not yet have been fully articulated. The search for primitive elements that generate motor actions dates back at least a century. Sherrington proposed stereotyped neuromuscular responses to sensory events—the *reflexes*—as building blocks of more complex actions (Sherrington, 1906; Gallistel, 1980; Elliott et al., 2001). The subsequent wave of behaviorist psychology explored how stimulus-response associations (S-R units) could become an "alphabet" for complex behavior. Learning a new action would comprise "chaining" such S-R units or reflexes such that each reflexive action resulted in sensory events that "triggered" the next (Bässler, 1986).

Discrete and rhythmic movements have been proposed as candidates for two classes of primitive actions (Schaal et al., 2000, 2003; Sternad et al., 2000; Sternad, 2008; Ijspeert et al., 2013). They have been termed *dynamic* primitives as they refer to patterns of behavior that may robustly emerge from dynamic systems. To explain, two of the prominent behaviors exhibited by non-linear dynamic systems are *point attractors* and *limit cycles*; a point attractor may describe a discrete movement to a stable posture; a limit cycle may describe a rhythmic movement. Even some of the simplest dynamic systems can exhibit these behaviors as may be seen by considering the class of negative-resistance oscillators from engineering (Strauss, 1970). Those second-order dynamic systems can exhibit robustly sustained oscillation (limit cycle behavior) or stable convergence to a single state (point attractor behavior); changing the value of a single parameter is sufficient to select or induce a transition between these two alternatives. More biologically plausible models of neural oscillators exhibit similar properties, thereby lending support for these mechanisms generating observable behavior (Fitzhugh, 1961; Nagumo et al., 1962; Matsuoka, 1985; Ronsse et al., 2009).

Discrete and rhythmic movements describe unconstrained behavior but frequent physical contact with the ground is an inescapable aspect of human locomotion. A different class of dynamic primitives is required to manage that physical interaction. Locomotion is often described as "controlled falling," yet most of the control occurs not during the fall, but during the sudden stop at its end. During single-legged support the body behaves approximately like an inverted pendulum and available control authority is quite limited. Most of the opportunities for control arise from the behavior of the swing leg as it contacts the ground. This dynamic "shock absorber" behavior is characterized by mechanical impedance. Controllable mechanical impedance is required as a third class of dynamic primitives to account for interaction, in locomotion as in object manipulation. We contend that, taken together, these three dynamic primitives may account for a wide range of behavior.

LEVELS OF ANALYSIS

To understand how dynamic primitives might account for human locomotor control, we distinguish between (at least) three levels of analysis: an *observational level* of overt, measurable behavior; a *combinatorial level* at which the dynamic primitives may be combined; and a *physiological level* from which the dynamic primitives may actually arise—e.g., through a combination of muscular and/or neural dynamics giving rise to submovements, oscillations, and impedances. These levels are loosely analogous to Marr's three levels of analysis—computational, algorithmic, and implementational (Marr, 1982). However, Marr's levels refer to computation or information-processing, specifically for vision. While control of locomotion also involves computation

or information processing, the control of physical interaction is essential and not adequately subsumed under information processing.

A failure to distinguish between these levels—observational, combinatorial, and physiological—all too frequently confounds sensorimotor neuroscience. The definitions of dynamic primitives we propose below describe *product* rather than *process*. That is, in an attempt to establish a foundation, we focus on the phenomenology of motor behavior, not on specific hypothesized mechanisms that may give rise to that observable behavior. For clarity, we define dynamic primitives in the mechanical domain of motions and forces at the interface (points of contact) between the neuro-mechanical system and the physical world.

ATTRACTORS

We define dynamic primitives as patterns of behavior that robustly emerge from dynamic systems, that is, as *attractors*. For example, a reasonably general representation of a dynamic system describes the evolution of behavior in a finite-dimensional state space, $\dot{\mathbf{x}} = f(\mathbf{x})$ where $\mathbf{x} \in R^n$ for finite n. An attractor is a subset of state space with at least two properties: first, it is an *invariant set*: if the system begins in an invariant set, it never leaves it. Secondly, that invariant set is *attractive*: if the system starts sufficiently close to it, the system will ultimately converge to the attractor. Attractor sets may have many forms. A *point attractor* is a single point in state space. An attractor set that is a closed path (or orbit) defines a *limit cycle*. There are alternatives: any feasible path in state-space—any trajectory—may be an attractor; this may describe discrete reaching movements, which exhibit trajectory stability (Lackner and Dizio, 1994; Shadmehr and Mussa-Ivaldi, 1994; Won and Hogan, 1995; Burdet et al., 2001). Other subsets of state-space (e.g., manifolds) may also be attractors; these may describe synergies. Chaotic dynamic systems may have *strange attractors*, prodigiously complex objects with fractal geometry, and there is evidence that locomotion may exhibit chaotic dynamics (Strogatz, 1994; Hausdorff et al., 1995, 2001).

One important feature of this definition of dynamic primitives is that an attractor exhibits a degree of robustness that might be termed "*temporary permanence*": permanence due to robustness to perturbation, temporary due to the fact that dynamic primitives may have limited duration. The pattern of behavior described by the invariant set will re-emerge after perturbation, at least for sufficiently small perturbations.

An important consequence of dynamic primitives defined as attractors is that it points to experiments that might test their objective reality (at least in principle). Due to the robustness of the attractor, a dynamic primitive should manifest as a common pattern of behavior observable in different contexts and despite the presence of noise or perturbations. This feature may lend itself to experimental testing.

DISCRETE MOVEMENTS AND SUBMOVEMENTS

An important requirement for a theory based on primitives is "composability"—it should be possible to combine the elements to generate a repertoire of behavior. In previous work we proposed precise quantitative definitions of discrete and rhythmic movements (Hogan and Sternad, 2007). Our definitions were deliberately confined to the behavioral or observational level, remaining silent about possible generative processes that might give rise to these observations. For a movement to be discrete, i.e., distinct from other movements, we reasoned that any consistent definition requires that it should begin and end with a period of no movement. With that definition, discrete movements can only be sequenced and cannot overlap in time. That would severely restrict the repertoire that could be generated.

To overcome this limitation, we propose that *submovements* are primitive dynamic elements of motor behavior. In essence, submovements are like discrete movements but they may overlap in time and their profiles may superimpose. A submovement is conceived as a *coordinative atom*: just as atoms are primitive units of chemical reactions, submovements are elements of dynamic coordination used to compose motor behavior. Just as atoms have complex internal structure, submovements may require complex patterns of neuromuscular activity to instantiate the dynamic process from which a submovement emerges as an attractor.

We define a submovement as an attractor that describes a smooth sigmoidal transition of a variable from one value to another with a stereotyped time-profile. For limb position, the variable is a vector in some coordinate frame $\mathbf{x} = [x_1, x_2 \ldots x_n]^t$. If it is foot position in visually-relevant coordinates, the elements of $\mathbf{x}$ might be the positions and orientations of the foot ($n \leq 3$ for location and $n \leq 6$ if orientation is included). If it describes the configuration of the entire limb, the number of coordinates may be substantially greater, e.g., all of the relevant joint angles. Each coordinate's speed profile has the same shape which is non-zero for a finite duration $d = e - b$, where b is the time when the submovement begins and e is the time it ends, i.e., it has *finite support*:

$$\dot{x}_j(t) = \hat{v}_j \sigma(t), \; j = 1 \ldots \; n$$

where $\hat{v}_j$ is the peak speed of element j; $\sigma(t) > 0$ if $b < t < e$ and $\sigma(t) = 0$ if $t \leq b$ or $e \leq t$. The speed profile has only one peak: there is only one point $t_p \in (b, e)$ at which $\dot{\sigma}(t_p) = 0$, and at that point, $\sigma(t_p) = 1$.

Note that this definition is deliberately silent about possible generative dynamic processes that might give rise to submovements. However, some constraints on those processes can be identified. It may seem that a dynamic process with a point attractor is appropriate. However, physiological evidence shows that at least in reaching movements, the CNS does not simply specify final position (Bizzi et al., 1984; Won and Hogan, 1995). It is the trajectory, rather than final position, that is controlled. Further, this trajectory has a stereotyped time profile (Atkeson and Hollerbach, 1985). This dynamic primitive may be termed a "trajectory attractor."

Composability

Submovements may be considered as *basis functions* and combined with overlap in time to produce a wide range of motion profiles. Though several combination operators are possible, linear vector superposition of discrete point-to-point reaching movements has been shown to provide an accurate description

of movement trajectories in which a target shifts abruptly (Flash and Henis, 1991). Combining m submovements yields

$$\dot{x}_j(t) = \sum_{k=1}^{m} \hat{v}_{jk}\sigma(t\,|b_k, d_k), j = 1\ \ldots n$$

where each submovement k has the same shape but may have different peak speed $\hat{v}_{jk}$, start time b_k and duration d_k.

Composability has its drawbacks. One important disadvantage is the concomitant difficulty of identifying submovements unambiguously from a continuous motion record. Some responses to this challenge are discussed below.

RHYTHMIC MOVEMENTS AND OSCILLATIONS

From a strictly mathematical perspective, a rhythmic dynamic primitive is not essential. Rhythmic movements could be described parsimoniously as a composite of overlapping submovements in opposite directions. However, rhythmic movement is very old phylogenetically. Available evidence indicates that oscillatory behavior of both upper and lower extremities is a *distinct* dynamic primitive element of biological motor control and not a composite of submovements (Brown, 1911, 1914; Grillner and Wallen, 1985; Schaal et al., 2004).

Because the term "rhythmic" has numerous confusing variations of meaning, to render precision, we denote the corresponding dynamic primitive as an *oscillation* (Hogan and Sternad, 2007). Describing limb position as a vector quantity, $\mathbf{x} = [x_1, x_2 \ldots x_n]^t$, we define the primitive as an attractor that describes almost-periodic motion:

$$\left|x_j(t) - x_j(t + \triangle t + lT)\right| < \varepsilon_j\ \forall t,\ l = \pm 0, 1, 2, \ldots,\ j = 1\ \ldots n,$$

where T is a constant (its smallest value is the period), $|\triangle t| < \delta$ and ε_j and δ are small constants. This definition allows for the ubiquitous fluctuations exhibited in biological behavior, whether due to stochastic processes (noise) or deterministic chaos (Raftery et al., 2008). The main point of this definition is that the *average* time-course of an almost-periodic behavior is strictly periodic. The amplitude and phase of each vector component may differ but all components exhibit an average time-variation with the same shape and period, T.

As with submovements, this definition is deliberately silent about possible generative processes that might give rise to these observations. However, it seems reasonable to conjecture that oscillations emerge from a generative dynamic process with a limit cycle attractor (Kay et al., 1991; Rabinovich et al., 2006).

Composability

Evoking Fourier's theorem, it is clear that a wide range of almost-periodic behaviors may be composed by superposition of oscillatory primitives,

$$\overline{x}_j(t) = \sum_{k=1}^{m} \hat{x}_{jk}\, s(t\,|T_k, \phi_k)$$

where the overbar denotes an average, $s(t\,|T_k, \phi_k)$ is a sinusoid with period T_k and phase ϕ_k as parameters, and $\hat{x}_{jk}$ is its amplitude. However, as with submovements, composability also implies a challenge. Unless their form is known precisely, unambiguous identification of type and number of oscillatory primitives from a continuous motion record is problematic.

MECHANICAL IMPEDANCE

To account for contact and physical interaction with the ground, a third class of dynamic primitives is required, mechanical impedances. Loosely speaking, mechanical impedance is a generalization of stiffness to encompass nonlinear dynamic behavior (Hogan, 1985). Mathematically, it is a *dynamic operator* that determines the force (time-history) evoked by an imposed displacement (time-history). The force and displacement must be *energetically conjugate*; that is, they must refer to the same point(s) so that incremental mechanical work dW may be defined i.e.,

$$dW = \mathbf{f}^t d\mathbf{x} = \sum_{j=1}^{n} f_j dx_j$$

where $\mathbf{x} = [x_1, x_2 \ldots x_n]^t$ is a vector of positions and $\mathbf{f} = \left[f_1, f_2 \ldots f_n\right]^t$ is a vector of forces, both defined with respect to any suitable coordinate frame. A mechanical impedance operator $\mathbf{Z}$ maps displacement onto the conjugate force.

$$\mathbf{f}(t) = \mathbf{Z}\,\{\triangle\mathbf{x}(t)\}$$

The form of this mapping may be nonlinear and time-varying. For convenience we often assume a state-determined representation

$$\dot{\mathbf{z}} = Z_s(\mathbf{z}, \triangle\mathbf{x}, t)$$
$$\mathbf{f} = Z_o(\mathbf{z}, \triangle\mathbf{x}, t)$$

where $\mathbf{z} = [z_1, z_2 \ldots]^t$ is a vector of state variables and Z_s and Z_o are algebraic functions. For brevity, we often omit the "mechanical" prefix.

The displacement inputs need not be at the same physical location in space, provided they can be paired with energetically-conjugate forces. For example, the several joints of the lower extremity (hip, knee, ankle, etc.) are in different physical locations. The limb configuration may be described using joint angles, $\boldsymbol{\theta} = [\theta_1, \theta_2 \ldots \theta_n]^t$, a special case of *generalized coordinates* (Goldstein, 1980). The corresponding *generalized forces* (joint torques) $\boldsymbol{\tau} = [\tau_1, \tau_2 \ldots \tau_n]^t$ are defined such that incremental mechanical work may be defined.

$$dW = \boldsymbol{\tau}^t d\boldsymbol{\theta} = \sum_{j=1}^{n} \tau_j d\theta_j$$

Joint mechanical impedance maps joint angular displacements onto the evoked joint torques.

$$\boldsymbol{\tau}(t) = \mathbf{Z}_{joint}\,\{\triangle\boldsymbol{\theta}(t)\}$$

Like submovements and oscillations, humans can voluntarily control mechanical impedance (Hogan, 1979, 1980, 1984, 1985; Burdet et al., 2001; Franklin and Milner, 2003; Franklin et al., 2007). The most obvious way is by co-contraction of antagonist

muscle groups but the configuration of the limb also has a profound effect—posture modulates impedance (Hogan, 1990). During locomotion the mechanical impedance of the lower limb at the point of contact with the ground, and hence the way it absorbs or transmits the shock of impact to the rest of the body, depends strongly on whether first contact is made with the heel or the ball of the foot, or whether the leg is straight or the knee slightly flexed.

Mechanical impedance is a different kind of primitive than a submovement or oscillation; nevertheless it has properties of an attractor as we identified above. Mechanical impedance is extremely robust to contact and interaction. While the force and motion of the foot are obviously sensitive to contact with the ground, mechanical impedance at, say, the ankle is a property that emerges solely from the dynamics of the neuro-mechanical system supporting the foot and is completely independent of contact. It exhibits the robustness that we require for a dynamic primitive. Neuro-muscular mechanical impedance depends on the intrinsic physical properties of the muscular and skeletal systems but it is also influenced by neural feedback loops, especially those involving muscle spindles and Golgi tendon organs at the spinal level or higher. A compelling case has been made that one important function of these feedback loops is to maintain the mechanical impedance of the neuro-muscular actuator (Nichols and Houk, 1976; Hoffer and Andreassen, 1981). Undesirable impedance reduction due to cross-bridge detachment evoked by imposed displacement is corrected by enhanced neural activation; this makes the impedance an attractor of the closed-loop system. Moreover, it is known that the gains of these feedback pathways are highly modifiable, either via gamma motoneuron activity or via descending drive to spinal interneuron pools (Prochazka et al., 2000). Thus, the attraction to a particular impedance that these feedback loops provide has the *temporary permanence* that we believe is a hallmark of dynamic primitives.

Composability: superposition of impedances

A remarkable feature of mechanical impedance is that, when coupled to skeletal inertia, *non-linear impedances may be combined by linear superposition* (Hogan, 1985). That is, given a set of different impedances $\{\mathbf{Z}_1, \mathbf{Z}_2, \ldots \mathbf{Z}_k\}$ appropriate for different aspects of a task, the total impedance is

$$\mathbf{Z}_{total} = \sum_{k=1}^{m} \mathbf{Z}_k$$

even if any or all of the component impedances, $\mathbf{Z}_k$ are non-linear. These are among the reasons why modulating mechanical impedance is a particularly efficacious way to control interaction tasks (Toffin et al., 2003; Hogan and Buerger, 2004; Franklin et al., 2007). They are also the reasons why we believe that mechanical impedance is an essential dynamic primitive for contact tasks.

COMBINING DIFFERENT CLASSES OF DYNAMIC PRIMITIVES

A theory based on dynamic primitives requires specification of how those primitives may be combined. An example may illustrate the challenge: a successful soccer kick requires skillful placement of the stance foot relative to the ball, a vigorous but carefully controlled motion of the swinging leg, and determination of appropriate impedance between foot and ball at the moment of contact, usually against the background of rhythmic running [1]. It is therefore essential to specify how the different dynamic primitives interact to produce observable forces and/or motions.

To do so we use the construct of a *virtual trajectory*, denoted $\mathbf{x}_0$. It summarizes the net motion due to commands from the CNS when the force exerted is identically zero. We make the mild assumption that the mechanical impedance is such that if the force is identically zero, the corresponding displacement is also identically zero: $\mathbf{f} \equiv 0 \Rightarrow \triangle\mathbf{x} \equiv 0$ or in words, if force and all of its time derivatives and integrals are identically zero, then the corresponding displacement and all of its time derivatives and integrals are also identically zero. This allows us to *define* the displacement input to the impedance operator, $\triangle\mathbf{x}$, to be the difference between virtual (zero force) and actual (non-zero force) trajectories: $\triangle\mathbf{x} = \mathbf{x}_0 - \mathbf{x}$, or in joint coordinates, $\triangle\boldsymbol{\theta} = \boldsymbol{\theta}_0 - \boldsymbol{\theta}$ (Hogan, 1985). If the force is zero, the virtual and actual trajectories coincide. If the force is non-zero, the virtual trajectory $\mathbf{x}_0(t)$ may be inferred from a knowledge of mechanical impedance $\mathbf{Z}$, force $\mathbf{f}(t)$, and actual motion $\mathbf{x}(t)$ as $\mathbf{x}_0(t) = \mathbf{x}(t) + \mathbf{Z}^{-1}\{\mathbf{f}(t)\}$. This requires the inverse mapping $\mathbf{Z}^{-1}\{\cdot\}$ to exist. Note that the magnitude of impedance may be small provided it is non-zero.

This is not the only way these three classes of dynamic primitives—submovements, oscillations and impedances—might be combined, but an advantage of this construction is that it defines a non-linear extension of the *equivalent networks* widely used in engineering to describe physical interaction between dynamic systems, e.g., an audio amplifier and the speakers it drives (Hogan, 1985; Johnson, 2003a,b; Hogan, in revision). According to our view of dynamic primitives, the virtual trajectory $\mathbf{x}_0(t)$ specified by the CNS may be composed of *submovements* and/or *oscillations*. Based on the difference between virtual and actual trajectories, *impedances* specified by the CNS determine the forces evoked by contact. With this representation, much prior engineering insight about dynamic interaction in machines may be re-purposed to help understand physical interaction in locomotion.

RELATION TO THE LAMBDA HYPOTHESIS

The virtual trajectory is related to the "lambda" or "equilibrium-point" hypothesis but is also distinct from it in important ways. A common theme running through the several variants of the lambda hypothesis is the proposal that the CNS encodes motor commands as time-varying equilibrium postures (Feldman, 1966, 1986; Feldman and Latash, 2005). This is a proposed description of at least part of the process of generating movement. However, the mere existence of an "instantaneous equilibrium point," though not guaranteed, is not by itself very surprising from a physiological perspective; for example, the variation of muscle tension with length may suffice. Therefore, an instantaneous

[1] To understand the importance of mechanical impedance, consider the difference between kicking a ball and "trapping" it; the former require stiffening the ankle to transfer momentum to the ball; the latter requires relaxing the foot to "deaden" the bounce.

equilibrium point does not by itself provide compelling evidence about how the CNS encodes motor commands.

To define a virtual trajectory only requires that mechanical impedance—a physically measurable quantity—has a well-defined zero as described above. Most descriptions of the neuromuscular actuator satisfy this requirement. If so, an "instantaneous equilibrium point" (which we term a virtual position) may always be defined. This construct is a consequence of observable neuro-muscular mechanics. It is a description of behavior (the *product*) and may have no relation to how the CNS goes about producing that behavior (the *process*). Existence of a virtual trajectory does not require or imply that the CNS knows about or uses this construct for control. Indeed, available evidence suggests that this would be at best an incomplete account (Lackner and Dizio, 1994).

DYNAMIC PRIMITIVES IN LOCOMOTION

What is the evidence that these dynamic primitives describe the control of locomotion? Walking clearly exhibits a strongly rhythmic character, but that by itself is not sufficiently informative; walking could be a sequence of discrete (or overlapping) steps and in some cases—e.g., the slow pacing used in a funeral march—it may be. Furthermore, what is the role of mechanical impedance?

Role of oscillations and submovements

Observations of fictive locomotion in non-human vertebrates provide unequivocal evidence that neural circuits capable of generating an oscillatory dynamic primitive—sustained rhythmic activity—exist in the spinal cord isolated from its periphery, though sensory feedback is known to play a key role (Brown, 1911; Grillner and Wallen, 1985; Kriellaars et al., 1994; Stein et al., 1995; Cazalets et al., 1996; Grillner et al., 1998; Pearson et al., 2004). For unimpaired humans, continuous leg muscle vibration produced locomotor-like stepping movements, and spinal electromagnetic stimulation applied to unimpaired human vertebrae induced involuntary locomotor-like movements (Gurfinkel et al., 1998; Gerasimenko et al., 2010). That suggests the existence of a rhythmic central pattern generator (CPG) in the human spinal cord that may contribute to generating locomotor activity, though feedback elicited by limb loading, hip extension or the pressure on the sole the foot also play important roles (Grillner and Wallen, 1985; van Wezel et al., 1997; Dietz and Harkema, 2004).

However, the relative contribution of rhythmic pattern generation to unimpaired human locomotion remains unclear. Human infants exhibit a primitive rhythmic stepping reflex but it typically disappears at about 6 weeks after birth without training (Yang and Gorassini, 2006). When independent walking emerges at about one year old, it does not initially exhibit the rhythmic pattern of mature walking and this cannot be ascribed to immature postural control (Ivanenko et al., 2005). Furthermore, the locomotor-like movements evoked by stimuli to unimpaired human subjects were observed in a gravity-neutral position, unlike normal walking, rendering it difficult to assess how those results would apply to upright walking (Gurfinkel et al., 1998; Gerasimenko et al., 2010).

Walking in unimpaired adults is characterized by a remarkably repeatable spatial trajectory of the foot (Ivanenko et al., 2002). In response to surface irregularity in the form of small obstacles, subjects adjusted their minimum toe clearance using subtle adjustments of lower-limb kinematics (Schulz, 2011). Patients with spinal cord injury (SCI) who recovered following body-weight supported treadmill training generated a foot trajectory that closely matched the normal pattern, although they used very different joint coordination patterns to do so (Grasso et al., 2004). Together, these observations suggest the presence of a trajectory attractor underlying foot motion similar to that underlying hand motion in simple reaching movements (Bizzi et al., 1984; Lackner and Dizio, 1994; Shadmehr and Mussa-Ivaldi, 1994; Won and Hogan, 1995; Burdet et al., 2001).

Given our definition of dynamic primitives as attractors, studying the stability properties of ambulatory behavior may help resolve this question. Robustly sustained oscillation emerges as a *limit cycle attractor* from nonlinear dynamical systems such as relaxation oscillators (van der Pol, 1926). Nonlinear limit cycle oscillators not only encapsulate the robust and stable rhythmic motion of the periphery in human walking; they also serve as competent models of neural rhythmic pattern generators (Matsuoka, 1987; Taga et al., 1991; Collins and Richmond, 1994; Taga, 1998; Rybak et al., 2006). One of their distinctive characteristics is that they may exhibit *dynamic entrainment*: under certain conditions they will synchronize their period of oscillation to that of an imposed oscillation and *phase-lock* to establish a particular phase relation with it (Bennett et al., 2002). Usually entrainment occurs only for a limited range of frequencies; it exhibits a *narrow basin of entrainment*. In fact, entrainment to periodic mechanical perturbation has been reported in several non-human vertebrates which show clear evidence of spinal pattern generators (Grillner et al., 1981; Pearson et al., 1992; McClellan and Jang, 1993; Kriellaars et al., 1994).

A recent study reported behavioral evidence that a neuromechanical oscillator contributes to human walking, though perhaps weakly (Ahn and Hogan, 2012b). As unimpaired human subjects walked on a treadmill at their preferred speed and cadence, periodic torque pulses were applied to the ankle. Though the torque pulse periods were different from their preferred cadence, the gait period of 18 of 19 subjects converged to match that of the perturbation (**Figure 1A**). Significantly, this entrainment occurred only if the perturbation period was close to subjects' preferred walking cadence: it exhibited a narrow basin of entrainment. Further, regardless of the phase within the walking cycle at which the perturbation was initiated, subjects' gait synchronized or phase-locked with the mechanical perturbation at a phase of gait where it assisted propulsion. These results were affected neither by auditory feedback nor by a distractor task. However, the convergence to phase-locking was slow, requiring many tens of strides.

The existence of a basin of entrainment, however narrow, indicates that a non-linear limit-cycle attractor underlies level treadmill walking but it does not discriminate between several physiologically-plausible mechanisms that might be responsible, e.g., a CPG in the spinal cord or a "closed chain" of reflexive actions such that each results in sensory events that "trigger" the next (Bässler, 1986; Gurfinkel et al., 1998; Gerasimenko

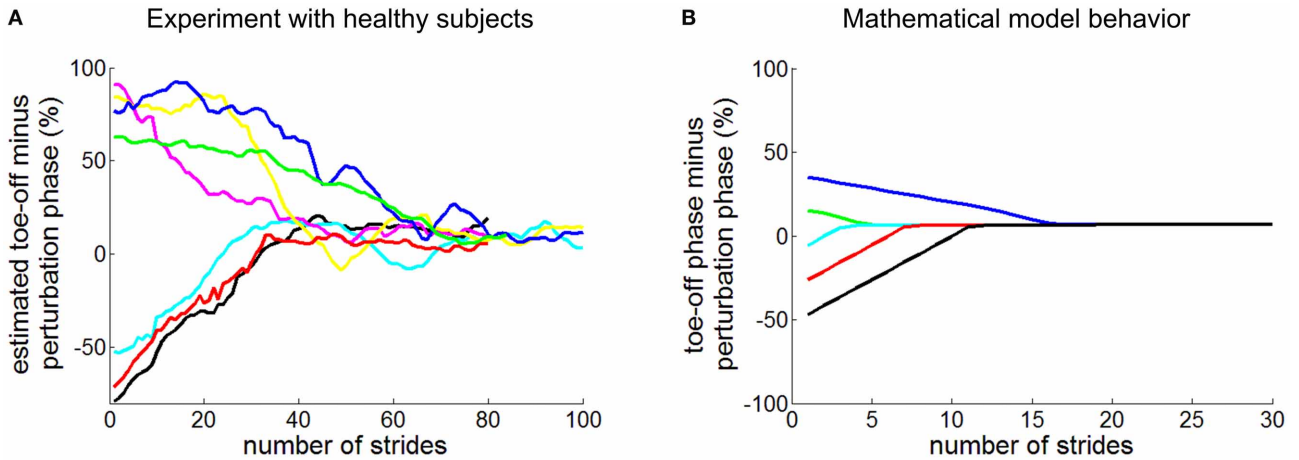

FIGURE 1 | Entrainment of human walking to periodic ankle torque pulses. Panel **(A)** shows experimental observation of unimpaired subjects (Ahn and Hogan, 2012b). The phase difference between toe-off (initiation of swing) and the initiation of the perturbation pulse is plotted as a function of stride number. Panel **(B)** shows comparable data generated by a simple mathematical model for various initial phases of the perturbation pulse (Ahn and Hogan, 2012a). In both **(A** and **B)**, regardless of initial phase, the perturbation pulses converged to phase-lock at the end of double stance, close to toe-off.

et al., 2010). Nevertheless, a highly-simplified mathematical model in which afferent feedback triggered actuation of the trailing leg reproduced all of the features observed experimentally (**Figure 1B**): (1) a periodic bipedal walking pattern; (2) local asymptotic stability of that periodic walking pattern; (3) entrainment of that walking pattern to periodic mechanical perturbations with a narrow basin of entrainment; and (4) phase locking to locate the perturbation at the end of double stance when entrained (Ahn and Hogan, 2012a; Ahn et al., 2012).

Role of musculo-skeletal mechanical impedance

A key insight derived from that model is that stable locomotion requires energy dissipation. Although collision-free legged locomotion is physically possible, to the best of our knowledge non-elastic interaction between foot and ground, which dissipates kinetic energy, is a common characteristic of legged animal locomotion. In human locomotion, muscles do more positive than negative work, even when walking at constant average speed on level ground, which provides evidence of energy dissipation (Devita et al., 2007).

The impact between the foot and the ground happens very rapidly; foot-ground forces have significant frequency content up to 15 or 20 Hz and beyond (Antonsson and Mann, 1985; Wakeling and Nigg, 2001). The bandwidth of lower-limb muscles in response to neural excitation is no more than a couple of Hz and the shortest transmission delay associated with spinal feedback is 50 ms or longer. As a result, reactive control of foot-ground interaction based on neural feedback is unworkable. However, musculo-skeletal mechanical impedance enables controlled reactions much faster than neural responses. Modulating shock absorption and energy dissipation depends on pre-tuning lower-limb mechanical impedance, i.e., using impedance as a dynamic primitive of motor control. The magnitude of the required shock absorption varies with walking speed and variation of lower-limb stiffness with speed of human locomotion has been widely reported (Farley and Gonzalez, 1996; Ferris et al., 1999; Holt et al., 2003).

In the simplified mathematical model described above, ankle mechanical impedance also affected the energy added during the push-off phase; a pre-stretched spring-like muscle was released (Ahn and Hogan, 2012a; Ahn et al., 2012). Though this is at best a crude approximation to the action of lower-limb muscles, it yielded a more stable walking cycle (i.e., a larger basin of attraction) than simply modeling muscle action as generating a force or torque pulse with zero impedance. This further supports our contention that musculo-skeletal mechanical impedance is one of the essential dynamic primitives required for human locomotion.

Interaction between dynamic primitives in locomotion

If dynamic primitives underlie locomotion, then interaction between them may also play an important role. One mathematical simulation study suggested that a hybrid dynamic walker was more stable when synchronized with an oscillator that acted as a clock than when it operated independently (Seipel and Holmes, 2007). Notably, the interaction between the oscillator and the periphery was exactly analogous to the equivalent network we propose: the oscillator specified a nominal limb trajectory; joint torque was exerted, determined by a simple mechanical impedance, as a function of the difference between nominal and actual limb trajectories.

In addition to rhythmic cycling of the limbs, functional locomotion requires the ability to place a foot, e.g., to avoid an obstacle or to secure an appropriate foothold on the first step of a flight of stairs. This requires the production of a discrete step against the background of an ongoing rhythm. In principle, that might be achieved by simple linear superimposition of a virtual trajectory corresponding to a submovement onto one corresponding to an oscillation. However, upper-extremity studies have shown that, against the background of rhythmic motion, the onset of a discrete action preferentially occurs at selected phases

of the ongoing rhythm, which implies a nonlinear interaction (Sternad et al., 2002). A model comprising a Matsuoka oscillator coupled to antagonist muscles acting about a single joint successfully reproduced this phenomenon (De Rugy and Sternad, 2003; Ronsse et al., 2009).

Whether similar phenomena occur in human walking is, to the best of our knowledge, unknown at this time. It seems clear that a single interposed discrete step—e.g., a sidestep—does not catastrophically disrupt an ongoing walking rhythm. However, it is less clear which aspects of that rhythm exhibit the stability of an attractor. Subjects exhibit a preferred cadence and step length that appears to be robust (MacDougall and Moore, 2005). However, transient lower-limb perturbations induce phase-resetting of the walking rhythm, a persistent change of phase relative to the pre-perturbation oscillation (Nomura et al., 2009; Feldman et al., 2011). This indicates that the oscillatory lower-limb trajectory, e.g., time history of joint angles, is not an attractor. Whether interposed side-steps evoke similar phase-resetting is a matter for future investigation.

IDENTIFYING DYNAMIC PRIMITIVES IN LOCOMOTION

Some progress towards identifying dynamic primitives and their interaction in locomotion has been made. Experimental identification of impedance requires mechanical perturbation; the evoked response at the point(s) of interaction is determined by impedance. However, even the static component of multivariable joint impedance (the relation between torque and angular displacement) may be highly structured. Measurements on unimpaired subjects show a pronounced weakness in inversion-eversion, the direction of most ankle injuries (**Figure 2**). Increasing muscle activation increases stiffness but does not eliminate this relative weakness (Lee et al., 2012c).

It is common to assume that the combination of skeletal inertia and neuro-muscular impedance exhibits second-order dynamics (Dolan et al., 1993; Tsuji et al., 1995). Though that may seem reasonable, it is not necessarily correct and there is good reason to expect higher-order dynamic behavior (Wakeling and Nigg, 2001). To avoid *a-priori* assumptions about the order of the dynamics, stochastic methods may be used to identify a locally linear approximation to dynamic behavior (Palazzolo et al., 2007; Chang et al., 2012). They have been applied successfully (**Figure 3**) to identify the steady-state multi-variable dynamic impedance of the ankle (Rastgaar et al., 2009, 2010; Lee et al., 2012b).

Stochastic methods may also be extended to identify *time-varying* mechanical impedance (Lortie and Kearney, 2001). They have recently been applied (**Figure 4**) to identify a time-varying trajectory of multivariable ankle mechanical impedance during level walking (Lee et al., 2012a; Lee and Hogan, 2013).

A virtual trajectory, $\mathbf{x}_0(t)$, can also be measured experimentally. If the point of interaction is the sole of the foot, then during swing phase the force is identically zero, $\mathbf{f} \equiv 0$, and because $\triangle\mathbf{x} \equiv 0$, the observed motion is the virtual trajectory. During stance phase the force is non-zero, $\mathbf{f} \not\equiv 0$ but $\mathbf{x}_0(t)$ may be inferred from a measurement of mechanical impedance, $\mathbf{Z}$, force, $\mathbf{f}(t)$, and actual motion, $\mathbf{x}(t)$ as $\mathbf{x}_0(t) = \mathbf{x}(t) + \mathbf{Z}^{-1}\{\mathbf{f}(t)\}$ provided $\mathbf{Z}^{-1}$ exists. If the point of interaction is at a joint—say, the ankle or the knee—then the dynamics between the joint and the point of force application must be identified and subtracted. The main difficulty is that estimates are exquisitely sensitive to the *assumed* order of the neuro-muscular impedance model used to infer a virtual trajectory—see Gomi and Kawato (1996) but compare with Gribble et al. (1998). However, there is no fundamental reason it cannot be determined and model-independent experimental methods have been demonstrated (Hodgson and Hogan, 2000).

Given a measured virtual trajectory, there remains the challenge of identifying underlying motion primitives, such as submovements and oscillations. Composability, the requirement that

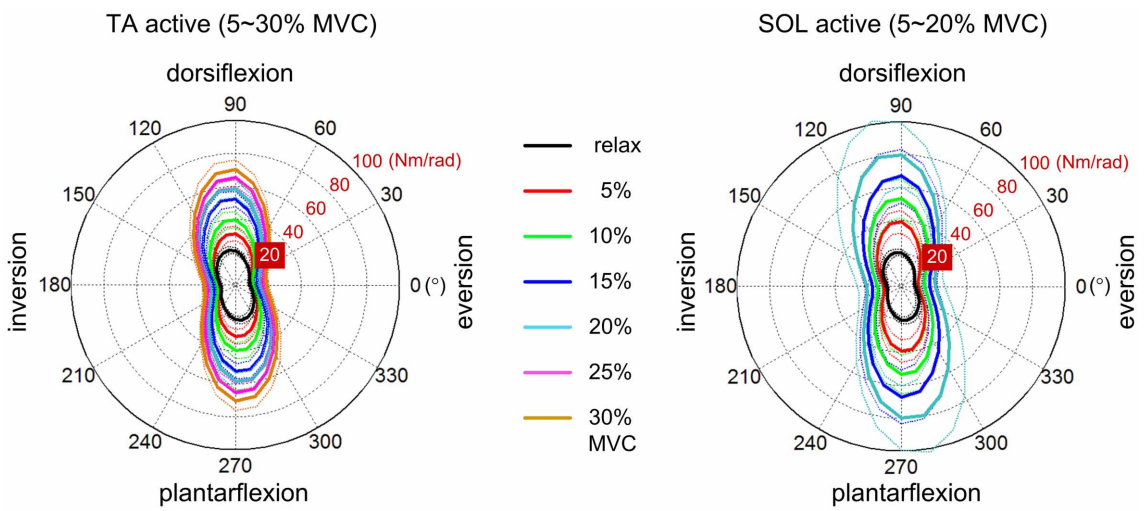

FIGURE 2 | Variation of static ankle mechanical impedance with muscle activation (Lee et al., 2012c). Polar plots show magnitude of restoring torque evoked by displacement in different directions. **Left panel**: Tibialis anterior active. **Right panel**: Soleus active. MVC denotes maximum voluntary contraction. Solid lines: mean of all subjects. Dotted lines: mean ± standard error. Note the pronounced weakness in inversion-eversion, the direction of most ankle injuries.

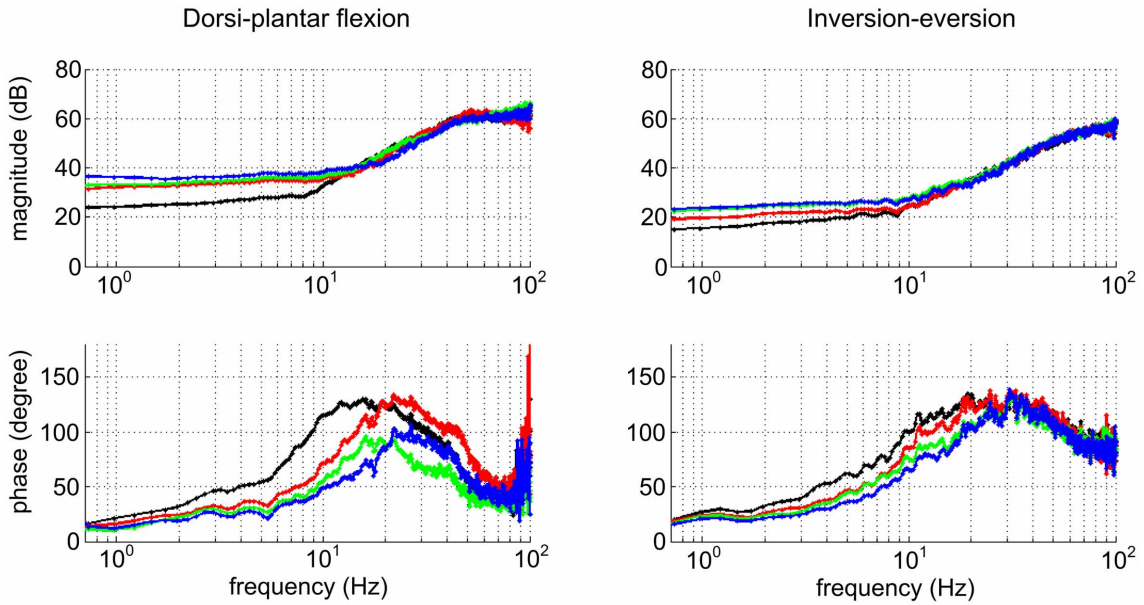

FIGURE 3 | Variation of dynamic ankle mechanical impedance with muscle activation (Lee et al., 2012b). Bode plots show impedance up to 50 Hz in principal axis directions. **Left column**: Dorsi-plantar flexion. **Right column**: Inversion-eversion. **Top row:** magnitude. **Bottom row:** phase. Color code: black, fully relaxed; red, tibialis anterior active at 10% maximum voluntary contraction (MVC); green, soleus active at 10% MVC; blue, tibialis anterior and soleus co-contracted, each at 10% MVC. The effect of muscle activation is to increase impedance below about 10 Hz, predominantly in dorsi-plantar flexion. The phase plots suggest dynamic behavior more complex than second-order.

dynamic primitives may be combined to produce behavior, may introduce ambiguities. One common approach to identifying submovements is to examine derivatives of the trajectory to identify local peaks, but that method is completely unreliable (**Figure 5**). A composite of two smooth submovements may yield one, two, or three local velocity peaks (Rohrer and Hogan, 2003).

Alternative methods use "greedy" algorithms which first find a submovement that best fits the trajectory in some suitable sense (least residual error, highest peak speed, etc.), then subtract it and repeat the procedure on the residual until the error between the sum of submovements and the original trajectory falls below a specified threshold. Unfortunately, these methods also yield spurious decompositions (**Figure 5**). Even in a simulated "test" case, where a sequence of submovements is known *a-priori* and used to compose a continuous trajectory, these methods cannot reliably recover the underlying submovements (Rohrer and Hogan, 2003).

However, global optimization methods have been developed which avoid spurious decompositions (**Figure 6**). With these methods it has been shown that (1) the statistics of the extracted submovement parameters are robust to the assumed submovement shape and (2) the errors introduced by inappropriate submovement shapes can be detected even in the presence of substantial measurement noise (Rohrer and Hogan, 2003, 2006).

LOCOMOTOR REHABILITATION

A theoretical framework based on dynamic primitives may have particular relevance for sensorimotor rehabilitation, both in the development of assistive technologies and in the design of therapeutic procedures.

ASSISTIVE TECHNOLOGIES

The design and implementation of assistive orthoses and amputation prostheses has unequivocally demonstrated the importance of controllable mechanical impedance. It is a key element of recent highly-successful designs of ankle-foot orthoses and transfemoral prostheses (Blaya and Herr, 2004; Au et al., 2007; Sup et al., 2008, 2009; Ha et al., 2011; Lawson et al., 2011; Sup et al., 2011). A central feature of these designs is the equivalent network structure referred to above, which is used to combine neural and mechanical influences on how the foot interacts with the ground. However, it is less clear whether submovements and/or oscillations play a prominent role. For example, the designs by Goldfarb and colleagues implement a finite number of states arranged in a closed cycle (Sup et al., 2008). Rhythmic behavior emerges as consequence of this closed cycle rather than due to any neurally-generated oscillation. To anticipate future work, this new technology may provide essential tools to test a theory based on dynamic primitives.

PHYSIOTHERAPY

A theoretical framework based on dynamic primitives may also have a substantial value for therapies to *recover* neuro-motor function rather than assist it or replace it. To date, therapeutic practices have lacked a basis in experimentally-verified theory. This is understandable because there is, as yet, little scientific consensus on the neural control of unimpaired locomotion, and certainly none on how the CNS responds to injury. Nevertheless, it is difficult to understand how rational design of therapeutic procedures might be accomplished without a fundamental theory of locomotion and its recovery.

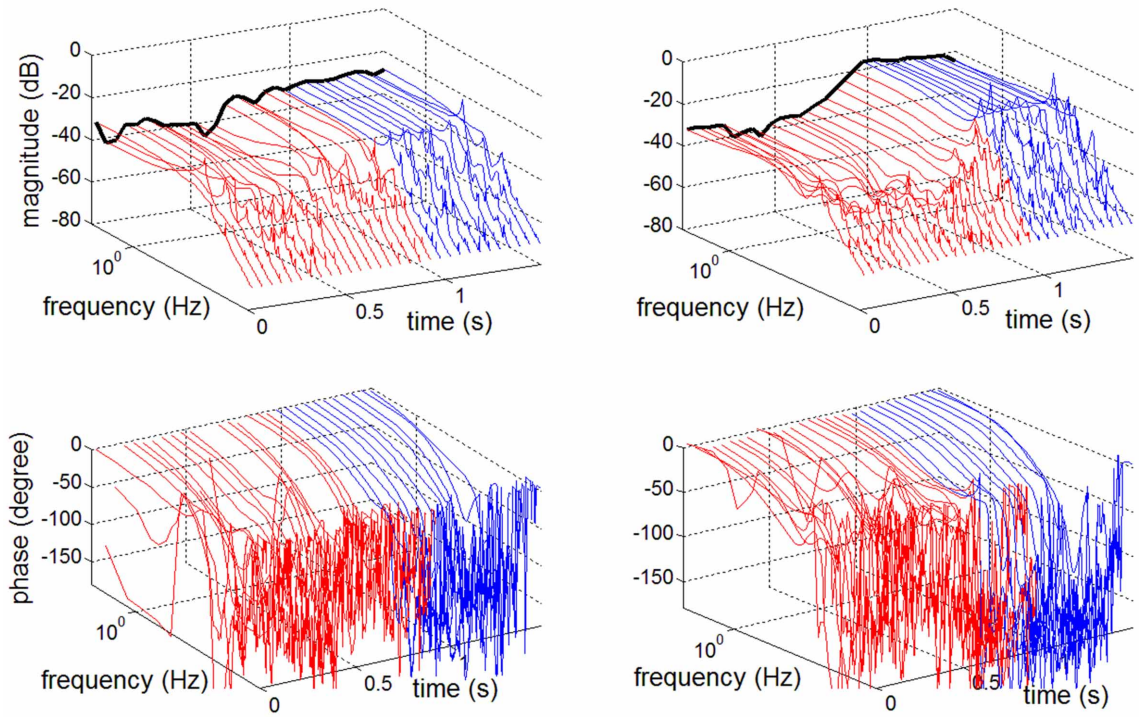

FIGURE 4 | Time-variation of ankle dynamics during level walking (Lee et al., 2012a). Bode plots of admittance (inverse of impedance) at 50 ms intervals. **Left column**: Dorsi-plantar flexion. **Right column**: Inversion-eversion. Top row: magnitude. Bottom row: phase. Time zero is at heel strike. Color code: red, stance phase; blue, swing phase. The black line depicts the static (zero frequency) component. Note the substantial magnitude changes throughout the gait cycle.

Most rehabilitation practices tacitly assume that motor recovery is loosely analogous to unimpaired motor learning. However, unimpaired motor learning happens in an intact nervous system and is not accompanied by the common sequelae of neurological injury, which include muscular weakness, spasticity, abnormal muscle tone, abnormal synergies, and disrupted or unbalanced sensory pathways (Hogan et al., 2006). Nevertheless, the most successful form of upper-extremity robotic therapy to date was designed to incorporate principles of motor learning and it has proven effective (Krebs et al., 2003; Miller et al., 2010). It therefore seems probable that something resembling motor learning is at least part of the recovery process.

We propose that motor learning (and, by extension, recovery) consists of encoding the parameters of dynamic primitives and subsequently using them to reconstruct the primitives, rather than details of behavior. Support is found in the analysis of infant reaching movements, which initially exhibit submovements but become essentially continuous at around 6 months of age (Hofsten, 1991; Berthier, 1996). More recent work showed that the earliest movements made by patients recovering after a paralyzing stroke were composed of submovements with remarkably stereotyped speed profiles, even for different patients with different lesions (Krebs et al., 1999). This degree of robustness or "temporary permanence" makes a compelling case that submovements are, indeed, a primitive dynamic element of human motor behavior. Studies of movement changes during recovery after stroke (**Figure 7**) showed that submovements grew progressively larger, fewer, and more blended as recovery progressed (Rohrer et al., 2002, 2004; Dipietro et al., 2009). Whether similar patterns will be found in lower-extremity behavior remains a topic for future research.

Muscular weakness, spasticity and abnormal muscle tone may all manifest as disruptions of mechanical impedance. Because impedance is at the *interface* between the CNS and the physical world, inappropriate impedance may hinder the recovery of effective motor actions. We therefore expect normalization of impedance concurrently with recovery. Support is found in recent preliminary studies of how ankle impedance influences recovery of locomotion. The ankle impedance of neurologically impaired subjects was significantly different from that of age-matched healthy subjects (Roy et al., 2009, 2011; Lee et al., 2011). Robot-aided therapy in which patients were seated with the foot clear of the ground ("open chain") and performed visually evoked "reaching" movements with the ankle while the robot provided graded assistance as needed successfully resolved the abnormality and—most remarkably—this form of therapy resulted in a 20% improvement of over-ground walking speed (Forrester et al., 2011).

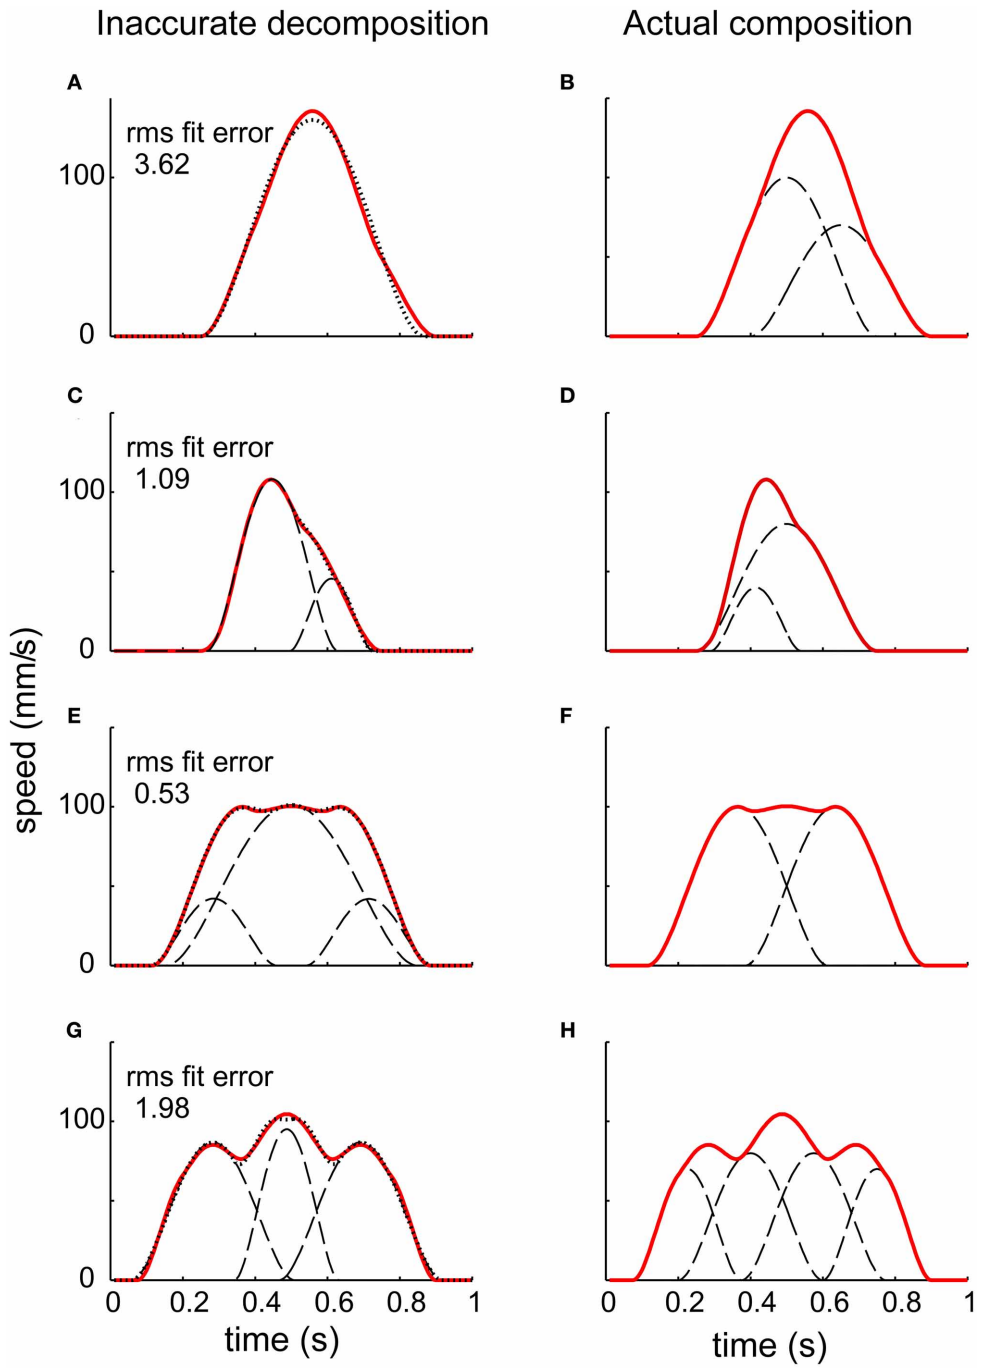

FIGURE 5 | The challenge of decomposing a continuous trajectory into submovements (Rohrer and Hogan, 2003). The right column shows simulated speed profiles resulting from different combinations of underlying submovements. Note that the number of peaks does not correspond to the number of submovements. The left column shows the result of decomposition using "greedy" algorithms. Though the RMS fitting error is low, the submovements identified do not resemble those used to construct the speed profiles.

This observation seems to suggest that correcting abnormal impedance due to weakness, spasticity or abnormal muscle tone is a *pre-requisite* for recovery, but caution is appropriate; changing impedance may not be a cause of recovery but a consequence. To elaborate, neurological injury may result in weakened and/or unbalanced descending neural drive from higher levels of the CNS to the periphery. This may alter the excitability of spinal segmental neurons, e.g., increasing reflex feedback gains by reducing inhibition, and that, in turn, may alter impedance. Active participation of the patient is an essential element of the

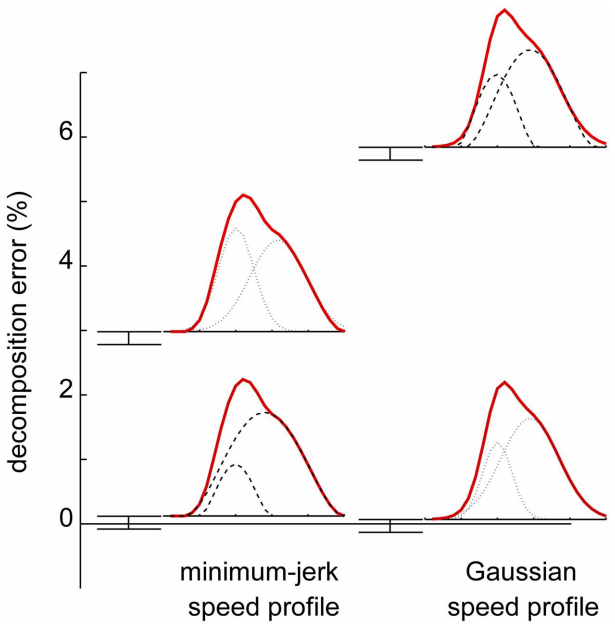

FIGURE 6 | Ability of decomposition based on global optimization to discriminate different submovement shapes underlying a speed profile (Rohrer and Hogan, 2003). Solid lines: simulated speed profiles. Dotted lines: Gaussian submovements. Dashed lines: minimum-jerk submovements. A speed profile composed of Gaussian submovements yields substantially greater fitting error when decomposed into minimum-jerk submovements (right column) and vice-versa (left column).

FIGURE 7 | Typical movement profiles between the same target positions from one patient recorded on the first and last days of therapy (Rohrer et al., 2004). Bold lines indicate measured tangential speed. Fine lines indicate submovements identified using a global optimization algorithm. The later profile shows fewer submovements, which have greater peak speed, duration and overlap.

robot-aided therapy that corrected abnormal ankle impedance (Forrester et al., 2011). Active participation may have increased descending drive, leading *both* to more normal impedance and improved overground locomotion. Of course, it must be emphasized that these are mere speculations; further study is needed to test whether they contain any grain of truth.

If motor learning is an essential part of neuro-recovery, we may expect that greater intensity of practice will yield better outcomes, and that is consistent with the success of upper-extremity robot-aided therapy. It might then seem that rhythmic practice should be most effective because it enables a greater intensity of practice—more movements per unit time than discrete movements spanning the same workspace. However, if rhythmic and discrete movements arise from distinct dynamic primitives, then learning one type may not generalize to improved performance of the other. In fact, recent studies of unimpaired subjects' adaptation showed that the benefits of rhythmic practice did not transfer to performance of discrete movements (Ikegami et al., 2010; Howard et al., 2011).

If that result generalizes to lower extremity actions, it might account for some of the difficulties that have thwarted attempts to improve locomotor therapy. Treadmill-based robot-aided therapy has been found less effective than conventional therapy and "…still in its infancy" (Miller et al., 2010). Human-administered locomotor therapy has fared little better: an extensive study of body-weight supported treadmill training found that it yielded no better outcome than a home-based exercise program that was "…expected to have little or no effect on the primary outcome, gait speed" (Duncan et al., 2007, 2011). Both of these treadmill-based approaches emphasized rhythmic practice of walking movements. However, any benefits may have generalized poorly to the wider context of functional walking, which may in addition require discrete actions and controlled impedance. Once again, these are no more than speculations, but they illustrate some of the insight that might be afforded by applying a theoretical framework based on dynamic primitives to both upper- and lower-extremity behavior.

FUTURE DIRECTIONS

We have attempted to outline how a theory based on dynamic primitives might be applied to describe control of human locomotion as well as object manipulation and the use of tools. This outline is no more than a tentative beginning. Our first concern is that a theory should be *competent* to account for a wide range of observed behavior. Where possible, we have attempted to be faithful to the underlying physiology but that is a secondary consideration at this point; fidelity without competence is useless.

Moreover, complete fidelity is probably unattainable and certainly impractical. For example, functioning nerves and muscles require expression of genes to produce essential proteins but our present knowledge of that process and how it is controlled remains profoundly limited. Even if it were possible, a theoretical description of motor control that attempted to include that level of detail would be hopelessly cumbersome. It would defeat the main purpose of formulating a theory, to gain insight.

Any sufficiently ambitious theory will inevitably be contradicted by some experimental observations but this does not mean that it should be discarded outright. A practical theory should be *incrementally revisable* to accommodate new knowledge as it is gained. Theory-building is an iterative, ongoing process. In order for the revisions to be incremental rather than catastrophic, the foundations must be reliable. This requires the theory—and especially its foundations—to have passed the test of falsification (Ajemian and Hogan, 2010).

That reveals one of the challenges of a theory based on dynamic primitives, and may explain why it has not yet been established despite more than a century of investigation. In order to describe the wide repertoire of human behavior competently, the primitives must exhibit what we have called

"composability"—observed behavior may be composed of multiple primitives overlapping in time. But composability also implies that unambiguously identifying primitives solely from measurements at the *observational* level is difficult. If the detailed form of the primitive (submovement, oscillation or impedance) is known, the problem is tractable. Without that knowledge, it is "ill-posed" in the sense that a unique solution may not exist. Some progress has been made on this problem by using optimization to provide regularization, but much remains to be done (Rohrer and Hogan, 2003, 2006).

Of course, scientific studies are not confined to this observational level. Studies at the *physiological* level may resolve the ambiguities. For example, it is not clear whether any convincing evidence of an oscillatory dynamic primitive can be found at the observational level; rhythmic movements could be a combination of back-to-back overlapping submovements in opposite directions. But physiological evidence clearly shows that rhythmic behavior cannot always be dismissed as a combination of submovements and is a distinct dynamic primitive.

Another open question is how many classes of primitives may be required. Here we have considered three—submovements, oscillations and impedances—but there are other possibilities. For example, synergies have been proposed as primitive elements of motor coordination to simplify the problem of managing the many degrees of freedom of the biological motor control system. That may be true, but it is also possible that at least some synergies may be an emergent property of mechanical impedance (Hogan and Sternad, 2012). Which of these possibilities is more competent requires further study.

We expect the parameters of individual exemplars within each class of primitives to be limited but we do not yet know the precise values of those limits. For example, a lower limit to the period of oscillatory movements seems uncontroversial (infinitely rapid movements are physiologically implausible) but there also appears to be an upper limit to the period of primitive oscillatory actions. Beyond that limit, submovements appear to predominate (Doeringer and Hogan, 1998; Dipietro et al., 2004, 2005a,b; van der Wel et al., 2010). Within their limits it is unclear whether the parameters may take on any of a continuous range of values or are confined to a finite set of values. Further research is required.

One essential aspect of our conception of motor control based on primitives is that they are attractors. That prompts the question: which attractors underlie human locomotion? They might be point attractors, e.g., to support foot placement; or trajectory attractors, e.g., to control foot trajectory; or limit-cycle attractors, e.g., to account for the orbital stability of the walking rhythm; or even chaotic attractors as reported by Hausdorff et al. (1995) and Hausdorff et al. (2001). Which of these attractors, or combinations of them, are demonstrable in human locomotion remains to be established.

To conclude, we do not have the temerity to claim that what we have outlined is yet a complete account of upper- and lower-extremity motor behavior. Yet we do contend that such a theory is possible, necessary and timely—perhaps even overdue. Its development will inevitably require considerable hard work from many contributors. To quote Ziman (1969):

> *This technique, of soliciting many modest contributions to the store of human knowledge, has been the secret of Western science since the seventeenth century, for it achieves a corporate, collective power that is far greater than one individual can exert.*

The main thing is to get started. This paper is an attempt to do so.

Grasping is a highly complex movement that requires the coordination of a number of hand joints and muscles. Previous studies showed that spinal premotor interneurons (PreM-INs) in the primate cervical spinal cord have divergent synaptic effects on hand motoneurons and that they might contribute to hand-muscle synergies. However, the extent to which these PreM-IN synaptic connections functionally contribute to modulating hand-muscle activity is not clear. In this paper, we explored the contribution of spinal PreM-INs to hand-muscle activation by quantifying the synaptic linkage (SL) and functional linkage (FL) of the PreM-INs with hand-muscle activities. The activity of 23 PreM-INs was recorded from the cervical spinal cord (C6–T1), with EMG signals measured simultaneously from hand and arm muscles in two macaque monkeys performing a precision grip task. Spike-triggered averages (STAs) of rectified EMGs were compiled for 456 neuron–muscle pairs; 63 pairs showed significant post-spike effects (PSEs; i.e., SL). Conversely, 231 of 456 pairs showed significant cross-correlations between the IN firing rate and rectified EMG (i.e., FL). Importantly, a greater proportion of the neuron–muscle pairs with SL showed FL (43/63 pairs, 68%) compared with the pairs without SL (203/393, 52%), and the presence of SL was significantly associated with that of FL. However, a significant number of pairs had SL without FL (SL∩!FL, $n = 20$) or FL without SL (!SL∩FL, $n = 203$), and the proportions of these incongruities exceeded the number expected by chance. These results suggested that spinal PreM-INs function to significantly modulate hand-muscle activity during precision grip, but the contribution of other neural structures is also needed to recruit an adequate combination of hand-muscle motoneurons.

Keywords: muscle synergy, grasping, spinal cord, spike-triggered average, cross-correlation

INTRODUCTION

Grasping is a highly complex movement that requires the coordination of a number of hand joints and muscles. The large number of degrees of freedom (DOF) of hand anatomy enable its flexible and varied movement, but this requires a high computational load and causes the "DOF problem" (Wing et al., 1996). Previous electromyographic (EMG) studies in non-human primates showed that hand-muscle activity can be explained by a linear combination of a few basic components (i.e., muscle synergy), suggesting that the neural system reduces hand anatomy DOF by using muscle synergies as modules (Brochier et al., 2004; Overduin et al., 2008).

Neural implementation of muscle synergy has been extensively investigated for hind-limb movement in frogs (Giszter et al., 1993; Mussa-Ivaldi et al., 1994; Tresch et al., 1999; Saltiel et al., 2001; Bizzi et al., 2002) and rats (Tresch and Bizzi, 1999), and spinal interneuron involvement has been suggested. As for hand-muscle synergy, we showed that spinal premotor interneurons (PreM-INs) had divergent facilitatory effects in multiple finger muscles by compiling the spike-triggered averages (STAs) of rectified EMGs in monkeys performing a precision grip task (Takei and Seki, 2010), and PreM-INs showed significant trial-to-trial correlations with grip force and target muscle activity (Takei and Seki, 2006). These results suggested that PreM-IN divergent connections facilitate the coactivation of hand muscles and that they could contribute to hand-muscle synergy formation. However, the extent to which these PreM-IN synaptic connections functionally contribute to activate hand muscles and to build muscle synergy is not clear.

In this study, we specifically tested how PreM-IN output contributes to hand-muscle activation by quantifying PreM-IN synaptic linkage (SL) and functional linkage (FL) with hand-muscle activity (Miller et al., 1993; McKiernan et al., 2000; Holdefer and Miller, 2002). In two macaque monkeys performing a precision grip task, we recorded PreM-IN activity in the cervical spinal cord (C6–T1), with EMG signals measured simultaneously from hand and arm muscles. SL was quantified by testing the existence of post-spike effects (PSEs) with STAs of the rectified EMG. FL was determined by calculating the long-term cross-correlation between the PreM-IN firing rate and each rectified EMG. Then, we compared the SL and

FL and examined the associations between the presence of SL and of FL. Our results showed that SL and FL between PreM-IN and their target muscle activities were significantly associated, indicating that spinal PreM-INs significantly contribute to modulating hand-muscle activity involved in grasp control. However, a significant number of incongruities between SL and FL were also found, suggesting that other neural structures contributed to recruiting an adequate combination of hand-muscle motoneurons.

MATERIALS AND METHODS

ANIMALS

Electrophysiological recordings were obtained from two adult macaque monkeys (*monkey A*: *Macaca fuscata*, male, 6.8 kg, and *monkey E*: *Macaca mulatta*, male, 5.6 kg). Experiments were performed in accordance with the National Institutes of Health Guidelines for the Care and Use of Laboratory Animals and were approved by the Animal Research Committee at the National Institute for Physiological Sciences, Japan.

PRECISION GRIP TASK

Details of the behavioral task, surgical operations, experimental setup, and procedures for recording single-unit and EMG activity were described previously (Takei and Seki, 2008, 2010). Briefly, monkeys were trained to grip spring-loaded levers with the index finger and thumb (precision grip task, **Figure 1A**). The lever positions were displayed on a computer screen as cursors, and monkeys were required to track targets. Each trial consisted of a rest period (1.0–2.0 s), lever grip, lever hold (1.0–2.0 s), and lever release. Successful completion of a trial was rewarded with a drop of applesauce. The force required to reach the target positions was adjusted individually for the index finger and thumb (monkey A: 0.4–2.0 N for index finger, 1.0–3.0 N for thumb; monkey E: 0.6–1.1 N for index finger, 0.1–0.3 N for thumb).

SURGICAL PROCEDURES AND DATA ACQUISITION

Unilateral laminectomy of vertebrae C5–T1 was performed while the animals were anesthetized with isoflurane (1.0–2.0% in 2:1 O_2:N_2O) or sevoflurane (1.5–3.0% in 2:1 O_2:N_2O) under aseptic conditions, and a custom-made recording chamber was implanted over the laminectomy (Perlmutter et al., 1998). During the recording, the monkey was seated in a primate chair with the head and upper back restrained. Single-unit activities from C5–T1 were recorded with a Tungsten or Elgiloy microelectrode. EMGs from the hand, forearm, and upper arm muscles were simultaneously recorded (**Figure 1B**). For EMG recording, pairs of stainless steel wires (AS632, Cooner Wire) were chronically implanted subcutaneously in 19 (monkey A) or 20 (monkey E) forelimb muscles, including intrinsic hand muscles: first, second, third, and fourth dorsal interosseous (FDI, 2DI, 3DI, and 4DI, respectively); adductor pollicis (ADP); abductor pollicis brevis (AbPB); abductor digiti minimi (AbDM); extrinsic hand muscles: flexor digitorum superficialis (FDS), radial and ulnar parts of flexor digitorum profundus (FDPr and FDPu), abductor pollicis longus (AbPL), extensor digitorum-2,3 (ED23), extensor digitorum-4,5 (ED45), extensor digitorum communis (EDC); wrist muscles: flexor carpi radialis (FCR), flexor carpi ulnaris

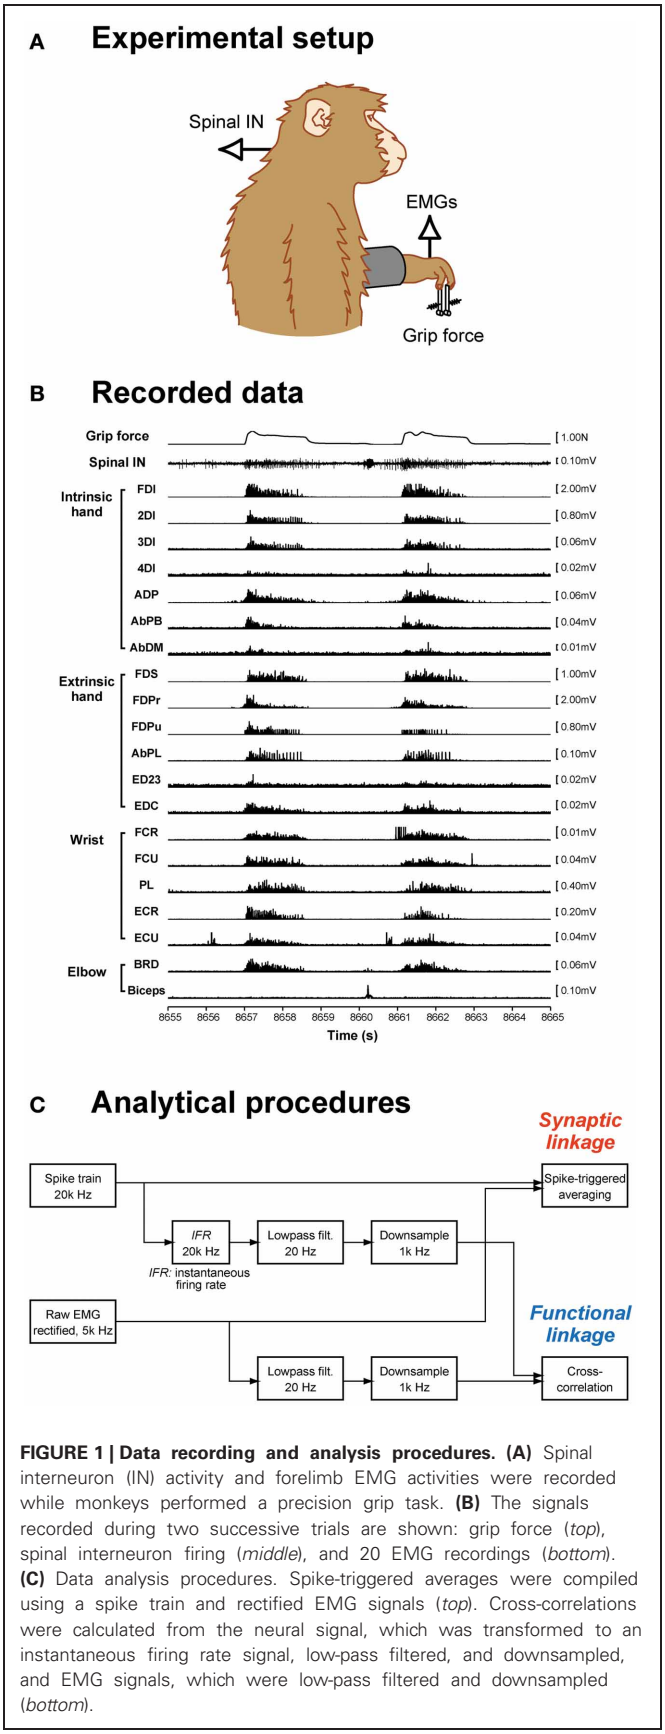

FIGURE 1 | Data recording and analysis procedures. (A) Spinal interneuron (IN) activity and forelimb EMG activities were recorded while monkeys performed a precision grip task. **(B)** The signals recorded during two successive trials are shown: grip force (*top*), spinal interneuron firing (*middle*), and 20 EMG recordings (*bottom*). **(C)** Data analysis procedures. Spike-triggered averages were compiled using a spike train and rectified EMG signals (*top*). Cross-correlations were calculated from the neural signal, which was transformed to an instantaneous firing rate signal, low-pass filtered, and downsampled, and EMG signals, which were low-pass filtered and downsampled (*bottom*).

(FCU), palmaris longus (PL), extensor carpi radialis longus and brevis (ECRl and ECRb), extensor carpi ulnaris (ECU); and elbow muscles: brachioradialis (BRD), pronator teres (PT), biceps brachii (biceps), and triceps brachii (triceps). The muscles recorded in each monkey were tabulated in a previous paper (Takei and Seki, 2010). Data recorded over at least 10 trials for each single unit were included in the present dataset.

SPIKE-TRIGGERED AVERAGING OF RECTIFIED EMGs

To quantify the SL from spinal INs to hand motoneuron pools, we computed the STA of rectified EMGs (**Figure 1C**). Details of the STA method were described previously (Takei and Seki, 2010). Briefly, STAs were compiled off-line for neuron–muscle pairs with at least 2000 recorded action potentials. All spikes recorded during whole-task phases (i.e., rest, grip, hold, and release phases and intertrial intervals) were used to compile the STAs. EMG was rectified and averaged over an interval of 80 ms, beginning 30 ms before and ending 50 ms after the spike onset. The baseline STA trend was subtracted using the incremented-shifted averaging (ISA) method (Davidson et al., 2007), and then the STA was smoothed with a flat five-point finite impulse response filter. Significant STA effects were identified with multiple-fragment statistical analysis (Poliakov and Schieber, 1998) at $p < 0.0025$ ($p < 0.05$ after Bonferroni's correction). The test window was set at a duration of 12 ms (i.e., between 3 and 15 ms) after the spinal neuron spike. Potential cross-talk between simultaneously recorded EMGs was evaluated by combining a cross-correlation method (Buys et al., 1986) and the third EMG differentiation (Kilner et al., 2002). STA effects potentially resulting from cross-talk between EMG recordings were eliminated from the present dataset.

The STAs of rectified EMGs can produce two types of effects: PSEs and synchrony effects (Schieber and Rivlis, 2005). PSEs reflect the mono- or disynaptic effects of trigger neurons on the motoneuron pool that facilitate or suppress the EMG signal (Fetz and Cheney, 1980). In contrast, synchrony effects are derived from synaptic inputs from other neurons in the motoneuron pool that are synchronized with the discharges of the trigger neurons (Fetz and Cheney, 1980; Schieber and Rivlis, 2005). Therefore, synchrony effects can appear in STAs even if no mono- or disynaptic connection exists between the trigger neuron and the motoneuron pool. Based on criteria established by Schieber and Rivlis (2005), we discriminated PSEs from other synchrony effects according to the onset latency and peak width at half maximum (PWHM) of the STA effects (Schieber and Rivlis, 2005). Onset latency was defined as the time when the averaged EMG exceeded two standard deviations (SDs) from the baseline mean (from 10 to 30 ms before the trigger). PWHM of the STA effect was determined by finding the level that was half of the peak amplitude above (or below for a trough) the baseline mean and by measuring the width of the peak (or trough) at this level. The earliest possible onset latency of the PSEs was set at 3.5 ms based on our previous investigation (Takei and Seki, 2010). The largest PSE PWHM was set at 7 ms based on theoretical considerations (Baker and Lemon, 1998). Therefore, if a neuron produced PSEs with an onset latency of >3.5 ms and PWHM of <7 ms on at least one muscle, the neuron was identified as a PreM-IN.

CROSS-CORRELATION BETWEEN PreM-IN AND EMG ACTIVITY

To quantify the FL between neuronal activity and hand-muscle activity, we calculated cross-correlations between the neuronal and muscle activities (**Figure 1C**). First, the instantaneous firing rate [$IFR(t)$] of PreM-INs was calculated as the inverse of the interspike interval:

$$IFR(t) = \frac{1}{t_{i+1} - t_i}, \text{ for } t_i < t < t_{i+1},$$

where t_i is the time of the ith spike. The instantaneous firing rate was then low-pass filtered (second order, Butterworth, cutoff of 20 Hz in forward and backward directions) and down-sampled to 1000 Hz. Rectified EMGs were also low-pass filtered (second order, Butterworth, cutoff of 20 Hz in forward and backward directions) and down-sampled to 1000 Hz. Continuously recorded 90-s data points, which contained ∼10 successive trials including whole-task phases, were used to calculate the cross-correlation. Cross-correlation significance was defined by a Monte Carlo method (Miller et al., 1993). To obtain the cross-correlations between non-correlated signals, we transposed the first and second halves of the spinal IN rate signal and calculated the full set of the cross-correlations to obtain the distribution of the peak values between the uncorrelated signals. The 0.5th and 99.5th percentiles of this distribution were used as the lower and upper levels of significance for the cross-correlations (i.e., $p < 0.01$). The transposed signal cross-correlations were compiled for 456 neuron–muscle pairs, and the lower and upper limits were set at −0.29 and 0.25, respectively. These analyses were performed off-line using MATLAB (MathWorks).

RESULTS

SYNAPTIC LINKAGE BETWEEN SPINAL PreM-INs AND HAND-MUSCLE ACTIVITY

Among the 210 spinal neurons recorded from the two monkeys (34 in monkey A, 176 in monkey E), 23 neurons produced 63 significant PSEs (51 facilitations and 12 suppressions, SL) in hand and arm muscles, and were identified as PreM-INs (18 excitatory and five inhibitory). The neurons had either post-spike facilitation (PSF) or post-spike suppression (PSS) effects on at least one muscle; no neuron had both PSF and PSS simultaneously. As an example, a single PreM-IN STA is shown in **Figure 2A**. This IN produced significant PSF in four hand muscles (FDI, ADP, AbDM, and FDS). In total, PreM-INs produced PSE in 2.7 ± 2.1 [mean ± standard deviation (SD)] muscles (excitatory: 2.8 ± 2.1; inhibitory: 2.4 ± 2.1) on average, which is referred to as a muscle field (Fetz and Cheney, 1980; Buys et al., 1986). This result indicated that the spinal PreM-INs had a divergent hand-muscle field rather than affecting the activity of a single muscle.

FUNCTIONAL LINKAGE BETWEEN SPINAL PreM-INs AND HAND-MUSCLE ACTIVITY

A majority of PreM-INs (19 of 23; 83%), including 17 excitatory and two inhibitory PreM-INs, had significant cross-correlations with at least one muscle (FL). In total, 246 of 456 neuron–muscle pairs had significant cross-correlations. Interestingly, FL polarity was positively biased; most FLs were positive (231 of

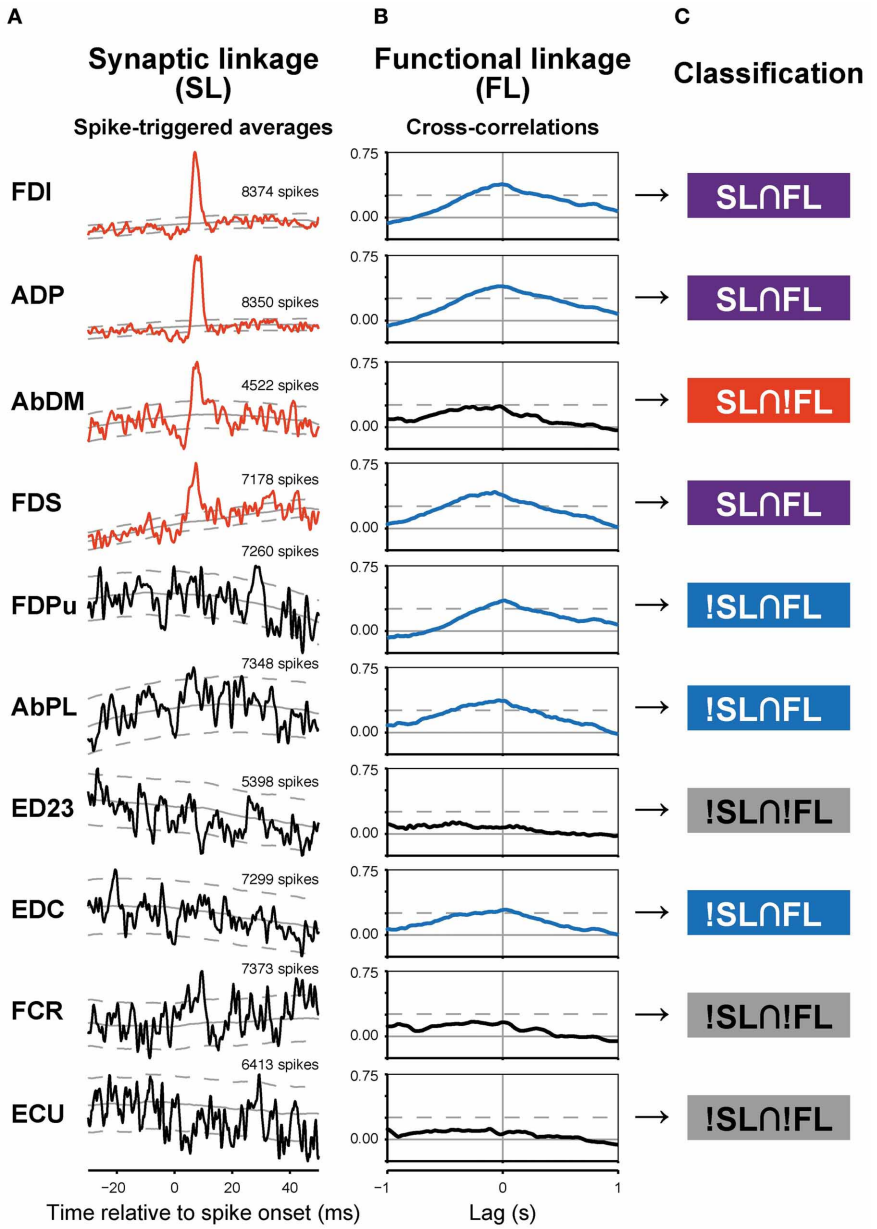

FIGURE 2 | Synaptic (SL) and functional linkages (FL) between a PreM-IN and hand muscles. (A,B) Spike-triggered averages **(A)** and cross-correlations **(B)** from a single PreM-IN (Monkey E, T1 segment). Data from 10 muscles were selected. Spike-triggered averages with significant post-spike effects (PSEs) are shown in red, and cross-correlations with significant peaks are shown in blue. The solid and dashed gray lines indicate the background level and significance limits, respectively. **(C)** Each neuron–muscle pair was categorized into one of four groups according to the existence of significant SL and FL as follows: both SL and FL were significant (SL∩FL); SL was significant but not FL, or vice versa (SL∩!FL and !SL∩FL); and neither SL nor FL was significant (!SL∩!FL).

246; 94%), and only a few pairs showed negative FLs (15 of 246; 6%). Moreover, all PreM-INs with significant FLs had positive FLs regardless of whether they were excitatory or inhibitory PreM-INs; two excitatory PreM-INs concurrently had negative FLs (**Table 1**). This result suggested that the excitatory and inhibitory PreM-INs were mostly coactivated with hand muscles during precision grip rather than being reciprocally activated. An example of cross-correlations in a single PreM-IN (same neuron as shown in **A**) is shown in **Figure 2B**. This IN had a significant positive cross-correlation with six hand muscles (FDI, ADP, FDS, FDPu, AbPL, and EDC). In total, PreM-INs had a FL with 10.7 ± 6.7 muscles on average, and the size was significantly larger than that of the muscle field of SL ($p < 0.05$, t-test). This result indicates that PreM-IN activity had significant covariation with muscles other than those on which they had output effects.

Table 1 | Summary of FLs of excitatory and inhibitory PreM-INs.

	Functional linkage				
PreM-IN	**Positive only**	**Negative only**	**Both**	**No FL**	**Total (cells)**
Excitatory	15	0	2	1	18
Inhibitory	2	0	0	3	5
Total	17	0	2	4	23

ASSOCIATION BETWEEN SYNAPTIC AND FUNCTIONAL LINKAGES

To test the relationship between synaptic connections and functional covariation further, SL and FL pairwise association was tested. The example in **Figure 2** shows various combinations of SL and FL. For example, FDI showed both significant PSF and cross-correlation, indicating that the PreM-IN had a strong excitatory effect on the motoneurons of this muscle, and their activities strongly covaried. This implies a causal relationship, as the PreM-IN activity modulated the target muscle activity. In addition to these congruent cases, however, there were many incongruent instances. The AbDM had a clear significant PSF from the PreM-IN, but the cross-correlation of their activities was not significant. In another example, FDPu showed a clear cross-correlation peak, but it had no significant PSE on the STA. To quantify the association between SL and FL, the neuron–muscle pairs were categorized into four groups according to the existence of significant SL and FL (**Figure 2C**): both SL and FL were significant (SL∩FL), SL was significant but FL was not, or vice versa (SL∩!FL and !SL∩FL); and neither SL nor FL was significant (!SL∩!FL). In the PreM-INs shown in **Figure 2**, three pairs (pairs with FDI, ADP, FDS) were SL∩FL, one pair (AbDM) was SL∩!FL, three pairs (FDPu, AbPL, and EDC) were !SL∩FL, and three pairs (ED23, FCR, and ECU) were !SL∩!FL.

Among a total of 456 neuron–muscle pairs, 266 pairs showed either a SL (PSF or PSS) or a FL (positive or negative), and 43 pairs concurrently showed both SL and FL (SL∩FL, **Figure 3A**, **Table 2**). The existence of SL and FL was significantly associated ($p = 0.014$, $\chi^2 = 6.0$); a greater proportion of pairs with significant SL than pairs without significant SL also showed significant FL (43/63 pairs, 68%, and 203/393, 52%, respectively), and only 20/63 pairs with significant SL lacked the significant FL. This clear association between SL and FL suggested that spinal PreM-IN output effects significantly modulate target muscle activities.

Interestingly, SL and FL association depended on whether the PreM-INs were excitatory or inhibitory (**Figures 3B,C**). In the excitatory PreM-INs, the majority (42 of 51; 82%) of neuron–muscle pairs with a significant SL (PSF) also showed a significant FL, and the association between SL and FL was significant ($p = 0.006$, $\chi^2 = 7.5$). On the other hand, for the inhibitory PreM-INs, only one of 11 neuron–muscle pairs with significant SL (PSS) showed a significant FL, and the association was not significant ($p = 0.6$, $\chi^2 = 0.3$). This result suggested that excitatory PreM-INs constituted the prime movers of the target muscle activity; inhibitory PreM-INs were involved to a lesser extent.

Although there was a significant association between SL and FL, there were many exceptions: 20 pairs had SL without FL (SL∩!FL), and 203 pairs had FL without SL (!SL∩FL). To test whether these incongruities occurred by chance, we quantified the chance level of these incidences. PSE significance was tested using $p < 0.0025$ (P_{SL}), and cross-correlation significance was tested using $p < 0.01$ (P_{FL}). Therefore, the chance level of SL∩!FL and

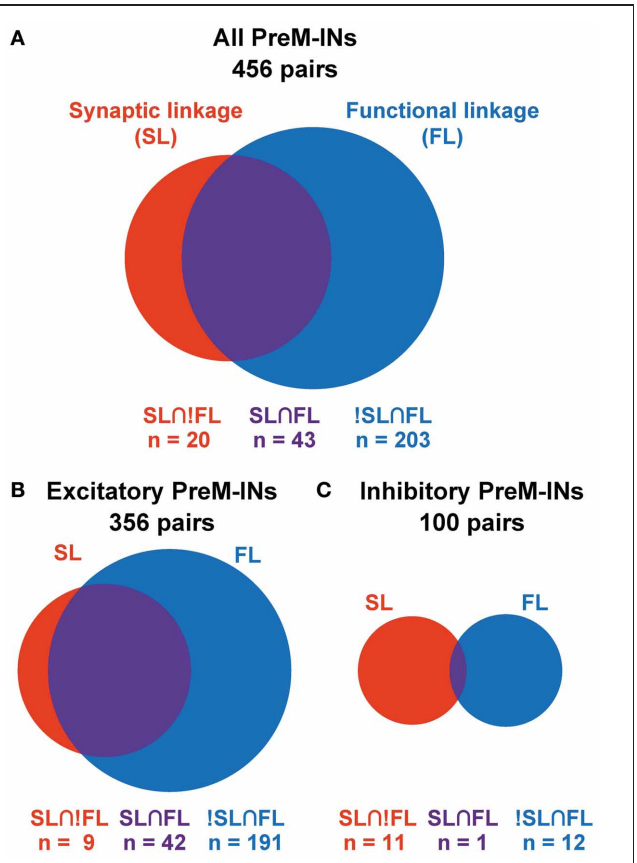

FIGURE 3 | Association between SL and FL. Venn diagrams showing the association between SL and FL in all PreM-INs **(A)**, excitatory PreM-INs **(B)**, and inhibitory PreM-INs **(C)**. Relative size of the red, blue, and purple areas are proportional to the number of pairs in each category: SL∩!FL, !SL∩FL, and SL∩FL, respectively.

Table 2 | Associations between SL and FL.

	Functional linkage			
Synaptic linkage	**Positive**	**Negative**	**No FL**	**Total (pairs)**
EXCITATORY PreM-INs (356 PAIRS)				
PSF	42	0	9	51
No effect	176	15	114	305
Total	218	15	123	356
INHIBITORY PreM-INs (100 PAIRS)				
PSS	1	0	11	12
No effect	12	0	76	88
Total	13	0	87	100
ALL PreM-INs (456 PAIRS)				
PSE	43	0	20	63
No effect	188	15	190	393
Total	231	15	210	456

!SL∩FL was set to $P_{SL}{}^{*}(1-P_{FL})$ and $(1-P_{SL})^{*}P_{FL}$, respectively. A binomial test showed that the number of SL∩!FL ($n=20$) and !SL∩FL ($n=203$) significantly exceeded the chance level ($p<0.001$, binomial test). These results indicated that SL and FL were clearly associated, but a significant number of incongruities between SL and FL also existed.

DISCUSSION

The existence of hand-muscle synergy and the modular control of primate grasping has been suggested (Brochier et al., 2004; Overduin et al., 2008), but neural implementation of hand-muscle synergy remained unclear. Here we explored how PreM-IN output effects contributed to hand-muscle activation by investigating the PSEs of PreM-INs on hand muscles (i.e., SL) and the long-term cross-correlation between PreM-IN and hand-muscle activity (i.e., FL). Our results showed that the existence of SL and FL were significantly associated and suggested that spinal PreM-IN output effects significantly contribute to hand-muscle activity modulation during grasp control. However, we also found considerable incongruities between SL and FL. This result suggested that although the PreM-IN output projections significantly affect hand-muscle activity modulation, other neural structures are needed to recruit an adequate combination of hand-muscle motoneurons.

ASSOCIATION BETWEEN SPINAL PreM-IN SL AND FL WITH HAND-MUSCLE ACTIVITY

The contribution of spinal interneurons to muscle synergy has been extensively investigated in the hind-limb movement of frogs (Giszter et al., 1993; Mussa-Ivaldi et al., 1994; Tresch et al., 1999; Saltiel et al., 2001; Bizzi et al., 2002; Hart and Giszter, 2010) and rats (Tresch and Bizzi, 1999). However, it was not self-evident that the analogous neural mechanism could be assumed for the primate cervical spinal cord and the control of hand grasping. Our results revealed that spinal PreM-INs in the primate cervical cord had divergent output effects on hand muscles and significantly functioned to modulate target muscle activity, suggesting that they could be a part of the neural implementation of hand-muscle synergy. This is analogous to frog lumbar spinal interneurons (Hart and Giszter, 2010). In hind-limb movement, a small number of motor primitives are represented in spinal cord, and their combination can construct a variety of reflexive and natural movements (d'Avella et al., 2003). As the motor primitives exist in the lower CNS (i.e., spinal cord), the control dimension in the higher motor structures might be reduced (Tresch and Jarc, 2009). Similarly, primate hand movements are characterized by very high DOF (Ogihara and Oishi, 2012) and therefore may have a computational advantage if a neural structure for hand muscle synergy is implemented in the spinal cord.

The clear association between SL and FL was specific to excitatory PreM-INs and was not found in inhibitory PreM-INs (**Figures 3B,C**). This suggests a functional difference between excitatory and inhibitory spinal PreM-INs related to the control of primate grasping. Excitatory PreM-INs mostly positively covaried with the target muscles (**Figure 3B**), suggesting that excitatory PreM-INs were a prime mover of hand-muscle coactivation. Conversely, few inhibitory PreM-INs significantly covaried with target muscles (**Figure 3C**). Because no inhibitory PreM-INs showed significant negative covariation with target muscle activity (**Table 1**), inhibitory PreM-INs may function to adjust the activities and response gains of agonist muscles (Chance et al., 2002; Berg et al., 2007; Kristan, 2007), rather than reciprocally inhibiting antagonist muscles.

POSSIBLE MECHANISMS OF INCONGRUENCE BETWEEN SL AND FL

In addition to the significant association between SL and FL, our results also showed a significant number of incongruities, i.e., !SL∩FL and SL∩!FL (**Figures 2**, **3**). Several mechanisms could explain these incongruities (**Figure 4**). First, the incongruities can be explained by assuming a common input into several PreM-INs, which have different types of muscle field. **Figure 4A** shows a schematic illustration of how a common input ("S") can produce these incongruities. Common input into two excitatory (IN1 and IN2) and one inhibitory PreM-IN (IN3) induces synchronization among these PreM-INs. This synchronization, in turn, would induce covariation between the activity of the recorded PreM-IN (IN1) and its non-target muscles (M4–5) due to the synchronized excitatory PreM-IN (IN2) input to them (!SL∩FL). Additionally, the inhibitory PreM-IN (IN3), synchronized with the recorded PreM-IN, suppresses the shared target muscle activity (M1), and this might result in decorrelation between IN1 and M1, even though IN1 had a synaptic effect on M1 (SL∩!FL). The correlation between spinal INs reported by Prut and Perlmutter (2003) may have been induced by divergent branching of the descending (Shinoda et al., 1981; Li and Martin, 2002) and afferent (Ishizuka et al., 1979; Brown, 1981; Ralston et al., 1984) axons to the spinal cord.

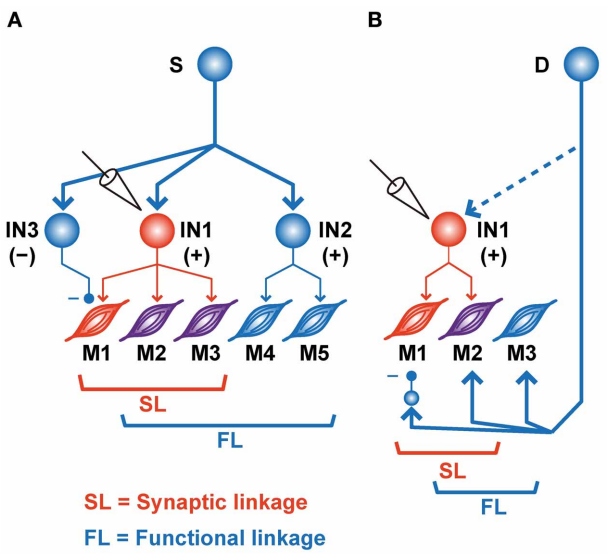

FIGURE 4 | Schematic illustrations of various SL and FL combinations. **(A)** Common input (S) to the various types of PreM-INs. IN1, recorded excitatory PreM-IN; IN2 and IN3, non-recorded excitatory and inhibitory PreM-INs, respectively. EMGs are categorized as SL∩!FL (M1, *red*), SL∩FL (M2–3, *purple*), or !SL∩FL (M4–5, *blue*). **(B)** A premotor input (D) parallel to PreM-IN. IN1, recorded excitatory PreM-IN. Again, EMGs are categorized as SL∩!FL (M1, *red*), SL∩FL (M2, *purple*), or !SL∩FL (M3, *blue*).

Another possible explanation for the incongruities is the involvement of other premotor systems (**Figure 4B**). If a premotor system ("D"), parallel to the spinal PreM-INs, primarily contributes to the formation of the hand-muscle coactivation pattern, the SL and FL between PreM-IN and the target muscle could produce incongruities (**Figure 4B**). For example, if a premotor system coactivates the target muscles (M2–3) and the recorded PreM-IN (IN1) while suppressing some of the target muscles (M1) via inhibitory neurons, the incongruences will occur between SL and FL of the recorded PreM-IN and its target muscles (M1 is SL∩!FL and M3 is SL∩!FL). Every premotor system that bypasses spinal PreM-INs [e.g., corticomotoneuronal (CM), rubromotoneuronal (RbM), reticulomotoneuronal (RtM), and group-Ia primary afferent cells] is a possible candidate for the premotor system that contributes to the coactivation of hand-muscle activity. CM cells have a selective hand-muscle field (Buys et al., 1986), and they could function to coactivate a small group of hand muscles. However, CM neurons are specifically active during precision grip as compared with power grip (Muir and Lemon, 1983), and their firing increases when one of the their target muscles is more active than another, in contrast to equal coactivation of the target muscles (Bennett and Lemon, 1996). Therefore, CM cells might function to fractionate hand-muscle activity rather than simply to coactivate the target muscles. The relative contribution of CM cells and PreM-INs to hand-muscle activity control and hand-muscle synergies should be further tested. RbM cells are another candidate for constructing muscle synergy. Several studies showed that RbM cells have a divergent hand-muscle field (Mewes and Cheney, 1991; Sinkjaer et al., 1995). However, it has been reported that their muscle field is strongly biased toward the forearm extensors (Mewes and Cheney, 1991; Sinkjaer et al., 1995); cells in the magnocellular division of the red nucleus, where most RbM cells are located, are preferentially activated when monkeys preshape their hand rather than when they grasp objects during a reaching-to-grasp task (Van Kan and McCurdy, 2001, 2002). These results suggested that RbM cells mainly contribute to constructing the muscle synergy for preshaping the hand rather than for grasping objects. Finally, Davidson (2011) recently reported the PSEs of pontomedullary reticular formation (PMRF) neurons on the extrinsic hand muscles (Davidson, 2011); hence, RtM cells may function to modulate hand-muscle activity involved in the control of grasping. In addition to these descending sources, Ia afferent to spinal motoneurons, which are also obvious premotor neurons, show task-relevant activity during wrist movement (Flament et al., 1992), but their contribution to hand-muscle movement is unknown. The afferent feedback may include functions that modulate the SL–FL relationship and define the final muscle activities according to context and external event. So far, as seen in these previous reports, the contributions of each descending tract to hand grasping have been separately investigated. Therefore, the differential contributions of these multiple premotor systems (spinal PreM-INs, CM, RbM cells, RtM cells, and primary afferents) to the control of hand grasping and the mechanism of their coordination for control of hand grasping remain to be clarified. To approach this issue, it is crucial to directly compare functional differences in the contributions of these parallel premotor systems to the formation of hand muscle synergy under the same behavioral paradigm and in the same subjects.

CONCLUSIONS AND FUTURE DIRECTIONS

In this study, we explored how PreM-IN output effects contribute to hand-muscle activation by investigating SL and FL between PreM-INs and hand-muscle activity in monkeys performing a precision grip task. Our results showed that SL and FL between PreM-IN and their target muscle activities were significantly associated, indicating that spinal PreM-INs contribute to hand-muscle activity modulation during control of grasping. However, a significant number of incongruities between SL and FL were also found, suggesting the contribution of other neural structures in recruiting an adequate combination of hand-muscle motoneurons. Further studies are needed to elucidate the relative importance of multiple premotor systems to the control of hand-muscle activity during grasping.

The co-existence of associations and incongruities between SL and FL may reflect that the modular control of hand movements is characterized by both fixed and flexible control (Macpherson, 1991). First, the clear association between SL and FL indicates that synaptic connections from PreM-INs significantly contribute to the modulation of hand-muscle activity. As PreM-INs have a divergent muscle field, these neuroanatomical or hardwired connections may produce the invariant activation patterns of the hand-muscle activities. On the other hand, the fact that FL is not always restricted to instances of SL but can be dissociated from the latter suggests that FL may be flexible according to the context or tasks (Nazarpour et al., 2012). Let us imagine that the monkeys in this study performed a different type of grasping task (e.g., power-grip task) in addition to the precision-grip task. It is possible that the PreM-INs activated during the precision grip would also be recruited in a different grasping task and that the mechanism shaping FLs would be flexible enough to modify the basic pattern of the SLs according to task demands. In this case, the SL for a specific movement would be generalizable to other types of movement. Alternatively, it is also possible that the power-grip task would recruit populations of PreM-INs, producing SLs that differed from those recruited for the precision grip, and that the PreM-INs would form FLs that would be adequate for the power-grip task. In this case, the generalization of a given SL would be rather limited, and a different movement would be controlled by different PreM-INs that exhibit unique SLs. Although results in this paper suggest a flexible FL, these two possibilities may not be mutually exclusive. Further studies investigating PreM-IN firing during different types of grasping may contribute to understanding the invariance and flexibility of the modular control of hand movements.

This article discusses the compositional structure of hand movements by analyzing and modeling neural and behavioral data obtained from experiments where a monkey (*Macaca fascicularis*) performed scribbling movements induced by a search task. Using geometrically based approaches to movement segmentation, it is shown that the hand trajectories are composed of elementary segments that are primarily parabolic in shape. The segments could be categorized into a small number of classes on the basis of decreasing intra-class variance over the course of training. A separate classification of the neural data employing a hidden Markov model showed a coincidence of the neural states with the behavioral categories. An additional analysis of both types of data by a data mining method provided evidence that the neural activity patterns underlying the behavioral primitives were formed by sets of specific and precise spike patterns. A geometric description of the movement trajectories, together with precise neural timing data indicates a compositional variant of a realistic synfire chain model. This model reproduces the typical shapes and temporal properties of the trajectories; hence the structure and composition of the primitives may reflect meaningful behavior.

Keywords: voluntary-movements, scribbling, compositionality, hand-motion-model, synfire chains, motion-primitives

1. INTRODUCTION

The hallmark of human cognition is compositionality. We compose words out of phonemes, phrases out of words, sentences out of phrases. Primate dexterity exhibits the same property and may even form the evolutionary origin of language. Compositionality may be manifested either by stringing components along in time, such as in speech, or simultaneously, such as in understanding a visual scene. In motor behavior both forms are found abundantly. Complex drawing motions may be generated by concatenating simpler strokes. Picking up an object (*prehension*) requires simultaneous coordination of three time-dependent motions: arm reaching, hand orientation, and finger shaping.

In drawings, as in language, not all possible combinations are utilized. The rules—which stroke may be concatenated to which—constitute the syntax of action. Motor compositionality, again like in language, is manifested at multiple levels starting from the way we activate groups of muscles to produce a movement, and ending in the way we coordinate fingers, hand and arm when using a tool.

This article explores continuous two-dimensional scribbling motions as a compositional product of brain activity. It integrates mathematical modeling of scribbling, recordings of multiple single unit activities during scribbling, the syntax of concatenating scribbling primitives into a continuous drawing. It also develops neural network scribbling models that are consistent with the known psychophysics of hand motion control and the observable properties of single units in the motor cortex. Overall, it is shown how such a compositional approach may be applied to two-dimensional scribbling. It is based on the rationale that whereas an infinite plethora of drawings could be created, in practice there are only a limited set of shapes that are generated spontaneously. This is suggested by an intuitive analysis of the drawings of small children; here the principles are demonstrated for monkey drawings as well as for adult scribbling.

Our data indicate that in a well-trained monkey, scribbling is composed of a small number of elementary shapes concatenated into a continuous drawing. Human subjects under similar conditions tend to behave similarly. Such elementary components may be regarded as drawing primitives if it can be shown that they exhibit the following properties:

1. They are reproduced over and over again with a fair amount of consistency.
2. They are used as building blocks for more complex drawing.
3. They cannot be stopped in the middle.
4. They are related to specific activity states of the brain.
5. One can extract clear rules for their concatenation.

While other reported studies have attempted to identify primitives at the kinematic dynamic and muscular levels (see for example, Brandon et al., 2002; d'Avella et al., 2003; Mussa-Ivaldi and Solla, 2004; Polyakov et al., 2009a,b; Dominici et al., 2011; Overduin et al., 2012a,b) while still others have proposed computational models for inferring sub-movements and/or primitives and for modeling other aspects of motor compositionality (Thoroughman and Shadmehr, 2000; Giese et al., 2009; Degallier and Ijspeert, 2010; Hogan and Sternad, 2012; Ijspeert et al., 2013, and see the current special issue of frontiers in Neuroscience), relatively a few studies have searched for the neural correlates of primitives or sub-movements at the cortical or spinal cord levels (Hatsopoulos et al., 2007; Hart and Giszter, 2010; Overduin et al., 2012a,b). Here we combined behavioral, neurophysiological and theoretical studies and have investigated the issues of the inference of motion primitives, their neural representations and the syntactic principles subserving their combination into sequences. We have also suggested novel concepts concerning temporal and spatial aspects of brain representations of complex movements based on the notion of synfire chains. In particular, generating a complex drawing shape repeatedly calls for precise sequencing of muscular activities. We suggest a neural network structure which is compatible with the known anatomy of the cortex, and can generate the sequence of elementary shapes observed in the behavior. We show by way of simulations that such networks may indeed generate the observed behavior and provide indirect evidence for its existence.

Our presentation is built on two levels. In section 2 we provide a synopsis in which we describe the main facts that lead to the above description. Following this synopsis each part is described in greater details and more supporting evidence is provided.

2. SYNOPSIS

Here we briefly describe our main results in the 7 sections. In section 2.1, we describe the monkey's scribbling data. In sections 2.2, 2.3 and 2.4 we describe various ways of analyzing the neural activities recorded while the monkeys were scribbling. In section 2.5 we describe a neural network that can produce scribbling similar to those of the monkey. Finally in sections 2.6 and 2.7 we analyse human scribbling and ways in which the syntax of concatenating simple strokelets into a complete drawing may be detected.

2.1. MONKEY SCRIBBLING

2.1.1. Materials and methods

Two monkeys (*Macaca fascicularis*) were trained to sit in a monkey chair and hold a low-friction, low-inertia manipulandum and continuously move it in the horizontal plane. The hand and manipulandum were under an opaque white screen so the monkey could not see them. A yellow dot was projected on the screen just above the position of the manipulandum's handle. The controlling computer was programmed to select a random (invisible) target in the working space. Once the monkey hit this target a beep was sounded, the monkey got a few drops of orange juice, and another target was selected at random. In this way the monkey was induced to move the manipulandum continuously. The X-Y position of the manipulandum was recorded at a rate of 100 per second. Target entry time, beep times and reward delivery were also recorded.

Once the monkey reached a stable behavior, it was anesthetized and prepared for recording of single-unit activities through metal microelectrodes. Spike shapes were detected by template matching either during the experiments or after it. Analysis of parallel spike trains in the cortex of behaving monkeys previously revealed a sequence of quasi-stable firing rate states (Radons et al., 1994; Abeles et al., 1995; Seidemann et al., 1996). This was also found to be true here.

2.1.2. Results

Initially the monkeys moved the manipulandum erratically but within several sessions the motion became rounded and more relaxed. Practice continued almost on a daily basis for a few weeks until the shape of the motion seemed stable. **Figure 1A** illustrates a short segment of a drawing. Red circles mark the points at which the monkey hit a target and got a reward.

Based on a previously suggested theory postulating the possible importance of equi-affine geometry in motion planning (Pollick and Sapiro, 1997; Handzel and Flash, 1999; Flash and Handzel, 2007), which was more recently extended to suggest a possible mixture of several geometries (Bennequin et al., 2009) it was postulated (Flash and Handzel, 2007; Polyakov et al., 2009a,b) that parabolas may subserve as drawings primitives. Indeed, we found that large segments of the drawings could be approximated by parabolas, where two parabolas are concatenated along their initial and final portions. **Figure 1B** illustrates such an approximation. The shape and orientation of a parabola may be specified by its focal distance (the radius of the circle at the tip) and the direction of its axis of symmetry. **Figure 1C** shows the distribution of these two parameters as the monkey's training progressed. Clearly, with time, the shapes "crystalized" into 2–3 parabolas.

Although the monkey often paused and occasionally drew some other shapes, the sequence of parabola #1 followed by parabola #2 followed by parabola #3 was by far the most prevalent.

If an entire parabola represents some elementary drawing component, there must be some expression in brain activity. This issue is examined in the next sections.

2.2. HIDDEN MARKOV MODEL ANALYSIS

Drawing a large segment of a parabola requires recruiting neurons with different directional tuning in the correct sequence at the correct timing. If such a sequence is produced repeatedly it is likely that there will be brain activity that determines the drawing.

Producing a sequence of shapes repeatedly can be considered to be similar to the situation in speech when sequences of phonemes are repeatedly produced. The exact sound may vary from production to production, but the intention is the same. Speech analysis has benefitted from treating it as a Hidden Markov Model (Rabiner, 1989) where the intended phoneme is a hidden state, and the actual sound is an expression of this state. It is assumed that the hidden states behave like a first order Markov process. In such a process, time proceeds in small steps and at each step the state of the system either remains unchanged or flips to another state. The probabilities of transitions (or lack thereof) are

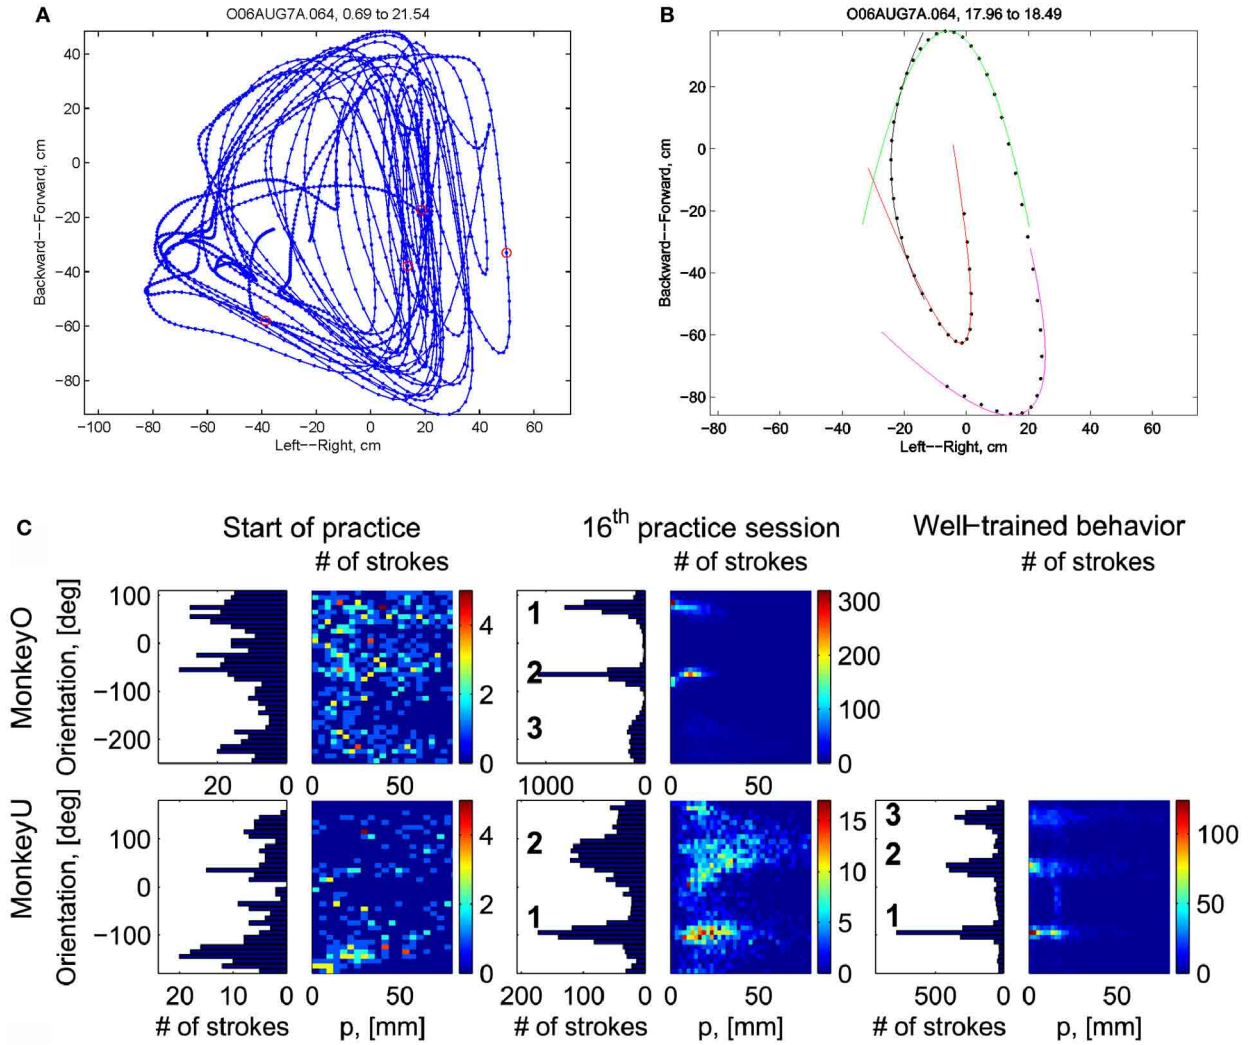

FIGURE 1 | Parabolic elements of scribbling. (A) Sample drawing. Motion is sampled at 100/s (blue dots) points at which reward was given are marked by red circles. **(B)** Breaking a piece into 3 parabolas. Black dots—the measurements; red, green, magenta—three parabolas. **(C)** Changes over the course of training. For each parabolic segment two parameters were extracted: the orientation of the parabola and its focal distance. Those are plotted in the 2 dimensional (2-D) histogram. On the left is the histogram of the orientations (Y-marginal of the 2-D histogram). Each pair of histograms is for 1 training day. The left pair is for an early training session; the middle after a several months; and the right after half a year. Clearly, with training, three classes of parabolas emerged.

specified by a matrix P that indicates the probability of changing from a state i to a state j for all pairs (i, j). This process is hidden, but at each state the system emits some outputs. The probability of emitting each possible output O at each state i is given by an emission probability matrix Q. Once P and Q are known, for any observable set of emissions the most likely sequence of hidden states the system went through can be computed.

In our case, the command or intention to draw a certain parabola can be considered to be a hidden state of the motor system. The brain activity during this state is the observed output. Applying Hidden Markov analysis to recorded brain activity may reveal hidden states that correspond to such intentions or commands **Figure 2** illustrates a small time span showing the probability of being in any one of six states over this time span.

2.2.1. Materials and methods

Once the monkey reached a stable behavior it was anesthetized and prepared for recording of single-unit activities through metal microelectrodes. Spike shapes were detected by template matching either during the experiments or after it. More technical details are described in section 3.

2.2.2. Results

In the past, analysis of parallel spike trains in the cortex of behaving monkeys did reveal a sequence of quasi-stable firing rate states (Radons et al., 1994; Abeles et al., 1995; Seidemann et al., 1996). This was found to be true also in the present analysis. **Figure 2** illustrates a small time span of analysis showing the probability of being at any one of six states over this time span.

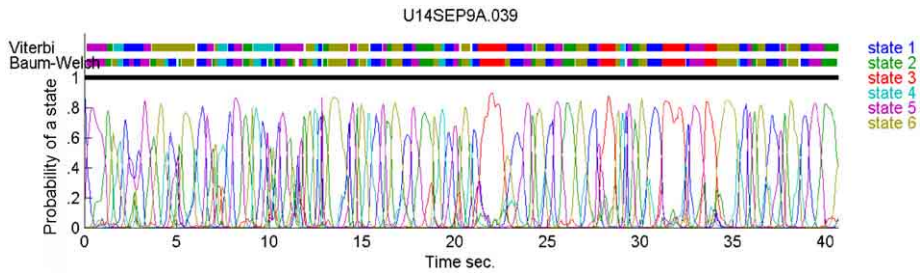

FIGURE 2 | Parsing data to HMM states. Data for 41 s of scribbling is shown. Top bars give the sequence of hidden states as revealed by Viterbi training algorithm and Baum-Welch algorithm, respectively. The bottom graphs represent the probability of each possible state as a function of time (computed by the Baum–Welch algorithm). Most of the time there is only one dominant state and the transitions are steep. When no state had a probability above 0.5 the system was considered to be in an unknown state (left blank in the upper state bars).

It is often difficult to judge whether the analysis truly reveals some underlying states or is an inevitable result of the assumption that the observed firing is the outcome of a Markov process. In our data there is a unique opportunity to tackle this problem. In addition to the sequence of states we observed the behavior of the monkeys. If the HMM reveals states that are linked in time to the production of the parabolas we can infer that there are activity states which represent the intention (or maybe the plan or command) to draw the parabolas.

In this study we recorded the activity of only a few neurons out of tens of millions that are probably involved in planning and execution of arm motion. The recording area was in the arm region of M1 and the pre-motor cortices. Activities there are assumed to be related to the velocity vector of the hand end point. As such, they are expected to change dramatically over the span of each drawn parabola. A-priori the chances of finding stable firing configuration that span a whole parabola seem slim.

Nevertheless, in our data we found in four out of eight cases clear connection between the hidden Markov states and the parabolas. Section 4 describes this analysis in more details. **Figure 3** illustrates the clearest case.

The findings that in some cases we found evidence of stable firing configurations that relate to the drawn parabolas support the notion that the parabolas represent a distinct entity in the monkey's scribbling. Is there any special significance for parabolas in hand motion? The next section addresses this issue from a mathematical point of view.

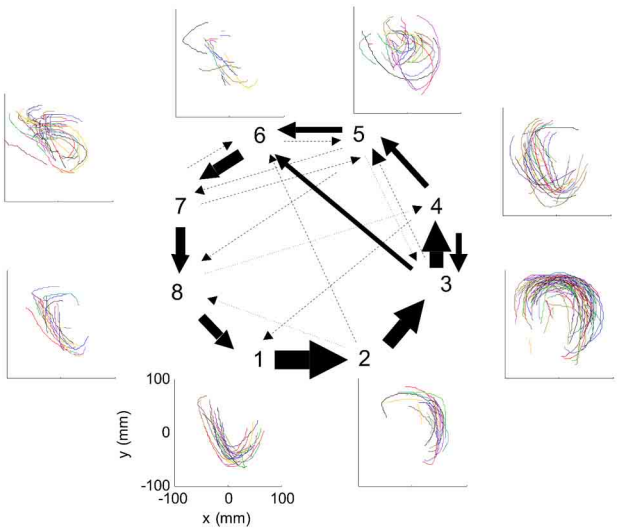

FIGURE 3 | HMM and drawings. The transition probabilities between states are coded by the thickness of the arrows. The actual drawing shapes associated with each HMM state are plotted near the state number. The different colors have no meaning, they are meant to facilitate discrimination among the various repetitions of similar shapes. State 1 appears to be associated with one parabola, while states 2 and 3 with the two others. The other states are associated with other drawings, many of which had to do with pausing or restarting to move.

2.3. EQUI AFFINE GEOMETRICAL ANALYSIS

Continuous two-dimensional (2D) drawings of human and monkeys obey a series of simple laws. One of them states that during continuous 2D drawings the drawing speed becomes slower as the curvature of the drawings become higher. The relation between angular speed and the curvature is described by a power law which may be written as:

$$A = KC^{\beta}$$

or by dividing by the radius (R):

$$V = KR^{(\beta - 1)}$$

where A is the angular velocity, C is the curvature, V is the tangential velocity, R is the radius, K is the velocity-gain constant, and β is typically near 2/3. Note that K becomes larger when the drawing is larger (isochrony) and smaller when the level of accuracy is higher (Fit's law). There is something fundamental in the 2/3 power law as it holds not only for production of movement but also for the perception of motion speed. When a dot moves along a convoluted line, it is perceived as though it were moving at a constant speed when its movement follows the 2/3 power law (Viviani and Stucchi, 1992; Pollick and Sapiro, 1997; Levit-Binnun et al., 2006).

In differential geometry, the local properties of a curve can be described by means of the derivatives of the path with respect to some measure of distance (i.e., arc-length) and looking for

invariant properties under some family of transformations. Of particular interest here are the equi-affine transformations in which a trajectory $<x(t), y(t)>$ parameterized by time (or by arc-length) is transformed into a new trajectory $<u(t), w(t)>$ by:

$$u(t) = ax(t)+by(t) + c$$
$$w(t) = dx(t)+ey(t) + f$$

with the condition: $ae - bd = 1$, i.e., the area within a closed loop is preserved by the transformation. When such trajectories follow the two-thirds power law in the time domain they have a constant equi-affine speed K.

All parabolas have zero equi-affine curvature. **Figure 4A** illustrates the equi-affine properties of a short piece of a monkey's drawing. We observe half a second stretch [from time of 0.2 up to 0.73 at which the equi-affine curvature is close to 0 (red trace)]. This segment is composed of 2 parabolas as can be seen in **Figure 4B**. In fact it was such a finding that drew our attention to the fact that the drawings tended to be composed of sequences of parabolas. This issue is described in more detail in section 4.

Thus in equi-affine differential geometry parabolas play the role of straight lines in Cartesian geometry. The finding that the monkey drawing is composed to a large extent of parabolas, and that both motion production and the perception of the speed of a moving target obey the two-thirds power law which is equivalent to having a constant equi-affine speed, raises the possibility that at least some of the neuronal activity in the brain is coding the equi-affine parameters of the motion. This analysis is described in detail in section 4 and is summarized in the next section.

2.4. TUNING OF SINGLE UNITS IN THE MOTOR CORTEX: PARTIAL CORRELATIONS

It is well accepted that activity of neurons in the arm areas of M1 and premotor cortices code for the direction and velocity of motion (Georgopoulos et al., 1982, 1986, 1988; Moran and Schwartz, 1999), although there is strong evidence that they code also for lower level representation of movement [muscle group activity (Kakei et al., 1999)] and for higher level representations such as sequential order of movement sequences (Carpenter et al., 1999) or other more complex features of the motion (Paninski et al., 2004). Many studies of velocity tuning of cortical motor areas have been based on a simple task where the monkey needs to move from one starting location toward one of eight peripheral targets. In such a task the direction of the velocity vector, the direction of the initial acceleration vector and the position of the final target vary together. For this reason it may be difficult to distinguish which of the three components (position, velocity, acceleration) the unit is tuned to. In the current experiments, where the monkey is scribbling, as well as in experiments where the monkey had to trace convoluted trajectories, the coupling is less tight. However, in these experiments as well there are couplings between the parameters. These are even stronger if variable delays between the parameters are allowed because for quasi-periodic movements the velocity vector often looks like its derivative (acceleration) shifted in time. For this reason we developed the idea of partial correlation to find solutions for simultaneous parameters each of which are tuned to its own delay. For three parameters x, y, and z (here x, y, z stand for position, velocity, and acceleration) we describe the firing rate of a neuron at time t [$\lambda(t)$] as a linear combination of the effect of the three components with three delays:

$$\lambda(t) = ax(t + \tau_x) + by\big(t + \tau_y\big) + cz(t + \tau_z) + d \qquad (1)$$

We fit the best coefficients a, b, c, and d for every possible combination of the three delays in the range of ±250 ms, (taking into account that the rate cannot be negative) and test the fit (Stark et al., 2006, 2009). The results may then be displayed in a cube whose three dimensions are τ_x, τ_y, and τ_z, with color reflecting the goodness of fit. However, as position, velocity, and acceleration may be highly correlated, it is better to build three such cubes for each neuron, one showing the regression on position when the contributions of velocity and acceleration are factored out; one for velocity when the contributions of position and acceleration are factored out; and one for acceleration when the other two are factored out. **Figure 5** illustrates examples of such cubes.

Eighty percent (218 out of 272) of the units recorded were tuned to at least one of these parameters. The most prevalent was velocity (71% of the tuned units), 19% included acceleration, and 10% position. Fifty-six percent of the tuned units were tuned to only one of these parameters but only very few to all three. It is worth noting that when a unit was tuned to more than one parameter, the delays were generally different, as illustrated in **Figure 5A2**.

In a similar way velocity tuning may be related to the tangential velocity or the equi-affine velocity. These two parameters are very strongly correlated, so the distinction is less clear. The fit of the firing rate f(t) would look like:

$$f(t) = a + b\dot{s}\,(t + \tau_{\dot{s}}) + c\dot{\sigma}\,(t + \tau_{\dot{\sigma}}) \qquad (2)$$

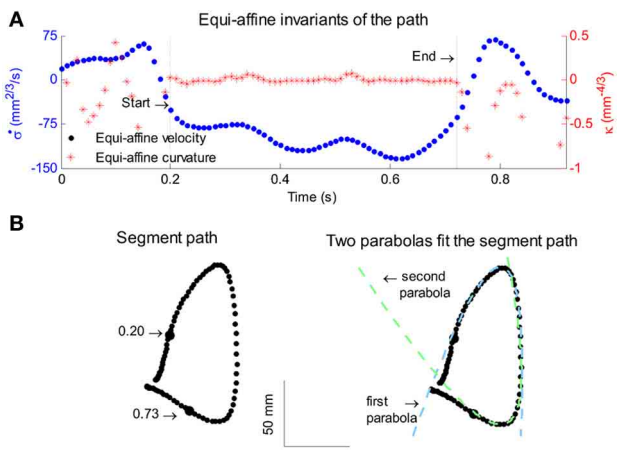

FIGURE 4 | Equi-affine differential geometry of monkey drawings. (A) Equi-affine velocity (dots) and curvature (+sign) for a scribbling segment. **(B)** The actual drawing made by the monkey. Since parabolas are characterized by zero equi-affine curvature, the motion segments can be well-fitted by parabolas (dashed lines).

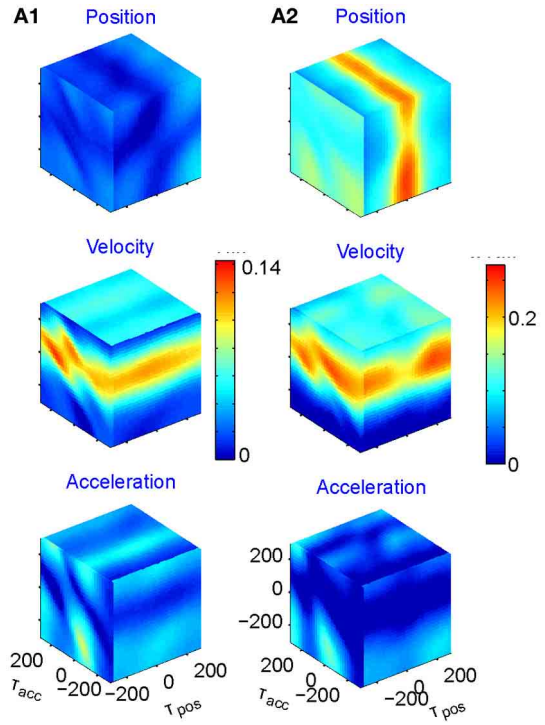

FIGURE 5 | Multi parameter tuning. Data for single units in motor cortex of a monkey tracing a convoluted trajectory. Three possible parameters were studied: position, velocity, and acceleration. For each of them all possible delays within ±250 ms were tried. The color within the cube shows the contribution to the variance of firing rate for one parameter (e.g., velocity) given the other two (e.g., position and acceleration). **(A1)** Velocity tuning. This single unit showed only one plane of higher contribution to the total variance. At the velocity cube (middle) we see a horizontal plane (for τ_{vel}) at time 70 ms (leading the velocity). **(A2)** Velocity and position tuning. For Position (given velocity and acceleration) we see a vertical plane at 0 delay and for the velocity (given position and acceleration) we see a horizontal plane leading the velocity by 90 ms. This single unit was coding two parameters at different delays.

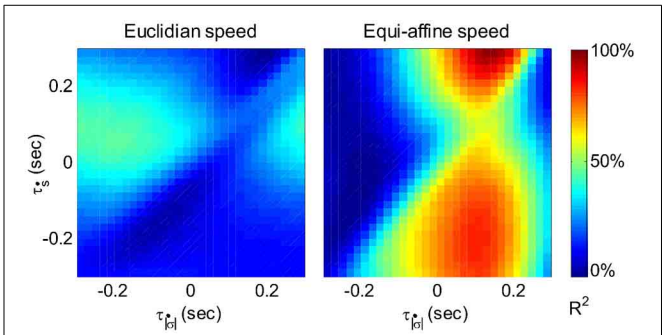

FIGURE 6 | Equi-affine tuning. As Euclidian velocity and equi-affine velocity have the same direction only the amplitude of the velocity vectors was considered here. All possible delay combinations within ±250 ms were evaluated. The (thick) vertical line when equi-affine speed was the main regressor indicates that this unit is tuned to equi-affine speed. The thickness of the line may be attributed to the fact that both types of speeds are highly correlated; hence the contribution of one, after factoring out the effect of the other, is noisy. $\tau_{|\dot{\sigma}|}$ and $\tau_{\dot{s}}$ are the delays of the amplitudes of the equi-affine and Euclidian velocities.

Where $\dot{s}$ and $\dot{\sigma}$ are the amplitudes of the Euclidian and equi-affine velocities, τ_s and τ_σ are the delays between firing and the Euclidian and equi-affine velocities.

Figure 6 illustrates a case with stronger tuning to equi-affine velocity.

In 6 out of 16 units for which this analysis was attempted, the tuning to Equi-affine velocity was stronger.

Even in M1 some single units may code not just for instantaneous position, velocity, or acceleration, but rather only for the serial order at which targets are presented, only to the direction of movement when the monkey moves its arm, or to both. Even when a single unit codes for both, the directions may be very different.

In our data, when the monkeys alternated between continuous curved motion (free scribbling or tracing) and center-out straight movements we found that 110 out of 304 units were directionally tuned during one of the tasks only, while only 72 during both. But even when a unit was directionally tuned in both tasks it did not necessarily have the same preferred direction. Thirty-eight of the seventy-two had preferred direction difference of more than 45°. Thus, representations in the motor cortex are far from uniform and heavily dependent on the context in which they are studied.

2.5. SIMULATION OF NEURAL NETWORKS FOR GENERATING PARABOLAS

2.5.1. Introduction

We saw that the monkeys' scribbling tends to be characterized by concatenating parabolas and that parabolas are special shapes in terms of equi-affine differential geometry. We also know that many of the motor-cortex-units are tuned to the direction and velocity of the hand motion.

Suppose that we plot these units in velocity coordinates (rather than in their topological position on the cortex). In such a plot the (x, y) position of the neuron is its velocity components in the X and Y directions. If we express its position in polar coordinates (φ, v) φ represents the direction of motion and v its speed. In these coordinates, motion with constant acceleration will be a motion on a straight line. By contrast, any straight line in these velocity coordinates represents motion along a parabola. This is illustrated in **Figure 7**.

Activity that moves at a constant acceleration along any such straight line in velocity space will represent motion along a parabolic trajectory while obeying the two-thirds power law.

If a neuronal network is behind the generation of a parabola it may be composed of groups of neurons that are activated one after the other, where each group of neurons has an appropriate location in velocity space. Each such group should be composed of neurons tuned for an appropriate direction and velocity such that when these groups are plotted in velocity coordinates they form a straight line. Activity should propagate with a constant delay from group to group. This description is consistent with the activity along a synfire chain. This notion was tested in simulations.

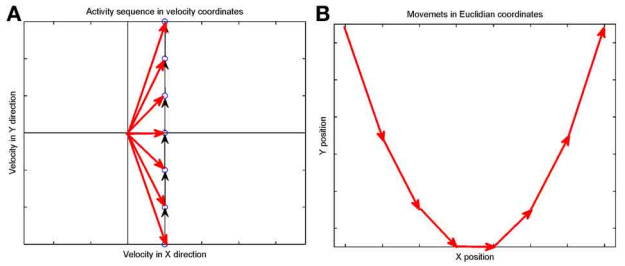

FIGURE 7 | Linear motion in velocity space. (A) Progression through groups of neuron positioned on a linear line in velocity space (black arrows). The polar coordinates (red arrows) of each group describe the direction and amplitude of the motion in Euclidian space. Each circle represents a large group of neurons with the same velocity tuning. **(B)** The shape of trajectory that the progressing activity will generate. Since the position of the groups is linear in the velocity space the produced motion is a parabola. If the speed of activity- progression is constant, then the drawing will obey the 2/3 power low. If instead of seven groups of neurons [as in **(A)**] we would have many more in between, the parabolas [in **(B)**] would be much smoother.

2.5.2. Simulations

A synfire chain is essentially a feed-forward network composed of many pools of neurons. Each pool excites the following one by multiple diverging—converging excitatory connections. In such a network activity may propagate as a synchronous volley of spikes travelling through the pools or dissipate in time and quench (Abeles, 1982, 1991; Diesmann et al., 1999). Any individual neuron may take part in several pools of the same chain as well as in pools of other chains. Theoretical work suggests that if the pools are large enough (on the order of 100 neurons per pool or more) and the overall average activity is low enough (5 per s per neuron) each neuron may participate in many (10–100) pools without confusion (Bienenstock, 1995; Herrmann et al., 1995).

A simulation that mimics cortical tissue in which multiple synfire chains are embedded needs to include a situation where there is both excitation and inhibition with balance between them, so that the membrane potential of each neuron randomly fluctuates below threshold and only very occasionally hits the threshold and fires (Brunel, 2000). Each neuron should also receive multiple, possibly uncorrelated, inputs from other brain regions [on average the number of excitatory inputs arriving at any cortical patch is on the same order of magnitude as the number of neurons in the patch (Abeles, 1991; Braitenberg and Schuez, 1998)]. This implies simulating many tens of thousands of neurons with hundreds of millions of connections among them. Despite the theoretical work on the feasibility of embedding multiple synfire chains in a large network, in simulations the entire network tended to explode into global synchrony in a periodic manner and lost the identity of the individual synfire chains. To enable the embedding of several synfire chains in the network while maintaining spontaneous low levels of asynchronous background activity the homogeneity of neuromime properties had to be broken. In such a network each neuron can participate in several pools. In these conditions it is possible to excite individual synfire chains while assuring the propagation of a synchronous wave along each of the chains. More details are provided in section 7.

Consider a situation where each pool in a synfire chain codes for a different direction and velocity, such that when the pools' positions are plotted in velocity coordinates they lie along a straight line. A wave of activity progressing with a constant delay from pool to pool of the chain will thus produce a parabolic trajectory. A wave in a synfire chain may be elicited by synchronous excitation in one of its pools, or by enhanced, asynchronous, excitation to several of its initial pools. In the monkey, after long training, a particular sequence of parabolas tended to appear repeatedly. The parabolas became connected so that the end of one was tangent to the beginning of the other, conveying the impression of a smooth transition from one to the other.

In the above scenario the end of a synfire chain producing one parabola was at the same velocity-space location as the beginning of another synfire chain which produced another parabola. There may be several synfire chains starting (or passing through) that very same velocity space region, but with practice the end of one chain becomes connected in a stronger fashion to the beginning of another specific chain. These stronger connections between chains may be thought as the basis for the drawing syntax, where after a particular parabola *A* there is a higher probability of drawing another particular parabola *B*. If with training the monkey tends to produce sequence *A, B, C, A, …* the end of the network producing *A* becomes connected to the beginning of the network producing *B* whose end becomes connected to the beginning of the network producing *C* and so on.

This situation was simulated in a network of 50,000 neuromimes with 10 synfire chains three of which were connected as described above. Once activity was initiated in one of them it would circulate through the three producing a sequence of parabolas. Sample results of this simulation are illustrated in **Figure 8**.

If parabolic drawings are produced by activity waves in synfire chains, it is reasonable to inquire how these chains came about. Were they always there, explaining the tendency to draw parabolas? Or, perhaps whatever induced the monkey to draw the same parabola several times generated the connections between the pools of neurons with the appropriate velocity-tuning to become connected to each other by spike-timing-dependent-plasticity. Once such connections are established, even in a weak form, activity tends to follow the same pattern and strengthen the connections until they form a reliable synfire chain and produce a reliable segment of a parabola. We cannot answer this issue at this stage.

The simulations show the feasibility of generating the drawings by synfire chains which needs corroboration by experimental evidence. Is there any experimental evidence to support this idea? The next section deals with this issue.

2.5.3. Experimental evidence

Direct observation of activity along a synfire chain requires the simultaneous recording of many neurons form the region in which the synfire chain is embedded. In simulations it was found that the activity of at least 200 neurons needs to be recorded simultaneously (Schrader et al., 2008). While recording

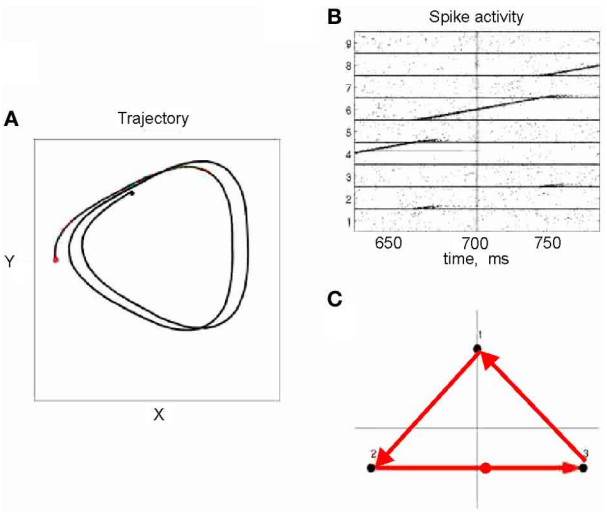

FIGURE 8 | Simulations of the production of 3 parabolas. (A) The shape of the drawings generated by the simulation. **(B)** Raster plot of the activity in the network. Abscissa describes time, Ordinate provide the cell #. Activity of each neuron is described by dots along one line. The neurons along the ordinate are arranged according to their participation in the synfire chains. Synfire chains 4, 6, and 8 are the ones generating the drawing on the left. **(C)** The layout of the 3 synfire chains in velocity space. The synfire chain which is currently active is colored in thick red. At the moment activity is at the red dot producing the vertical motion near the maximal curvature of the parabola. Note that when one single synfire chain ends there is a competition among several others. E.g., at 750 synfire 6 ended and synfires 3, 7, and 8 show enhanced activity. After a short while synfire 8 wins.

techniques approach this limit, they typically record from a much larger volume than that in which a single synfire chain is expected to exist. The recording methods employed in the present study were unable to match the above figures. Thus, the most we can hope for is that by luck we record from two to three neurons that take part in the same chain.

If we record from two neurons that take part in a single chain, every time a wave sweeps through this chain we expect the two neurons to fire with some fixed interval in between. If the chain is associated with part of the monkey's drawing we expect to see this interval appearing repeatedly. In our data with approximately 10 neurons simultaneously measured and drawing quantized to approximately 22 different strokes we can construct $10 \times 9 \times 22 = 1980$ different neuronal pairs for all the quantized drawings. If for each such pair we consider 50 possible intervals, there will be $50 \times 1980 = 99{,}000$ possible intervals, some of which will definitely contain a large number of repetitions even if there was no real preferred interval. To overcome this problem we adopted an idea proposed by Bienenstock and Geman (Geman et al., 2000; Amarasingham et al., 2003) as follows:

1. Define a statistics which you believe depends on the precision of intervals between spikes of different neurons. It should be one number that is extracted from the entire dataset.
2. Replace each spike time in the data by a random time within $\pm W/2$ of the true time. If two spikes from the same neuron become closer than the refractory period, re-teeter their times till refractoriness is preserved.
3. Repeat all the calculations of the statistic on these teetered data.
4. Repeat steps 2 and 3 many (1000) times and build a histogram of the statistics of the teetered data.
5. Evaluate the probability of getting the statistics of the real data by finding what fraction of the histogram is equal to or larger than the real statistic.
6. Select increasingly smaller W. The value of the real statistic does not change, but the histogram of teetered statistics moves toward the real value as W becomes smaller. Find the smallest value of W for which the chance probability is smaller than the chosen significance.

This smallest W provides an estimate of the time precision of the data. **Figure 23** illustrates the results of steps 1, 2, 3, and 4, for $W = 10$ ms. The precision obtained in this way is an upper bound on the spike-timing precision. Clearly, by defining a better statistics, a smaller W would be sufficient to obtain a significant difference between the real-data statistic and the teetered distribution.

This statistics, dubbed the "relations-score" was based on estimating the probability of getting N or more repetitions of each possible interval for each possible pair of neurons around each of the drawing strokelets. Minus the log of the product of the smallest 10 probabilities (p_i) was defined as the relations-score:

$$'Relations - score' = -\sum_{i=1}^{10} log_{10}\left(p_i\right)$$

We took several measures to assure that large relations-scores would not be due to imperfect spike sorting, or merely to some strong correlations for one particular pair.

1. Only pairs recorded through different electrodes were used.
2. Each pair was allowed to contribute to only one of the smallest p_i used to compute the relations score.
3. As a control we selected the time sections for which the correlations are computed at random, rather than around specific shapes of the drawings.

Eight experimental days in which the spike shape isolation was good and the firing rates stayed stable along the recording session were selected for analysis. This analysis was repeated for W of 10 ms and less, up to 0.3 ms. In five of the eight, accuracy was 8 ms or better. **Figure 9** summarizes this analysis. If 5% is chosen as the significance level accuracy can reach 0.5 ms!

Accuracy did not reach even 10 ms on any day for randomly selected times during the recordings. Thus, the observed accuracy is clearly associated with the shape of the drawings. While these findings show that precise spiking intervals exist, and that they are associated with particular segments of the drawings, they do not prove that the drawings are produced or controlled by activity in synfire chains. However, we tried to disprove the hypothesis that the drawings were produced by synfire chains by looking for

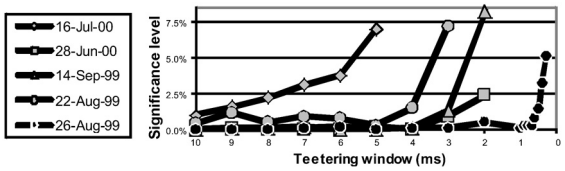

FIGURE 9 | Accuracy of spike intervals. Significance level for different teetering windows is shown for each experimental day whose significance was at least 2.5% for 10-ms precision. Abscissa is the teetering window (from 10 to 0.3 ms); ordinate is the probability value of finding the relation-score by chance. Because we looked for significant values in drawing components based on both direction and velocity separately, all probabilities have to be multiplied by 2. That is, a significance of 2.5% in this figure stands for a significance of 5%, and so forth. As can be seen, the days have significant values for teetering at 0.5, 2, 2, 3, 4, 6, and 8 ms.

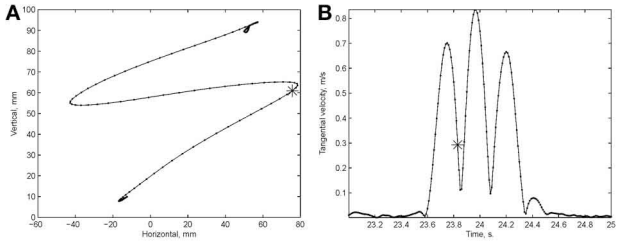

FIGURE 10 | Point of no return. (A) The drawing. **(B)** The tangential velocity. At the star the stop sound was given. The subject continued to draw for half a second producing two additional peaks of speed.

precise timing. Had we found none, the support for our hypothesis would be weakened. Nevertheless, we did find precise timing in five out of eight datasets at a precision of 0.5 ms. While these findings support our hypothesis, stronger support or disproof must wait until technology allows us to measure the spiking activity of many hundreds of neurons in a small volume in behaving subjects.

Elements of the drawings that repeat again and again can be produced by synfire chains. A movement primitive was defined as an entity that cannot be intentionally stopped before its completion (Polyakov et al., 2009a,b). A hint for such behavior was found in a well-trained monkey where the movement was usually decelerated after receiving a reward, but it stopped only after the completion of a sequence composed of several parabolic segments. A more direct test for the existence of "point of no return" in human scribbling is examined in the next section.

2.6. POINT OF NO RETURN: ANALYSIS OF HUMAN SCRIBBLING

To study the existence of the "point of no return" we trained human subjects in the same setup as the monkeys. The subjects sat holding the manipulandum. They were told to keep moving it so as to hear as many sound beeps as possible. The working space was tiled with invisible hexagonal targets. Whenever the manipulandum handle passed through one of them a beep was sounded and another hexagonal target was selected at random. Some subjects tended to produce rounded movements while others moved essentially only to and fro (as the monkey initially did).

After a few sessions the task was changed. The subject was told to move, as before, but to stop immediately after hearing a beep and wait until told to start moving again.

Examination of the velocity of drawing indicated a succession of peaks with deep troughs in between. If stopping in the middle of the drawing caused no problems, we would expect the subject to stop at the next trough after the stop signal + processing delay. **Figure 10** illustrates an example where the drawings continued for several up and down cycles after the stop signal, suggesting that the subject had to complete some pre-planned sequence of strokes before stopping. Such behavior was repeatedly observed in 6 out of 9 subjects. For more details see (Sosnik et al., 2007).

The existence of drawing elements that repeats over and over again in scribbling, and the finding that some cannot be stopped in the middle support the notion that these represent some sort of drawing primitives. The idea that each such primitive is generated by an activity wave propagating through a synfire chain is attractive in the sense that it explains the sequencing in time of the series of small movements (strokelets) that compose the primitive and explains why it is very difficult to stop such elements of motion in the middle. However, the available data do not either prove this idea or disprove the possibility that some other type of neural network is responsible for producing such elements. The scribbling was often composed of several distinct repeating elements and tended to show regularities in terms of the order of recruitment of these elements. These regularities may be treated as the "syntax" of scribbling. The next section discusses how this syntax can be detected.

2.7. THE SYNTAX OF SCRIBBLING

Some of the human subjects carrying out the scribbling tasks tended to move to and fro in a regular manner. **Figure 11** illustrates such a scribbling session. To the human eye and brain this strategy is quite clear. The subject is scanning the work space horizontally and once finished, scans it vertically and then horizontally again etc. ...Can this structure be revealed automatically?

We start the analysis by breaking the scribbling into smaller segments (strokelets). The velocity of scribbling shows multiple peaks separated by deep troughs. It is reasonable to assume that each section between two successive velocity minima should be considered as one segment. Nevertheless, in the monkeys' scribbling the different parabolas were concatenated at points of maximal velocity. Lacquaniti et al. (1983), showed that when parsing tracing motion according to the 2/3 power law, one obtains segments with close- to- constant velocity gain coefficients (K) with abrupt shifts in K at the points of maximal velocity. For these reasons we decided to parse the scribbling between adjacent extrema in the velocity.

Each such strokelet was then described by the direction of motion at 10 points along its trajectory, and whether it was accelerating or decelerating during the strokelet. The strokelets were clustered into 47 clusters, 23 for accelerating strokelets and 24 for decelerating. We then used the information bottleneck analysis (Tishby et al., 1999; Slonim and Weiss, 2000) to cluster these

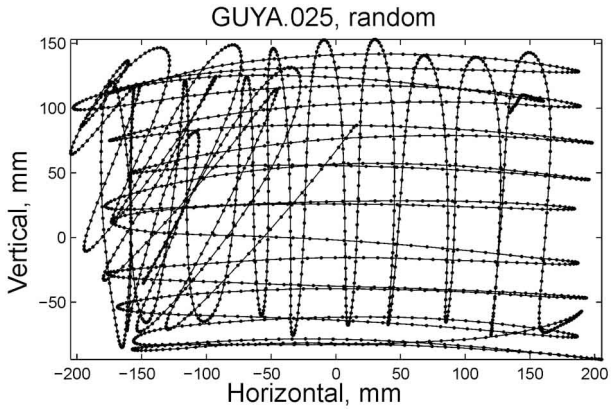

FIGURE 11 | Sample of scribbling. Scribbling was sampled at 100/s. The subject scribbled until told to stop. Several such segments were concatenated for the analysis.

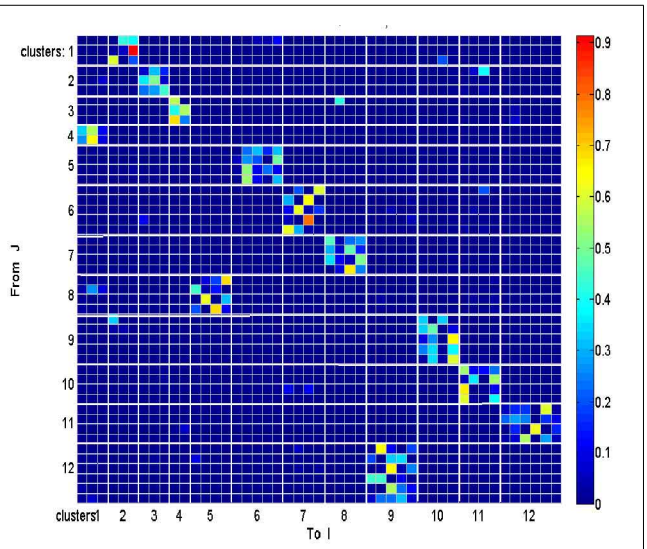

FIGURE 12 | Conditional transition matrix.

47 groups so as to preserve the maximal mutual information between each strokelet and its subsequent one. The results are depicted in the matrix in **Figure 12**. Cluster 1 (top left in the matrix) is composed of 3 groups of strokelets. They are followed by strokelets in cluster 2 which are followed by strokelets in cluster 3 which are followed by strokelets in cluster 4 which are followed by strokelets from cluster 1. Thus, with a few exceptions cycles of clusters $1 \rightarrow 2 \rightarrow 3 \rightarrow 4 \rightarrow 1 \rightarrow \ldots$ This could be compared to spoken language. Each of the 47 groups is like a phone. A cluster of phones with similar transition properties is like a phoneme, and the sequence of frequently connected phonemes (e.g., 1, 2, 3, 4) is like a word. In this analogy, there are three words: A composed of clusters 1, 2, 3, and 4; B composed of clusters 5, 6, 7, and 8; C composed of clusters 9, 10, 11, and 12. The sentences in this analogy are: "α" composed of the sequences A, A, A,…; or "β" composed of B, B, B,…; or "γ" composed of C, C, C,… The transition between sentences is not random. Sentence β is followed only by sentence α. This transition occurs only when one of the group members ("allophones") of cluster 8 is followed by one of the group members of cluster 4 in sentence α. Similarly, sentence γ is followed by sentence α only when one of the group members of cluster 9 is followed by one of the group members of cluster 2 in sentence α. Sentence α, on the other hand may be followed by either sentence β or γ. Here too the transitions are through one specific "allophone" from cluster 3 in α into cluster 8 in β; or from cluster 2 in α into cluster 11 in γ. Thus, the structure of a paragraph in this analogy is: β, α, γ, α, β,…

Sentence β is composed of left-right-left … strokes, sentence γ is composed of up-down strokes and sentence α of diagonal strokes. While this is a very simple example it shows that there is some internal "syntax" for the scribbling and illustrates how this syntax can be revealed without human interpretation.

The language of scibling in monkeys and men is very limited. The above method would probably be insufficient to reveal the syntax of handwriting. Yet this analysis shows that scribbling does have its internally driven syntax.

More details on this analysis can be found in section 8.

2.8. SUMMARY

This overview described how scribbling is generated, the brain activity correlates of scribbling, what neural networks can generate the scribbling and how the rules by which simple elements of scribbling are concatenated when a longer drawing is generated. Although each of these topics deserves fuller exploration, these findings are sufficient to support our hypothesis that synfire-chain-like structures are likely to underlay the neural data. It can conversely reproduce the behavioral data.

3. DATA ACQUISITION

3.1. MATERIALS AND METHODS

Monkey subjects (*Macaca fascicularis*) were trained to hold a low friction and low inertia manipulandum and carry movements in the horizontal plan. The subjects could not see their hand or manipulandum. An opaque white screen was positioned just above the manipulandum and a cursor (yellow circle) was projected on a point just above the manipulandum's handle. When necessary, additional targets were projected too on the same screen. A juice spout was in touch with the subject lips. The desired behavior was reinforced by releasing a few drops of orange juice whenever the subject successfully completed a trial. No negative reinforcements (punishments) were employed.

Three types of experiments were performed: Free scribbling, tracing and a center-out task. In the free scribbling the subject was motivated to continuously move the manipulandum in the following way. A target zone (invisible to the subject) was selected at random. When the target was hit, a short beep was heard, the subject was rewarded, and the target jumped to another random location.

In the tracing task, a trial was started by projecting a green target on the opaque screen in front of the subject. As soon as the subject brought the cursor into this green target, a convoluted trajectory was displayed in gray. The initial target disappeared and

an elongated target made out of eight partially overlapping green circles was displayed on the gray trajectory just in front of the initial target. Once the subject placed the cursor into the first circle it disappeared and another circle was added in front of the elongated target. In this way it appeared as if the subject was chasing an elongated worm that progressed along the convoluted trajectory. When the subject reached the end of the trajectory it was rewarded by a few drops of orange juice. On each day a set of different 40 trajectories was selected out of a repertoire of 100 trajectories. The trajectories were generated by spline interpolation between 10 randomly selected points.

3.2. SURGERY AND MONKEY HANDLING

Following training, a localizing MRI scan was performed and a chamber (22×22 mm) was implanted in aseptic conditions [halothane anesthesia, induced by ketamine and medetomidine hydrochloride (Domitor)] over the left hemisphere. The dimensions of the chamber were selected in order to allow access to both motor and premotor areas. Analgesia [pentazocine (Talwin), carprofen (Rymadil)] and antibiotics (ceftriaxone) were administered peri-operatively. The dura mater was left intact. Location of sulci was confirmed visually during surgery and, following chamber implantation, by another MRI scan.

All the procedures were supervised by the institution veterinary, approved beforehand by the institutional ethics committee and conformed the laws in Israel, and the NIH Guide for the Care and Use of Laboratory Animals (1996).

3.3. NEURAL AND BEHAVIORAL RECORDINGS

During each recording session up to eight glass-coated tungsten micro-electrodes (impedance 0.2–2 M at 1 kHz) were inserted through the dura. Electrodes were arranged in a circular guide tubes (MT, Alpha-Omega Engineering, Nazareth, Israel), such that inter-electrode spacing within a circle was $\sim 300\,\mu$m. Each electrode was moved independently (EPS 1.31, Alpha-Omega Eng.). The electrodes were inserted either into the primary or the premotor areas. The signal from each electrode was amplified (10 K), band-pass filtered (1–6000 Hz), and sampled at 25 kHz (Alpha-Map 5.4, Alpha-Omega Eng.). Eye movements were recorded using an infra-red beam system (Oculometer, Dr. Bouis, Karlsruhe, Germany) tracking movements of the right eye. The 2D signal from this system, as well as the position of the robotic arms, was sampled at 100 Hz. Behavioral events (LEDs, switches, lights, and so on) were sampled at 6 kHz. The workspace and monkey's movements were monitored using three infra-red CCD video cameras synchronized to the task and recorded on computer disk.

3.4. NEURAL DATA PREPROCESSING

An offline procedure was applied to identify spike waveforms in the 25 kHz digitized traces (Bar-Hillel et al., 2006). Spikes were subjected to manual offline spike-sorting (Abeles and Goldstein, 1977) (Alpha-Sort 4.0, Alpha-Omega Ind.), and the clusters defined examined for unit isolation (ISI histograms, individual spike shapes) and unit separation (Ben-Shaul et al., 2003). Long-term (trial-to-trial) stationarity of the responses of each unit was determined by an algorithm based on a time-varying Poisson counting process and validated by visual inspection of raster plots.

Further details on the methods of analysis of the behavior and spike trains are described in the appropriate places of the following sections.

4. GEOMETRIC APPROACH TO MOVEMENT ANALYSIS

4.1. PIECE-WISE PARABOLIC PATTERNS EMERGE IN SPONTANEOUS OVER-TRAINED PRIMATE DRAWINGS

Since the pioneering work of Bernstein (1967), there has been a general consensus that we have mental templates of motions which we try to follow when executing motor tasks. For example, reaching movements consist of fairly straight lines with bell shaped velocity profiles. Several optimization criteria have been suggested as the basis for the selection of these motion primitives (Flash and Hogan, 1985). The shape of the velocity profiles is invariant under changes in speed (Atkeson and Hollerbach, 1985) unless there are accuracy demands, in which case the movements obey Fitts' law (Fitts, 1954).

Simple curved motions which contain several velocity peaks may be observed during obstacle-avoidance movements or when the target jumps in the middle of the motion. Such motions seem to be composed of the summation of straight or slightly curved motions, which are partially overlapped in time (Morasso and Mussa-Ivaldi, 1980). Similarly, the analysis of movements generated by stroke patients or during load adaptation tasks has shown that template for the speed of hand trajectory might be composed of a single or a few velocity primitives (Krebs et al., 1999).

Continuous two-dimensional drawing motions tend to follow a power law (Lacquaniti et al., 1983) $A = KC^{\beta}$, where A is the angular velocity, C is the curvature, the power β is often near 2/3, and K is a gain factor which has been shown to be piecewise constant. The value of K depends on the linear extent of the segment, in a way that conforms to the isochrony principle (Viviani and Schneider, 1991). Thus, in spite of the apparent continuity of drawing movements, they may be, in fact, intrinsically discontinuous and constructed of individual segments. We term such intrinsic components as "primitives" of motion. While there is experimental evidence supporting the idea that complex motion is composed of primitives (Flash and Hochner, 2005; Hart and Giszter, 2010), not everybody agrees on that (Tresch and Jarc, 2009).

To examine the nature of movement elements from which monkey scribbling movements are constructed, three data sets recorded from two monkeys were analyzed and included two data sets recorded during 16 or 17 sessions at the beginning of the practice period and one data set recorded from one of these monkeys during 17 sessions conducted following a full year of practice. Kinematic analysis of the scribbling movements of the highly trained monkey showed that these movements can be well-approximated by parabolic segments. The movements were first segmented into periods of rest and active drawing and the drawing movements were then kinematically analyzed and various geometric, temporal and kinematic variables were calculated. These variables included hand velocity and acceleration, Euclidean arc-length and curvature and equi-affine arc-length curvatures.

To empirically examine whether the monkey movements can indeed be shown to be composed of a sequence of parabolas, the movement records were segmented into separate strokes, each lying between local minima of Euclidean curvature, and containing a single maximum of Euclidean curvature. These strokes were then fitted with parabolic segments whose canonical representation is $y = \frac{x^2}{2p}$. The parameter p is the focal parameter of the parabola, its value being equal to the radius of curvature at the point of maximum curvature. For more details see Polyakov et al. (2009a,b).

The error in fitting a stroke with a parabolic model was estimated using the parameter D evaluating the proportion of the data variance unexplained by the parabolic model, namely:

$$D = 1 - R^2 = \frac{\sum \left(y_i - \frac{x_i^2}{2p} \right)^2}{\sum \left(x_i - \text{mean}(x) \right)^2 + \left(y_i - \text{mean}(y) \right)^2}$$

4.2. PARABOLIC PATTERNS DURING DRAWING: EVIDENCE FROM MONKEY SCRIBBLING

Recorded trajectory segments were fitted with parabolic strokes (see **Figure 13**). The length of the movement segments that were well-approximated by parabolas was found to be longer for data derived from well-trained behavior vs. those derived from movements performed during the beginning of the practice period (see **Figure 14A**). **Figure 14B** shows the values of the D parameter estimating the error in fitting parabolas to the extracted segments. As is clear from this figure such error became smaller as a function of the amount of practice the monkeys have had. To assess the degree to which scribbling movements are well-approximated by parabolic-like strokes, the values of the equi-affine curvature along these strokes were derived (see also **Figure 4A**) and their modifications with practice were examined.

This analysis showed that the distributions of the equi-affine curvature k of the fitted strokes peaked at zero (histograms in **Figure 15A**) with both negative and positive values. Moreover it was found that during the first five to six practice sessions, the absolute values of the equi-affine curvature $|k|$ consistently decreased, converging toward nearly zero equi-affine curvature (**Figure 15B**). Hence, with practice, the extracted movement segments indeed tended to become more parabola-like. We also assessed what other geometric forms besides parabolic strokes may possibly provide a good fit to the extracted scribbling segments. These other geometric forms included ellipses and polynomials of third, fourth, and fifth order. Several considerations suggest that parabolic rather than elliptic or polynomial segments provide a better model for drawing movements [for further details see Polyakov et al. (2009b)]. To quantify the trade-off between goodness-of-fit and model simplicity (number of parameters of the fitted curve) the Schwarz information criterion (SIC) (Schwarz, 1978) was used (Polyakov et al., 2009b). This analysis showed that the parabolic model yielded the highest SIC score indicating that the parabolic model is optimal in the sense of goodness-of fit vs. simplicity trade-off. Hence, taken together these results suggested that parabolas might be considered as more attractive candidates for serving as plausible movement primitives.

4.3. CLUSTERING OF THE EXTRACTED PARABOLIC SEGMENTS

The focal parameter and the orientation define a unique parabola up to translation (see **Figure 16**). The parabolic segments that were fitted to the recorded movement segments were then clustered into different clusters according to their spatial orientation. In comparison to the lack of distinct clusters in the histograms obtained for the parabolic segments derived from the movements recorded during the beginning of the practice period the parabolic segments extracted from the well-practiced movements

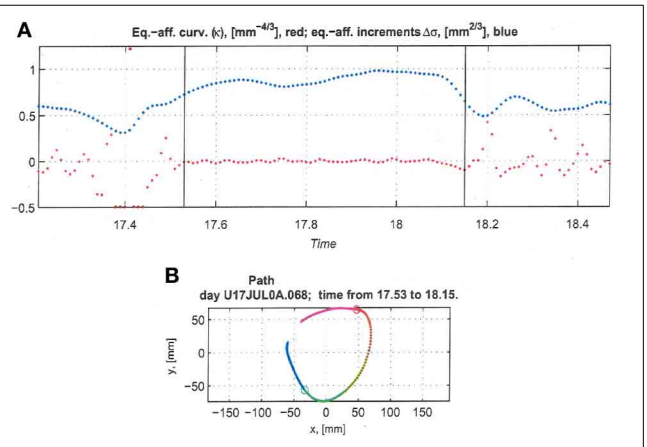

FIGURE 13 | Equi-affine analysis of drawing and parabolic fit. A short stretch of the monkey's drawing is shown. **(A)** Equi-affine analysis shows that between time 17.53 and 18.15 the equi-affine curvature (red) was almost 0. **(B)** Fit to parabolas was close to perfect. The section between 17.53 and 18.15 is between the green and red circles. It is fitted by two parabolas painted red and green.

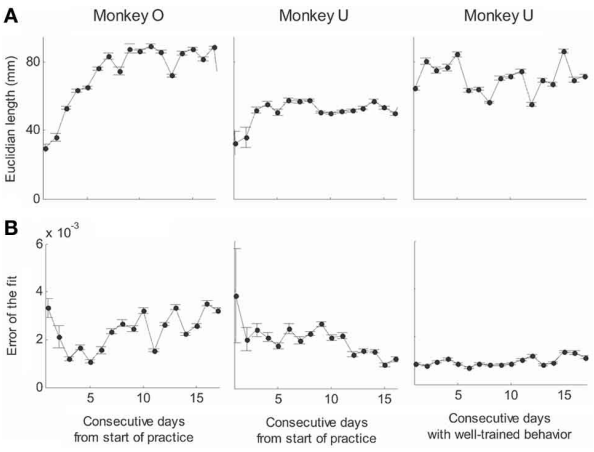

FIGURE 14 | Degree of fit and length of the parabolic strokes fitted to movement segments. (A) Euclidean lengths of the fitted parabolic strokes. In each plot, median values (over sessions) and 95% confidence intervals are shown. **(B)** Values of the D parameter estimating the error in fitting parabolas to the extracted segments.

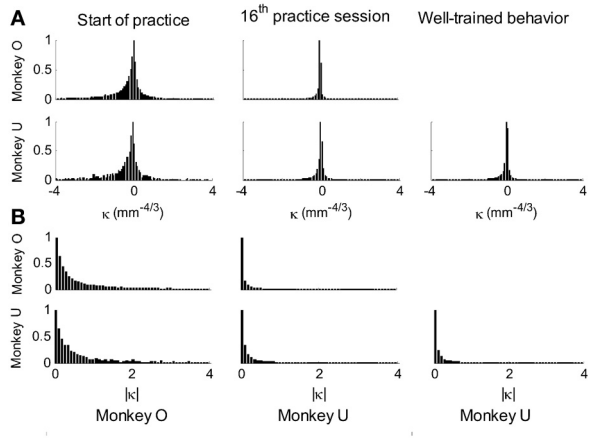

FIGURE 15 | Equi-affine curvature and its modifications with practice. **(A)** Distributions of equi-affine curvature (measured in $mm^{-4/3}$) for the first recording session, a session conducted following 16 practice days, and another session of well-trained behavior. **(B)** Distributions of the magnitude of the equi-affine curvature (same data).

clearly showed convergence toward a few well-separated clusters (see **Figure 16**). Hence the well-practiced movements could be fitted by three parabolic segments (see **Figure 16B**). Further examination of the locations of the vertices of similarly oriented extracted parabolic segments also showed that after a period of practice, these locations could be separated into three distinct locations.

4.4. NEURAL CODING BY MEANS OF EQUI-AFFINE VARIABLES

While the above analysis has indeed supported the hypothesis that parabolas might be considered as likely candidates for serving as movement primitives, further analysis was carried out to directly examine whether equi-affine speed is indeed represented in single unit motor cortical activities recorded during well-trained scribbling. This analysis was based on the method suggested by (Stark and Abeles, 2007). Here we describe the procedure used to compare the representation strengths of Euclidean vs. equi-affine speeds [for details of the method see Stark and Abeles (2007) and Polyakov et al. (2009b)].

Given that the equi-affine and Euclidean speeds were found to be highly correlated for the recorded scribbling movements the neural activities related to one of these two variables is expected to be trivially related to the other variable at a similar time lag. Hence, to overcome this problem, the relation between single-unit firing rates vs. Euclidean and equi-affine speeds were simultaneously analyzed at multiple time lags using the following multiple linear regression model as described in Equation 2 of section 2.4:

$$f(t) = a + b\dot{s}\,(t + \tau_{\dot{s}}) + c\dot{\sigma}\,(t + \tau_{\dot{\sigma}}) \qquad (3)$$

where $f(t)$ is the unit's firing rate at time t, $\tau_{\dot{s}}$ and $\tau_{\dot{\sigma}}$ are the time lags for the Euclidean and equi-affine speeds, respectively, and a, b, and c are regression coefficients. Positive time lags correspond to the neural activity preceding the movement. Note that Euclidean and equi-affine velocity vectors have the same direction. Therefore, we ignore the direction of the velocity vectors and relate only to the amplitude of these vectors. The influence of the Euclidean and equi-affine speeds was estimated using the measure of contribution defined in (Stark et al., 2006).

Following Stark et al. (2006) [for further details see Polyakov et al. (2009b)] a stripe (horizontal or vertical set of values) in a contribution matrix, all corresponding to the same time-lag of one of the two speed parameters was deemed dominant if at least half of the constituent values were above $max(R^2)/2$, where the maximum is taken over all R^2 values at all time-lag combinations of the two parameters. Using this method, the activity of 87 well-isolated units recorded during the scribbling task was analyzed. The activity of 72 units (83%) was related to the monkey's hand position, velocity, acceleration, or some combination of these kinematic variables.

The contribution matrices for the combined speed model for one of these units are shown in **Figure 17A**. For the unit depicted there, the firing rate is movement-related because contribution of equi-affine speed to the firing rate variance is dominant as the right matrix contains a vertical dominant region around the time lag of 0.12 s, indicating that neural activity precedes movement (permutation test, $P < 0.05$). In contrast, the contribution matrix for the Euclidean speed (left) does not contain a dominant stripe. Further analysis showed that the combined Euclidean/equi-affine speed model (see above) provided a good fit for the firing rates of 16/72 (22%) of the movement-related units (permutation test, $P < 0.05$; **Figure 17B**). The activity of seven of these units (44%) was related to both Euclidean and equi-affine speeds. However, equi-affine speed was dominant in the activity of six units (38%) whereas Euclidean speed was dominant for only three units.

5. ANALYSIS OF NEURAL STATES IN PARALLEL SPIKE TRAINS

In this section we wish to treat the parallel recorded spike train as a time-varying vector of activity. We do this by considering the recorded activity as the output of a Markov chain.

In a first order Markov chain a system may be in one of N states while time progresses in discrete steps. For each state there is a vector of probabilities that the system would flip to any other state or remain where it is now. The state of the system may not be known explicitly, but is observable by some output that is related to the state in a probabilistic manner. The observed information can be disentangled by an estimation of the most likely state by a Hidden Markov Model (HMM). HMMs were used for the analysis of spike trains in the past (Radons et al., 1994; Abeles et al., 1995; Gat et al., 1997). In our analysis, we assume that the little piece of cortex in which our electrodes were placed behaves like a Markov chain, and the activity of several (M) recorded neurons is the observable output of the system. Thus, we assume that the piece of cortex may be in one of N states, we first find an optimal $N \times N$ matrix of the probability for transitions among states (P) and an optimal set of M firing rates at each state (An $N \times M$ matrix of firing rates Λ). As firing rates are typically low, time steps had to be fairly big (50 ms). We will assume that the probability of observing n spikes of a certain single unit

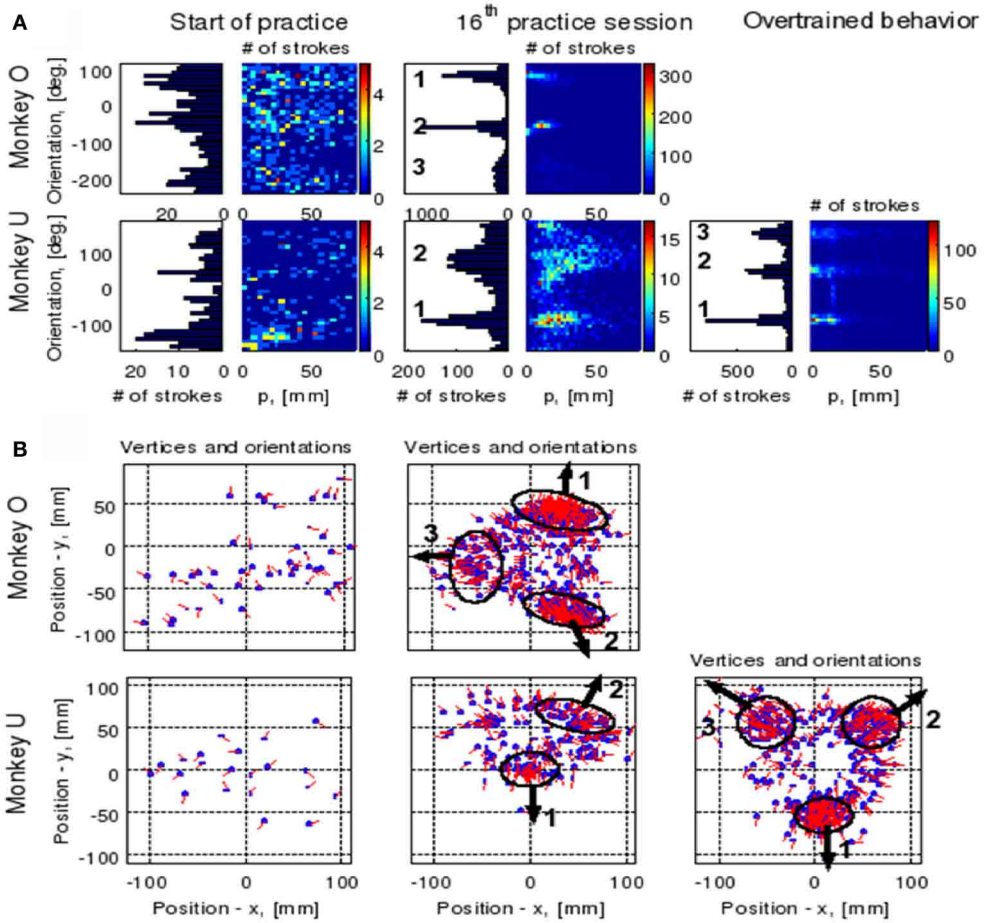

FIGURE 16 | Emerging parabolic clusters and dimensionality reduction. **(A)** Typical histograms for the fitted parabolic segments. In the one-dimensional histogram (left), the segments are counted according to their orientation. In the color histogram (right), they are counted in distinct bins according to the orientation and focal parameter of the parabola. **(B)** Location of the vertex and orientation of the parabola for every 10th parabolic segment for the recording sessions in **(A)**. Locations of the vertices of the similarly oriented parabolas are also clustered. The clusters are marked by ellipses and the mean orientations of the parabolas within each cluster are depicted by arrows.

is: $p(n|x) = e^{-x}x^n/n!$, where x is the expected number of spikes given by $x = \lambda\Delta t$, where λ is the firing rate and Δt is the duration of the step. We further assume that the different single units independently fire.

With these assumptions and knowing P and Λ, we may estimate the likelihood of observing the measured spike trains throughout the recorded period for any possible series of the states of the Markov chain. We start with a guess of P and Λ and improve them by expectation maximization procedure. Here we used both the Viterbi training algorithm and the Baum-Welch algorithm, and once optimal P and Λ are found we can also specify the state-sequence that provides the best likelihood of observing the recorded spike train. Typically, for any given spike train, within a window of 50 ms, no spikes at all were observed in many cases, occasionally there was one spike, and rarely two or three. This situation produces a very uneven terrain of likelihood (as a function of P and Λ). Therefore, the initial guess of P and Λ may be critical. We used the following algorithm to obtain the initial guess.

For each 50 ms window and each spike train, we computed the probability of observing so many spikes, given the number of spikes observed in the preceding 200 ms. The product of these probabilities for all the recorded spike trains provided an estimate for the likelihood that the firing rates at the present 50 ms are the same as in the previous 200 ms. **Figure 18** illustrates a small stretch of such a computation.

Instead of the probability itself, we used the negative log of the probability (MLL for minus log likelihood). Peaks in MLL that exceeded five times the standard deviation of MLL were taken as points in time at which the activity flipped from one stationary state to another.

The number of states of the HMM was preselected between $N = 6$ and $N = 8$ as the results with this number of states seem to yield best results, as described below. Any series of observations will converge to some optimal P and Λ. How do we know that the HMM is a reasonable one. One way is to look at the probability of the Markov chain to be at each possible state as a function of time. A good fit to an HMM would result in

sharp transients of probabilities, as may be seen in **Figure 2**. In the present experiments, we have the advantage of observing the behavior (scribbling) during the time that the brain activity was recorded. Thus, we may confront the series of hidden state with the drawings as illustrated in **Figure 19**.

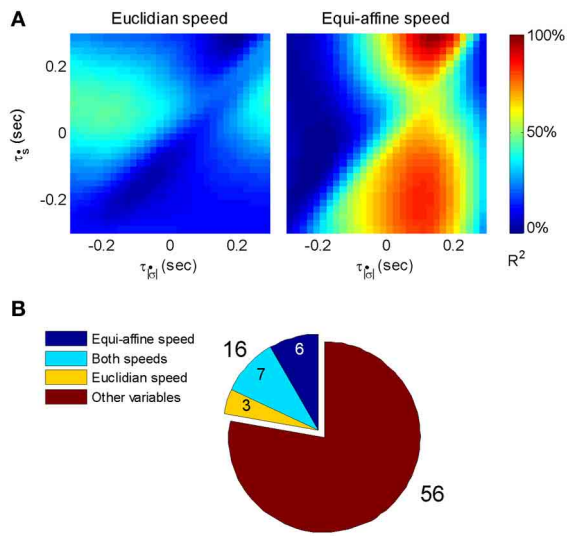

FIGURE 17 | Motor cortical activity related to equi-affine speed. (A) Contribution matrices, used to compare the representation strength of Euclidean (left) and equi-affine (right) speeds in the activity of one motor cortical unit. Contributions are shown as fractions of the total (0.12 in this case) of a linear model including both speeds (see Equation 3). The vertical stripe in the right matrix indicates that the equi-affine speed is more strongly represented. The stripe appears at a time-lag of 0.12 s, where neural activity precedes the movement. This part was reproduced in **Figure 6**. **(B)** Number of movement-related units whose activities receive dominant contribution from the equi-affine and/or Euclidean speeds.

In motor areas of the arm the majority of units are related to direction of movement of the arm's end-point. Indeed as seen in **Figure 19** most of the time the individual HMM states map into short arches of the scribbling with similar directions.

However, we also showed in section 4 that the monkey's drawings tend to be composed of concatenations of 3 parabolas. One can hope that on some days HMM may reveal also the "intention" to draw parabolas. If unique states of ensemble activity of motor cortical cells represent movement primitives, it should be possible to associate such states with distinct movements having common characteristics. To test this possibility, we used a HMM (Abeles et al., 1995; Gat et al., 1997) and the recorded motor cortical activities were segmented in an unsupervised manner without using any information about the concurrent movements. The HMM analysis was applied to the activity of a group of simultaneously recorded motor cortical units (5–12 units/session, 8 sessions). To be considered dominant, a state had to have a probability above 0.5 for at least 0.1 s with its time-average being at least 0.75.

One such segmentation is demonstrated for the results shown in **Figure 20A**. The HMM provided the a posteriori probabilities of the states as a function of time. **Figure 20C** shows a period when state 1 was dominant. Movement periods associated with the periods of dominance for the eight identified states were identified by finding an optimal time lag between the neural state and the corresponding movement segments. An optimal time lag for each state was determined by seeking a time lag providing the highest similarity between the geometrical shapes of the movement segments associated with each state lagged relative to the neural activity. A single time lag was used, although many units were active during each state and different neurons may have diverse time lags (Moran and Schwartz, 1999; Stark and Abeles, 2007). The paths identified with each state are

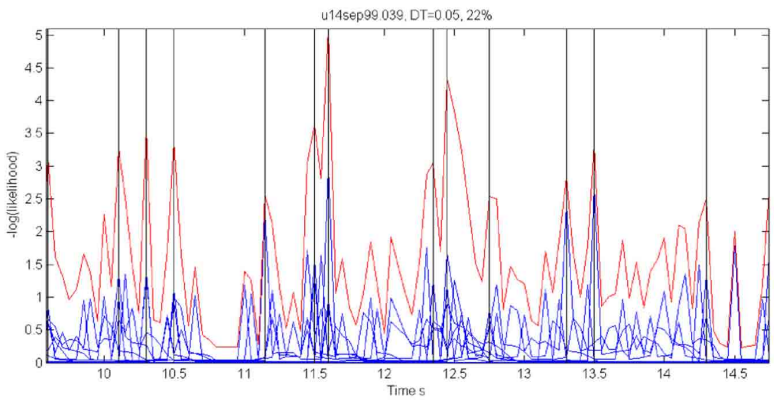

FIGURE 18 | Cooperative changes in firing rates. Negative log-likelihood that the activity is stationary during a 5-s time interval. For all the spike trains we compute $\mathrm{MLL}_i = -\log$ [prob(#spikes now | #spikes in the past 200 ms)] and $\mathrm{MLL} = \sum_{i=1}^{M} \mathrm{MLL}_i$. We show the MLL of 11 well-isolated and stable spike trains (blue traces), the sum of the blue traces (red trace) and times of transition (black lines). Top 22% of the peaks were taken as transition times. Note that several individual MLL's have peaks at the same points indicating the tendency of cooperative changes in firing rates. For each such "stationary" piece we computed the mean firing rates of every single unit obtaining a vector of M firing rates. The vectors of mean firing rates were clustered into N groups by the k-means algorithm. The probability of transition from state i to state j was estimated by counting how many times activity assigned to group i was followed by activity assigned to group j. The firing rate for group i was computed by pulling together all the time slices judged to belong to group i. These were, then, used to initialize P and Λ.

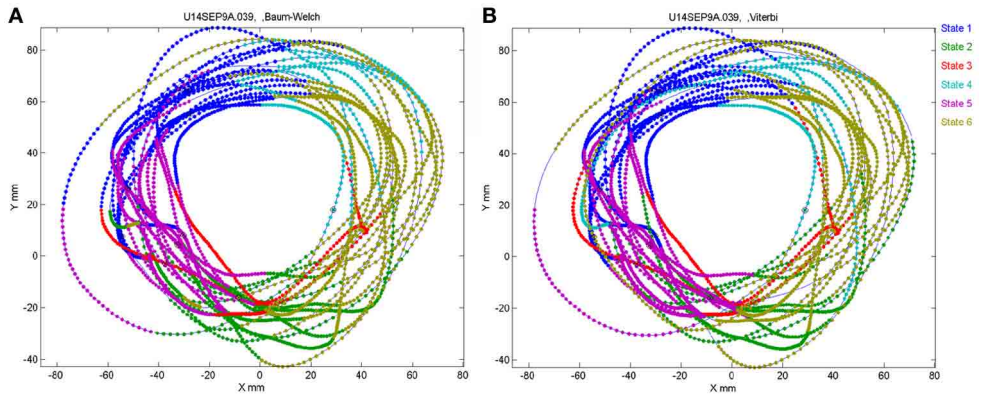

FIGURE 19 | Correspondence between drawing and HMM states. Data for 41 s of monkey's drawing is shown. Hand position was sampled at 100 Hz. Periods defined by the HMM state are plotted in different colors. For our data Baum–Welch **(A)** provided somewhat better fit with the drawings than the Viterbi training algorithm **(B)**.

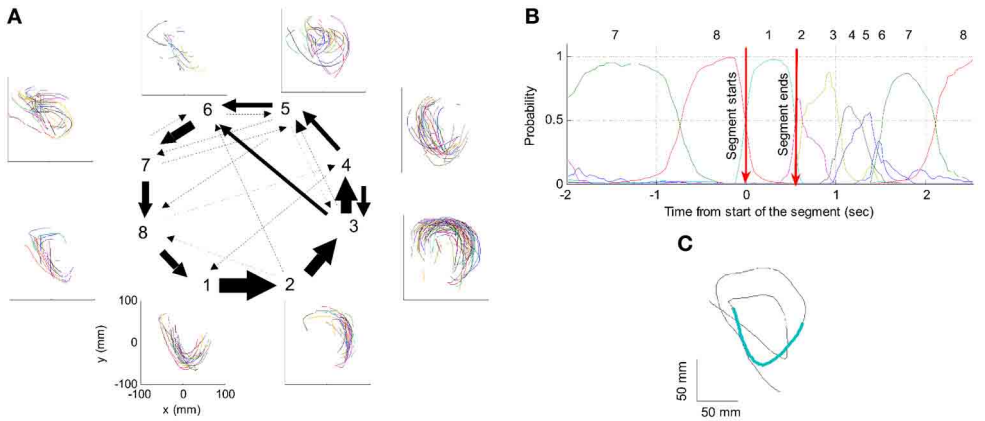

FIGURE 20 | Illustration of movement segmentation according to a Hidden Markov Model (HMM). (A) An example of HMM results for one session. Center: Transition probabilities between states. The thickest arrows correspond to the highest probabilities, and the dashed and dotted arrows correspond to gradually lower probabilities. The largest depicted probability is about 15 times higher than the lowest depicted probability. Periphery: paths corresponding to the states (for presentation purposes, the paths with shortest and longest durations within each state were omitted so only 90% of the paths are shown). This part is reproduced in **Figure 3**. **(B)** Only a short time period of the data is illustrated. The HMM model, learned here for eight states, provides posterior probabilities as temporal functions. The neural activities can then be segmented based on the dominant probabilities. The numbers above the plot correspond to the state with the highest instantaneous probability. **(C)** The movement corresponding to the analysis in **(B)**. The segment based on state 1 is highlighted; this segment is parabolic.

depicted in **Figure 20A**. Nearly 50% of duration of the neural data analyzed in this session was identified with the periods of dominant a-posteriori probabilities of the hidden states. States 1–4 corresponded to geometric strokes easily identifiable as parabolic strokes with specific orientations. State 1 (**Figures 20B,C**), for example, corresponded to parabolic strokes having an orientation of 270 degrees (direction of the normal at the vertex). States 1 and 2 could be identified with single parabolic strokes, whereas states 3 and 4 corresponded to elements from sequences composed of two parabolic strokes. States 5–8 corresponded to slower movements, presumably associated with periods of rest. Thus, the HMM segmentation, although unsupervised, resulted in partitioning the movements into sets of parabola-like elements.

6. TIME PRECISION OF NEURAL DATA

In the cerebral cortex, where each nerve cell is affected by thousands of others, it is a common belief that the exact time of a spike is random up to an averaged firing rate. Precise time relations of several neurons have been observed in brain slices (Ikegaya et al., 2004) and in behaving animals. In behaving monkeys, the time intervals between spikes, measured in correspondence to a specific behavior, may be controlled to within the milliseconds range with the best case reaching 0.5 ms. The realization that time relations among different neurons could be precisely controlled and read out, can also imply that complex representations could be built from simpler ones efficiently and very fast. We used data-mining techniques and rigorous statistic testing to test how precise can time intervals between spikes of different neurons be.

6.1. DATA MINING ON THE SPIKES RECORDING

Single-unit activity was recorded from 8 microelectrodes inserted into the motor and premotor cortices of a monkey while it was freely scribbling as described in section 3. Spike data analysis was carried out for two sets of measurements. In the first set (consisting of three experimental days), time resolution of recording was 1 ms, while in the second set (consisting of five other days) it was 0.1 ms.

The basic entity of the neural data is a single spike generated at a specific time by a specific neuron. A neural component was defined as a triple ($n1$,$n2$,δ), where $n1$ and $n2$ are two neurons and δ is a time-interval (between spikes generated by these neurons). In this way, each pair of spikes in the neural data could be interpreted as an occurrence of some neural component. For the results given in this article, the total number of time-intervals between spikes was limited to 50. In the first set of measurements, time-intervals were quantized to 2 ms. In the second set, in which spikes were recorded with a resolution of 0.1 ms, the bin width was 1 ms.

Spike sorting by shapes that were recorded through a single electrode can result in confusions. Intracellular properties which may generate precise time intervals can be confused with precise timing which is generated by the organization of activity in the network. Therefore, we considered only neural components consisting of two neurons that were recorded through different electrodes. For example, if we have three electrodes recording spikes from two neurons each, there are $30 - 6 = 24$ valid pairs of neurons (note that the pairs $<n1,n2>$ and $<n2,n1>$ are different). Combining with the 50 possible time intervals per component, we have $24 \cdot 50 = 1200$ potential neural components, some of which are frequent while others may never occur. In the days analyzed there were thousands of such neural components.

6.2. DATA MINING ON THE DRAWING RECORDING

The hand position was sampled 100 times per second (dots in the trajectory drawings). The monkey mostly drew in a counter clockwise direction. In order to find repeated patterns of drawing we used data-mining techniques. For this purpose the continuous drawing must be converted into a sequence of events (drawing events). In one experimental day there are hundreds of such events. Searching for repeating sequences of events is greatly facilitated by algorithms of data-mining. A drawing event was marked as occurring at the time at which a certain drawing-property changed from one range of values to another. The property itself may be arbitrarily chosen. For example, it could be defined as a change in the drawing direction from a range of 0-30° to a range of 30-60°. Other definitions can be based on changes in the curvature or in the velocity of the drawing. Once a set of criteria for identifying drawing events is defined, the drawing data is translated into a sequence of these events along the time axis. Then, data-mining algorithms are activated to detect repeating subsequences in the translated data. The repeating subsequences are called drawing components. Naturally, different definitions of the set of criteria lead to different drawing components.

Repeated scribbling paths were extracted by data-mining algorithms. These paths are called drawing components. In a typical day there are 12–22 such drawing components. **Figure 21** illustrates the monkey's drawings and two simple drawing components.

6.3. COMPARISON

To determine whether there are precise timing relations between the spikes of two neurons and the drawing, we selected a time slice before the start of each drawing component. For a given pair of neurons, we counted how many times a spike in the first neuron was followed by a spike in the second neuron within each of 50 particular time intervals. For the first set of measurements, these intervals were: 0–1 ms, 2–3 ms,..., 98–99 ms and for the second set they were: 0–0.9 ms, 1–1.9 ms, 2–2.9 ms,..., 49–49.9 ms. The interval that repeated the largest number of times was hypothesized to show precise firing times in relation to this particular drawing component. For example, the interval 37–38 ms between neuron 1 from electrode 8 (denoted by 8.1) and neuron 2 from electrode 1 (denoted by 1.2) repeated 372 times within the time window 400 ms to 100 ms prior to the drawing component that is shown in **Figure 21B**. **Figure 22** depicts 62 of these repetitions (uniformly distributed such that 1 of each 6 is shown).

To assess the probability of chance events we generated 1000 surrogate spike trains by randomly teetering the time of each spike within 10 ms around its real time. For each of these surrogates we used the same idea for counting all possible intervals between neurons 8.1 and 1.2, which were repeated around the same drawing component during the same time slice. Similarly, the maximal frequency of these intervals was taken as a representative of that surrogate. For the 2 single units whose firing is illustrated in **Figure 22**, the 1000 maximal frequencies tended to be significantly smaller than 372. Their mean and their variance were used to estimate the probability of these 372 repetitions, assuming normal distribution of counts. For this drawing component and pair of neurons the mean was 350.7 and the standard deviation was 5.0, yielding a probability of 0.00001.

The counting process is not likely to be distributed normally, so that assessing probability by the mean and variance may be misleading. A much more complicated issue involves finding a rare event for all twelve drawing components recorded that day.

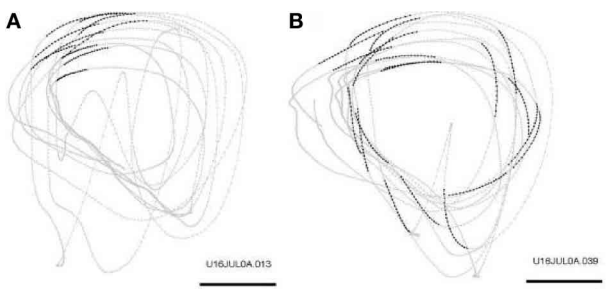

FIGURE 21 | Drawing components. Examples of two drawing components during scribbling for 30 s. Scale bar is 50 mm. **(A)** Occurrences of the drawing component: "Transitions of drawing direction from a range of 180–210° to a range of 210–240°" are marked by larger dots. **(B)** Occurrences of the drawing component: "Transitions of drawing velocity from a range of 20–30 cm/s to a range of 10–20 cm/s" are marked by larger dots.

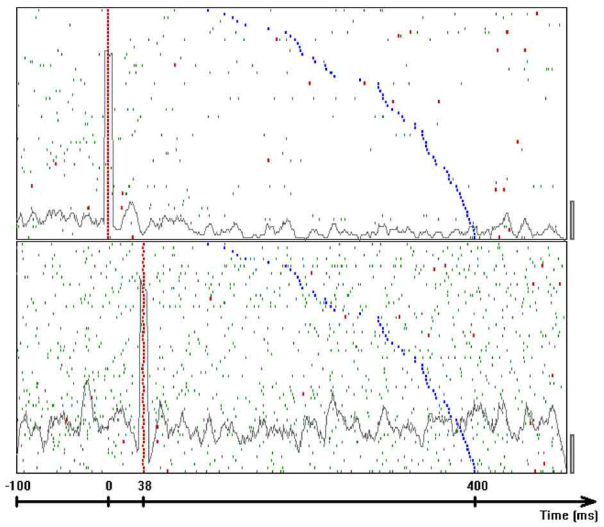

FIGURE 22 | Frequent inter-spike intervals. Dot display showing occurrences of a frequent inter-spike interval around occurrences of the drawing component that was shown in **Figure 21B**. **Top panel** shows the firing times of unit 8.1. The **bottom panel** shows the firing times of unit 1.2. Each linelet represents a single spike. Linelets representing spikes which took part in the selected interval are colored red. The rasters were aligned on the first spike of the selected interval. The time of onset of the drawing is colored blue. Trials are sorted by increasing delays between the neural intervals and the drawing components. The gray line in each panel represents the average firing rate considering all 372 common occurrences using bins of 9 ms. Scale bars at the bottom right corner of each panel are 50 spikes per second.

We analyzed all the 50 possible pairs of neurons on that day, all 50 possible time intervals for each pair, and for seven different time slices around the start of each of the drawing components. Picking the rarest event out of all these possibilities should yield a highly unlikely event. Hence, we need to assess the likelihood of finding such low probabilities when multiple trials are conducted.

Once we had the time occurrences of all the drawing components and the neural components, we were interested in finding relations between drawing components and pairs of neurons. For each drawing component A and for each possible pair of different neurons $<n1,n2>$ we counted the occurrences of each neural component around A that consisted of a spike from $n1$ and a spike from $n2$. In other words, we were interested in the total occurrences of each relevant time-interval between a spike of $n1$ and a spike of $n2$. The time regions in which we counted these intervals were determined relative to the occurrences of A by two external parameters $T$from and $T$to. Formally, suppose that during a recording day A occurred at $\{T1,T2,T3,\ldots,Tn\}$, then the time regions are $[Ti + T_{\text{from}}, Ti + T_{\text{to}}]$, where $1 \leq i \leq n$.

Eventually, we defined the support of a relation to be the total number of occurrences of the most frequent interval. Note that in practice the supports of the relations were computed for several $[T_{\text{from}},T_{\text{to}}]$ windows. For the first set of measurements the windows were: $\{[-1.4, -1.1], [-1.2, -0.9], [-1.0, -0.7],\ldots,[-0.2, 0.1]\}$, while for the second test, they were: $\{[-1.0, -0.9], [-0.9, -0.8], [-0.8, -0.7], \ldots, [-0.1, 0.0]\}$ At a later stage, the range with the strongest result was selected for each recording day.

Figure 22 shows the spike activity around the appearances of the drawing components in **Figure 21A**. This figure provides further indications that the relations between the neural interval and the drawing component were not random or due to trivial artifacts: The delay between the neuronal component and the drawing component (blue marks) is not evenly distributed between -0.4 and -0.1 s as might be expected for chance relations. Second, in the lower panel the firing rate is stationary. In this condition, had the red marks been random, the spike density around these dots marks should have approximated the autocorrelation function which must be symmetric. However, the little troughs on both sides of the peak (relative refractoriness) are not symmetric. The difference is significant at 0.013.

Using statistical analysis we showed that the probability for synchronization in the scribbling—neural activity is more than 99.8%. Using the computed support for each relation in a recording day, a statistic called the *relations-score* was extracted for this day (details are given below). Intuitively, relations-score gets larger as the likelihood of the support for the relations decreases. Once a relations-score was computed for the actual data (denoted by $S0$), we evaluated its probability of its occurring by chance.

As relations between hand motion and firing rates of neurons have been studied extensively, we wanted to test whether $S0$ was significantly higher than what we would expect from random data that have similar firing rates. In order to simulate random data that preserves firing rates of neurons, we randomly teetered the time of each original spike within a small window of size W (Geman et al., 2000; Amarasingham et al., 2003).

For example if $W = 10$ ms and the original time of some spike was 125 ms, its new time after teetering may be any time within (120, 130 ms). Using this technique, we generated 5000 such surrogate spike trains (when the first set of measurements was analyzed) or 1000 such surrogates (when the second set was analyzed). Each surrogate train was given a relations-score ($S1$, $S2$, $S3$, … respectively) following exactly the same procedure as for computing $S0$ (including: re-teetering for 1000 times to evaluate the probability of each relation, re-selecting the best support among all possible intervals, and re-selecting the best time slice $[T_{\text{from}},T_{\text{to}}]$ that leads to the largest relations-score). These 5000 values were used for estimating the probability [denoted by $p(S0)$] of getting the value $S0$ by chance. For example, if only 50 surrogate trains exceeded the relations-score of the actual data, then $p(S0)$ was estimated by $50/5000 = 1\%$. **Table 1** shows the minimal width of the teetering window for each day that led to a significant value of $p(S0)$.

A significant value for this probability indicates that the relations between drawing components and pairs of neurons (in that day) are damaged as a result of teetering within a window of size W. By this we can conclude that around the occurrences of similar behavior, pairs of spikes tend to prefer specific Inter-Spike Intervals (ISIs). We considered only which ones were involved

in significant relations (i.e., relations with an estimated probability less than 0.05). Note that due to the fact that only a minute set of neurons in the cortex is recorded, not necessarily all the recorded neurons would show the real time accuracy of the brain.

A solution which can be used to test the null hypothesis that spike times are random within a window of width W was offered (Geman et al., 2000; Amarasingham et al., 2003). If this null hypothesis is true, then replacing the time of each spike by a randomly selected time within W around its true time should not affect any of the statistics extracted from the spike times. To use this idea we need to describe the entire set of relations between firing intervals and drawing by one statistic. To do so we defined a statistic based on the ten least likely relations between pairs of spikes and any of the drawing components. We termed this the *relations-score*. Intuitively, relations-score gets larger as the existing relations are less likely to exist by chance. For each recording day we computed a relations-score for the actual data. Then we randomly teetered all spike times within some time window W and recomputed it for the teetered data. Given a teetering width W, the computation of the relations-score statistic for a recording day involves the following steps:

1. Generate a set of 1000 independent teetered neural data (denoted by J_{1000}) by teetering the actual data within the window W. Observe that the same W was used to create both J_{1000} and all surrogates for which we re-calculated the relations-score.
2. Recognize all potential relations between a drawing component and a pair of neurons.
3. For each relation R do the following:
   (a) Compute the support of R (denoted by R_{support}).
   (b) Skip R if its support is less than a predefined noise threshold. This step is carried out in order to prune noisy relations. Note that the values used for this threshold were 60, 40, 20, 20, 30, and 30 for the six significant recording days listed in **Table 1** from left to right respectively (depending on the firing rates of the neurons in that day).
   (c) Compute the support of R for each neural data in J_{1000} (using the same drawing component).
   (d) Compute the mean μ and the variance σ^2 of these 1000 values.
   (e) Estimate the probability of R_{support} assuming the normal distribution $N(\mu, \sigma^2)$.
   (f) Set R_{surprise} to $-\log_2 P(R_{\text{support}})$.
4. Sort all relations by descending order of their computed R_{surprise}. If several relations involve the same two neurons and the same interval between them, delete them all except from the first (the one whose R_{surprise} is the highest).
5. Set relations-score by the sum of the R_{surprise} values of the first 10 relations.

Independent teetering was done 5000 times (for the first set of measurements) or 1000 times (for the second set), and a histogram of the relation-scores for teetered data was constructed. After each teetering all the parameters for extracting the relations score were re-evaluated to obtain the highest possible value for each teetered data set. **Figure 23**-left illustrates this histogram for $W = 10$ ms. As stated above, all computations of relations score for each teetered data set were performed de novo by the same process; the same was done for the actual data (including multiple trials of all possible drawing components, pairs of neurons, time intervals and time slices).

This method was used to estimate the probability p of the relations-score value of the actual data. From this probability we derived the surprise-value defined as $-\log_2(p)$. **Figure 23**-right shows the surprise values for one recording session, obtained when spike times were teetered within different windows between 2 and 8 ms. Clearly, teetering within 3 ms already had a significant effect on the surprise value. Thus, **Figure 23** right already indicates that the spike times of the cortical neurons are accurate within 3 ms. Although we used 2 ms bins for measuring the intervals in that day, note that teetering by 2 ms is not pointless, due to the fact that intervals are binned only after teetering is done. Since

Table 1 | Minimal widths of teetering windows.

First set of measurements		Second set of measurements	
Day	**Minimal width of teetering window**	**Day**	**Minimal width of teetering window**
16 Jul 00	3 ms	26 Aug 99	0.5 ms
28 Jun 00	6 ms	14 Sep 99	3 ms
27 Jun 00	12 ms	22 Aug 99	4 ms

The table shows minimal widths of the teetering windows used in each of the six (out of eight) recording days to obtain a value of p(S0) which was less than 5%. The second set of measurements, where spike times were recorded at a resolution of 0.1 ms (instead of 1 ms), led to much better precision. Note that no significant results were achieved when smaller teetering windows were used.

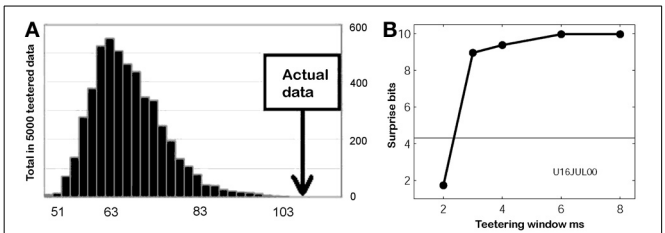

FIGURE 23 | Relations-score and teetered data. (A) Distribution of relations-scores for surrogate spike trains and the actual data. Five thousand surrogate spike trains were independently generated by teetering spike times within 10 ms. For each of these a relation-score was extracted. The distribution of these relations-score values was estimated by a histogram. The actual data had a value of 106.37 (arrow). None of the 5000 surrogate trains had a value above it. Hence the *p*-value for the actual data was estimated as less than 1/5000. **(B)** Surprise values for different teetering windows. Abscissa is the teetering window, ordinate is the surprise value. The horizontal line shows the surprise value for significance of 0.05. Thus, teetering within 3 ms already had a significant effect.

the original data are measured at a resolution of 1 ms in this case, intervals may be still damaged by teetering.

Significant relations-score values were observed in 3 days (out of three) for the first set of measurements and in three (out of five) for the second set in this study (total of six significant days). For the 3 days of the first set, the smallest teetering windows producing significant results were 3 ms (shown here), 6 ms, and 12 ms. For the 3 days of the second set these windows were 0.5, 3, and 4 ms. Note that this represents an upper bound for the resolution. One may find that a different statistic can indicate even higher time precision.

When the same procedure was repeated step by step for the neural data around randomly selected points in time (instead of time occurrences of drawing components), no significant surprise values were found (for a teetering window W of 10 ms). Thus, we only obtained significant time relations by relating the neural intervals to specific features in the behavior. Furthermore, no significant surprise values were found when the same procedure was repeated taking a teetered neural data instead of the original data.

In section 7 we will present a specific implementation of a neural architecture, the synfire chain (Abeles, 1991) that provides an explanation for the observation of these timing relations.

7. MODELING NEURAL MOVEMENT CONTROL WITH SYNFIRE CHAINS

7.1. SYNFIRE CHAINS

Here we describe neural network simulations of synfire chains and consider in particular how multiple synfire chains may be embedded in a large network. Synfire chains can be seen as constituting sub-networks of the local cortical network and interact in the context of the ongoing background activity. The original version was a chain of length l composed of groups of w neurons each (the chain width), with full unidirectional connectivity between successive groups. A group together with its output connections can interchangeably be called a link in the synfire chain. Such a chain structure propagates near-synchronous activity in each group along successive groups like a row of dominoes. Detailed properties of various versions of such systems have received considerable theoretical attention; stability properties (Herrmann et al., 1995) have been studied as well as structural variations such as partial group to group connectivity or such as feedback when a given neuron occurs in more than one group. There also have been studies of partially interconnected synfire chains to define the conditions in which activity can jump between chains (Hayon et al., 2005).

For a theoretical framework, we will refer to the balanced random network architecture which is a common single layered model of the local cortical network (van Vreeswijk and Sompolinsky, 1996; Amit and Brunel, 1997; Brunel, 2000). It explains the asynchronous irregular low rate activity of cortical neurons and the large fluctuations of the membrane potential observed *in vivo* and will serve as the basic architecture also here, see **Figure 24**. Our network (**Figure 24**) differs from previous approaches in two essential properties: First, there is heterogeneity in the number of dendritic synapses. Second, the excitatory-to-excitatory sub-network is purely composed of synfire chains.

The dynamics of the network is adjusted to the asynchronous irregular (AI) regime to reproduce relevant aspects of cortical dynamics: Low-rate firing of the individual neurons with Poisson-like interval statistics and large fluctuations of the membrane potential. The model consists of 80% excitatory and 20% inhibitory integrate-and-fire point model neurons (see **Figure 24** for the full set of parameters). For the E-I, I-I, and I-E connections the neurons establish a random number (drawn from a binomial distribution) of dendritic synapses. The mean of the distribution is a tenth of the size of the possible connections which does not exclude multiple synapses between

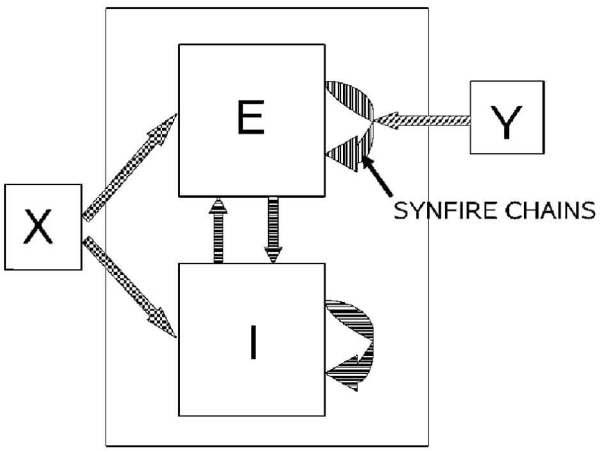

FIGURE 24 | Sketch of the cortical network model. All connections between the 40,000 excitatory neurons in the model network are formed by synfire chains (vertically striped arrow). A neuron can occupy only one position in each chain but may contribute to several ones out of the total of 50 chains. Each chain consists of 20 pools each of which is fully connected to the next pool. The intra-chain synapses enable excitatory postsynaptic potentials (EPSPs) of $a = 0.5$ mV generated by alpha-function current with a rise time $\tau\alpha = 0.2$. Synaptic delays are drawn from a uniform distribution between 0.5 and 3 ms, but are identical for all synapses connecting one pair of pools. Chains are stimulated at 1 Hz with independent Poisson sources. Stimuli arrive only at the neurons in the first pool of a chain and consist of 100 spike times drawn from a Gaussian distribution with standard deviation $\sigma = 1$ ms. In addition to the excitatory (E) neurons there are 10,000 inhibitory (I) neurons which are recurrently interconnected (horizontally striped arrows): each neuron establishes a random number of synapses drawn from a binomial distribution with the mean given by 10% of the size of the respective target population. EPSP amplitudes outside chains are $a = 0.1$ mV, inhibitory postsynaptic potential [IPSP] amplitude are 6-fold larger and have a rise time of 0.6 ms. Delay distributions are the same as within chains. Each neuron receives (cross-hatched arrows) an excitatory DC drive of 350 pA. Further parameters for the integrate-and-fire point neurons are $\tau = 20$ ms, $C = 250$ pF, $\theta = 20$ mV, $\tau ref = 2$ ms. Excitatory neurons are randomly chosen to form 50 completely connected synfire chains (vertically striped arrow). A neuron can occupy only one position in each chain but may contribute to several chains. Intra-chain synapses are 5-fold stronger than other EPSPs. Intra-chain delays are drawn from the same distribution as others but are identical for synapses connecting a particular pair of neuron links. Chains are stimulated at 1 Hz with independent Poisson sources. A stimulus consists of 100 spike times drawn from a Gaussian distribution with standard deviation $\sigma = 1$ ms and is received by all the neurons of the first link in a chain.

a pair of neurons. The excitatory-to-excitatory sub-network is here, in contrast to other works, purely composed of a superposition of $m = 50$ synfire chains. These chains are consecutively constructed. First, we randomly select *wxl* neurons (here: $w = 100$, $l = 20$) from the population of excitatory neurons without repetitions. In the next step, these neurons are connected into a feed-forward sub-network of l successive links of w neurons. Each neuron, except the neurons in the first link, establishes a dendritic synapse with all the neurons in the preceding group. The connection procedure is repeated m times and leaves us with complete divergent and convergent connectivity between the links (Griffith and Horn, 1963; Abeles, 1982).

An excitatory neuron may participate in several chains but occurs at most once in any given chain. The synaptic delays are drawn from the distribution specified earlier for the other synapses but is kept fixed for all synapses connecting two subsequent links of neurons. The amplitudes of postsynaptic potentials of synapses in the chains are fivefold larger than those of other excitatory connections. In the absence of specific stimuli the synfire chains are not active and the excitatory neurons spike irregularly at a low rate. For the data presented herein we apply independent 1-Hz Poisson trains of stimuli to the synfire chains. A stimulus consists of a volley of 100 spikes. The individual spike times are drawn from a Gaussian distribution centered at the time of stimulation with standard deviation of 1 ms. This volley is sent to all the neurons of the first group in a chain using synapses as strong as the intra-chain synapses.

Synfire activity stably propagates, but several chains can be active simultaneously. With a load of 50 chains the dynamics is still stable, although the global activity exhibits large fluctuations mainly due to the initiation and termination of chains.

In the neural net simulations we deliberately randomized the identity of neurons with respect to the embedded synfire structures to mimic the random sampling in real recordings. It is instructive, however, to remap some data so that adjacent lines in the raster are associated with particular links and chains. The strong, nearly vertical lines in the raster are firings of the synfire chain, background neuron firings in the raster represent either spontaneous activity or the activity of other chains, since each neuron in this chain is also a member of two to three other chains. **Figure 25B** shows a portion of this raster with high time resolution revealing details of several chain runs. The offset between short vertical segments corresponds to activations of successive links; the offset is the interlink propagation or synaptic delay. Note that failure of propagation is possible such as shown in the middle run of the chain.

Without the remapping of neuronal identities (**Figure 25**) synfire chain sequences are not visible in raster-plots. **Figure 26A** shows a 5-s segment of the activity of 150 excitatory neurons randomly selected (and not remapped according to chain membership) from a synfire simulation (50,000 neurons, 50 fully connected synfire chains independently stimulated by low-frequency Poisson trains); the raster has no particular structure. The raster from a larger set of 10,000 excitatory neurons over the same time range is shown in **Figure 26B**. Again, since the neurons are chosen randomly, there are no structures like those in **Figure 25B** that are directly ascribable to activations of individual synfire chains. However, there is an obvious broader vertical striping that connotes a coordinated fluctuation in the population activity; this striping becomes increasingly visible when the raster display shows a large number of neurons (contrast **Figure 26A** vs. **B**). It turns out that these coordinated rate fluctuations are the result of fluctuations in the number of synfire chains that have been activated at any time. Individual neurons, however, experience no rate increase.

Figure 27 juxtaposes (1) the times of chain stimulations with (2) their (low-pass) temporal representation (i.e., the number of chains activated at any time) and (3) the fluctuations of total population rate. These are clearly strongly, although not completely, related.

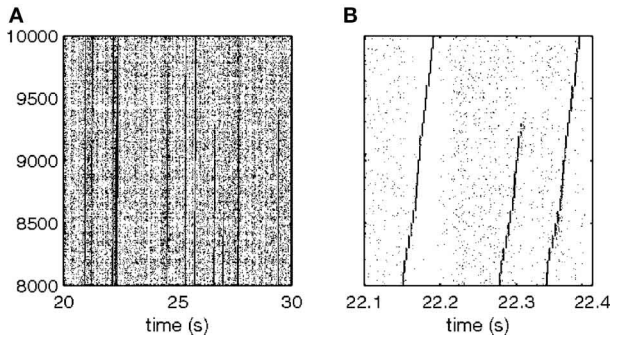

FIGURE 25 | Raster representation of the activity of the neurons in a particular synfire chain. (A) The randomly assigned neuron numbers have been remapped so that the 2000 neurons of the chain are labeled 8001–10,000 (ordinate). The data show an arbitrary 10-s segment (abscissa) of activity. The thin black, almost vertical lines represent runs of this chain. **(B)** Temporal magnification of a portion of **(A)**. Two complete runs and one partial run of the chain are shown. At this timescale the nearly synchronous activity of each link in the chain becomes visible, as does the propagation time between links.

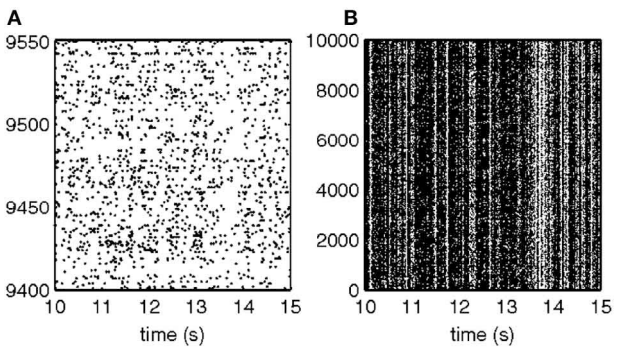

FIGURE 26 | Fluctuations in network activity. (A) Raster of 150 randomly selected neurons (ordinate) during a period of 5 s (abscissa). The activity of the neurons appears uncorrelated, irregular, and fairly stationary in time. **(B)** A raster of 10,000 neurons during the same time period as in **(A)**. The activity exhibits prominent vertical bands.

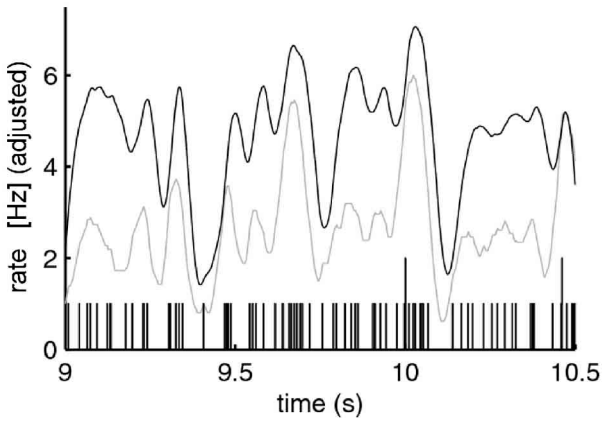

FIGURE 27 | Relation of population firing rate and synfire activation rate. The black curve represents the smoothed population activity (triangular filter, full width 51 ms); the gray curve represents smoothed stimulation times (same filter) of all synfire chains. The actual stimulation times are shown as vertical bars at the bottom.

The framework described so far combines general ideas about the dynamics of neural activity in the cortex and observations of precise firing patterns related to motor activity. We will now formulate a model that supports the evidence for such relations. An obvious question is now how movement primitives are represented in a dynamic network of spiking neurons.

It has previously been shown that networks of synfire chains can generate sequences of primitives in an abstract model (Schrader et al., 2010; Hanuschkin et al., 2011). We will consider a functional model that is simultaneously capable of reproducing several experimental findings on cortical activity and generating trajectories which exhibit key features of free monkey scribbling. Recent theoretical studies suggest that coupled synfire chain structures can demonstrate compositionality, the hierarchical representation of complex entities in terms of parts and their relations (Abeles, 1982; Hayon et al., 2005).

7.2. MOVEMENT REPRESENTATION MODEL

The model consists of a topologically organized network of synfire chains. Neurons in the same pool of a chain encode the same preferred velocity vector, thus realizing a population coding for movement (Georgopoulos et al., 1986). The trajectories generated by our model consist of a series of parabolic segments similar to those identified experimentally (Polyakov et al., 2001, 2009b) which fulfill the well-established two-thirds power law relationship of velocity and curvature (Lacquaniti et al., 1983; Viviani and Flash, 1995). It has previously been demonstrated that monkey scribbling is well approximated by parabolic strokes (Polyakov et al., 2001, 2009b). Parabolic movement primitives obey the two-thirds power law, are invariant under equi-affine transformations and minimize end effector jerk.

A parabola can be constructed from a constant acceleration produced by a homogeneous force field. Assume the initial position and velocity of a point mass is $X^0 = \left(x_0, y_0\right)^T$ and $V_0 = \dot{X}_0 = \left(\dot{x}_0, \dot{y}_0\right)^T$, respectively. If the point mass experiences a constant acceleration $a = \left(a_x, a_y\right)^T$ then the trajectory of $x = \left(x, y\right)^T$ is given by

$$x(t) = x_0 + v_0 t + \frac{1}{2} a t^2$$

The curvature of the path is

$$c = \frac{\left|\dot{x}\ddot{y} - \dot{y}\ddot{x}\right|}{v^3} \tag{4}$$

where $v = \|\dot{x}\|$ is the tangential velocity. Since $\left|\dot{x}\ddot{y} - \dot{y}\ddot{x}\right| = \left|\dot{x}a_y - \dot{y}a_x\right|$ is constant, c and v obey the following relation

$$v = Kc^{\frac{1}{3}} \tag{5}$$

where K is named velocity gain factor. Equation 5 is thus satisfied by parabolic movement segments.

Constant accelerations are equivalent to velocities that change linearly in time, as $a = \frac{dv}{dt}$. In velocity space, linearly evolving velocities ($\dot{v} = \text{const}$) are represented by a uniform motion along a straight line. Therefore, straight lines in velocity space can be mapped into parabolic trajectories in position space.

A neural architecture which can be associated with a uniform motion is the synfire chain (SFC) (Abeles, 1991). In the simplest formulation of the SFC concept, excitatory neurons are grouped in pools and each neuron is connected to all neurons of the following pool creating a chain of convergent and divergent feed-forward connections. If the first group is stimulated with sufficient strength and a sufficiently high degree of synchrony, a wave of synchronous activity propagates along the chain. The propagation along the chain is at constant speed (Wennekers and Palm, 1996; Diesmann et al., 1999) and stable under fairly general conditions (Herrmann et al., 1995).

An appropriate mapping of preferred velocities to the pools of a synfire chain enables the generation of an individual parabolic segment. By extension, a series of parabolic strokes in position space can be realized by uniform motion along a graph of connected straight lines in velocity space. Each arrow in velocity space is realized by a synfire chain with the corresponding velocity mapping. By construction, the velocity at the end of one parabolic stroke is equal to the velocity at the beginning of the next. When the activity volley in a synfire chain reaches the final pool, feed-forward connections to the initial pools of the two potential successor chains initiates the propagation of an activity volley in each of them. Assuming a strong competition between the two stimulated chains, such that only one of the chains can continue propagating the activity, a trajectory of parabolic segments is produced. We analyze the properties of the generated trajectories to see whether they are sequences of parabolic segments in accordance to the above remarks on equi-affine geometry.

The activity of single cells in the motor cortex has been shown to be directionally tuned to arm movements (Georgopoulos et al.,

1982). The arm trajectory can be estimated by calculating the population average over all neurons (Georgopoulos et al., 1986, 1988). Similarly, we use population coding to generate a trajectory from simulated neuronal activity:

$$v = \sum_{k}^{\text{neurons}} w_k a_k(t) p_k = \sum_{i}^{\text{chain}} \sum_{j}^{\text{pool}} w_i^j a_i^j(t) p_i^j \qquad (6)$$

where $\boldsymbol{v}$ is the instantaneous velocity, $a_i^j(t)$ is the activity in the j^{th} group of the i^{th} chain and p_i^j its i preferred velocity. The weights are set to $w_i^j = 0.02s\ \forall i, j$ resulting in velocities comparable to the monkey experiments [median 300 mm/s as given by Polyakov et al. (2009a,b)]. The propagation speed of the activity volley in an SFC from one pool to the next is constant as described above. We can therefore map an SFC to an arrow in the velocity space. Each pool of the SFC is assigned its preferred velocity p_j according to its position along the arrow, i.e., for a chain consisting of n pools mapped to an arrow starting at v_0 and ending at v_1,

$$p_i = \frac{i-1}{n-1}(v_1 - v_0) + v_0 \qquad (7)$$

This is illustrated in **Figure 28A**; the activity of the corresponding synfire chain is given in **Figure 28B**. As the preferred velocity for each chain j changes linearly with the pool index i and the propagation speed from one pool to the next is constant, the instantaneous velocity vector also evolves linearly resulting in parabolic motion as derived in section 7.2. **Figure 28C** shows the parabolic trajectory in position space generated by the synfire activity in **Figure 28B**. To extract the trajectory from the simulated neuronal activity, we bin the activity in 1 ms intervals and reconstruct the motion according to the population coding scheme given by Equations 6 and 7.

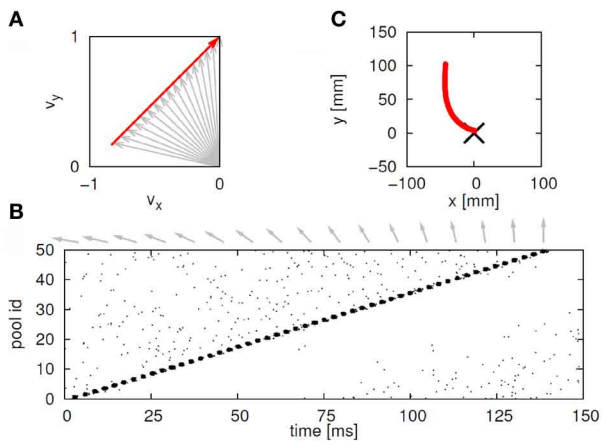

FIGURE 28 | Mapping synfire activity to parabolic movements. (A) The preferred velocity vectors for the pools of the synfire chain (gray arrows; shown for every third pool of the chain) are determined by sampling a straight line in velocity space (red arrow). **(B)** The spiking activity of an activity volley propagating with constant speed along a synfire chain. Preferred velocity vectors for every third pool as in **(A)** are shown as gray arrows above the dot display. **(C)** Generated parabolic trajectory. The black cross at (0,0) indicates the start position.

7.3. COMPETITION AND COOPERATION BETWEEN CHAINS

We develop a spiking network model to realize a generator of random trajectories consisting of parabolic segments. Our model comprises two interconnected networks. The synfire chain network (SFCs) consists of ten chains, each chain corresponding to one of the arrows in velocity space and thus encoding a parabolic segment. Each chain consists of 80% excitatory neurons that make feed-forward connections with dilution factor $p_d = 0.75$ and 20% inhibitory neurons making k_g random connections to other neurons in the SFCs network. To distinguish the random inhibitory connections from other connectivity patterns, we will refer to k_g as the global inhibition parameter.

Feed-forward connections join the final group of each chain to the initial groups of two other chains, e.g., the final group of chain 1 has feed-forward connections to the initial groups of chains 2 and 7, see **Figure 29**. The preferred velocity of the last group of a chain is the same as the first groups of the chains it connects to in order to generate trajectories that are smooth at the transition points. Reliable switching at the transition points is enabled by mutual inhibition between potential successor chains.

We create a synfire chain with feed-backward as well as feed-forward connections, both with a dilution factor of p_d (a backward-and-forward connected chain, BFC). One end of the BFC makes excitatory feed-forward connections with dilution

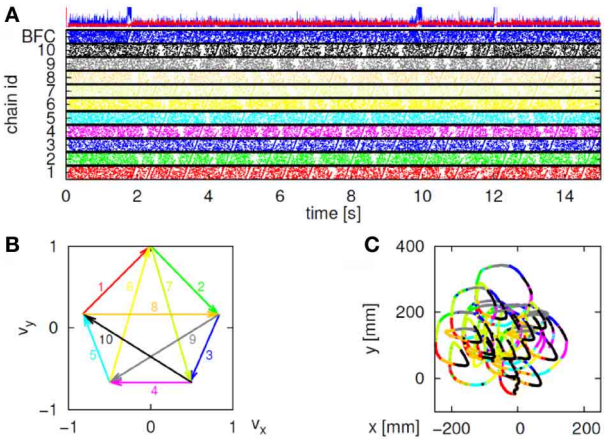

FIGURE 29 | Generation of scribbling trajectories. (A) Spiking activity of bidirectional and synfire chain networks. Colors of the activity of each chain corresponds to the colors of the arrow in velocity space shown in **(B)**. Above the raster plot the average firing rate of the synfire network (red) and the bidirectional network (blue) is plotted. **(B)** Abstract generator for trajectories consisting of parabolic segments. Uniform motion along straight lines in velocity space is equivalent to parabolic motion in position space. Each colored arrow represents a parabolic segment and its direction of execution. When the end of an arrow is reached, one of the two successor arrows is selected. **(C)** Scribbling trajectory extracted from the spiking activity using population coding. Segments are drawn in the color of the most active synfire chain.

factor p_d to the initial pool of chain 1 in the SFC network. Each inhibitory neuron in the SFCs network makes k_B connections to neurons randomly selected from the BFC network, thus inhibiting its activity when synfire activity is present. If synfire activity is extinguished, the drop in inhibition causes a self-ignition in the unstable BFC, which in turn triggers a fresh wave of activity in chain 1. Thus, the recurrent connections between the SFCs network and the BFC network ensure sustained activity. The dynamics of the BFC network and of the interaction with the SFCs network are investigated in section 7.4. The scaling of inhibitory synapses with respect to excitatory synapses and the rate of the external excitatory Poisson input to each neuron in the SFC network are chosen such that in the absence of synfire activity, the network spikes in the asynchronous irregular (AI) regime (Brunel, 2000).

Each of the chains in the SFC network represents a parabolic movement primitive. To produce a series of primitives, it is necessary that activity reliably propagates from one SFC to exactly one of multiple (here two) potential successor SFCs at the vertices of the network graph. In our model, cross-inhibition between two competing SFCs realizes this switching between two simultaneously activated SFCs. There are two possible approaches to achieve reliable switching: (1) cross-inhibition can be structured such that synchronous activity in each pool directly inhibits the activity in the next pool of the competitor chain. This approach is motivated by the idea of synfire binding (Hayon et al., 2005; Schrader et al., 2010), in which two simultaneously active chains can bind a third chain due to structured excitation. In an alternative approach (2) the cross-inhibition is unstructured. Synfire chain competition relying solely on global inhibition has recently been proposed by Chang and Jin (2009). However, in their study the synfire chain activity is "driven": a supra-threshold driving input is combined with dominant global inhibition. In contrast, our model exhibits activity in the asynchronous irregular regime due to balanced global inhibition (van Vreeswijk and Sompolinsky, 1996) and only exhibits synfire activity if the initial pool of a chain receives additional stimulation. Due to our different activity regime, additional assumptions on the inhibition between chains need to be made to realize reliable switching.

Each neuron in the initial pools of the potential successor chains is activated by p_{CE} randomly chosen excitatory neurons from the final pool of the preceding SFC. The symmetric connections ensure that the successor chains are stimulated equally. All inhibitory neurons of pool i of one potential successor chain project to kc neurons of pool $i+1$ of the other potential successor chain, and vice versa. Thus, each wave of synchronous activity directly inhibits the propagation of the activity to the next pool in the competitor chain, leading to a competition. The activity in the losing chain dies away leaving the activity in the winning chain to continue propagating, thus realizing a switching mechanism.

7.4. ACTIVITY STATE TRANSITION IN THE BFC

When the backward-and-forward connected chain (BFC network) described above is not being inhibited by the presence of synfire chain activity in the SFCs network, the external drive is just strong enough to induce spontaneous synfire activity and so re-ignite activity in the SFCs network. The ignition of synfire activity in the network can be understood intuitively as follows: random synchronous activity in a small subset of the neurons in a given pool i will be projected to the pools $i \pm 1$, which in turn project back to i, thus building a recurrent positive feedback loop. Synfire activity emerges spontaneously at around 380 ms and propagates in both directions along the chain. Once the spike volleys have reached the ends of the BFC the synfire activity is extinguished. A reflection of activity does not occur because for any activated pool, the neurons in the previously activated pool have been reset by the propagating volley. When the SFCs network has been re-ignited, the increased inhibition decreases the net drive to the network such that no spontaneous synfire activity occurs.

Synfire volleys caused by spontaneous self-ignition tend to be of limited duration. Activity volleys traveling in different directions cancel each other when they meet and volleys reaching either end of the BFC are not reflected. Furthermore, the high activity in the BFC during synfire activity results in strong global inhibition and a reset of nearly all neurons, which in turn decreases the probability of self-ignition until activity has built up again. However, if the pool size is chosen sufficiently large, a single self-ignition results in ongoing pathological high firing rates.

The spiking activity of the complete network underlying the average firing rates is given in **Figure 29A**. The trajectory extracted from the synfire activity is shown in **Figure 29C**. The trajectory consists of a long random sequence of parabolic movement primitives. Small overlaps can be seen at the transition points where both successor chains are active before one of the chains wins the competition. The distribution of the length n of an uninterrupted sequence is well fitted by $P(n) = p_0 \left(1 - p_0\right)^n$, where p_0 is the probability that neither successor chain is activated during synfire chain switching.

We analyze the characteristics of the trajectory shown in **Figure 29C**. Due to the piece-wise constant accelerations we conclude that the trajectory does indeed fulfill the two-thirds power law (e.g., Viviani and Flash, 1995). The equi-affine curvature of the trajectory is close to 0. We therefore conclude that the trajectory does indeed consist of a series of parabolic segments.

8. COMPOSITIONAL NATURE OF THE DRAWINGS

8.1. TEMPORAL PROPERTIES OF STROKELETS

We will now describe another approach to analyze the compositional nature of the drawings. Using machine learning techniques, we show how very elementary strokelets can be treated as allophones of spoken language, which can be in turn clustered into equivalence groups (like phonemes of language) and how by Hidden Markov modeling combined with the information-bottleneck technique, these groups can be composed into words. Furthermore, the syntax of sequencing these words into sentences is revealed in this analysis.

Human subjects were tested on the hidden target task as described in the methods (Section 3). Each subject was first

holding the manipulandum while searching for an invisible target. Each target hit added a little sum to the subject's fee, so subjects were highly motivated to hit as many as possible targets. After a few sessions of this type, subjects were told that every time they hear a beep they should stop as fast as possible.

We postulated that if the searching motion is composed of primitives (Sosnik et al., 2007), then it would be hard to stop anywhere. Rather if the "command" to draw a primitive was already issued it will execute to completion. Indeed, it was found that typically motion continued with several peaks in the tangential velocity. **Figure 10B** illustrates that. The delay from the instruction till stopping was longer then delays reported for stopping a simple motion. Furthermore, in subjects where the motion-style showed repetitive patterns the piece of drawing which continued after the "stop instruction" was similar to the typically repeated pattern.

Figure 10 also illustrates the well-known phenomenon of isochrony. The duration of each hill in the drawing was approximately identical and those after the stop instruction had the same duration as those while freely scribbling. We argue that the neural networks responsible for such behavior should have similar properties: constant duration of activity and hard to stop in the middle. Indeed, the synfire chains as proposed in section 7 have these properties.

To get a better glimpse at what are the elements of these drawings we broke the drawing to small pieces and studied the rules of combining the pieces into a whole. Breaking into pieces was done by considering the drawings between successive extrema of tangential velocity as drawing elements. It may look artificial to break a motion into two elements at the peak velocity. However, drawing parameters may change abruptly at points of maximal tangential velocity. Our analysis in the previous parts pointed at parabolas as being drawing primitives in monkey scribbling. These primitives too, start and end at maxima of tangential velocity. **Figure 30** illustrates a little piece of the drawing and how it was decomposed into little strokelets.

8.2. PARSING THE MOTION

The scribbling in one block of motion for one subject is illustrated in **Figure 11**. If we look on a short stretch from this block (**Figure 30B**), it is clear that he moves at a high speed when the trajectory is close to straight and slows down when it is curved. **Figure 30A** shows the tangential velocity (speed) of drawing for this section. It is composed of 3 hills of almost equal duration (isochrony).

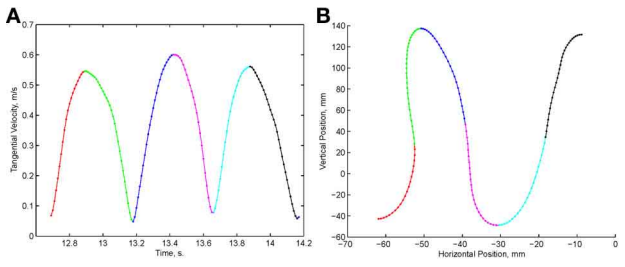

FIGURE 30 | Breaking a drawing into strokelets. One second of human drawing is shown. **(A)** The tangential velocity. **(B)** The drawing. Each strokelet is colored differently to facilitate visualization.

We used this features to parse the drawing into small strokelets. **Figure 30A** shows the tangential velocity during 1 s of scribbling. Each strokelet spans the time between adjacent extrema and is colored differently. **Figure 30B** shows the actual drawing shape of each of these strokelets.

We selected 10 equally spaced points on each strokelet and computed the angle of the tangent at this point. These, ten dimensional vectors were then grouped by a Gaussian Mixture Model (GMM). By construction, an accelerating strokelet must be followed by a decelerating one and vice versa, except at the very beginning and end of the drawing. Therefore, we grouped separately the two kinds of strokelets. GMM was able to divide the strokelets into 30–50 groups.

8.3. INFORMATION BOTTLENECK METHOD

We further clustered the groups using the information bottleneck idea (Tishby et al., 1999). Suppose we deliver a large number of stimuli (X) and make observations of the responses (Y). We can ask whether we can represent X by a small number of clusters (P) such that the mutual information I (P; Y) between P and Y will be close to that between X and Y. If so, P will be the "stimulus features" represented in the responses. Alternatively, we may ask whether we can cluster Y into a small number of clusters Q, such that I (X; Q) is close to I (X, Y). If so, then Q represents a feature representation in the responses. In our case, we treat the strokelets as "stimulus" and the following strokelets as "responses." Thus, the sets X and Y are the same. Therefore, we expect P = Q [see Erez et al. (2009) for more details]. Using this idea, we clustered the groups of strokelets into twelve clusters, see **Figure 31**. We can take the matrix of probabilities of transitions between strokelet-groups and reshuffle rows and columns so that all strokelets in the same cluster are at neighboring lines (and columns) in **Figure 12**.

Several features jump to the eye when examining **Figure 12**. Nonzero transitions are concentrated in patches. We observe that there are three distinct cycles. Clusters {1, 2, 3, 4} follow each other in cyclical manner and so do {5, 6, 7, 8} and {9, 10, 11, 12}. Finally transitions from one cycle to another happen only at particular groups. If we compare the drawings to language, we can say that each individual strokelet is like a phone, the 47 groups of strokelets are phonemes, the cycles are words and the sequences of words are sentences. Let us call the cycles W_1, W_2, W_3, then the sentences look like: "W_1 W_1 W_1 … W_1" followed by "W_3 W_3 W_3 … W_3" followed by "W_2 W_2 W_2 … W_2." The transition between sentences happens with specific allophones (for example W_3 changes to W_1 mostly by one allophone of cluster 9 to one allophone of cluster 2).

This structure can be seen readily in the actual drawings (**Figure 11**) where the subject is scanning the workspace repeatedly from left to right and back, then vertically and then obliquely. We note that this form of scribbling is not just less elegant than the monkey's scribbling (**Figure 1**), but also involves much

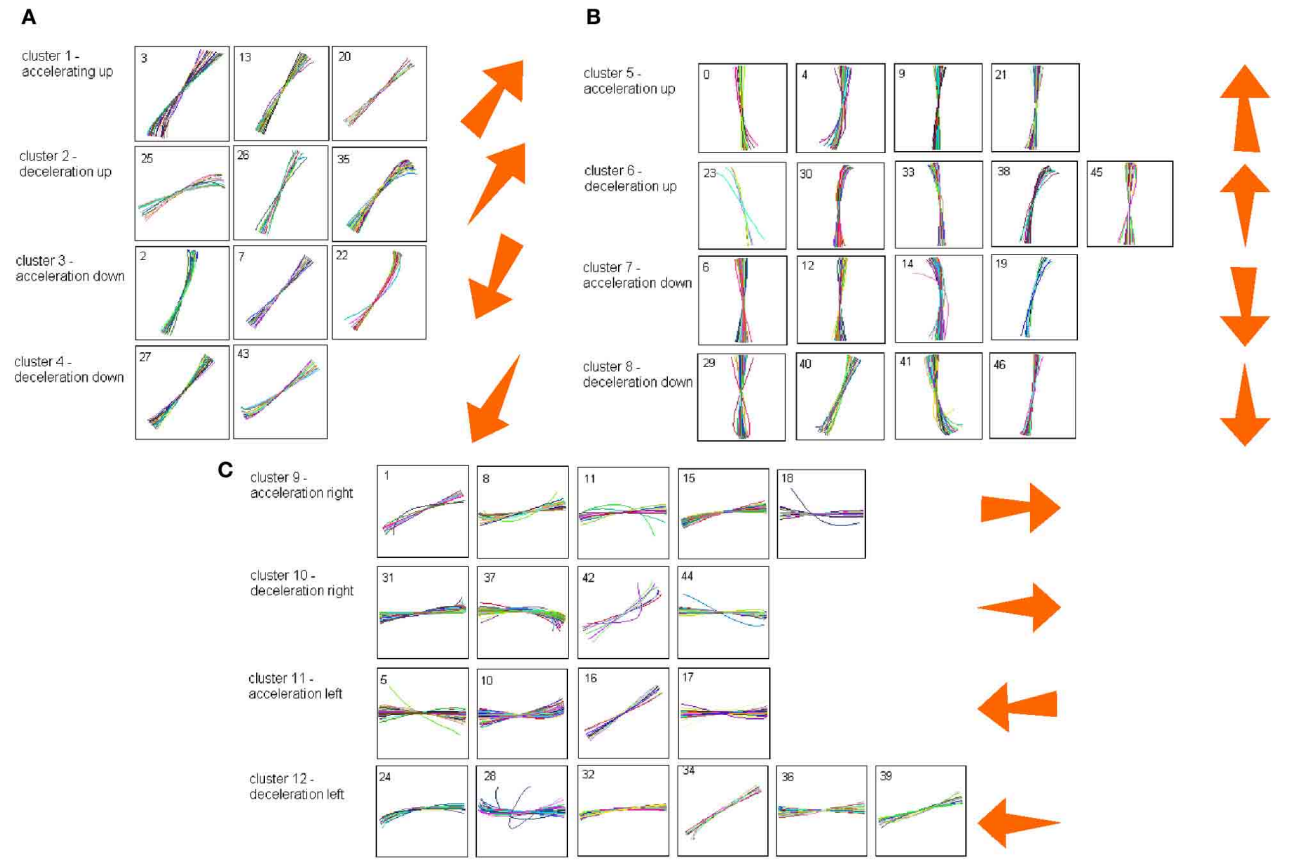

FIGURE 31 | Clustering of strokelets. Each little panel shows all the strokelets that belong to one group. They are colored differently to facilitate visual discrimination among them. All the strokelets within the same group are stretched to the same length and plotted on top of each other. Each line of groups belongs to the same cluster. The arrow to the right of each row represents the direction of motion in this cluster. Expanding arrows symbolize accelerating strokelets and shrinking arrow represent decelerating ones. **(A)** oblique movements. **(B)** Vertical movements. **(C)** horizontal movements.

higher accelerating—decelerating motion and larger distances between hitting targets and obtaining the reward. We conclude by stating that we found strong evidence for primitives in human scribbling and for hierarchical organization of the drawing elements.

9. SUMMARY

In sections 3–8 we provided further evidence to support our working hypothesis. According to this hypothesis when a subject repeats again and again he same scribbling task, the entire scribbling may be regarded as a composition of a few elementary shapes. These shapes may be produced by activity propagating between neuron-groups. In each group the neurons have similar velocity tuning and the propagation is with approximately constant delay from group to group. When the drawing elements are parabolas they are better described by equi-affine parameters and the sequence of neuronal groups are laid along a straight line in velocity space. We provide some evidence that for neurons that are tuned to the speed of motion equi-affine speed is somewhat more adequate descriptor then the Euclidian speed.

The synfire chain model is a simple network that may have the required properties. We show that it is feasible to generate drawings similar to that of a monkey by such networks. We also provide indirect support to this idea by showing that one can detect precise timing relation between pairs of neurons in relations to the drawings.

Finally we show how the preferred sequence of such elements in the drawings can be revealed, and suggest that such preferred sequences are generated by partial connections among synfire chains.

The supporting evidence given here is partial and there is room for considerable more experimental and theoretical work on all the points suggested here.

ACKNOWLEDGMENTS

We thank our students and post-docs and colleagues who contributed to most of the work described here: I. Asher, Y. Ben Shaul, H. Bergman, R. Drori, K. Erez, K. Fiedler, J. Hass, A. Electrical microstimulation studies provide some of the most direct evidence for the neural representation of muscle synergies. These synergies, i.e., coordinated activations of groups of muscles, have been proposed as building blocks for the construction of motor behaviors by the nervous system. Intraspinal or intracortical microstimulation (ICMS) has been shown to evoke muscle patterns that can be resolved into a small set of synergies similar to those seen in natural behavior. However, questions remain about the validity of microstimulation as a probe of neural function, particularly given the relatively long trains of supratheshold stimuli used in these studies. Here, we examined whether muscle synergies evoked during ICMS in two rhesus macaques were similarly encoded by nearby motor cortical units during a purely voluntary behavior involving object reach, grasp, and carry movements. At each microstimulation site we identified the synergy most strongly *evoked* among those extracted from muscle patterns evoked over all microstimulation sites. For each cortical unit recorded at the same microstimulation site, we then identified the synergy most strongly *encoded* among those extracted from muscle patterns recorded during the voluntary behavior. We found that the synergy most strongly evoked at an ICMS site matched the synergy most strongly encoded by proximal units more often than expected by chance. These results suggest a common neural substrate for microstimulation-evoked motor responses and for the generation of muscle patterns during natural behaviors.

Keywords: motor, movement, muscle, synergy, hand, macaque, grasping, cortex

INTRODUCTION

In numerous studies, motor primitives have been defined as "synergies" in which a group of muscles is simultaneously recruited, each with a specific balance of activation. These investigations have involved frog axial and hindlimb behaviors (Tresch et al., 1999), cat axial and hindlimb behaviors (Ting and Macpherson, 2005) and forelimb reaches (Yakovenko et al., 2010), rat forelimb reaches and grasps (Kargo and Nitz, 2003), monkey forelimb reaches and grasps (Brochier et al., 2004; Overduin et al., 2012), and human axial and hindlimb behaviors (Torres-Oviedo and Ting, 2007) and forelimb reaches, grasps and gestures (d'Avella et al., 2006; Klein Breteler et al., 2007; Berger et al., 2013). Analogous synergies have also been defined at the kinematic level (e.g., Santello et al., 1998; Gentner and Classen, 2006; Gentner et al., 2010).

Much of the direct evidence for synergistic muscle control by the central nervous system (CNS) comes from studies of the spinal cord. For instance, chemical intraspinal microstimulation in the frog evokes topographically-organized, low-dimensional electromyographic (EMG) activity patterns (Saltiel et al., 2001). In spinalized frogs, too, neurons including those in the intermediate zone of the spinal cord are better correlated with synergistic premotor drives than to the activity of individual muscles (Hart and Giszter, 2010). The spinal cord of primates contains premotor interneurons facilitating multiple muscles, including those intrinsic to the hand (Takei and Seki, 2010), and has been proposed as a substrate for synergies (Tresch et al., 1999; Cheung et al., 2009). Phasic activation of such units may be responsible for multi-muscular EMG bursts (Kargo and Giszter, 2008).

Synergies may be encoded at supraspinal as well as spinal levels, e.g., in the brainstem (Roh et al., 2011). At the level of the primary motor cortex (MI), in rodents learning a reaching task the firing rates of a minority of neurons are correlated with changes in the activation of synergies extracted from forelimb muscle EMG activity (Kargo and Nitz, 2003). Continuous neural control of synergistic muscle groups in primates is also circumstantially suggested by the ability to reconstruct forelimb EMG profiles as the weighted sum of an ensemble of neurons (Morrow and Miller, 2003; Schieber and Rivlis, 2007). MI neurons have muscle fields (defined by the strongest cell-EMG correlations) that appear to fall into relatively few, synergy-like clusters (Holdefer and Miller, 2002). Such cortical muscle fields may be "hard-wired," changing their structure rarely, if ever (Kargo and Nitz, 2003). This may be particularly true of corticospinal and corticomotoneuronal cells, which facilitate small sets of muscles relatively directly (Fetz and Cheney, 1980; Bennett and Lemon, 1994). The latter cell

population may define a "new MI" that affords muscular coordination unconstrained by synergies encoded in the spinal cord (Rathelot and Strick, 2009).

As with intraspinal microstimulation, application of relatively long trains of suprathreshold electrical current to individual sites in motor cortex can evoke complex movements. In cats (Ward, 1938), rats (Haiss and Schwarz, 2005; Ramanathan et al., 2006), prosimians (Stepniewska et al., 2005, 2011), and macaques (Graziano et al., 2002a, 2004b, 2005), suprathreshold microstimulation trains lasting several hundred milliseconds evoke complex multijoint forces that frequently drive the animal's body toward invariant postures. Shorter-train (<100 ms) intracortical microstimulation (ICMS), in contrast, typically evokes simpler twitch-like movements, often restricted to single joints (Graziano et al., 2002a; Stepniewska et al., 2011).

In the case of forelimb and hand areas of non-human primate motor cortex, ICMS has been shown to evoke behavioral fragments including reaching and defensive motions (Graziano et al., 2002a; Kaas et al., 2013). It has been suggested that motor cortical areas may be defined by a continuous map of endpoint postural space (Graziano et al., 2002b), e.g., divided according to the 3D regions around the monkey to which the forelimb is driven by ICMS (Graziano et al., 2002a), or to distinct behaviors like reaching and defending (Graziano et al., 2005). Whatever the nature of the topographical clustering of ethologically-relevant movements on the motor cortical surface, this organization appears to be reflected by distinct, interconnected regions in premotor and posterior parietal cortex (Stepniewska et al., 2005, 2011, 2013; Gharbawie et al., 2011).

Recently, we demonstrated that ICMS of monkey motor cortex elicited EMG patterns that could be decomposed into muscle synergies—ones similar to those seen in natural behavior (Overduin et al., 2012; for discussion see also Diedrichsen and Classen, 2012; Bizzi and Cheung, 2013; Santello et al., 2013). These EMG patterns co-occurred with movements of the hand toward a convergent posture. Like the apparent topographical organization of spinally-encoded synergistic limb movements (Tresch et al., 1999; Bizzi et al., 2000, 2002, 2008; Tresch et al., 2002), we also observed a non-uniform representation of each forelimb synergy on the cortical surface of macaques (Overduin et al., 2012). Much as microstimulation of multiple points in the spinal cord of frogs (Mussa-Ivaldi et al., 1994; Lemay et al., 2001) and rats (Tresch and Bizzi, 1999) evokes a linear summation of convergent forces and end posture, when ICMS is applied at multiple points in the motor cortex of anesthetized cats, the evoked EMG activity tends to sum linearly (Ethier et al., 2006). Together these results suggest a role of muscle synergies in simplifying (even to the point of linearizing) motor control.

Yet even if ICMS is able to evoke movements through combination of hard-wired muscle synergies, this does not imply that the synergies are *organized* intracortically. In humans, for instance, cortical stroke appears to spare some or most synergies (Cheung et al., 2009, 2012; Cruz and Dhaher, 2009), suggesting encoding at a subcortical locus. In the absence of descending signals from the brain, the spinal cord remains fully capable of generating complex behaviors and muscle activations (Pearson and Rossignol, 1991; Zimmermann et al., 2011), as well as microstimulation-evoked convergent forces (Giszter et al., 1993; Aoyagi et al., 2004).

Here, we examined motor cortical activity during voluntary behavior to see if it might play any role in controlling the activation (if not the structure) of muscle synergies. In particular, we tested a simple experimental hypothesis motivated by our earlier microstimulation work (Overduin et al., 2012), namely that cortical units should preferentially encode synergies similar to those evoked by ICMS at the same electrode. (Our null hypothesis, in contrast, was that whichever synergy was most strongly encoded by a given unit would bear only at-chance similarity to those evoked by ICMS near the unit.) If so, this would suggest that intracortical currents—whether endogenously generated by motor planning or exogenously introduced by microstimulation—may determine the degree to which downstream synergies are recruited.

MATERIALS AND METHODS

SUBJECTS

Behavioral, muscular, and cortical data were collected from two rhesus macaques (*Macaca mulatta*): G1 (a 5.9-kg, 8-year-old female) and G2 (a 6.5-kg, 4-year-old male). Procedures were approved by the MIT Committee on Animal Care, and conformed to the National Institutes of Health *Guide for the Care and Use of Laboratory Animals.*

BEHAVIOR

Subjects used their left hand to press a start button and then reach for, grasp, and carry objects between two wells spaced 20 cm apart. Reward (0.2–0.3 ml of apple juice or water) was given if the object was removed from the first well within 1.0 s, and released into the second well within another 1.0 s, where it had to remain for at least 0.1 s. Button press, reward dispensation, and data from two photosensors (E3T-SR12; Omron, Kyoto, Japan) mounted within each well were recorded together, allowing trials to be divided into reach and carry phases (Overduin et al., 2008). The 25 Delrin plastic objects (density 1.4 g/cm^3) included 5 spheres of variable diameter (ranging from 1.6 to 3.6 cm), 5 cubes of variable width (1.5–3.6 cm), and 15 cylinders of which 5 each spanned one of three dimensions (height, 0.6–5.7 cm; uniform diameter, 1.3–3.8 cm; inner diameter, 0.6–3.2 cm). The number of objects presented in a given day, or spanned by any one single unit recorded in a given session, could be fewer than 25. The same object was presented enough times consecutively for the animal to be able to perform 10 successful trials, before another object was pseudorandomly selected. During recordings, subjects were head-restrained via an implanted cranial post.

SESSIONS

Cortical recordings from monkey G1 comprised 7798 successful left-target-directed trials performed over 20 recording sessions spanning 45 days; those from G2 comprised 775 left-target-directed trials performed over 6 sessions spanning 6 days. The analysis presented here, however, was focused on the subset of these data for which ICMS experiments were performed on the same days as the cortical recordings (4485 trials over 13 sessions from G1 and 544 trials over 4 sessions from G2). Muscle

recording was done in each of these sessions from G1 and G2, and also included trials (as well as other, interspersed sessions) when cortical recording was not done. The EMG data from which synergies were extracted (Overduin et al., 2008, 2012; **Figure 3A**) thus include trials recorded both with and without simultaneous neural data. In particular, of G1 and G2's 1000 left-target-directed trials used to construct trial-averaged EMG activity for synergy extraction, 482 and 462 trials overlapped with the 4485 and 544 trial subset we focus on here, respectively. The EMG data of the remaining 89% (4003/4485, G1) and 15% (82/544, G2) of trials are new to this report. None of the cortical data have previously been presented.

SURGERY

Cortical surgeries followed (G1) or occurred along with the first of (G2) the muscle electrode implantation surgeries (described in Overduin et al., 2008). These surgeries were performed under sterile conditions and general anesthesia (0.05 mg/kg atropine and 10 mg/kg ketamine injected intramuscularly, followed in G1 by 5 mg/kg sodium pentobarbital intravenously or in G2 by inhalation of 1–2% isoflurane with 2 L O_2). Craniotomies were centered over right-hemisphere motor cortex. Custom stainless steel wells (G1: 28 mm wide, G2: 20 mm) were secured with bone screws and bone cement. The animals were given analgesics and systemic antibiotics following the surgeries. The dura was kept intact during surgery, and was subsequently treated with topical antibiotics and anti-inflammatories. Fresh connective tissue growth above the dura was further controlled by periodic ($\sim 1\times$ weekly) mechanical scraping, done under light anesthesia through the weeks of recording.

MUSCLES

EMG recordings were made via 15 (G1) or 19 (G2) electrodes chronically implanted in muscles of the left forelimb. Proximal muscles acting on the shoulder and elbow included Del (deltoideus), Pec (pectoralis major), TriU and TriR (triceps brachii, ulnar and radial short heads), Bic (biceps brachii longus), and BR (brachioradialis). Wrist and extrinsic hand extensors included AbPL (abductor pollicis longus), ECRB (extensor carpi radialis brevis), EDC (extensor digitorum communis), ED23 (extensor digiti secundi and tertii proprius), ED45 (extensor digiti quarti and quinti proprius), and ECU (extensor carpi ulnaris). Wrist and extrinsic hand flexors included FCR (flexor carpi radialis), FDS (flexor digitorum superficialis), FDPU and FDPR (flexor digitorum profundus, ulnar and radial), and FCU (flexor carpi ulnaris). Intrinsic hand muscles included AbPB (abductor pollicis brevis), AdP (adductor pollicis), OpP (opponens pollicis), F5B (flexor digiti quinti brevis manus), and Op5 (opponens digiti quinti manus). EMG data were recorded on a trial-by-trial basis (between button-press and reward events). These data were bandpass-filtered (between 10 and 1000 Hz), notch filtered (60 Hz), and differentially amplified ($5000\times$) by a programmable signal conditioner (CyberAmp 380; Molecular Devices, Sunnyvale, CA) under software control (CyberControl; Molecular Devices). Data were digitized (2 kHz) via a data acquisition board (NI PCI-6035E; National Instruments, Austin, TX) under custom software control (LabVIEW; National Instruments). EMG channel subselection following cross-talk analysis is described in Overduin et al. (2008).

CORTEX

Single units were recorded from dorsal premotor cortex (PMd), ventral premotor cortex (PMv), and MI (**Figure 1**). Areas were identified using magnetic resonance imaging data and sensorimotor mapping including ICMS. MRIs were collected 2 years after (G1) or 4 months before (G2) the recordings presented here. At the beginning of recording sessions, unit somatosensory (proprioceptive and cutaneous) response fields were estimated by passively moving the monkey's limbs and by stimulating its skin. Both in early exploratory sessions and at the end of each recording session, ICMS was applied via tungsten microelectrodes (FHC, Bowdoin, Maine; 0.3–3-MΩ impedance, 250-μm shaft diameter tapered to a 3-μm-wide tip). Up to 10 such electrodes were acutely introduced into the brain in each session using a manual microdrive (30-μm depth resolution). The microdrive was mounted on a grid that was secured to the recording well and that constrained the interelectrode spacing to 1 mm. The ICMS-evoked movements and stimulation thresholds were used to identify the portion of cortex sampled by the electrodes. Stimulation parameters used for this mapping included 2×0.2-ms pulse duration (cathodal-leading), 10–150-μA current, 330-Hz pulse frequency, and 0.05-s train duration. Modified ICMS parameters were used to evoke longer-lasting movements at the end of some sessions (**Figure 2A**): 8–100-μA current, 200-Hz pulse frequency, and 0.15–0.5-s train duration (as in Overduin et al., 2012). We consider only the first seven ICMS trains delivered at each site, this being the minimal number applied across the 33 (G1) or 13 (G2) sites (including 32 in MI, 9 in PMd, and 5 in PMv; Overduin et al., 2012).

UNITS

Extracellular, intracortical voltages were recorded through the same electrodes used for ICMS. During recordings, no attempt was made to record from units within particular cortical layers or in sulcal sites, and the laminar location of recorded units was generally unknown given limited depth resolution and dimpling of the cortex upon penetration. Instead, we selected for recording the first stably-firing and well-discriminated unit(s) (if any) discovered along a given electrode track, as revealed by audio and oscilloscope monitoring of the recorded voltage. We rejected all cortical sites wherein somatosensory stimulation or ICMS had indicated response fields extending beyond the left forelimb (e.g., to the face or leg). We did not require the remaining sites to demonstrate sensorimotor responses, only that they be within topographical regions convexly bounded by sites that did. No other criteria were applied to units; i.e., we treated all as potentially task-related. We only consider units recorded at ICMS electrode sites (33 sites in G1, 13 in G2; Overduin et al., 2012); these comprise 94 units (83 in G1, 11 in G2). Signals were preamplified at unity gain by a headstage located ∼5 cm from the electrodes, and then passed to an amplifier for amplification ($10{,}000\times$) and bandpass-filtering (600–6000 Hz, 2nd-order filter with roll-off on both ends) before digitization (Neuralynx, Inc., Tucson, Arizona). Spikes were identified online when electrode voltages exceeded a manually-set threshold, and 1.1-ms waveforms (including the

threshold-crossing moment at 0.26 ms into the waveform), sampled at 30 kHz, were stored to disk. Spike times and other event times were recorded together for later synchronization of behavioral, EMG, and neural data. Offline, single units were identified based on spike waveform features and interspike intervals (ISIs), using manual clustering with MClust (MClust-3.4, A. D. Redish et al.) and custom routines written in MATLAB (MathWorks, Natick, Massachusetts), for this and the following analysis. Particular care was taken to ensure that waveform features and firing rates remained relatively constant over the recording span of each accepted unit. The 94 units had mean firing rates between 1.0 and 58.0 Hz, and signal-to-noise ratios between 2.4 and 24.3 (deCharms et al., 2009), with 1% of ISIs <1 ms.

PREPROCESSING

After preprocessing as described in Overduin et al. (2008), grasping-related EMG data were integrated over 9-ms (G1) or 11-ms (G2) bins, and normalized to each channel's maximum integrated EMG over object conditions. The EMG data of 40 trials within each of the 25 object conditions were aligned on the time of object removal from the first well, cropped to a 100-sample window around this event [G1:$(-0.35 : +0.55)$ s, G2:$(-0.5 : +0.6)$ s], and then averaged over trials within each object condition. (The different window and integration times for the two animals were chosen based on their different movement latencies; Overduin et al., 2008.) ICMS-evoked EMG data were integrated over a $(+0.025 : +0.150)$ s window relative to ICMS onset for each of 7 trains applied at each stimulation site, and normalized by the same factors as the grasping-related EMG data (Overduin et al., 2012). With regards to the neural data, mean firing rates were computed on a within-object basis, using all trials fully spanned by a unit. Trials were time-aligned on the time of object removal from the origin well (as for the grasping-related EMG data). Subsequent analysis was restricted to a $(-0.4 : +0.5)$ s (G1) or $(-0.55 : +0.55)$ s (G2) window around this event, i.e., to the same windows as for the grasping-related EMG data minus a fixed 50-ms delay (Morrow and Miller, 2003; Schieber and Rivlis, 2007; Stark et al., 2007). Within this window, each unit's spikes were summed within 9- or 11-ms bins (again, for consistency with the grasping-related EMG data binning). The units' mean firing rate profiles within each object condition were then smoothed by convolution with a 50-ms Gaussian kernel. (This smoothing, evident in **Figure 3B**, did not have a qualitative effect on the summary results of **Figure 4**.) All preprocessing was done in MATLAB.

SYNERGIES

Non-negative matrix factorization (NNMF) was used to identify a set of synchronous synergies underlying each monkey's muscle patterns (Lee and Seung, 1999; Tresch et al., 1999). There were two sets of muscle patterns to consider: ICMS-evoked EMG data $\boldsymbol{I}$ (including the data evoked at the sample site in **Figure 2A**, *right*), and grasping-related EMG data G (shown averaged over object conditions in **Figure 3A**, *bottom*). Matrix $\boldsymbol{I}(e,\ s,\ l)$ pools together the activity in E EMG channels evoked by each of S stimulation trains delivered at each of L ICMS locations (Overduin et al., 2012). $\boldsymbol{I}$ thus has dimensionality $15 \times 7 \times 33$ (G1) or $19 \times 7 \times 13$ (G2). Matrix $\boldsymbol{G}(e,\ t,\ o)$ specifies trial-averaged EMG activity over the same E channels, but across each of T time points in each of the O object conditions. G thus has dimensionality $15 \times 100 \times 50$ (G1) or $19 \times 100 \times 50$ (G2). Data $\boldsymbol{I}$ and $\boldsymbol{G}$ were independently reconstructed as combinations of $n = 1, \cdots, N^{\mathrm{I}}$ or $n = 1, \cdots, N^{\mathrm{G}}$ synergies, respectively, where both N^{I} and N^{G} were evaluated up to the number of EMG channels E, i.e., 15 (G1) or 19 (G2). Each ICMS-evoked or grasp-related synergy $\boldsymbol{w}_n^{\mathrm{I}}(e)$ or $\boldsymbol{w}_n^{\mathrm{G}}(e)$ is a vector of length E capturing a unique balance of activation across the EMG channels. In reconstructions, each synergy was multiplied by a scalar, non-negative weighting coefficient $w_n^{\mathrm{I}}(s,\ l)$ or $w_n^{\mathrm{G}}(t,\ o)$. These coefficients could vary both within conditions (i.e., over stimulation trains s or time samples t) and across conditions (i.e., over ICMS locations l or objects o). The reconstructions can be expressed as:

$$\boldsymbol{I}(e,\ s\ ,\ l) = \sum_{n=1}^{N^{\mathrm{I}}} w_n^{\mathrm{I}}(s,\ l) \cdot \boldsymbol{w}_n^{\mathrm{I}}(e) \tag{1}$$

$$\boldsymbol{G}(e,\ t,\ o) = \sum_{n=1}^{N^{\mathrm{G}}} w_n^{\mathrm{G}}(t,\ o) \cdot \boldsymbol{w}_n^{\mathrm{G}}(e) \tag{2}$$

For a given N^{I} or N^{G}, the algorithms iteratively updated the structures $\boldsymbol{w}_n^{\mathrm{I}}$ or $\boldsymbol{w}_n^{\mathrm{G}}$ and coefficients w_n^{I} and w_n^{G} until the total reconstruction error, R^2, increased by less than 0.001 over 10 iterations. The algorithms were repeated five times for each extraction; the set of synergies with the highest EMG variation explained was selected for further analysis. Dimensionalities (N^{I} and N^{G}) were chosen by applying a threshold of $R^2 = 95\%$ (Overduin et al., 2012).

MATCHING

Synergies $\boldsymbol{w}_n^{\mathrm{I}}$ were compared and matched to synergies $\boldsymbol{w}_n^{\mathrm{G}}$ using a greedy search procedure (Tresch et al., 1999; Overduin et al., 2012). For all $N^{\mathrm{I}} \times N^{\mathrm{G}}$ possible pairs of ICMS-evoked and grasping-related synergies, we first computed dot products (e.g., $6 \times 8 = 48$ dot products, for G2. The pair of ICMS-evoked vs. grasping-related synergies with the highest dot product was defined as the best-matching pair. The pair with the highest dot product among the remaining $(N^{\mathrm{I}} - 1) \times (N^{\mathrm{G}} - 1)$ pairs (e.g., $5 \times 7 = 35$ pairs, for G2) defined the second-best match. This process was repeated until all synergies in one set had been paired (e.g., over $\min(6,8) = 6$ times for G2). We then used Monte Carlo simulation to assess the significance of each match. We repeated the greedy search algorithm 10,000 times for each monkey, after first randomly shuffling EMG channel identity each time. (For G2, for instance, this involved finding $10{,}000 \times 48 = 480{,}000$ dot products.) We then compared the highest (best-matching) dot product between *actual* ICMS-evoked and grasping-related synergies with the distribution of highest dot products from the 10,000 comparisons of *shuffled* synergies. If the former value exceeded the 95th percentile of the distribution of latter values, we took the match as significant at $p < 0.05$. We then repeated this comparison for the second-best actual synergy pair vs. the distribution of second-best shuffled pairs, etc.

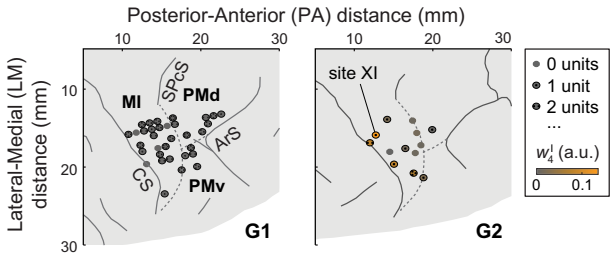

FIGURE 1 | A portion of each monkey's right hemisphere as viewed from above. Solid lines represent sulci (CS, central sulcus; SPcS, superior precentral sulcus; ArS, arcuate sulcus); dashed lines show estimated inter-areal borders separating MI, PMd, and PMv. The circles show stimulation and recording sites, with dots indicating the number of units (if any) recorded at the site. For G2, ICMS sites are colored according to the degree to which the evoked muscle EMG activity was similar to (i.e., reconstructed by) synergy $\boldsymbol{v}_4^I$. (Specifically, the color scale indicates the mean amplitude coefficient $\overline{w_4^I}$ used in reconstructing the ICMS-evoked EMG vectors at a site with synergy $\boldsymbol{v}_4^I$, averaged over ICMS trains.) Of G2's ICMS sites, this synergy was most strongly evoked at site XI, in MI.

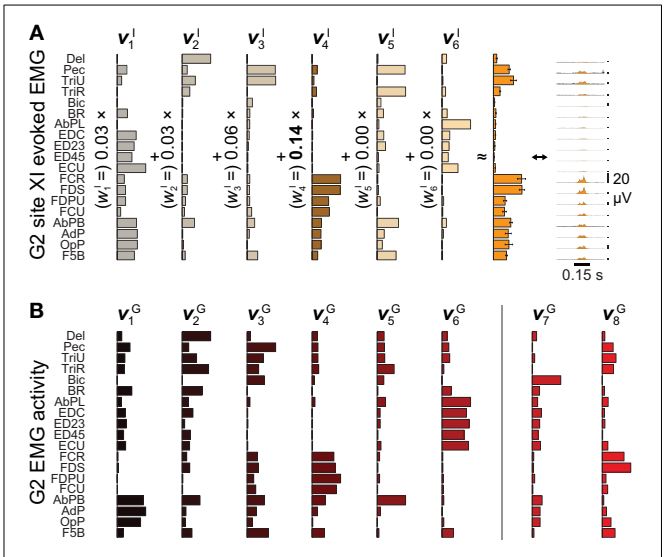

FIGURE 2 | Microstimulation-evoked muscle activity and reconstruction by synergies. (A) The EMG activity evoked during the first 0.15 s of ICMS at site XI from **Figure 1**, shown both in gold-colored profile (*far right*) and as the integrated mean ± SE of this activity over stimulation trains (*second from right*). (The vertical 20-μV scale bars to the right of the EMG profiles give the relative level of activation in each channel.) The mean activity could be reconstructed by six ICMS-evoked synergies $\boldsymbol{v}_n^I$ (*left*), with the largest weighting given to $\boldsymbol{v}_4^I$. **(B)** Of eight muscle synergies $\boldsymbol{v}_n^G$ derived from an object grasping behavior, synergies $\boldsymbol{v}_1^G$-$\boldsymbol{v}_6^G$ could be matched in structure to ICMS-evoked synergies $\boldsymbol{v}_1^I$-$\boldsymbol{v}_6^I$.

ANALYSIS

In reconstructing the ICMS-evoked EMG vectors at a given site, the synergy $\boldsymbol{v}_n^I$ most "evoked" at the site was the one with the largest weighting coefficient $\overline{w_n^I}$, averaged over ICMS trains (**Figure 2A**, showing results for site XI in **Figure 1**, *right*). To determine which synergy was instead most "encoded" by a unit, the unit's firing rate profile was correlated against the task-related synergy scaling profiles w_n^G, and the largest positive correlation was identified. Results were insensitive to the use of linear (Pearson) or rank (Kendall or Spearman) correlation. To determine which task-related synergy was most evoked at a recording site, the site's ICMS-evoked EMG patterns were decomposed into combinations of synergies, which in turn were matched to task-related synergies (as described above). Over units, we counted the frequency at which the most-encoded synergy was the same as the most-evoked synergy at the electrode, defined as above. The chance frequency of such matches was $1/6 = 17\%$, as the analysis considered the 6 muscle synergies both evoked by ICMS (in the case of G2, **Figure 2A**, *left*) and observed in the task data (**Figure 2B**). Results of this χ^2 test were evaluated for significance at a $p < 0.05$ threshold.

RESULTS

In a recent study (Overduin et al., 2012), we examined ICMS-evoked movements and muscle activity in two rhesus macaques ("G1" and "G2"). EMG data were recorded from 15–19 electrodes chronically implanted in muscles of the shoulder, arm, and hand. As we reported (Overduin et al., 2012), ICMS within MI and dorsal and ventral premotor (PMd and PMd) cortex (**Figure 1**) appeared to drive the forelimb toward an invariant, site-specific posture, and at the same time to replace voluntary muscle activity with an invariant, site-specific tonic EMG pattern (as in Griffin et al., 2011).

After aggregating ICMS-evoked EMG data over multiple stimulation sites, these pooled data could be decomposed into combinations of a reduced set synchronous synergies using NNMF (Lee and Seung, 1999; Tresch et al., 1999). Each of the ICMS-derived synergies $\boldsymbol{v}_n^I$ ($n = 1,\ldots,N^I$) captures a pattern of synchronous firing over muscles. We found that $N^I = 6$ (G2) or 7 (G1) synergies were sufficient to reconstruct ≥ 95% of the variability in the ICMS-evoked EMG data (Overduin et al., 2012). Such data reconstruction is exemplified in **Figure 2A** for G2's ICMS site XI, in MI. The figure depicts the ICMS-evoked activity at this site in the form of: the time-varying, trial-averaged EMG signal (*far right*); an ICMS-evoked EMG vector integrating this per-ICMS activity over time (*middle*); and as a vector sum of ICMS-derived synergies, each scaled by the weighting coefficient w_n^I (*left*). For this site, the ICMS-evoked EMG activity was dominated by synergy $\boldsymbol{v}_4^I$, as shown.

We also studied a manual behavior performed by these subjects (Overduin et al., 2008, 2012), in which they had to reach for an object presented in a well, grasp it, and then carry it to the opposing well. To elicit a variety of hand postures and forces, the objects included 25 spheres, cubes, and cylinders of different dimension. Pooled over multiple days, the EMG data could be decomposed into combinations of grasping-related synergies $\boldsymbol{v}_n^G$ ($n = 1,\ldots,N^G$). We found that $N^G = 8$ (G2) or 10 (G1) synergies were sufficient to reconstruct ≥ 95% of the variability in the grasping-related EMG data (Overduin et al., 2012). For each monkey, 6 of these synergies could be matched uniquely to one of the ICMS-derived synergies (**Figures 2A** vs. **2B**) using a greedy search procedure. **Figures 2B**, **3A** illustrate the synergies found for one animal and their reconstruction of average EMG activity.

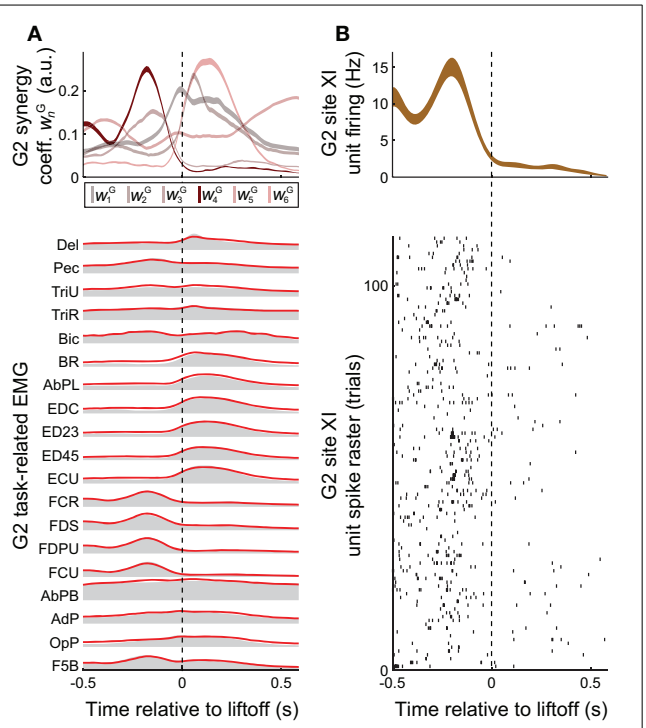

FIGURE 3 | Task-related muscle activity and reconstruction by synergies, vs. cortical activity. (A) EMG activity in the grasping task (gray envelopes at *bottom*) could be decomposed as a summation of grasping-related synergies $\boldsymbol{v}_n^G$ (*red* lines at *bottom*), each weighted by the coefficients w_n^G (*top*). EMG activity and synergy coefficients are shown as mean (*bottom*) and mean ± SE (*top*), over all 25 objects and 733 trials spanned by this monkey's EMG dataset. **(B)** The task-related firing rate of a unit recorded at monkey G2' site XI, shown both as a spike raster (*bottom*) and as the binned activity mean ± SE (over the 22 objects and 113 trials spanned by this unit, *top*). Of all the task-related synergies $\boldsymbol{v}_1^G$-$\boldsymbol{v}_6^G$ used in reconstructing EMG activity unit's activity (**A**, *top*), the one corresponding to $\boldsymbol{v}_4^I$ (i.e., $\boldsymbol{v}_4^G$) had an activation profile most similar to the unit's activity (**B**, *top*).

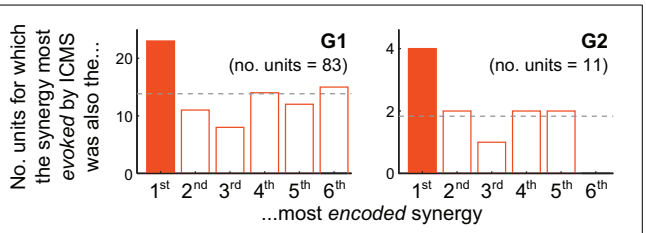

FIGURE 4 | Motor cortical units are biased toward encoding synergies evoked by nearby microstimulation. For both G1 and G2, the muscle synergy most strongly evoked by ICMS was also the synergy most likely to be best-correlated with the firing of cortical units at the same electrode. The unit depicted in **Figure 3B**, for instance, contributes to G2's solid-colored bar.

Synergies could provide the animal with a mechanism to continuously and efficiently control its muscles, by specifying a task-specific amplitude coefficient time course w_n^G for each of the synergies (**Figure 3A** *top* vs. *bottom*). The involvement of motor cortex in this control is circumstantially suggested by the correspondence in synergy structure whether these are derived from ICMS-evoked or voluntarily-generated EMG data (**Figures 2A** vs. **2B**). Here, we sought more direct evidence for the role of motor cortex. In particular, we looked for evidence that the muscle synergies evoked by ICMS (and matched to those generated voluntarily) were also encoded by single motor cortical units near the ICMS electrodes.

A positive example of such a correspondence is shown in **Figure 3A** (*top*) and **Figure 3B** (*top*), for monkey G2. The MI unit shown in **Figure 3B** is at site XI, the location of which is highlighted in **Figure 1** (*right*), and the ICMS-evoked EMG activity of which is shown in **Figure 2A**. The single unit recorded at this site exhibited a strong burst of activity just prior to the time when the object was retrieved from its origin well, and was largely quiet during the following carry and release movements (**Figure 3B**). (These modulations were captured in the unit's firing rate, derived from spike counts binned at 50 ms and smoothed with a 50-ms Gaussian kernel.) Of all the grasping-related synergies $\boldsymbol{v}_1^G$-$\boldsymbol{v}_6^G$, the one whose activation profile was most positively correlated with that of the unit was $\boldsymbol{v}_4^G$ (**Figure 3A**, *top*), which appeared to capture the coactivation of forearm flexor muscles (**Figure 2B**). And of all the ICMS-evoked synergies $\boldsymbol{v}_1^I - \boldsymbol{v}_6^I$, it was the matching synergy $\boldsymbol{v}_4^I$ that was most dominant in reconstruction of the evoked EMG activity.

How consistently did the muscle synergy most encoded by a unit match the synergy most evoked by ICMS at the same site (as in the foregoing example)? For this analysis we simply counted the number of MI, PMd and PMv units for which the grasping-related synergy most strongly encoded by the unit matched the primary muscle synergy evoked by ICMS at the electrode. (This analysis is restricted to those ICMS sites at which units were also recorded; these are highlighted in **Figure 1**.) As shown in **Figure 4**, the actual frequencies were significantly higher than the $1/6 = 17\%$ chance frequency [26 of 94 units, or 28%; $\chi^2_{(1)} = 6.82$, $p < 0.01$], as was true for G1 alone [$22/83 = 27\%$ of units; $\chi^2_{(1)} = 4.82$, $p < 0.05$] and supported by a trend among G2's smaller population of units [$4/11 = 36\%$ of units; $\chi^2_{(1)} = 2.56$, $p = 0.07$]. (Note that the "1st most encoded synergy" in this plot is not necessarily $\boldsymbol{v}_1^G$, but instead whichever synergy $\boldsymbol{v}_n^G$ was most strongly correlated with the unit's firing profile, e.g., $\boldsymbol{v}_4^G$ for the unit shown in **Figure 3B**. Similarly, the "most evoked synergy" is whichever synergy $\boldsymbol{v}_i^I$ was dominant in reconstruction of the EMG activity evoked at the unit's electrode. In general, $\boldsymbol{v}_3^I$, $\boldsymbol{v}_4^I$, and $\boldsymbol{v}_5^I$ appeared to be most commonly evoked by ICMS, being the synergies "evoked" at 18/83, 28/83, and 20/83 of monkey G1's units, respectively, and by 3/11, 3/11, and 4/11 of G2's units.)

While the qualitative pattern for G2 followed very closely that of G1 (**Figure 4**), it likely failed to reach significance due to insufficient sampling of units (11 units, vs. 83 for G1). Also, these trends were weakened by inclusion of PMv units. Considering *only* MI and PMd units, the fraction of cases in which the grasping-related synergy most strongly encoded by a unit matched the synergy most strongly evoked by proximal ICMS was significantly higher than 1/6 in G2 [$4/10 = 40\%$ of units; $\chi^2_{(1)} = 3.27$, $p < 0.05$] as well as G1 [$20/73 = 27\%$ of units; $\chi^2_{(1)} = 5.04$,

$p < 0.05$], and in both animals combined [24/83 = 29%; $\chi^2_{(1)} = 7.47, p < 0.01$].

While the synergies $\boldsymbol{w}_i^I$ extracted from ICMS-evoked EMG activity did cluster non-uniformly on the cortical surface (Overduin et al., 2012), we observed no tendency of the subset of sites at which similar synergies were both encoded and evoked to be topographically grouped on the cortical surface.

DISCUSSION

Our results suggest that direct stimulation of patches of motor cortex generates synergistic combinations of muscle activity that are weighted toward synergies encoded at the stimulating electrode. A common motor cortical substrate appears to be activated both by endogenous currents during voluntary behaviors and by exogenous currents introduced by electrical microstimulation. In either case, these currents appear to modulate the amplitude, not structure, of a shared set of downstream muscle synergies. Our earlier work also suggests that each synergy (and the posture reached through its tonic activation) may be represented by a non-uniform map over the motor cortical surface (Overduin et al., 2012).

It may be contested that electrical currents injected into the CNS via microstimulation elicit non-natural patterns of neural activity (even if the downstream muscle activity is resolvable into well-organized movements and natural muscle synergies). The biological basis of ICMS, and even the extent of cortex activated, remain poorly understood (Butovas and Schwarz, 2003; Tolias et al., 2005), despite recent studies using single-cell recording, behavioral methods, functional magnetic resonance imaging (Tehovnik et al., 2006), and two-photon calcium optical imaging (Histed et al., 2009). Moreover, these investigations of ICMS have largely been limited to more conventional, short-train and/or subthreshold ICMS rather than the form used here. In applying ICMS in motor cortex, researchers have traditionally used short train durations (typically 25–70 ms) and sub- or per-threshold currents (typically 10–60 μA; e.g., Asanuma and Rosén, 1972; Sato and Tanji, 1989; Donoghue et al., 1992) in order to map the overt response of cell populations including corticomotoneuronal cells. Such studies neither sought nor reported convergent movement responses of the sort found here and by others (Graziano et al., 2002a,b), and have naturally aroused some controversy (Strick, 2002).

Together with Overduin et al. (2012), our findings indicate that movements, muscle patterns, and cortical activations evoked by relatively long-train ICMS can be related to those observed in natural behavior. Indeed, it can be argued that a physiologically realistic model of motor activation *requires* ICMS with relatively long trains, as well as suprathreshold currents and intermediate pulse frequencies (optimally 80–140 μA and 80–140 Hz, in the case of primate MI forelimb-area ICMS; Van Acker et al., 2013). Graziano and coworkers (Graziano et al., 2002a) have emphasized that ∼500-ms stimulation trains approximate the time scale of natural movements like primate reach and grasp (Georgopoulos et al., 1986; Reina et al., 2001). Even in spinalized amphibians, in whom convergent force patterns were first observed (Mussa-Ivaldi et al., 1990; Giszter et al., 1993; Loeb et al., 1993), these movements were evoked by similarly long-train (typically 300-ms) intraspinal microstimulation. Researchers using ICMS to study oculomotor and somatosensory systems have also used relatively long trains. For instance, 400-ms trains were applied to the arcuate sulcus to replicate the time scale of typical regular head movements (Freedman et al., 1996), and 500-ms trains were applied to primary somatosensory cortex to mimic a tactile stimulus (Romo et al., 1998). While trains shorter than ∼500 ms elicit truncated movements when delivered to primate MI (Graziano et al., 2002a; Van Acker et al., 2013), in Overduin et al. (2012) we show that even 150 ms of ICMS yields convergent movements with a predictable equilibrium point and synergistic muscle activation.

For the majority of units we sampled, firing rate profiles were more correlated with muscle synergies *other* than the most-evoked synergy (**Figure 4**, non-shaded bars). There are many ways to account for these other units. For example, units may encode other continuously-controlled quantities like the position, velocity, or acceleration of extrinsic effectors or intrinsic joints, or the forces underlying these kinematics, or the muscle contractions determining these dynamics (Carmena et al., 2003; Morrow and Miller, 2003; Schieber and Rivlis, 2007; Stark et al., 2007; Velliste et al., 2008; Ganguly and Carmena, 2009; Hochberg et al., 2012; Collinger et al., 2013). Motor cortical encoding of purely extrinsic variables may be unlikely based both on theoretical grounds (Todorov, 2000; Paninski et al., 2004) and on empirical evidence that neurons' intrinsic muscle fields are more stable than their tuning to extrinsic dimensions like hand direction (Morrow et al., 2007), with such tuning observed to fluctuate even during stable within-session behavior (Carmena et al., 2005; Rokni et al., 2007; cf. Chestek et al., 2007). However, the purpose of this report was not to determine whether motor cortical units encode muscle activity, synergy coefficients, or any other motor variable. Instead, we simply sought to test whether the units were more likely than chance to encode those synergies evoked by ICMS at the same electrode.

Another way to account for units which appeared to encode different synergies than those evoked by nearby ICMS is to recognize that the number of units affected by ICMS current far exceeds the handful sampled at an electrode. With the stimulation currents needed to elicit complex movements (≤ 100 μA in this report), cortex is no doubt activated far outside the 100-μm radius assumed for ∼ 10 μA stimulation (Ranck, 1981). Such suprathreshold trains are likely to recruit other cells beyond those immediately next to the stimulating electrode through synaptic connections (Histed et al., 2009), and indeed may be required to transsynaptically activate non-direct connections between motor cortex and the spinal cord (Strick, 2002).

Another possibility to be explored in future work is that populations of units may specify not only continuous variables like synergy amplitude, but also sequential recruitment of muscles (e.g., via synergies) in the form of discrete "motor programs" (Keele, 1968; Polit and Bizzi, 1978, 1979; Georgopoulos et al., 1983). Elsewhere these programs have been referred to as "time-varying synergies," in distinction from the "synchronous synergies" discussed in the present report (Kargo and Nitz, 2003), and have been extracted from muscle data using a modified

form of NNMF (d'Avella et al., 2003, 2006; Overduin et al., 2008). A dynamical systems approach may also be appropriate for capturing time-varying patterns within population-level neural and muscular data (Churchland et al., 2012).

Besides studies of voluntary neural and muscular dynamics, microstimulation studies are also broadly consistent with the idea of discrete movement encoding. Intraspinal microstimulation of sufficient duration generates forces that tend to drive a limb to particular postures or through sequences of postures, in frogs (Mussa-Ivaldi et al., 1990; Giszter et al., 1993; Kargo and Giszter, 2000), cats (Lemay and Grill, 2004) and rats (Tresch and Bizzi, 1999). Sufficiently-long ICMS trains applied to mammalian motor cortex (Ward, 1938; Graziano et al., 2002a, 2004a, 2005; Stepniewska et al., 2005, 2011; Ramanathan et al., 2006) can evoke complex multijoint forelimb behaviors with multiple phases (such as reach, grasp, then retraction) and invariant endpoints. The stimulation-evoked convergent forces (Giszter et al., 1993; Kargo and Giszter, 2000), invariant endpoints (Graziano et al., 2004a; Graziano and Aflalo, 2007), and bell-shaped speed profiles (Graziano et al., 2005) all tend to overlap with motions and postures found in subjects' natural behavior. Together with the present results, these studies indicate that microstimulation-evoked movements are not artifactual, and indeed can provide insights into natural movement planning.

ACKNOWLEDGMENTS

This work benefited from the assistance of Margo Cantor, Charlotte Potak, Jinsook Roh, and Sylvester Szczepanowski. The project was supported by fellowships to Simon A. Overduin from the Canadian Institutes of Health Research and Dystonia Medical Research Foundation, and a National Science Foundation grant EFRI-1137267 to Jose M. Carmena.

We have previously described a modular organization of the locomotor step cycle in the cat in which a number of sparse synergies are activated sequentially during the swing phase of the step cycle (Krouchev et al., 2006). Here, we address how these synergies are modified during voluntary gait modifications. Data were analysed from 27 bursts of muscle activity (recorded from 18 muscles) recorded in the forelimb of the cat during locomotion. These were grouped into 10 clusters, or synergies, during unobstructed locomotion. Each synergy was comprised of only a small number of muscles bursts (sparse synergies), some of which included both proximal and distal muscles. Eight (8/10) of these synergies were active during the swing phase of locomotion. Synergies observed during the gait modifications were very similar to those observed during unobstructed locomotion. Constraining these synergies to be identical in both the lead (first forelimb to pass over the obstacle) and the trail (second limb) conditions allowed us to compare the changes in phase and magnitude of the synergies required to modify gait. In the lead condition, changes were observed particularly in those synergies responsible for transport of the limb and preparation for landing. During the trail condition, changes were particularly evident in those synergies responsible for lifting the limb from the ground at the onset of the swing phase. These changes in phase and magnitude were adapted to the size and shape of the obstacle over which the cat stepped. These results demonstrate that by modifying the phase and magnitude of a finite number of muscle synergies, each comprised of a small number of simultaneously active muscles, descending control signals could produce very specific modifications in limb trajectory during locomotion. We discuss the possibility that these changes in phase and magnitude could be produced by changes in the activity of neurones in the motor cortex.

Keywords: locomotion, motor cortex, voluntary gait modifications, cat, synergy

INTRODUCTION

The question of modularity within the locomotor control system has a long history. From the original proposition of Graham Brown (1911, 1914) that two half-centres are responsible for generating locomotion grew a body of experimental work to determine the neuronal basis of the alternating rhythmical activity observed during locomotion (Jankowska et al., 1967a,b; Lundberg, 1981). This work took a new and, initially, controversial, direction when Grillner postulated the existence of a central pattern generator (CPG) for locomotion (Grillner and Zangger, 1975, 1979; Grillner, 1981). Subsequent studies have shown that this CPG in the spinal cord has the intrinsic ability to generate an intricate and complex pattern of locomotor activity (Pearson and Rossignol, 1991). From the original concept of the CPG as a single neuronal entity (or network) has grown the idea that the CPG may in fact be considered as a series of modules that are interconnected and provide the capacity to produce a rich behavioral repertoire, involving flexible and coordinated activity around multiple joints.

A key evolution in this respect was the formulation of the concept that the CPG is comprised of a number of unit pattern generators (Grillner, 1981; Grillner and Wallen, 1985). Grillner suggested the existence of four pairs of unit pattern generators responsible for producing the rhythmical pattern of activity in the hip, knee, ankle, and toe muscles. He proposed that relatively simple command signals to modify the connections between the hip and knee modules, for example, could easily change the pattern of muscle activity required for forward progression into that required for walking backwards.

In the turtle spinal cord, such an organization of interconnected modules has been demonstrated electrophysiologically to generate several different scratch patterns depending on the location of the offending stimulus (Berkowitz and Stein, 1994; Stein and Smith, 1997). Additional evidence for modularity in the turtle has come from the studies of deletions, in which bursts of activity in some populations of interneurones and their associated motor pools are absent in some scratch cycles while others persist (Stein and Daniels-McQueen, 2002; Stein, 2008). However, the neuronal mechanisms leading to modularity within the mammalian spinal cord are more difficult to study because of the size and complexity of the neuronal networks. As in the turtle, some evidence for modularity, although not necessarily for independent burst generators, has also come from the study of deletions (Grillner and Zangger, 1979; Jordan, 1991; Smith et al., 1995;

Lafreniere-Roula and McCrea, 2005; Zhong et al., 2012). These deletions are observed in flexor and extensor motoneurones and, in many cases, have no effect on cycle timing, supporting views that rhythm generation (defining the basic rhythmicity of the step cycle) and pattern generation (defining the spatio-temporal organization of the muscle bursts within the step cycle) are separate (Lennard, 1985; Koshland and Smith, 1989). These results have led to a particularly interesting computational model of locomotion consisting of a rhythm generator and distinct pattern generators (Rybak et al., 2006; McCrea and Rybak, 2007; Zhong et al., 2012).

As an extension of these ideas, and particularly on the basis of Grillner's unit CPG model, we suggested (Drew, 1991a) that the existence of such modules could provide a substrate by which the motor cortex could exert a precise control over the magnitude, duration and relative timing of specific muscles groups while at the same time ensuring that these changes are appropriately integrated into the locomotor cycle. Similar ideas were incorporated into computer simulations designed to determine how supraspinal command signals might interact with spinal unit CPGs in a human model of locomotion (Taga, 1995, 1998).

More recently, the idea of modularity within the spinal circuits has been developed to incorporate the idea of muscle synergies. This development, which owes much to the studies of Bizzi and his collaborators (Bizzi et al., 1991; Tresch et al., 1999, 2002; d'Avella et al., 2003; d'Avella and Bizzi, 2005), posits that the nervous system produces complex movements by combining the activity of a limited number of synergies, 4–6 in most studies. In brief, synergies are defined mathematically, by using decomposition methods such as non-negative matrix factorization (NNMF), as a matrix of weights that differentially activate *all* of the muscles involved in producing a movement. By modifying the magnitude and the phase of activity of each synergy, a wide range of movement patterns can be produced (Tresch and Jarc, 2009). Such synergies have been described during locomotion, scratching and swimming in the frog (Giszter et al., 1993; Saltiel et al., 2001; Cheung et al., 2005), during postural compensation to perturbation in cats and humans (Ting and Macpherson, 2005), during human locomotion (Ivanenko et al., 2004; Lacquaniti et al., 2012) as well as in reaching movements in primates and humans (d'Avella et al., 2006, 2008; Overduin et al., 2008). Muscle synergy analysis has also been used to study the deficits in movement after stroke (Cheung et al., 2009, 2012; Clark et al., 2010). In some of these experiments, and particularly those performed in spinal animals, these synergies have been suggested to form the basis of unit burst generators of the type proposed by Grillner (Hart and Giszter, 2004; Cheung et al., 2005).

In our own studies of synergies (Krouchev et al., 2006; Drew et al., 2008a), we have taken a different approach in which synergies are defined using more classical, physiological methods. In our approach, a synergy is defined as a group of muscles that are synchronously activated such that the period of activity during locomotion begins and ends simultaneously in all muscles in a synergy. By applying a custom clustering algorithm we were able to identify 11 synergies in the forelimb of the cat during unobstructed locomotion, with nine of these occurring during the swing phase. These synergies differed from those identified most commonly by using mathematical decomposition methods (see above) in that they were both more numerous and contained only a small proportion of the total number of muscle bursts recorded. We refer to these as sparse synergies to differentiate them from those synergies comprised of all periods of muscle activity (see preceding paragraph). Our suggestion, as in our original work on this issue (Drew, 1991a), is that the motor cortex modulates these sparse synergies in order to modify limb trajectory during locomotion (Drew et al., 2008a,b).

The question remains, however, as to *how* these synergies are modified during voluntary gait modifications and whether the modifications in synergies that are observed are compatible with the discharge activity of neurones in the motor cortex recorded during the same behaviors. To answer that question, we have extended our previous analysis to examine how synergies are modified when cats step over obstacles. We consider two conditions. First we examine how synergies are modified in the lead (when a given limb is the first to step over an obstacle) and the trail (second to step over the obstacle) condition, for which our previous studies showed differential patterns of muscle activation related to the biomechanical requirements of the gait modification (Drew, 1993; Lavoie et al., 1995; McFadyen et al., 1999). Second, we examine how the synergies are modified when the cats step over obstacles of different shapes and sizes (Drew, 1988, 1991b, 1993). We then discuss the implications of these results for the cortical control of voluntary gait modifications.

METHODS

The methods used in this study were either identical or similar to those previously detailed (Krouchev et al., 2006) and will only be briefly described here. All animals used in this study were originally used for other studies (Drew, 1993; Stapley and Drew, 2009; Yakovenko et al., 2011). Details concerning the methods used for animal training and implantation methods in the different animals used in the current manuscript can be found in those manuscripts. Details concerning the analytical methods are found in Krouchev et al. (2006).

TRAINING

Cats were trained to walk on a treadmill at 0.35–0.5 m.s^{-1}, first in the absence of any obstacles (unobstructed locomotion) and then in the presence of 1 or 2 obstacles attached to the treadmill belt. In these experiments, the obstacles always moved at the same speed as the treadmill. The obstacles were visible to the cat a minimum of two steps before the step over the obstacle. Most data were obtained from studies in which the cat stepped over a cylindrical obstacle of 10 cm cross-section. Additional data were obtained during steps over a high obstacle (13 cm high, 1 cm wide), a small high obstacle (7.5 cm high, 1 cm wide) and a wide obstacle (2.5 cm high, 15 cm wide) (see Drew, 1993 and **Figure 8E**).

SURGERY

After the cats were trained, they were prepared for surgery under general anesthesia and in aseptic conditions following the protocols approved by the animal ethics committee at the Université de Montréal and according to the recommendations of the Canadian

Council for the Protection of Animals. Details for different animals can be found in the references above. Heart rate and temperature were monitored during surgery and anesthesia level was regularly verified by testing for a corneal reflex. Solutes were administered throughout the surgery and analgesics were provided prior and subsequent to the surgery.

In all animals, pairs of Teflon-insulated, braided stainless steel wires were implanted into multiple muscles of the left forelimb. Wires were led sub-cutaneously to a 51 pin connector attached to the cranium of the cat. Although other surgical procedures were practiced on these cats, they are not reported here, as they are not relevant to the data illustrated. Details of these supplementary procedures can be found in the published manuscripts (see above). All data presented in this manuscript were obtained several weeks following the surgical procedures.

PROTOCOL

Electromyographic (EMG) activity was normally recorded along with cell activity during locomotion. Data were generally recorded during unobstructed locomotion and then during periods of locomotion when cats stepped over 1 or 2 obstacles attached to a treadmill belt. EMG data were filtered at 100 Hz to either 450 or 500 Hz and amplified by a factor of 1–10 K to produce a signal of ∼1 volt. Data were digitized at 1 KHz. Video recordings of the locomotion were obtained simultaneously with the EMG data and synchronized with the aid of a SMPTE (Society of motion pictures and television engineers) digital time code.

ANALYSIS

The video recordings were initially screened for sections of stable locomotion in which the cat maintained its position in the center of the treadmill. As such, we chose sections of data in which EMG activity was uniform from cycle to cycle with no evidence of intermittent changes. We then manually marked the onset and offset of each burst of EMG activity within these sections (**Figure 1A**) and classified them as either steps over the obstacle with the left leg leading or trailing, or as unobstructed locomotion (either no obstacles attached to the treadmill or at least two steps before a step over an obstacle; see Drew, 1993). A step cycle was defined as the time between two successive periods of activity in either the brachialis (Br; **Figures 1**–**7**) or the cleidobrachialis (ClB; **Figure 8**) muscle, each of which becomes active at approximately the onset of swing. The step cycle was normalized to unity (1.0) and the onsets and offsets of periods of activity in each selected muscle were then expressed as a proportion, or phase, of the step cycle. Measured events occurring after the onset of the ClB or Br were given positive values while those occurring before ClB or Br onset were given negative values. Data were plotted in phase space in which the phase of offset of a given burst was plotted as a function of its onset (**Figures 1C**, **2A**).

Associative clustering

Trial data points are formed pairwise in the phase plane ($x =$ *onset*, $y =$ offset) and one or more bursts may be *associated* in clusters as described in Krouchev et al. (2006). It is important in this respect to realize that the data points for each muscle

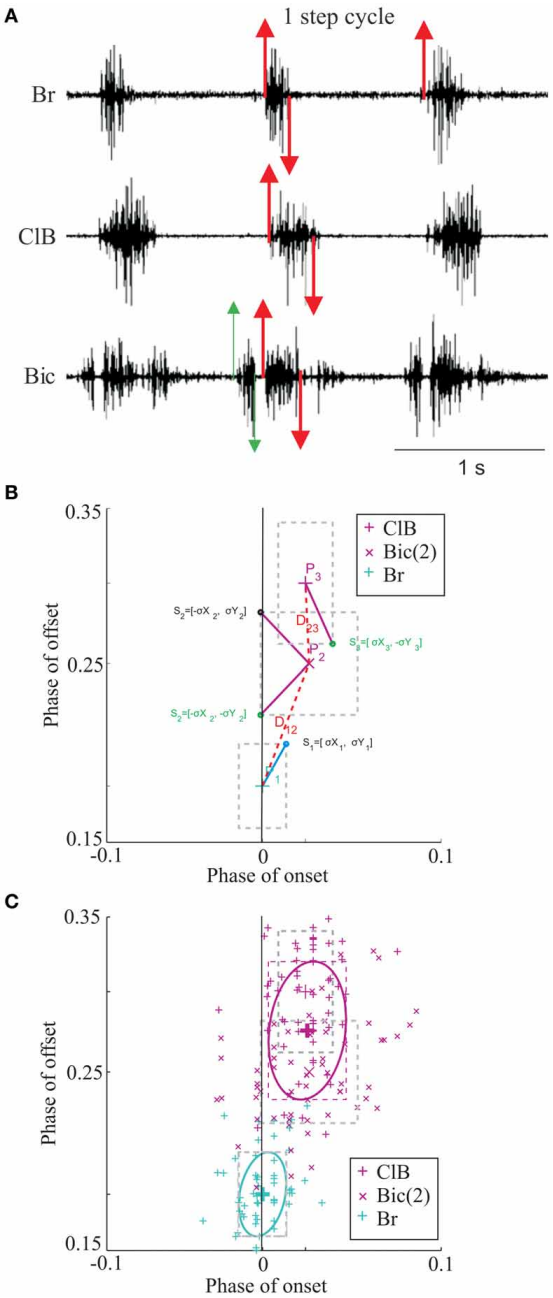

FIGURE 1 | Data selection and clustering algorithm. (A) Untreated data during locomotion from the brachialis (Br), Cleidobrachialis (ClB), and Biceps brachii (Bic) muscles. Upward and downward directed arrows indicate onset and offset of muscle burst activity, respectively. All activity was synchronized to the Br and burst onset activity is defined as phase = 0.0. A step cycle is defined as the time between two successive bursts (phase = 1.0). Activity in other bursts is defined with respect to Br onset. The red arrows indicate data illustrated in **(B,C)**. The green arrows define the first burst of activity in Bic [Bic(1) in **Figure 2**]. **(B)** The rectangles define 1SD of the mean onset and offset of the activity of each muscle (P1–P3, individual data illustrated in **C)**. A vector is drawn from the center of each rectangle to the vertex closest to the center of the nearest neighbor (thick lines, Sn). The vector distance (dotted line: Dn) is then calculated as described in the text. **(C)** Bivariate ellipses are drawn around the centroid of each cluster (see text). Same dataset as in **Figure 2**.

are defined as belonging to that muscle and cannot be divided among different clusters. In the clustering algorithm, it is assumed that each burst is fully described by its centroid—i.e. the mean (onset, offset) phase vector, and the associated pair of standard deviations (SD's: σX, σY; assumed uncorrelated). Hence, each burst is assumed equivalent to the encompassing rectangle $[-\sigma X, \sigma X] \times [-\sigma Y, \sigma Y]$ around the centroid mean values $[X, Y]$ (**Figure 1B**).

Sufficiently overlapping rectangles form clusters, or synergies (Krouchev et al., 2006). Thus the algorithm associates sets of data points from different muscles rather than dissociating them as do most clustering methods.

First, the individual data points are tested for outliers using Rosner's test (Rosner, 1983) with a 2 SD margin. For each burst $\boldsymbol{i}$, the phase-plane vectors of mean phase:

$$P_i = (X_i, Y_i) = mean\left(onset_i, offset_i\right)$$

and of standard deviations

$$S_i = (\sigma X_i, \sigma Y_i) = std\left(onset_i, offset_i\right)$$

are calculated. The distance between two bursts $\boldsymbol{i}$ and $\boldsymbol{j}$, is expressed as the phase-plane vector (**Figure 1B**):

$$D_{ij} = P_i - P_j$$

Two bursts are considered part of the same cluster when:

$$q_{ij} = max\left\{\left(P_i \pm S_i\right) D_{ij} + \left(P_j \pm S_j\right) D_{ij} - ||D_{ij}||^2\right\} / ||D_{ij}|| > 0 \quad (1)$$

where the maximum is taken over all possible combinations (**Figure 1B**), the products are the dot (scalar) vector products, and $||\cdot||$ is the usual Euclidean norm in the xOy phase plane.

For all possible pairs of bursts $\boldsymbol{i}$ and $\boldsymbol{j}$ $(i = 1, 2 \ldots, n, j = i + 1, \ldots, n)$— where $\boldsymbol{n}$ is the total number of bursts to classify, Equation (1) is verified and thence a boolean $\boldsymbol{n} \times \boldsymbol{n}$ upper-triangular adjacency matrix $\mathbf{B}$ is obtained ($\mathbf{B}_{ij} = 1$ when $\mathbf{q}_{ij} > \mathbf{0}$, and zero otherwise). The latter adjacency matrix is then the input to a Matlab implementation of an algorithm due to Press et al. (1992) to determine the equivalence classes—i.e., the clusters. The final cluster numbers are rearranged so that their mean onsets proceed in an ascending order.

The clustering proceeds in two sub-stages. First, we cluster the bursts coming from the first (and most elaborate and ample) subset of the data—coming from the same animal. In the second sub-stage, additional bursts (coming from additional animal data sets) are either allowed to join an existing cluster, or to form a new one. In cases in which the existing cluster has more than one member, the new candidate burst will join if it overlaps with at least two bursts from the existing cluster. It should be noted that this associative clustering method is robust to even relatively large changes in the centroids of EMGs making up a cluster. In a previous publication (Krouchev et al., 2006; supplemental information), we tested the stability of the methods by introducing random jitter to the centroids of the muscles making up a cluster. In 970/1000 cases in which each centroid was displaced by <0.6 SD, there was no change in cluster composition compared to that obtained using the actual data.

CONSTRAINED vs. UNCONSTRAINED CLUSTERS

In the analysis in our original papers (Krouchev et al., 2006; Drew et al., 2008a) the algorithm was always unconstrained in that muscles were formed into clusters, and therefore synergies, simply on the basis of the rules summarized in the preceding paragraph. A similar approach was used to obtain the synergies active during unobstructed locomotion (**Figure 2**) as well as during the lead and trail conditions of the voluntary gait modifications. However, because of the addition of periods of muscle activity that occurred only during the gait modifications, and because of the relative changes in phase of some muscles, there were small changes in the composition of some of the synergies. This makes a direct comparison of changes in the phase and magnitude of synergies during all three conditions problematic. We, therefore, also used a constrained analysis in which muscles bursts were confined to the same clusters identified during unobstructed locomotion. This allowed us to directly compare the changes in phase and magnitude of synergies comprised of the same muscles in all three conditions. Further details of the approach and of its limitations are provided in the Results and Discussion.

Direct component analysis (DCA)

For each cluster we derive a temporal activation profile, which is labeled a *direct* component (DC). The latter contrasts to the muscle activation components in the literature, which most often are obtained through abstract mathematical decomposition.

DCs are derived directly from the corresponding overall (onset, offset) phase statistics, which describe the periods of activity of the muscles (or bursts) forming the cluster. For each cluster, we calculate the 2 *marginal univariate* Gaussian probability density functions (pdf) for the onset and the offset phases. For each cluster $\boldsymbol{k}$, the onset/offset pdf is, respectively, $N(X_k, \sigma X_k)$ and $N(Y_k, \sigma Y_k)$ and activation of the muscles forming this cluster is assumed to span the phase interval $(X_k - 3\sigma X_k, Y_k + 3\sigma Y_k)$.

We further assume that the overall shape of the temporal activation profile for cluster $\boldsymbol{k}$ is captured by Gaussian basis-functions. Hence its DC $\boldsymbol{u_k(t)}$ is described by:

$$u_k(t) = \begin{cases} \exp\left(-(t - Z_k)^2 / 2\sigma_1\right), & t < Z_k \\ \exp\left(-(t - Z_k)^2 / 2\sigma_2\right), & t > Z_k \end{cases}$$

where

$$Z_k = (X_k + Y_k)/2, \sigma_1 = (Z_k - X_k)/3 + \sigma X_k, \text{ and}$$
$$\sigma_2 = (Y_k - Z_k)/3 + \sigma Y_k$$

Cluster statistics and representation

In this paper we use a correlated bivariate-normal model. The data scatter for burst $\boldsymbol{k}$ is captured by the pdf:

$$f\left(x, y\right) \sim \exp\left(-z/2w\right) \quad (2)$$

where:

$$z = u^2 + v^2 - 2\,uv\rho \quad w = 1 - \rho^2$$
$$u = (x - X_k)/\sigma X_k \quad v = \left(y - Y_k\right)/\sigma Y_k$$

Hence, each cluster is represented by an ellipse of the form:

$$u^2 + v^2 - 2\,uv\rho = 1 - \rho^2 \tag{3}$$

The ellipses' skewing and orientation depend on the value of $\boldsymbol{\rho}$. Krouchev et al. (2006) assumed no (x,y) correlation—i.e., $\boldsymbol{\rho} = 0$. This yielded ellipses with major axes, respectively (σX, σY), parallel to the coordinate axes. For the general case of non-zero $\boldsymbol{\rho}$, it may be shown that the ellipse described by Equation (3) touches the $\pm 1SD$ encompassing rectangle exactly at the points ($\pm\mathbf{1}$, $\pm\boldsymbol{\rho}$) and ($\pm\boldsymbol{\rho}$, $\pm\mathbf{1}$) (**Figure 1C**).

Statistics

To determine whether the phase and/or the magnitude of the synergies were significantly different in each condition we used ANOVAs across the conditions (unobstructed, lead and trail). Individual One-Way ANOVA's were performed for each of the synergies using the data for the individual periods of activity of each muscle within a synergy. Tests for difference in the phase of activity were made using the onset $\sim N(X_k, \sigma X_k)$, the offset $\sim N(Y_k, \sigma Y_k)$ and the peak phase $(X_k + Y_k)/2$ of activity. The null-hypothesis for each ANOVA is that condition has no significant effect on the range of phase-values in the sample. For synergies that showed a significant ($p < 0.05$) effect of the locomotion condition, we performed pair-wise t-tests between conditions. Individual One-Way ANOVA's were also performed to determine if the magnitude of the synergies also varied as a function of condition (see Results).

RESULTS

DATABASE

The database for the principal analysis in this paper is based around cat RS26, as in a previous publication (Krouchev et al., 2006) examining synergies during unobstructed locomotion. Supplementary muscles in that previous publication were obtained from 3 other cats, PCM3, MC8 and RS23. Ideally, we would have used the same database in the current manuscript. Unfortunately, however, data for voluntary gait modifications were not available from all animals. We have, therefore, complemented the data from RS26 with data from cats MC29 and RS23 for the current analysis to produce a full dataset during unobstructed locomotion consisting of 27 bursts of EMG activity from 18 muscles of the forelimb, all recorded on the same side. The 10 clusters defining the muscle synergies in this dataset during unobstructed control locomotion are illustrated in **Figure 2** and the average activity of some of these muscles can be observed in **Figure 3** (black lines). Note that the clusters defined in the present analysis are very similar to those published previously (Figure 6 in Krouchev et al., 2006). The major difference is that the current dataset produced 10 clusters of activity rather than the 11 that we defined previously. This was primarily caused by the muscles in cluster #2 forming a single cluster (including EDC, LtD and TrM) rather than being divided into 2 clusters as in our previous analysis. One other difference is the presence of a very early burst of activity in the Bic, preceding activity in all other muscles. Apart from these minor differences with our previously described dataset (Krouchev et al., 2006), the essential features of these synergies are maintained. These include: the sequential pattern of activation of the synergies; the sparse nature of each synergy; the fact that a given muscle may be represented in more than one synergy and the fact that a given synergy can include muscles acting proximally together with others acting distally (e.g., EDC and TrM in cluster #2).

CHANGES IN PHASE OF SYNERGIES DURING GAIT MODIFICATIONS (LEAD AND TRAIL CONDITIONS)

During the gait modifications, there were substantial changes in the magnitude and phase of some of the bursts of EMG activity as we have also described elsewhere (Drew, 1993; Lavoie et al., 1995; Drew et al., 2008a). The changes observed in selected muscles of the current dataset are illustrated in **Figure 3** for the lead and trail condition. The EMG data for all muscles are normalized in time to the average cycle duration for the original dataset in which they were recorded, and normalized in amplitude to the largest magnitude recorded from any one given muscle. As such, changes in amplitude and relative changes in phase are clearly visible in the presentation. Several points need to be emphasized. First, in both conditions, there are changes in amplitude and phase in a number of muscles. During the lead condition, these changes are primarily expressed as changes in amplitude (e.g., Br and BrR) with fewer changes in phase, although see phase delay in EDC. In contrast, during the trail condition, there are major changes in both phase and amplitude in a number of muscles. This is particularly clear in the shoulder retractor muscles (LtD and TrM) and in the muscles acting around the wrist and digits (PrT, EDC). Last, one other major difference from the control activity is the presence of periods of activity during the gait modifications (**Figure 3**, arrows) that were not present in the unobstructed condition. The clearest examples are the supplementary periods of activity in the EDC, SpD and the Tri at the onset of swing in the trail condition. There are also small changes in some of the extensor muscles. These occur after the step over the obstacle in the lead condition and before the step over the obstacle in the trail phase.

In general, most of the changes in phase of the muscles active during swing occur during the trail condition, before the onset of swing (defined here as Br onset) while the more modest phase changes in lead occur after swing onset. As discussed previously (Drew, 1993; Lavoie et al., 1995; McFadyen et al., 1999), this difference is related to the constraints of the task. During the lead condition, swing begins with the obstacle well forward of the paw and the major requirement is to lift the limb above and over the advancing obstacle. During the trail condition, swing begins with the obstacle close to the trail paw and the major requirement is to retract the limb sufficiently to ensure that the limb is lifted away and above the obstacle as it continues to advance (see Drew, 1993).

To determine the effects of the changes in the pattern of muscle activity on synergy composition, we performed the cluster

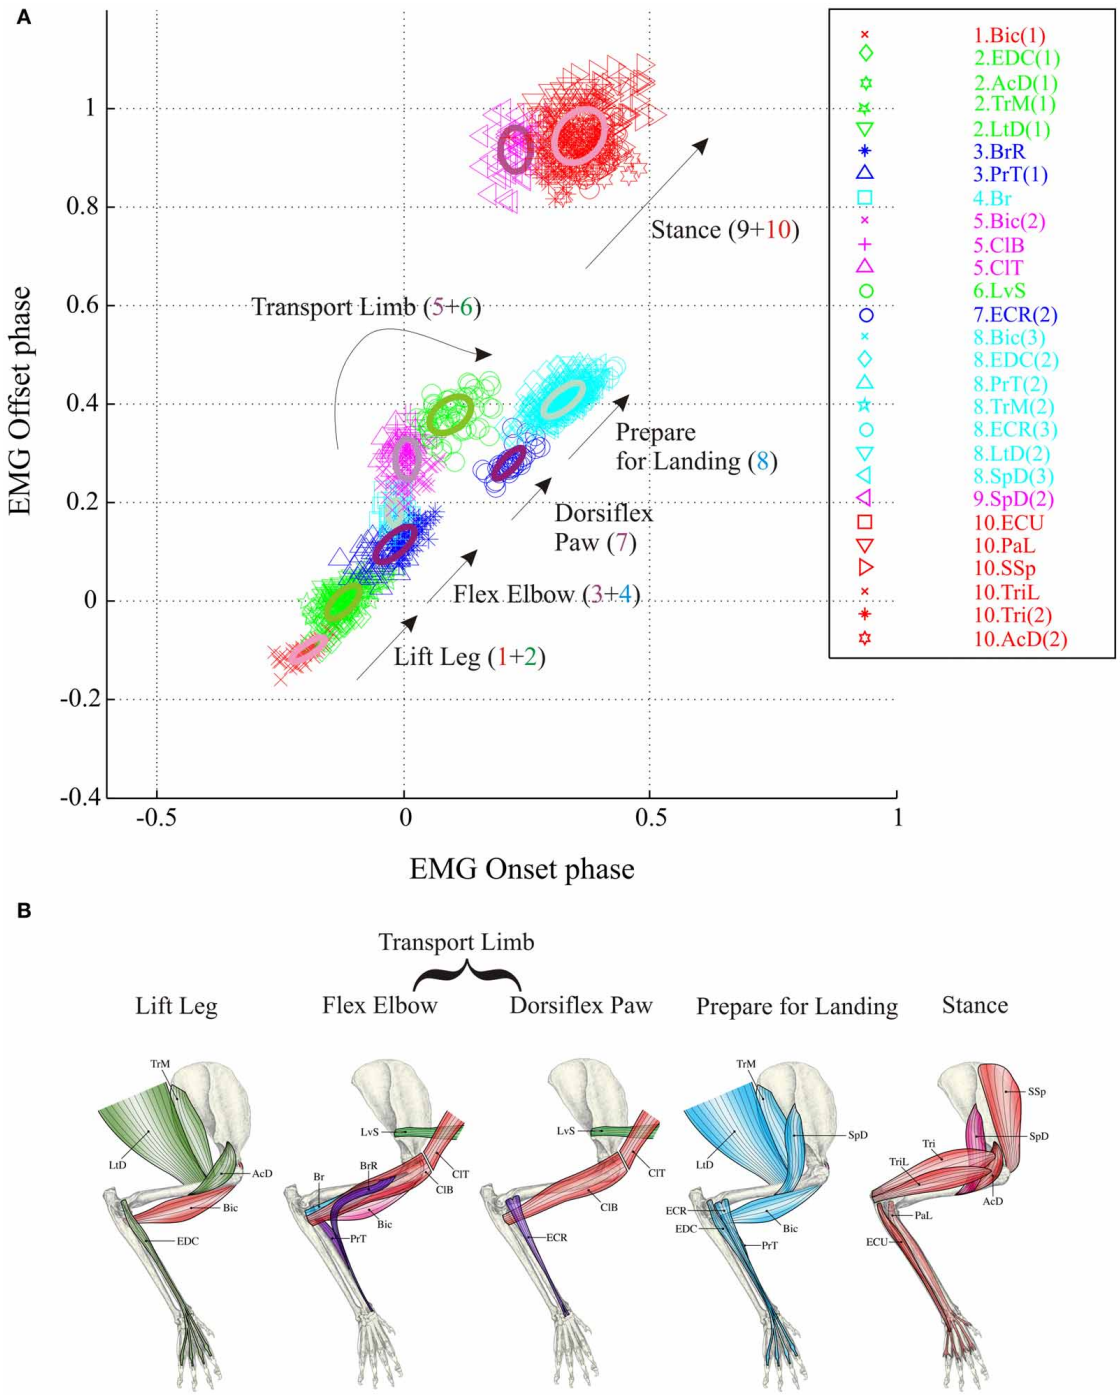

FIGURE 2 | Synergies during unobstructed locomotion. (A) The results of the cluster analysis are illustrated for a total of 27 periods of EMG activity recorded from 18 muscles in 3 cats (30–70 values for each muscle burst). 10 clusters, each corresponding to a muscle synergy, are identified by color and the EMG bursts in each cluster are identified by symbol and color as shown in the key to the right. The same order of muscles is used in the key of all figures except when a change in synergy composition makes it impossible. The spatial location of each cluster is illustrated by the ellipses (thick lines). EMG onsets and offsets are referenced to the onset of activity in the brachialis (Br) muscle (phase = 0.0). Negative phase onsets indicate muscle bursts active prior to the onset of activity in the Br. **(B)** the muscles used in this study are illustrated on stick figures of the cat's forelimb taken from Crouch (1969). Clusters are organized according to the biomechanical function and the colors of the muscles correspond to the colors of the synergies. Note that colors accorded to some muscles are different from those used in Krouchev et al., 2006 because of a slightly different composition of the synergies (see text). Muscle Abbreviations: AcD, acromiodeltoideus; BrR, brachioradialis; ClT, cleidotrapezius; ECR, extensor carpi radialis; EDC, extensor digitorum communis; ECU, extensor carpi ulnaris; LtD, latissimus dorsi; LvS, levator scapularis; PaL, palmaris longus; PrT, pronator teres; SpD, spinodeltoideus; SSp, supraspinatus; Tri, triceps bacchii, long head; TriL, triceps brachii, lateral head; TrM, teres major.

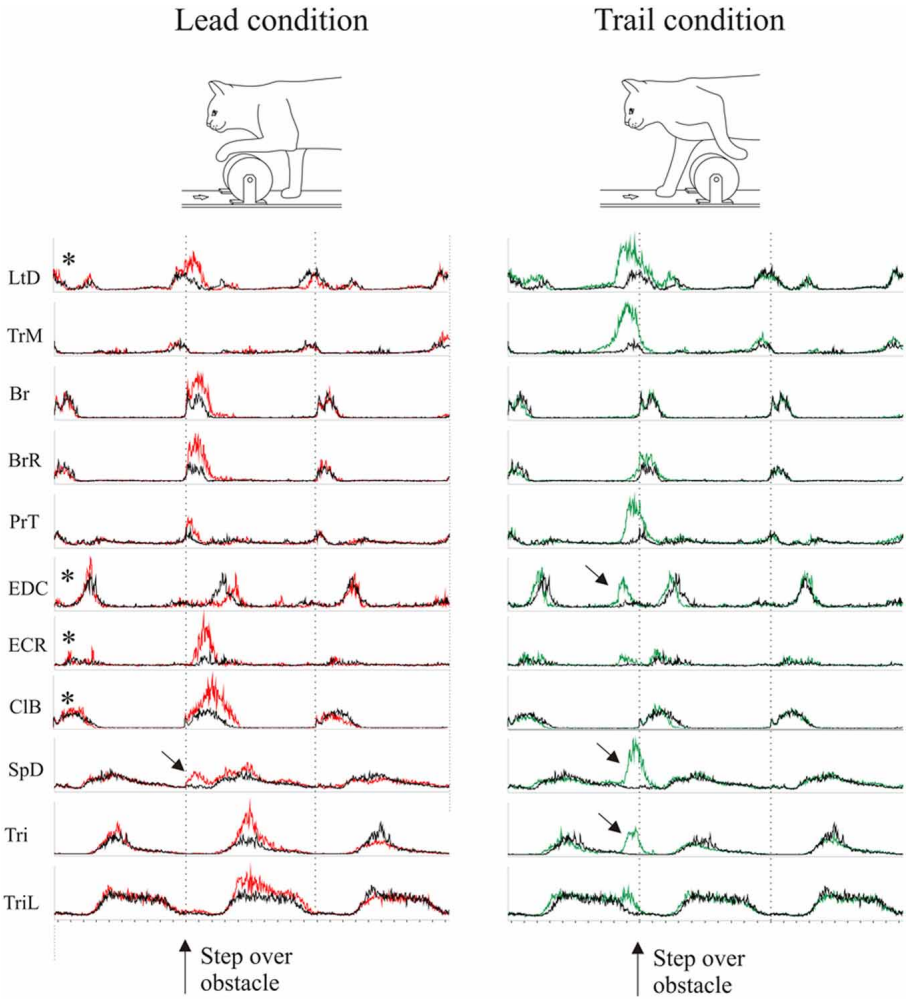

FIGURE 3 | Averaged EMG activity during voluntary gait modifications. The figure shows the activity of 11 representative muscles during the lead (left column, red traces) and the trail (right column, green traces) condition. Average activity during gait modification is superimposed onto the activity in the unobstructed condition (black traces). Data are synchronized to the onset of the Br and the duration is normalized to the average control step cycle duration. The amplitude of the activity in each EMG is scaled to the same value for all three traces (lead, trail and unobstructed). EMG traces with an asterisk are taken from cat MC29, those without an asterisk are from cat RS26. Arrows indicate bursts of activity that were not present in the unobstructed condition.

analysis on the datasets for the voluntary gait modifications (lead and trail conditions) using all available bursts of EMG activity including those that were present only during the voluntary gait modifications (**Figure 4**). As explained in the Methods, we used two complementary approaches to examine changes in synergy. In the first instance, we applied the clustering algorithm to the entire dataset in the lead and the trail condition in exactly the same way as we did for the unobstructed data. We refer to this as the unconstrained condition (**Figures 4A,B**). In this approach, we are effectively asking whether the same synergies are found in all three conditions studied, unobstructed, lead and trail. In the second approach, and the one that we used for all further analyses, we constrained the synergy composition during the lead and trail conditions to be identical to that observed in the unobstructed condition (**Figures 4C,D**). In this instance, we are determining how the phase of the synergies identified during unobstructed locomotion needs to be modified in order to obtain the patterns of activity observed during the gait modifications. In this second approach, we used the adjacency matrix to determine to which cluster the bursts activated only during the gait modifications were associated. This, constrained, approach has the advantage of allowing us to provide a direct comparison of the changes in phase and magnitude that occurred in each synergy during these gait modifications.

The results obtained by using the unconstrained algorithm show that the muscles bursts observed during the voluntary gait modifications are organized into synergies that are fully consistent with those observed in the unobstructed condition. Specifically, the analysis results in the presence of a similar number of synergies as in the unobstructed condition, with the same sequential organization as in unobstructed locomotion and with each synergy being comprised of a small number of muscles (**Figures 4A,B**).

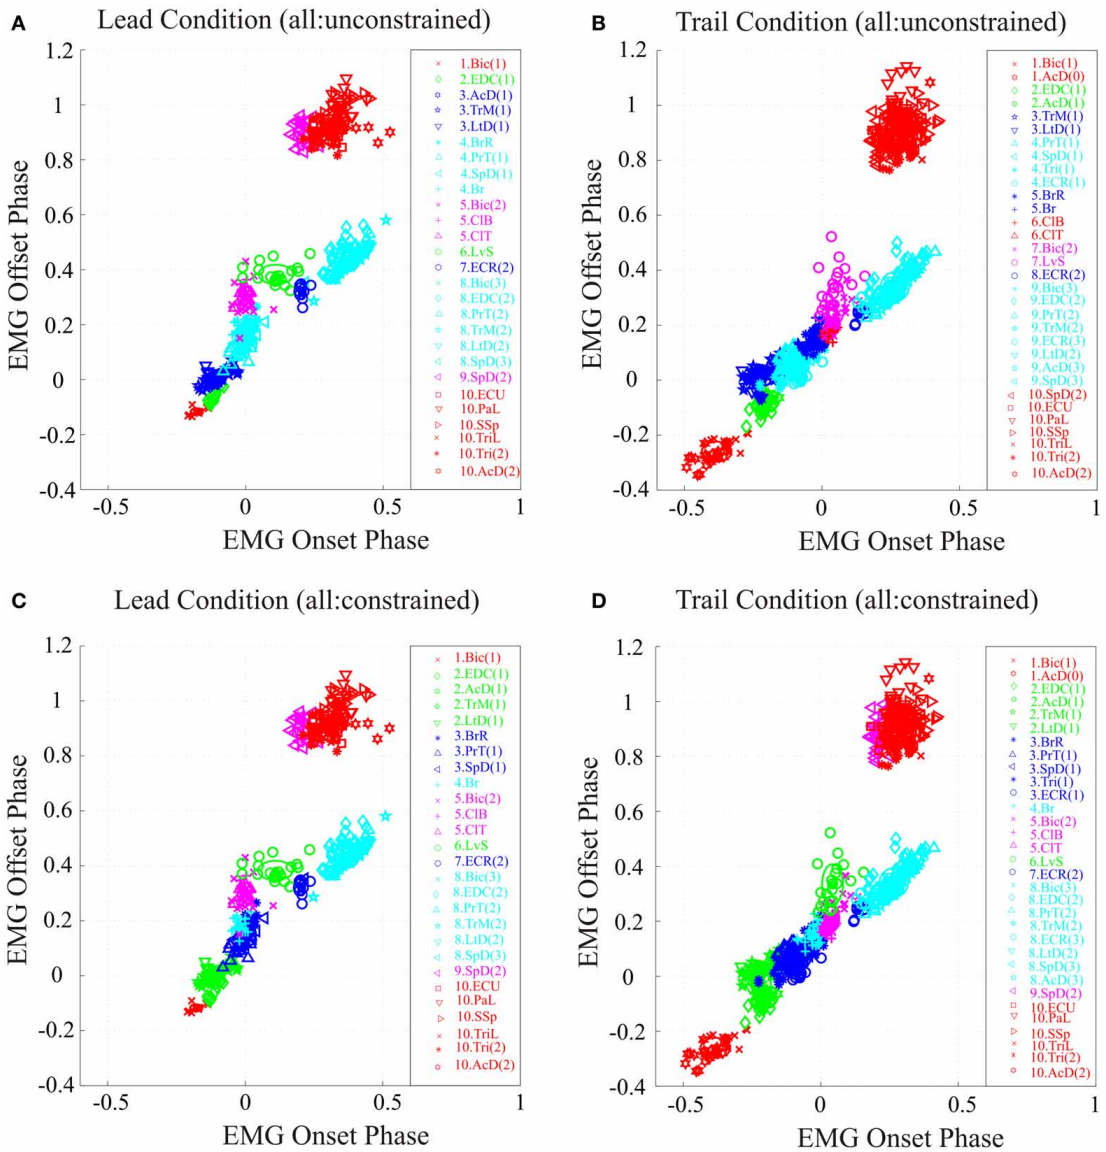

FIGURE 4 | Synergies during the lead and trail conditions. (A,B) clusters formed by applying the analysis to all bursts recorded in each condition and allowing the analysis to define the resulting clusters (unconstrained). **(C,D)** analysis performed using all bursts but with the clusters constrained to have the identical composition as in the unobstructed condition (**Figure 2**). Note that in the unconstrained condition, the colors describing some clusters are different from those used in **Figure 2** because of the modification of synergies detailed in the text. In the constrained condition, the colors are identical to those used in **Figure 2**.

However, there were some differences in cluster composition, compared to the unobstructed condition as can be seen by examining the legend identifying the clusters in **Figures 4A,B**. These differences are illustrated in more detail in **Figure 5** where the synergies identified during the swing phase in the unconstrained condition (thin ellipses) are compared to those obtained in the constrained condition (thick ellipses) for the lead (**Figure 5A** and trail (**Figure 5B**) conditions (see also **Table 1**).

In the lead condition, there were only minor changes between constrained and unconstrained synergies as can be seen by the overlap of the ellipses representing the synergies obtained in the two conditions (**Figure 5A**) and by inspection of **Table 1A**. Indeed, 7 of the 10 clusters showed no changes at all in the two conditions (**Table 1A**). Among those clusters that were modified in the two conditions, the largest change was the division of cluster #2 (as defined in the unobstructed condition) into 2 clusters in the unconstrained condition. This was because of a slight phase advance of the EDC(1) burst with respect to the other three muscles in the cluster. Note, however, that even for this relatively large modification in phase, the change in centroid position of the EDC (0.059) was substantially less than the distance between the centroids of clusters #1 and #2 (0.13) and between clusters #2 and #3 (0.19) in the constrained condition. In addition, the Br was included in a cluster with the PrT and the SpD instead

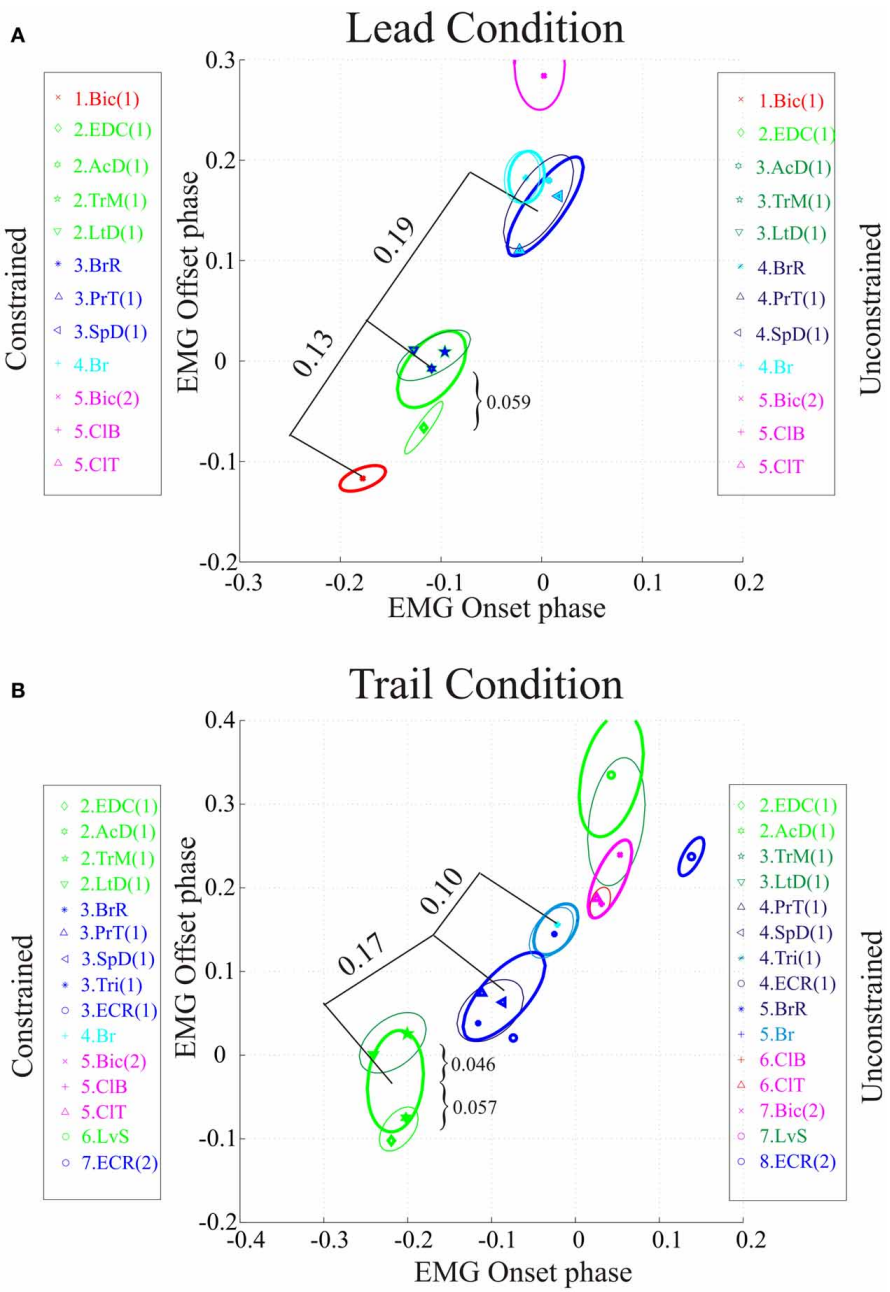

FIGURE 5 | Comparison of synergies in the constrained and unconstrained conditions. Data are illustrated for the first 5 clusters in the lead condition **(A)** and for clusters 2–8 in the trail condition **(B)**. Ellipses indicating clusters calculated using the constrained condition are illustrated as thick lines and those from the unconstrained condition as thin lines. Each symbol represents the centroid of a burst of activity in a given muscle as indicated by the key for the constrained condition (to the left of each illustration). It should be emphasized that the location of the centroid of each muscle is identical for the constrained and unconstrained condition. Numerical values on the plots indicate the Euclidean distance between the centroids of adjacent constrained clusters (straight lines) or, in **(B)**, between the centroids of the constrained and unconstrained clusters ({). Cluster #1 in the trail condition is not displayed because of the scale used. Note that the colors identifying each muscle and each ellipse are the same for the constrained and unconstrained conditions and identical to those used in **Figure 2**. As a result, muscles with the same colors sometimes belong to different clusters in the unconstrained condition (see key).

of being separate as in the unobstructed condition. This cluster in the unconstrained condition was only displaced by 0.008 from the location in the unconstrained condition (**Table 1A**). Despite these small changes in the unconstrained condition, it is evident that the basic elements of the synergies identified in the unobstructed condition are equally visible in the step over the obstacle.

Similar qualitative changes were seen in the trail condition as can be seen in **Figure 5B**. Again, the muscles comprising cluster

*The tables show the differences in the phases of the centroids of the constrained and unconstrained clusters as illustrated in **Figures 4**, **5**.*

#2 in the unobstructed condition were divided, this time into 2 groups of 2. Both clusters, however, remain well separate from the next cluster in the sequence. For example, the differences of the two unconstrained clusters (#2 and #3) from constrained cluster #2 was 0.057 and 0.046, respectively (**Table 1B**), while the distance between constrained clusters #2 and #3 was 0.17, three times as large. (The distance between cluster #1 and cluster #2 was 0.29). There were also changes in the other clusters, but in all cases, these involved the transfer of one muscle from one cluster into an adjacent cluster without change in the overall sequential nature of the activation of both individual muscles and clusters. In other words, in both the unobstructed condition and during the step over the obstacle, activation of e.g., LvS, follows activation of ClB and ClT, which follow activation of Br, which follows activation of PrT and SpD . . . etc.

Overall, the underlying principle of sequential activation of sparse synergies is well supported by the analysis (see Discussion). In particular, the analysis serves to illustrate that the synergies observed during the voluntary gait modifications are fully consistent with those observed during the unobstructed condition. More specifically, they serve to illustrate that the changes in the pattern of EMG activity that results in the modified limb trajectories required to step over the obstacles can be produced by changing the phase of activity of the synergies that underlie the EMG pattern during unobstructed locomotion.

To directly compare the phases of activity of the synergies in the lead and trail conditions with those identified during the unobstructed condition, we transformed the clusters obtained by using the constrained analysis into DCs, centered on the centroids of each cluster (**Figures 6A–C**) as described in the Methods (see also Krouchev et al., 2006; Drew et al., 2008a). These DCs, for each of the three conditions, are shown superimposed in **Figure 6D**, which allows the changes in phase of activation of each group of synergies to be synthesized in an economical manner. Changes in amplitude are ignored in this display but are addressed below. During the lead condition (red traces) the changes in phase are relatively minor apart from the phase delay in clusters 7 and 8, which are responsible for the wrist dorsiflexion and the preparation of the limb for landing. There is an increase in the duration of clusters #5 and #6, which include the Bic and the ClB (see **Figure 2**), and which are responsible for transporting the limb over the obstacle. In the trail condition, the phase advances observed in the activity of individual muscle bursts (**Figure 3**) have a substantial effect on the phase activity of a number of different synergies, and particularly those active prior to the onset of swing (i.e., Clusters #1–3). Note that treating cluster #2 as separate clusters as suggested by **Figures 4A,B**, **5** does not change the basic conclusion of a phase advance of muscle activity in this phase of the step cycle.

A One-Way Anova for phase of onset, phase of offset and peak phase (three different tests) as a function of locomotion condition showed significant differences for all combinations except 1 (phase of offset for synergy #9). Pair-wise comparisons of the

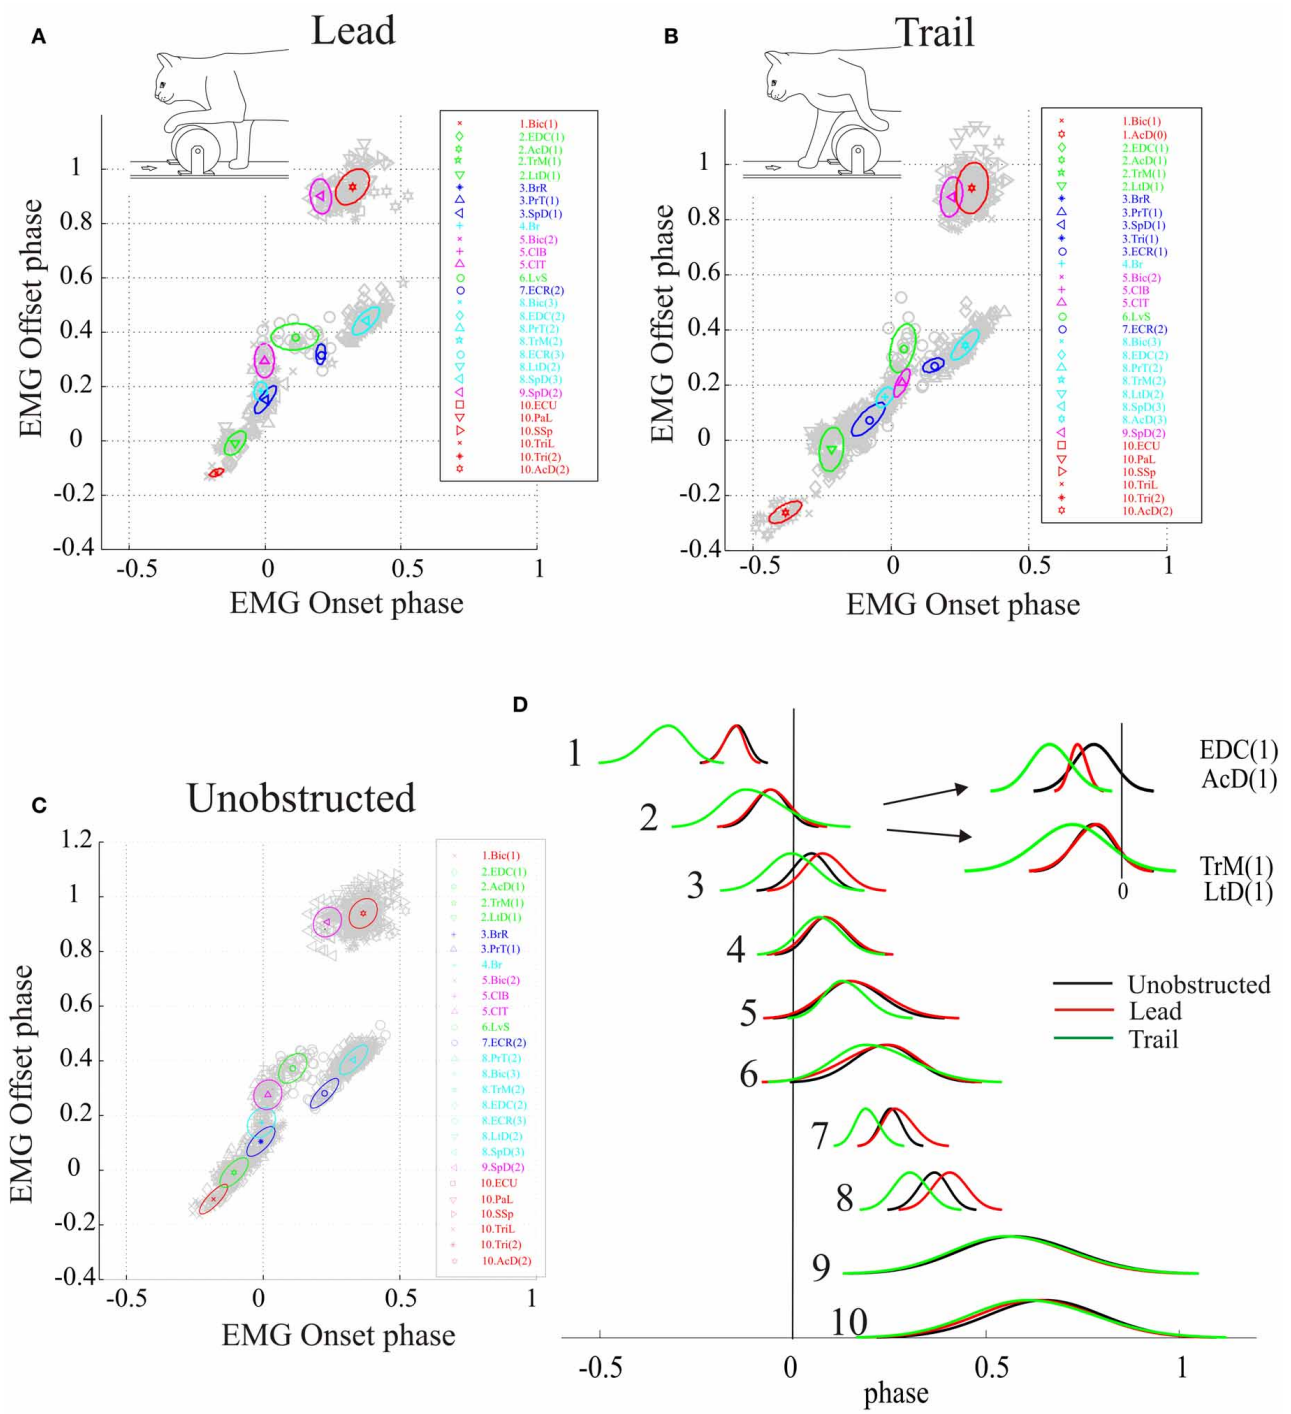

FIGURE 6 | Changes in phase of activity of synergies during gait modifications. (A–C) centroids of the synergies obtained in the lead **(A)**, trail **(B)** and unobstructed **(C)** conditions. **(D)** direct components showing the changes in phase of the synergies in the lead (red traces) and trail (green traces) compared to the unobstructed condition (black traces). The inset in **(D)** divides synergy #2 into two synergies, as suggested by the analysis in the unconstrained condition (**Figures 4**, **5**).

three conditions likewise showed significant changes of at least one of the measured variables (onset, offset, peak) for all three comparisons (control-lead, control-trail, and lead-trail). In the control-lead comparisons, phase of onset was unchanged for four synergies while phase of offset was changed for all 10 synergies, reflecting the fact that most changes occur after swing onset in this condition. In the control-trail comparison, phase of offset was unchanged in three synergies. Overall these results emphasize

that gait modifications require changes in the phase of activation of all synergies.

CHANGES IN AMPLITUDE OF SYNERGIES DURING GAIT MODIFICATIONS (LEAD AND TRAIL CONDITIONS)

We measured the magnitude of the EMG activity of each burst of activity used in the analysis for the unobstructed, lead and trail conditions by integrating each 1 ms bin of activity between the measured onset and offset of the period of activity. These values were then divided by the duration of the burst (in ms) to give a value that represents the level of activity of the muscle burst in each condition, independent of any changes in duration of the muscle activity.

The results from this analysis are shown in **Figure 7A**, with each measured EMG burst being classified according to the synergy to which it is assigned. As expected from the data illustrated in **Figure 3**, muscles such as the Br, ClB and ECR(2) show a large increase in activity (up to 200%) during the lead condition while others, such as the PrT(1), and the TrM(1) show their largest changes (up to 400%) during the trail condition. In most cases, these changes were significantly different (asterisks) from control levels in both the control and lead conditions. Furthermore, in many cases, muscle amplitudes were significantly different between lead and control. Note that changes in the magnitude of activity cannot be displayed for muscle bursts that were inactive in the unobstructed situation.

In general, changes in magnitude of muscle bursts (relative to unobstructed locomotion) for clusters comprised of several muscles (e.g., clusters 2, 5, 8, and 10) were of the same sign and of similar magnitude. For example, in cluster #2 all of the muscles in the cluster showed a significant increase in activity during the trail condition. In clusters #3 and #5, each muscle shows a significant increase in the lead condition while in synergy #10, the magnitude of muscles in the lead condition is either unchanged or shows only a small increase. Only in cluster #8, does one muscle show a significant decrease in activity during the lead condition while the other five muscles either show an increase or are unchanged. A One-Way ANOVA for the changes in amplitude as a function of condition (control, lead, and trail) showed significant changes for all 10 synergies. Comparison between the pairs of conditions showed significant changes in at least seven synergies in all three conditions.

These results indicate that the voluntary gait modifications require changes in the magnitude of muscles in most synergies and that these changes in magnitude are different for the lead and trail conditions.

To provide an illustration of how control signals would need to change in both magnitude and phase in order to produce gait modifications, we used the average value for the EMG bursts in each cluster to scale the amplitude of the DCs that we illustrated in **Figure 6**. The results from this procedure are illustrated in **Figure 7B** which serves to illustrate that the gait modifications require coordinated changes in both amplitude and phase of the synergies. In the lead condition, the changes in phase or amplitude in the first two synergies (mainly responsible for paw lift) were small. Subsequently, there were changes primarily in amplitude in synergies 3–6 that are responsible for flexing the limb above the obstacle and transporting it forwards. Subsequently in synergies 7 and 8, responsible for wrist dorsiflexion and then placement of the paw on the substrate, there are increases in amplitude and a phase delay of synergy 7. Minimal changes are observed in the subsequent period of extensor muscle activity. In contrast, in the trail condition, there are both phase advances in the first 3 clusters and an increase in magnitude in clusters #2 and 3. There are minimal changes in phase or magnitude in clusters 4–6 although the slight decrease in duration of cluster #5 leads to a phase advance of the activity in clusters 7 and 8.

EFFECT OF OBSTACLE DIMENSIONS

Changing the shape and size of an obstacle changes the limb trajectory as the cat steps over it (Drew, 1988). This implies that the relative magnitude, duration and timing of bursts of EMG activity in each synergy have to be precisely modulated to produce the appropriate limb trajectory. This is illustrated in **Figure 8** with a different cat (MC8) for which data were available from a more limited number of muscles but for a variety of obstacles (**Figure 8E**).

Figure 8A illustrates EMG activity from representative muscles during control locomotion (black trace) and during steps over a thin high obstacle (**Figure 8Eiii**) in the lead (red trace) and trail condition (green trace). As in the example illustrated in **Figure 3**, there were characteristic changes in activity with phase advance of the TrM burst prior to swing onset in the trail condition, together with an increase in EMG amplitude of the ClB and phase delay of the burst of the EDC in the lead condition. Performing the cluster analysis on the EMG activity during unobstructed locomotion (**Figure 8B**) provides the same sequential pattern of activity that was obtained with our full database, despite the smaller number of muscles bursts that were available in this cat. However, because of the smaller number of EMG bursts in this database we identified only seven synergies.

The changes in phase and amplitude in the DCs constructed from these clusters are illustrated in **Figure 8C** for the lead condition and in **Figure 8D** for the trail condition. For all of the obstacles for which data were analysed these changes are similar in form to those obtained with our main database synthesized in **Figure 7B**. Anovas showed a significant effect of both condition and obstacle on the phase and magnitude for many of the synergy. In the lead condition, the effect of obstacle was significant for synergies #3, 6, and 7. In the trail condition, there was an effect of obstacle on all seven synergies.

In general, the change in phase and magnitude were smallest for the small high obstacle (green) and largest for the very high (mauve) and round (orange) obstacles. In cluster #3, in the lead condition, for example, there is a large increase in magnitude for the very high obstacle, presumably because of the need for shoulder retraction to raise the limb above the obstacle. In clusters #4 and 5, there are large changes in amplitude and duration for the 3 largest obstacles and relatively smaller ones for the small high obstacle. In cluster #6 there are large changes for the very high and round obstacles that require the paw to be raised above the obstacles and correspondingly large phase delays in cluster #7, especially for the wide obstacle. In the trail condition, changes in amplitude of cluster #3 are particular clear for the very high obstacle and to a lesser extent in the small high and the round

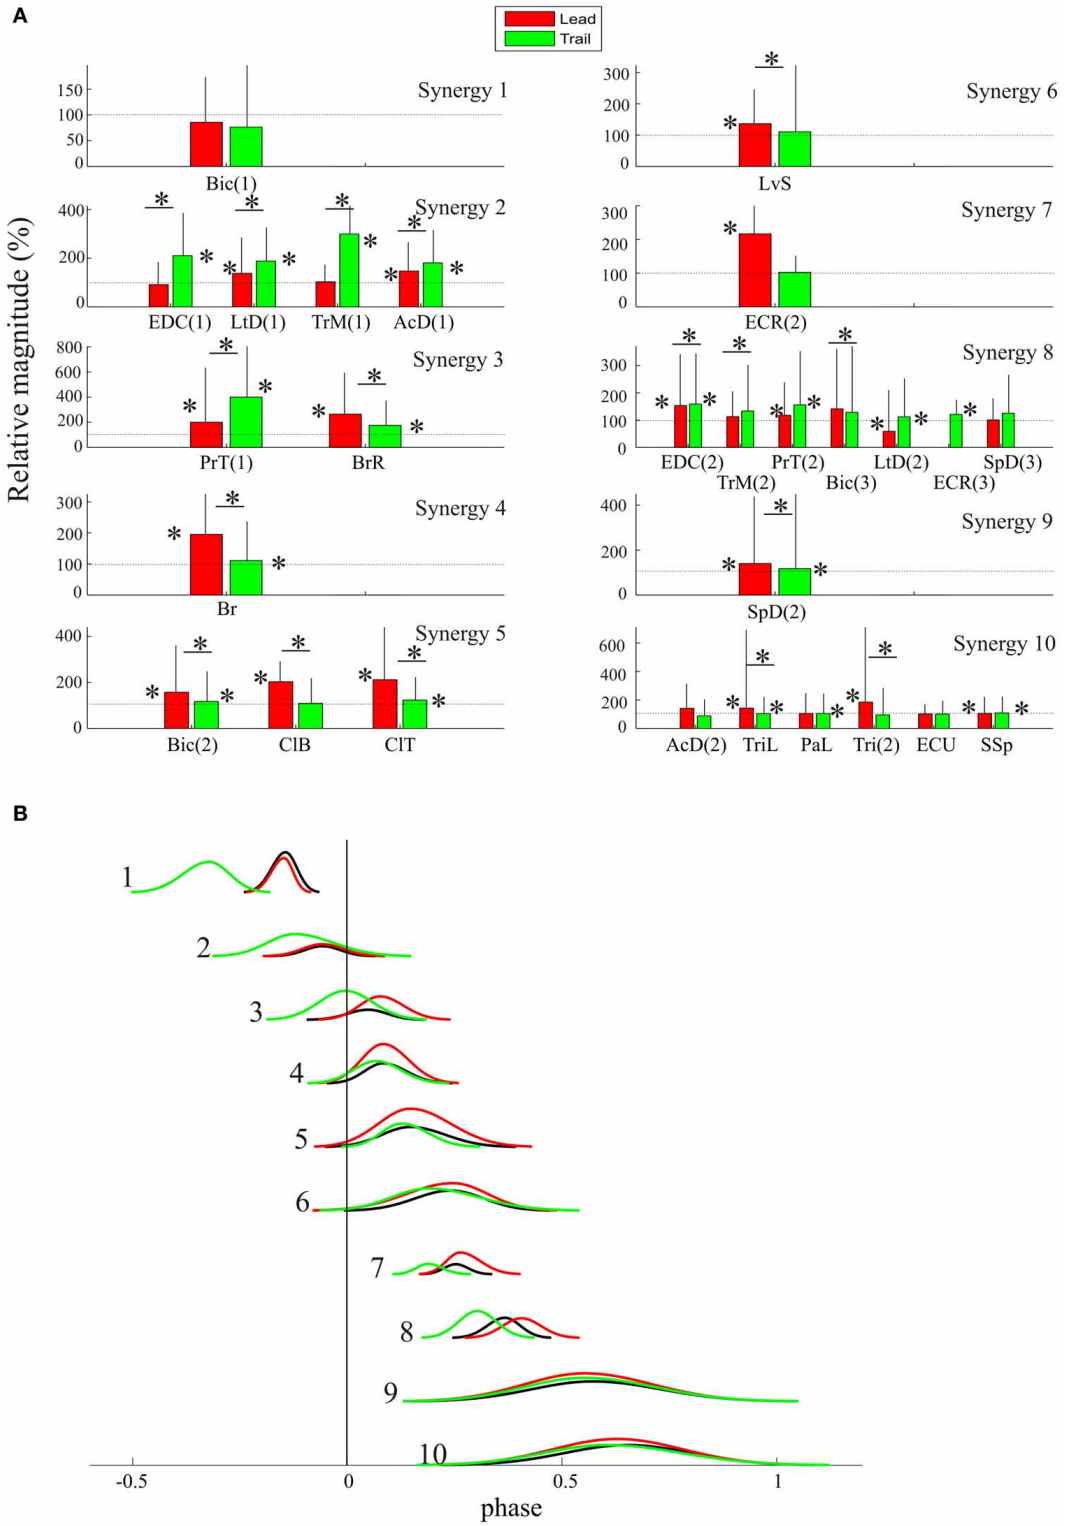

FIGURE 7 | Change in magnitude of the synergies. (A) the mean magnitude (+SD) of the activity in each muscle during lead (red bars) and trail (green bars) is expressed as a percentage of the activity in the unobstructed condition (100%, thin horizontal line). The magnitude is normalized to the duration of the burst (see text). Asterisks beside the bars indicate muscle bursts that were significantly different from control ($p < 0.05$). Horizontal lines with an asterisk indicate muscle bursts that were significantly different between the lead and trail conditions. **(B)** the average change in the level of activity from each of the synergies is used to modify the magnitude of the direct components, which now provide a representation of both the change in phase and the change in magnitude of the synergies that is required to step over the obstacles in the lead and trail condition.

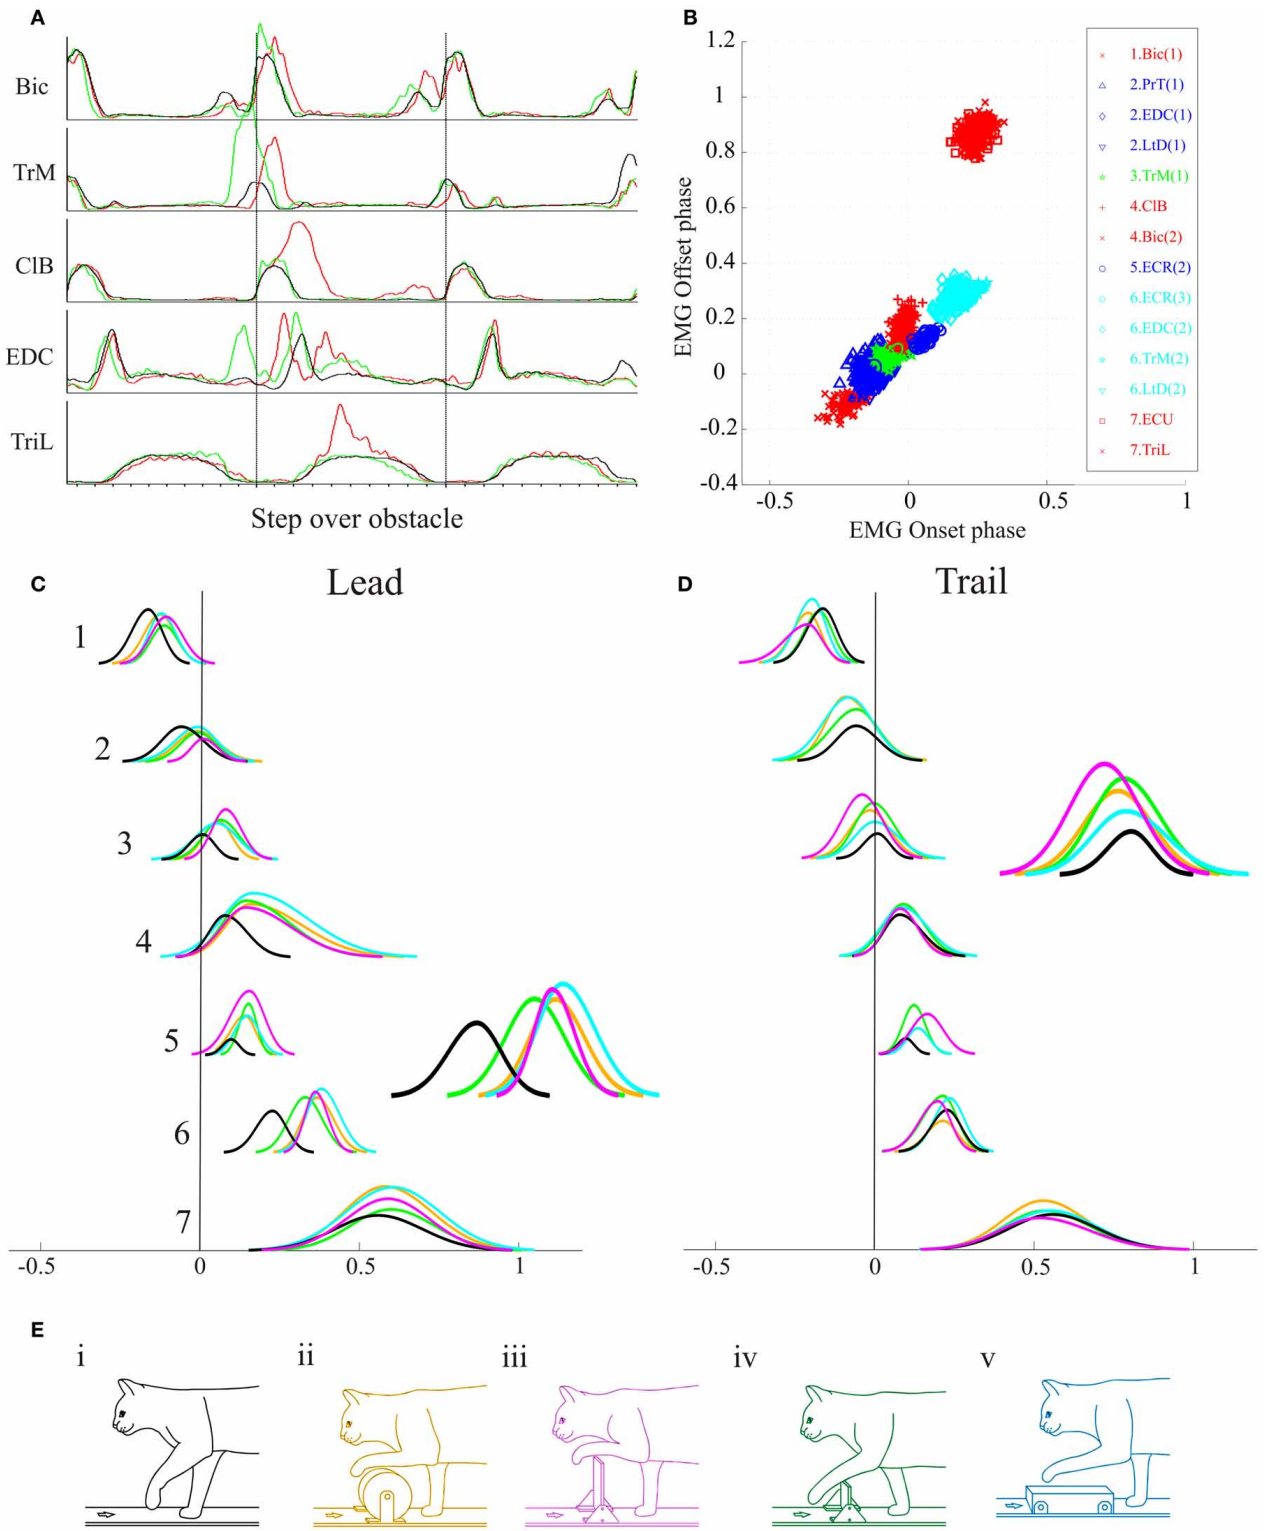

FIGURE 8 | Modification of synergies during steps over obstacles of different size and shape. (A) averaged activity of 5 representative muscles during the lead (red), trail (green) and unobstructed (black) conditions. Data are synchronized to the onset of activity in the ClB. **(B)** Cluster analysis for the database of 14 muscle bursts available from this cat. **(C,D)** direct component analysis illustrating the relative changes in phase and magnitude of each synergy when the cat steps over obstacles of different sizes and shapes in the lead **(C)** and trail **(D)** conditions. The insets amplify the traces representing synergy #6 in the lead condition and synergy #3 in the trail condition. The color code for the obstacles is represented by the color of the cats in **(E)**.

obstacle. The changes in amplitude are least for the wide obstacle (which was also the least high). These changes are needed to retract the limb above the obstacle. The changes in duration are minimal except for the ECR (cluster #6). This latter is presumably because of the greater excursion required to bring the wrist into dorsiflexion in the trail condition (Lavoie et al., 1995).

DISCUSSION

We have argued in previous publications (Krouchev et al., 2006; Drew et al., 2008a) that small modifications in the activity of the sparse synergies defined by our analysis could provide a flexible manner of producing modifications in limb trajectory during walking. The results obtained in the current study support this premise by clearly demonstrating that small changes in the phase and magnitude of the synergies identified during unobstructed locomotion can produce the changes in limb trajectory required to step over obstacles of different sizes and shapes, both in the lead and the trail condition.

SYNERGY DEFINITION AND COMPOSITION

Our definition of a synergy is a group of muscles that become active simultaneously and remain active for the same period of time. One of the results of this definition is that our synergies include only a limited number of muscles (hence sparse synergies) compared with those defined by mathematical decomposition that generally contain all muscles contained in the dataset (see below). Indeed, some of our synergies contain only a few, or in some cases, only one muscle (e.g., Cluster #7 in **Figure 2**). As we have argued previously (Krouchev et al., 2006), this is simply the result of recording a limited number of muscles and one would expect other wrist and digit extensors to be included in this synergy, if recorded. A correlate of using our definition of a synergy is that we define a relatively large number of synergies (10–11) compared to the 4–6 that are normally identified by the more commonly used decomposition methods (d'Avella et al., 2003; Tresch and Jarc, 2009). It is, however, interesting to note that synergies with similar compositions to those obtained using our methods can be obtained if the number of synergies defined by the linear decomposition methods is increased to 10 or 11 (Krouchev et al., 2006). Similarly, synergies comprised of a limited number of muscles can be obtained by other methods by including only those that show significant differences from lower amplitude weights (Hart and Giszter, 2004).

In this study we have taken the approach of defining our synergies on the basis of the muscle activity patterns generated during a single behavior, unobstructed locomotion, and then defining how these synergies must be modified to produce other behaviors. This differs from the more common approach in which synergies are defined on the basis of all behaviors under study (see e.g., d'Avella and Bizzi, 2005. In other words, most studies ask what parameters (weighting and phase) applied to all muscles in the dataset will result in all behaviors under study. In contrast, the question that we are asking is, how does one need to modify the magnitude and phase of the synergies obtained during unobstructed locomotion in order to obtain the patterns observed during voluntary gait modifications?

One of the results of defining synergies on the basis of a single behavior is the possibility that in addition to magnitude and phase, synergy composition may also be modified in other behaviors (see e.g., Ivanenko et al., 2005; Kargo and Giszter, 2000, see below). Indeed, we observed some changes in synergy composition in the unconstrained condition of our analysis (**Figures 4A,B**, **5**). This raises the question of whether the voluntary gait modifications are really the result of modifying synergies that define unobstructed locomotion or whether there is a real need to modify synergy composition as suggested by **Figures 4A,B**. In some cases, such as the division of cluster #2 in the unobstructed condition into two clusters (#3 and #4) in the voluntary gait modifications, there is reason to think that this might indeed reflect a true need to modify the synergies. In most other cases, however, such as the merging of clusters 4 and 5, it is probable that this reflects the variability in the measurements of the onset and offset of EMG activity together with the modifications of the adjacency table because of the addition of bursts of activity not present in the unobstructed condition. Certainly in the absence of additional independent methods to define synergies this must remain an open question. However, what is clear is that the basic sequential activation of the muscles bursts and resultant synergies observed in the unobstructed condition is maintained in the voluntary gait modifications. For example, all 4 of the muscles comprising cluster #2 in the unobstructed condition are activated subsequent to the activation of the Bic(1) and prior to the activation of the Prt and SpD. Moreover, all 4 of these muscles show similar changes in magnitude during both the lead and the trail condition (**Figure 7A**). Lastly, as illustrated in **Figure 6D**, treating these muscles as 2 clusters does not alter the basic facts that the muscles active at this time are phase advanced compared to the unobstructed condition. Similar considerations hold for the other synergies. For example, whether the Br forms part of a synergy with the PrT (**Figure 5A**) or is in a separate synergy (**Figures 2**, **5B**) does not change the fact that activity in both of these muscles occurs after the period of activity in the EDC and the TrM and before the period of activity in the ECR. Thus the basic concept of a sequential activation of a (relatively) large number of sparse synergies is fully supported by the data while the exact composition of each synergy must remain open to further investigation. Nonetheless, by maintaining the same number of synergies and the same composition, this approach has the advantage of allowing us to directly address some of the properties of the descending signals that would be required to modify gait by modifying the phase and magnitude of muscle synergies.

CORTICAL CONTROL OF SYNERGIES

Our results demonstrate the existence of a relatively large number of synergies, each of which is comprised of a small number of muscles (sparse synergies) and each of which is active during only a small part of the step cycle. These synergies are activated sequentially during the step cycle and show well defined modifications during the gait modifications.

In the lead condition, the major change is the increased duration and the phase delay of the synergies active at or after swing onset. These changes lead to the increased swing duration and the delayed onset of the activity of the muscles related to paw placement. There is also an increase in the magnitude of the synergy that leads to increased elevation over the obstacles. These changes in phase and magnitude are scaled to the size and the shape of

the obstacle. Wider obstacles lead to progressively increased durations and longer phase delays. Higher obstacles lead to smaller changes in duration and smaller phase delays but increased amplitude in synergies related to limb flexion. In contrast, during the trail condition, the major changes are the phase-advance and increased amplitude of the synergies active before swing onset, particularly those active at paw lift and responsible for lifting the paw above the obstacle. The data therefore illustrate how differentially modifying the activity of different synergies can lead to adaptive changes in limb trajectory that allow for avoidance of obstacles covering a relatively wide range of sizes and shapes. There seems little doubt that the phase and magnitude of these synergies could be modified to produce an infinite range of limb trajectories that could be adapted to any specific obstacle that was encountered during locomotion.

In the most parsimonious reasoning, one might expect that the activity of these synergies would be modified by control signals with similar characteristics. This is exactly what is seen in recordings from the cat motor cortex during locomotion (Drew, 1993; Drew et al., 1996, 2008a). During voluntary gait modifications, a large population of motor cortical cells (86% in Drew, 1993) show a modification in activity (increase or decrease) consisting of changes in magnitude, duration and/or the relative timing (phase of onset) of the discharge (Drew, 1993; Drew et al., 1996). Sub-populations of motor cortical cells recorded during locomotion, and particularly during gait modifications, are each activated during only a small part of the step cycle in a sequential pattern (Lavoie and Drew, 2002; Drew et al., 2008b). Examples of these activity patterns during the lead condition taken from the database used in a previous publication (Drew, 1993) are summarized in **Figure 9A** which serves to illustrate both the discrete, phasic nature of the activity patterns observed in different pyramidal tract neurones (PTNs) in the motor cortex and the sequential nature of this activation pattern. PTN1, for example, is active at the onset of the swing phase as the paw is lifted from the support surface at the onset of swing. This discharge occurs at the same time as the activity observed in muscles such as the TrM and the LtD. Subsequently, other PTNs become active coincident with the elbow flexion, characterized by activity in Br (PTN2); then with the wrist dorsiflexion, characterized by activity in the ECR (PTN3) and finally during paw placement, characterized by activity in muscles such as the EDC, TrM and the LtD (PTN4).

Particularly striking in our database (Drew, 1993) were cells whose discharge activity covaried with the first period of activity in the TrM (e.g., PTN1 in **Figure 9A**). As illustrated in **Figure 9B** these cells generally show a phase advance together with a major increase in the magnitude of their discharge in the trail condition, in the same manner as does the activity in synergy #3 (**Figures 6**, **7**), containing the TrM. Importantly, discharge activity in these cells is scaled for different obstacles in the same way as the muscle synergy.

Overall, the data from our previous recording studies suggest that there are multiple sub-populations of PTNs, each of which regulates the activity of a specific sparse synergy. We suggest that there should be as many sub-populations of cortical neurones as there are synergies. However, we emphasize that some of the neurones that we recorded did not correlate with the activity of any of the muscles recorded. Such neurones might be related to controlling higher-level aspects of the movement or may even relate to more general kinematic variables (see Morrow et al., 2007).

The changes in phase and magnitude of cell discharge frequency of the overall population of task-related PTNs suffice to modify appropriately activity for those muscles in a synergy that are active in all three conditions (lead, control, and trail). A question arises, however, as to how muscles active only during the voluntary gait modifications are controlled. This is a particularly important consideration for those muscles that are strongly activated only in the trail condition, e.g., the Tri(1) burst. There are several possible ways in which this burst could be controlled. First, it is possible that cells that contribute to the production of activity in the extensor muscles during stance would discharge an additional burst of activity in the swing phase during the trail condition and contribute to activity both during swing and stance. However, an examination of the database of cells used in previous publications (Drew, 1993; Drew et al., 1996) showed little evidence for this pattern of activity. A second possibility is that there is a separate population of cells that discharge only, or primarily, in the trail condition and are responsible for the production of these additional bursts of activity. Again, there was little evidence for this in our population. A third possibility is that the discharge activity in the population of cells that influence activity in e.g., the TrM(1) is sub-threshold to produce activity in e.g., the Tri(1) during the unobstructed and lead conditions. The large increase in activity observed in these cells during trail, however, would be sufficient to produce a (non-linear) increase in the excitation of this muscle. Such a non-linear effect might be facilitated by a change in afferent input produced by the modified movement. It is interesting to note, for example, that low intensity stimulation of peripheral afferents during the swing phase of locomotion evokes strong responses in the Tri, despite the lack of any natural activity in the motoneurones at this time (Drew and Rossignol, 1987).

In addition to issues of the characteristics of the control signal, one also has to consider the anatomical bases for the proposed control system. If a given synergy is controlled as a unit by activity in a small homogeneous subpopulation of PTNs, then one would expect one or both of the following conditions to be met: (1) given that there are no monosynaptic connections from the motor cortex to motoneurones in the cat (Illert et al., 1976), PTNs should project to interneurons in the spinal cord that selectively activate the muscles identified as belonging to a single synergy (**Figure 10A**) and/or (2) cells in the motor cortex with more restricted projections to a subset of the muscles identified as belonging to a single synergy are connected by intra-cortical connections (**Figures 10B,C**). General evidence for both of these propositions exists. The anatomical studies of Alstermark (Tantisira et al., 1996) and the electrophysiological studies of Lundberg et al. (1987) emphasize that interneurons within the spinal cord branch to activate groups of proximal and distal muscles. In addition, Shinoda has very elegantly shown that individual corticospinal axons branch to multiple levels of the cervical spinal cord (Shinoda et al., 1976, 1986; Futami et al., 1979). Together, this provides two mechanisms by which small populations of cortical neurones could activate muscle synergies.

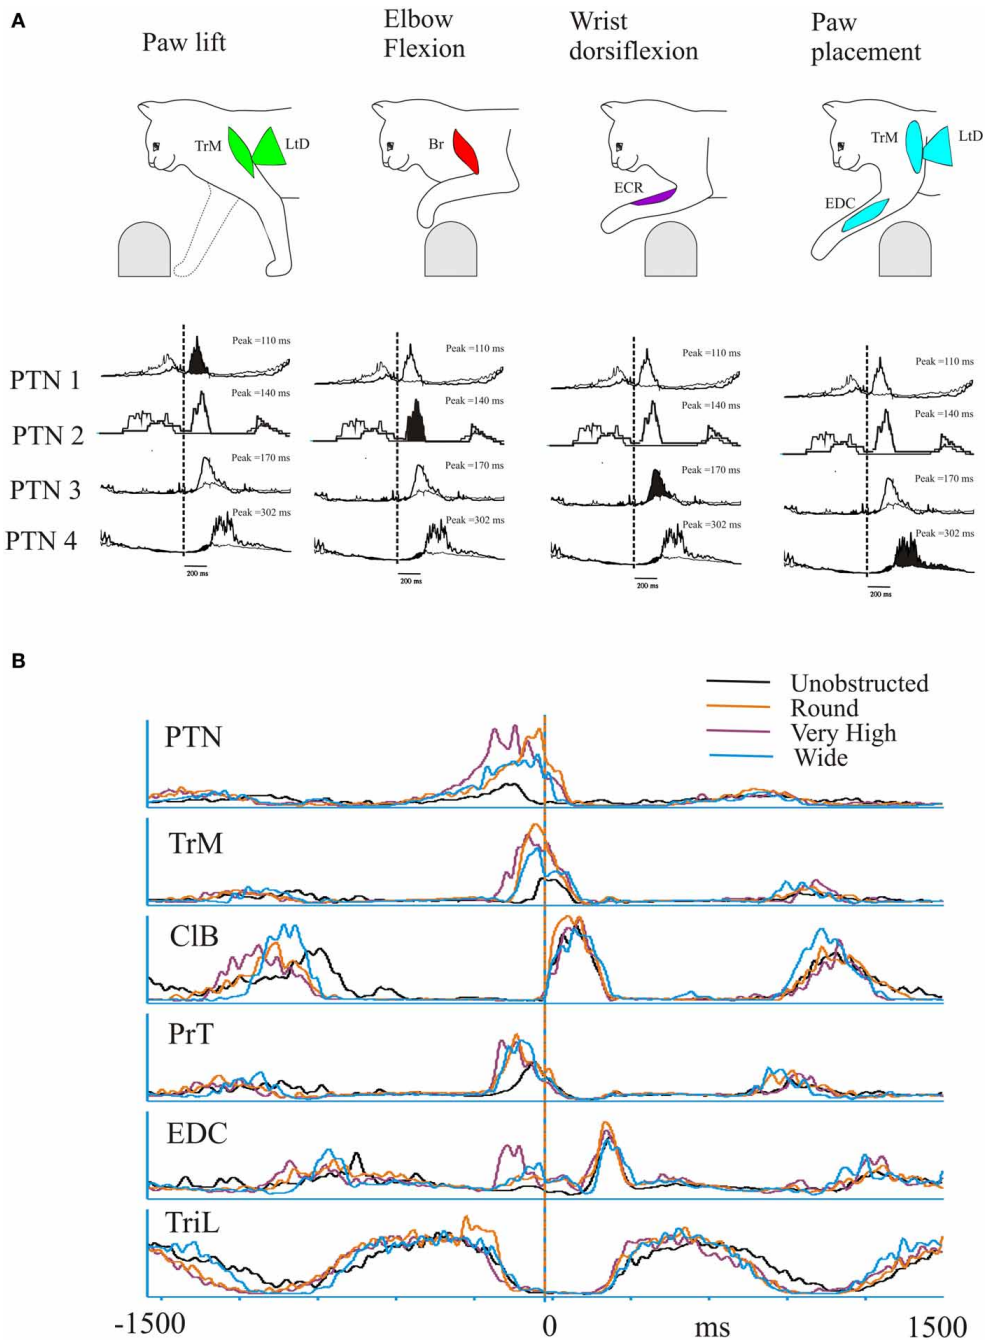

FIGURE 9 | Discharge activity of a pyramidal tract neurone (PTN) during the trail condition. (A) (top) a representation of the sequential activation of selected muscles during a step over an obstacle. Below each figurine we illustrate the averaged activity of 4 PTNs, whose activity is synchronized to the onset of activity in the CIB (vertical dotted line). Each PTN is activated sequentially (filled histogram) as the cat steps over the obstacle. (Figure adapted from Drew et al., 2008b). **(B)** We illustrate activity of a PTN (different from those illustrated in **(A)** and five representative muscles during unobstructed locomotion (black trace) and during the trail condition during steps over the round (orange) very high (mauve) and wide (cyan) obstacle. Data are synchronized to the onset of activity in the CIB and are illustrated for 1500 ms before and after this event. Note the parallel changes in the magnitude and phase of the PTN and the TrM. The data for these illustrations is taken from a previous publication (Drew, 1993).

Interestingly, Hart and Giszter (2010) have used spike triggered averaging (STA) to demonstrate that the muscles activated by a given interneurone in the frog spinal cord correlate strongly with the weighting matrix of individual motor primitives, or synergies. Furthermore, in the primate, STA demonstrates that individual corticomotoneuronal neurones in the motor cortex can influence the activity of multiple muscles including those acting at proximal and distal joints (McKiernan et al., 1998; Griffin et al., 2008).

Similarly, microstimulation of the motor cortex, particularly during locomotion (Armstrong and Drew, 1985) simultaneously activates both proximal and distal muscles. At the cortical level, there are abundant references to show the richness of the cortico-cortical connections between both adjacent and more distant regions of cortex (Huntley and Jones, 1991; Schneider et al., 2002; Capaday et al., 2009, 2011; Smith and Fetz, 2009). In addition, the motor cortex receives abundant input from premotor cortex and from the posterior parietal cortex (Ghosh, 1997; Andujar and Drew, 2007), which might also serve to coordinate activity between different subpopulations of PTNs.

Missing from the experimental data in the mammal, however, is the information as to whether the muscles linked anatomically or functionally in the studies mentioned above correspond to the synergies identified by our, or other, studies. In addition, there is no evidence of a direct link between the discharge pattern of individual cells and the muscles of the synergy that is activated or influenced by its discharge.

COMPARISON WITH OTHER MODELS OF MODULARITY

Our model shares the same basic concept proposed by Bizzi (see Introduction for references), namely that a complex series of behaviors can be produced by the differential combination of a finite number of synergies. This base concept has been tested and confirmed in a large number of behaviors as listed in the Introduction. However, the majority of these models, whether based on synchronous or time-varying synergies (d'Avella et al., 2003), propose a small number of synergies, typically 4–6, although sometimes fewer, to control a wide range of complex movements. Moreover, the control signals, represented by the waveforms resulting from the mathematical decomposition, especially those obtained using principal component analysis (PCA), are generally quite broad and occupy a large proportion of the step cycle (e.g., Lacquaniti et al., 2012) or the movement phase (e.g., Overduin et al., 2008). These control signals activate muscles according to a weighting matrix. As such, all muscles are activated to varying amounts by all control signals and the movement produced is the sum result of the muscle activation although generally a small number of muscles has relatively large weights in each synergy (see e.g., Kargo and Nitz, 2003; Hart and Giszter, 2004). Moreover, the calculation of the synergies is generally performed by including as wide a range of movements as possible to ensure that the resultant synergies are capable of reproducing a large behavioral repertoire. It is generally considered that these signals are then transformed at the level of the spinal cord to produce the appropriate periods of muscle activity (see e.g., Ting, 2007 for a schema for postural control). Some support for this view of motor control comes from recent experiments by Overduin et al. (2012) who showed that the EMG responses evoked by long trains of stimulation (150–500 ms) at distributed points in the primate motor cortex could be reduced to three synergies. Moreover, the synergies evoked by microstimulation corresponded to the synergies defined by EMG activity during reach and grasp movements.

In contrast, our approach and resulting conceptual model differs in two important considerations from those of the more commonly used methods. The first is that we use a more classical method of defining a synergy (see above) and place no limit on the number of synergies that can be defined. During locomotion, this results in the identification of 10 or 11 synergies rather than the 4–6 more commonly used. Moreover, the large number of synergies and the fact that a single muscle burst cannot be included in more than one synergy results in the sparse synergies defined in this manuscript and in Krouchev et al. (2006). These synergies occupy only a small part of the step cycle and are compatible with a control mechanism by which each synergy is modulated by a specific sub population of cortical neurones as defined in the previous section. The second difference is that we define our synergies during only a single behavior, locomotion. This is based on the premise that the neural circuits in the spinal cord primarily evolved to be optimal for producing the basic pattern of locomotion. As such, we propose that the motor cortex (and other descending pathways) act via these circuits, adapting their activity to the behavior as required. In some cases, as demonstrated here for voluntary gait modifications, modifying the phase and magnitude of these synergies is sufficient to produce changes in behavior. In other behaviors, however, the challenge might well be to modify these synergies by changing both the number and the composition of these synergies (see also Kargo and Giszter, 2000, 2008). This contrasts with the idea of a limited number of immutable synergies that can be used to produce a wide range of behaviors (d'Avella and Bizzi, 2005; Overduin et al., 2008).

Our results can also be compared to other studies and in other tasks that have specifically studied the contribution of motor cortical discharge to the control of synergies. Kargo and Nitz (2003), for example, also showed motor cortical cells that were sequentially activated in rats trained to reach. They used independent component analysis (ICA) to identify a number of synergies active throughout a reach. Cross-correlation analyses showed that a majority of task-related motor cortical cells showed a significant correlation with only a single independent component (IC). When cross-correlated with the activity of individual muscles, neurones were significantly correlated with many, although not all of the muscles included in a synergy. Miller (Holdefer and Miller, 2002; Morrow et al., 2009) also suggested the existence of a number of muscle synergies during a reaching task, with each synergy controlled by separate populations of motor cortical neurones. These synergies were relatively stable across task (Morrow et al., 2009). In our own work (Yakovenko et al., 2011), using similar methods to those in this manuscript, we have also shown sparse synergies during reaching movements that are similar to those observed during locomotion and we have suggested that PTNs in the motor cortex control the limb trajectory during reaching in the same manner that we propose for voluntary gait modifications.

The model that we propose is clearly most similar to the original modular concepts proposed by Grillner (1981). As illustrated in Grillner and Wallen (1985), we propose that descending pathways act via modules in the spinal cord to modify locomotion. We further propose that the detailed motor commands observed in sub-populations of motor cortical neurones (Drew, 1993; Drew et al., 1996, 2004, 2008b) provide a means for exerting specific control over muscle activity while ensuring that the resulting gait

modifications are fully integrated into the base locomotor rhythm (Drew, 1991a; **Figure 10D**). However, it should also be noted that in the majority of these experiments, again including our own, the synergies that are identified are multi-articular and not confined simply to a single joint as in the original model of Grillner (1981).

It could be argued that the synergies that we are defining in the intact cat emerge from the concerted activity of a unit CPG of the type produced by Griller, moulded by descending and peripheral afferents to produce our more fractionated, multi-joint modules. Indeed, a recent study by Markin et al. (2012), using methods similar to those described here, found some differences

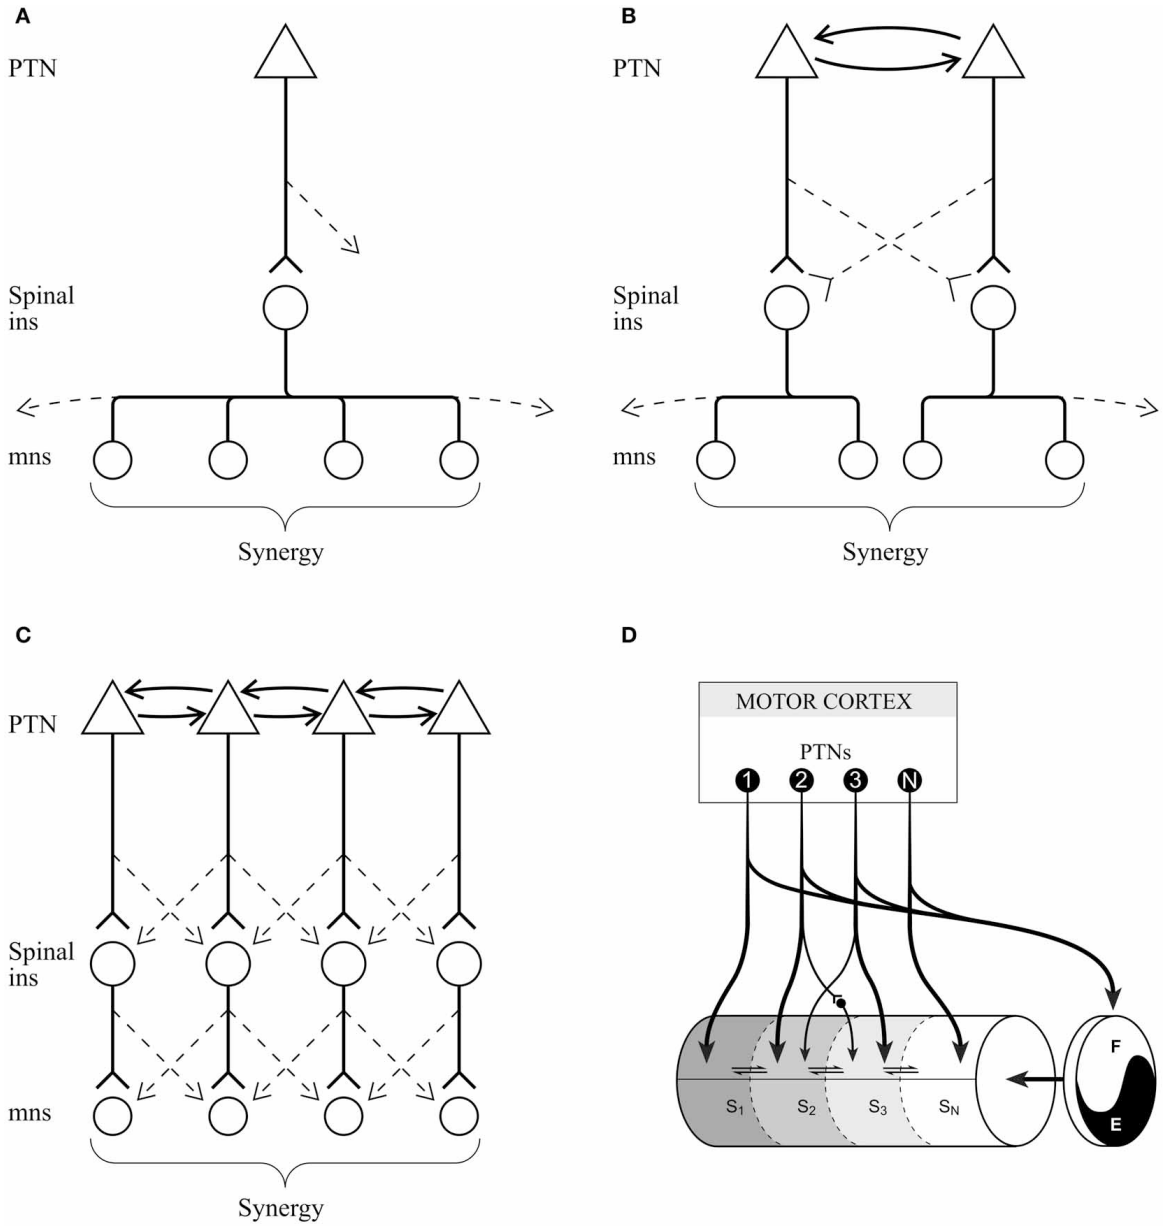

FIGURE 10 | Schematics to illustrate possible corticospinal connections. **(A)** a single subpopulation of PTNs connects with spinal interneurons (ins) that project to the motoneurones (mns) of all muscles in a synergy. **(B)** Two subpopulations of PTNs, linked by intracortical connections, and discharging simultaneously during locomotion connect with different populations of spinal interneurons, each of which innervate only part of the total muscle synergy. **(C)** Same principal as **(B)** but providing the possibility of more fractionation. Dotted lines in **(A–C)** indicate weaker connections to interneurons and motoneurones that are not part of the synergy directly modified by the motor cortical signal. **(D)** conceptual model illustrating the interaction of sub-populations of PTNs with spinal modules comprising the CPG. Each module will activate the motoneurones of a given synergy. Note that in this illustration we have separated the rhythm generator from the pattern generator elements as in the model by Rybak et al. (2006) and as supported by the results of our microstimulation studies (Rho et al., 1999). **(D)** is modified from Drew (1991a); Drew et al. (2008b). Abbreviations: E, extensor part of rhythm generator; F, flexor part of rhythm generator; in, interneurone; mn, motoneurone; PTN, pyramidal tract neurone; Sn, synergy #n.

in the synergies identified in the hindlimb of intact cats and those identified during fictive locomotion in decerebrate cats. These differences were primarily observed in muscles acting around two joints suggesting that the expression of the final pattern of activity in such muscles is modified by peripheral input. In this respect, it is important to realize that the patterns of activity observed in spinal animals are strongly modulated by peripheral input (Pearson and Rossignol, 1991; Rossignol et al., 1993; Lemay and Grill, 2004; Saltiel and Rossignol, 2004a,b; Cheung et al., 2005).

SYNERGIES AS A UNIT OF CONTROL OF GENERAL MOTOR ACTIVITY

Even in cats a large number of forelimb movements do not involve the simple sagittal pattern of intralimb coordination that we have so far examined and in primates, and especially in humans, the patterns of limb movement become more and more flexible. This is especially true when we consider grasping movements that involve both arm movement and control of the hand. Indeed, the extent to which control of hand movements may be explained by synergies is quite controversial (Brochier et al., 2004; Theverapperuma et al., 2006; Kutch et al., 2008; Overduin et al., 2008). How then does the concept of a control of movement by synergies, at least those of the type that we propose, lend itself to a flexible control of limb movement throughout a wide behavioral range?

The answer to this question lies to some extent in whether one considers muscle synergies as a concept that simplifies motor control, as is generally assumed (see Tresch and Jarc, 2009) or one that is the result of an evolution in which more recently developed descending pathways must act through spinal circuits that have been conserved (see Krouchev et al., 2006; Giszter et al., 2007; Giszter and Hart, 2013). As mentioned above, we favor the second possibility. We suggest that with the parallel evolution of the nervous system and the musculoskeletal system, spinal circuits became adapted to provide more flexible and agile locomotor limb movements, culminating in reaching and ultimately, in primates, reaching and grasping movements (Georgopoulos and Grillner, 1989). In this view, as movements became more complex, the challenge for the nervous system was to produce flexible movements that are independent of the more stereotypical arm movements observed during locomotion. Indeed, from an evolutionary viewpoint one might speculate the development of a hierarchical control system that evolved together with the increasing flexibility required in the control of movement. Such a hierarchy is frequently discussed in the locomotor literature (Rossignol, 1996) but less frequently with respect to voluntary movements (see Ting, 2007; Roh et al., 2011).

During locomotion, it is well established that circuits in the spinal cord generate a rhythm that contains details about the pattern of muscle activity (see Introduction). These spinal circuits are then subject to modification by brainstem and cortical inputs. The brainstem pathways are suggested to regulate the level of muscle activity and posture, for example, during walking uphill (Orlovsky, 1972; Drew et al., 2004). This general control of muscle activity is facilitated by the fact that the axons of neurones in the brainstem pathways, the reticulo- and vestibulo-spinal tracts, have diffuse termination patterns that influence muscle activity around multiple joints, and in multiple limbs (Matsuyama et al., 1988; Drew and Rossignol, 1990a,b). Moreover, the signals recorded from reticulospinal neurones during unobstructed locomotion (Drew et al., 1986; Matsuyama and Drew, 2000) and during voluntary gait modifications (Prentice and Drew, 2001) do not show the same level of fractionation as signals from the motor cortex. Indeed, many cells in the reticulospinal system show broad patterns of modulation that are more compatible with the waveforms identified by many of the decomposition studies than those observed in the motor cortex. Moreover, rather than specifying the exact patterns of motor activity that need to be produced, we have suggested that the signals from these pathways are integrated with the rhythmical signals in the spinal cord to modify the production of many of the more stereotypical patterns of behavioral activity, including locomotion (Drew et al., 2004). In some respects, therefore, the activity and connectivity of brainstem pathways resembles that postulated for synergies in general, and especially those implicating the brainstem (Roh et al., 2011). Nonetheless, it should be emphasized that there is little evidence for a limited subset of discharge patterns among reticulospinal cells during locomotion as might be expected if they represented a small range of synergies. Moreover, it should also be noted that synergy studies generally concentrate on the activity within a single limb whereas many neurones in the reticulospinal pathways appear to be involved in coordinating activity in two, or more, limbs.

At a higher level of the hierarchy, the motor cortex (and the red nucleus) provides a more specific level of control of locomotion. During unobstructed locomotion, the contribution is likely to be one of step-by-step regulation of the step cycle superimposed on the control exerted at lower levels of the nervous system. A contribution at this level is supported by the fact that motor cortical cells, including PTNs are modulated during unobstructed locomotion [reviewed in Drew et al. (1996)] and that microstimulation of the motor cortex can modify both the pattern and the timing of the step cycle (Armstrong and Drew, 1985; Rho et al., 1999). The major contribution of the motor cortex, however, is in the control of precise locomotor movements on the basis of visual information (Drew, 1988, 1993; Beloozerova and Sirota, 1993). As developed in this manuscript, we propose that the motor cortex produces gait modifications by altering the timing, duration and relative timing of muscle synergies. As suggested above, these signals are likely to be mediated by the same neuronal circuits responsible for the generation of the locomotor rhythm and the pattern of locomotion. This allows a specific control over the level of activity in the different synergies, thus adapting activity to the specific requirements of the task while still integrating this into the step cycle (**Figure 10D**). In our model, control of voluntary gait modifications does not require the production of new synergies but rather modification of the synergies already present in unobstructed locomotion. This should be compared with the results of Ivanenko et al. (2005) in which stepping over an obstacle by human subjects required the addition of a new principal component that was responsible for explaining >20% of the overall variance in the EMG patterns.

At the highest level there is a need to control movements that are non-stereotypic. This might involve breaking apart synergies or the addition of new synergies. For example, during corrective

manoeuvres, Kargo and Giszter (2000) have shown there is a need to modify synergy composition to correct for perturbations. In other conditions, for example when making relatively simple movements, there might be a need to activate 1 or 2 sparse synergies independently of others. Other movements may require separation of synergies, for example, uncoupling activity in wrist and elbow muscles. This may be achieved by activating only a part of the population of PTNs contributing to muscle activity in a given synergy (e.g., **Figure 10B**). Additionally, it might require inhibiting some of the motoneurones that would normally be activated by a given sub-population of PTNs. Indeed, it has been suggested that the development of the motor cortex and, in primates, the corticomotoneuronal system, provides the ability to generate more fractionated movements, in part by inhibiting some synergies and activating others (Lemon and Griffiths, 2005; Drew et al., 2008a). In other movements, particularly those involving the fingers, the number of patterns of motor cortical recruitment makes it difficult to argue that movement is controlled by synergies. Poliakov and Schieber (1999), for example, failed to find any evidence of broad groups of motor cortical neurones controlling finger movements and instead reported a highly diverse pattern of activity suggesting control by a distributed network.

SUMMARY

The data illustrated in this manuscript are compatible with a view that motor cortical cells contribute to the control of locomotion by modulating the activity of a limited number of sparse synergies. We suggest that a relatively simple control system can serve to control limb trajectory under a wide range of situations simply by modifying the phase and magnitude of the period of activity in a limited number of functionally segregated populations of PTNs. In addition, Yakovenko et al. (2011) showed that similar synergies are observed during reach as during locomotion. Indeed, the sequential organization of sparse synergies in unobstructed locomotion, stepping over obstacles and even reaching, is strongly suggestive of a relationship to prime mover muscles and their agonists. These relationships, in turn, are activated subject to biomechanical (kinematic, dynamic) constraints and to existing neural circuits provided by subcortical and spinal neural pattern- and rhythm- generating circuitry.

Background: Motor imagery (MI) is the mental performance of movement without muscle activity. It is generally accepted that MI and motor performance have similar physiological mechanisms.

Purpose: To investigate the activity and excitability of cortical motor areas during MI in subjects who were previously trained with an MI-based brain-computer interface (BCI).

Subjects and Methods: Eleven healthy volunteers without neurological impairments (mean age, 36 years; range: 24–68 years) were either trained with an MI-based BCI (BCI-trained, $n = 5$) or received no BCI training ($n = 6$, controls). Subjects imagined grasping in a blocked paradigm task with alternating rest and task periods. For evaluating the activity and excitability of cortical motor areas we used functional MRI and navigated transcranial magnetic stimulation (nTMS).

Results: fMRI revealed activation in Brodmann areas 3 and 6, the cerebellum, and the thalamus during MI in all subjects. The primary motor cortex was activated only in BCI-trained subjects. The associative zones of activation were larger in non-trained subjects. During MI, motor evoked potentials recorded from two of the three targeted muscles were significantly higher only in BCI-trained subjects. The motor threshold decreased (median = 17%) during MI, which was also observed only in BCI-trained subjects.

Conclusion: Previous BCI training increased motor cortex excitability during MI. These data may help to improve BCI applications, including rehabilitation of patients with cerebral palsy.

Keywords: brain-computer interface, motor imagery, navigated TMS, functional MRI, neurorehabilitation

HIGHLIGHTS

- The cerebellum, thalamus, and Brodmann areas 3 and 6 were activated during motor imagery.
- The primary motor cortex was activated in BCI-trained subjects and not in controls.
- TMS motor threshold was decreased by 6–18% (median, 17%) during motor imagery in BCI-trained subjects.
- In BCI-trained subjects, evoked motor responses were larger during motor imagery than at rest.

INTRODUCTION

Modularity is important concept in understanding mechanisms of motor control and motor learning. Recent investigations of muscle synergies, motor primitives, compositionality, basic action concepts, and related work in machine learning have contributed to advance our understanding of the architecture underlying rich motor behaviors (Lacquaniti et al., 2013). One of the most interesting topic in researches of motor system modularity and organization is study of motor imagery and changes in neural networks during it.

Motor imagery (MI) activates brain regions that participate in motor control (Crammond, 1997; Jeannerod, 2001; Stippich et al., 2002; Ehrsson et al., 2003; Neuper et al., 2005). These structures include the premotor and supplementary motor cortices (Brodmann area 6), parietal cortical areas, cingulate gyrus, basal ganglia, and cerebellum. The primary motor cortex (Brodmann area 4) is also active during MI (Jeannerod, 2001; Neuper et al., 2005; Sharma et al., 2006; Dickstein and Deutsch, 2007; Mulder, 2007). Furthermore, several studies using transcranial magnetic stimulation (TMS) demonstrated increased corticospinal excitability and increased amplitudes of motor evoked potentials (MEPs) during MI (Fadiga et al., 1999; Hashimoto and Rothwell, 1999; Vargas et al., 2004; Cicinelli et al., 2006; Stinear et al., 2006; Pichiorri et al., 2011).

These previous findings led scientists to develop an MI training paradigm to stimulate neuroplastic changes in patients with paresis resulting from brain injury, or for use in athletic training. An electroencephalography (EEG)-based brain-computer interface (BCI) is a promising method to support MI during such training. The BCI transforms EEG signals generated

during MI into commands that can control an external device (Prasad et al., 2010; Mokienko and Chernikova, 2011; Shih et al., 2012). Modulation of the sensorimotor rhythm can serve as the signal of brain activity during MI (Pfurtscheller and Lopes da Silva, 1999). However, the plasticity-related changes resulting from BCI-supported MI training have not been studied in detail. Furthermore, no study has included the navigated transcranial magnetic stimulation (nTMS) method, or compared functional magnetic resonance imaging (fMRI) and nTMS data for functional mapping during MI in BCI-trained and not trained subjects. The aim of our experiment was to investigate the activity and excitability of different cortical motor areas during MI in BCI-trained and BCI-naïve subjects.

MATERIALS AND METHODS

PARTICIPANTS

The inclusion criteria were an age of 20–70 years old, an absence of neurological disorders, normal vision, right-handedness, and written informed consent. Eleven volunteers (mean age, 36 years; age range, 24–68 years; 7 males and 4 females) were included into the study. Subjects of group 1 ($n = 5$, mean age = 45.8 y.o) had 10 to 15 sessions of BCI-supported training 20–30 min each. The training course was followed by fMRI and nTMS examinations. Subjects of group 2 ($n = 6$, mean age = 27.6 y.o) were tested without preliminary training session. All subjects underwent fMRI and nTMS after the training sessions. The protocol was approved by the local Ethical Committee of the Research Center of Neurology of RAMS, Moscow. All subjects provided written informed consent.

BCI TRAINING

The BCI training was based on EEG activity patterns recording during grasping MI. Subjects sat comfortably in an armchair located 1 m from a computer screen that presented visual instructions. Subjects visually fixated on a circle presented in the center of the screen and received instructions from three surrounding figures (rhomboidal arrows). Subjects were given three commands instructing them to relax (upper arrows were illuminated) or imagine slow grasping movements with the right or left hand (right or left arrow illuminated). The "Relax" command meant that the subject had to sit still and look at the center of the screen. Commands were presented randomly, each of 10-s duration. For each subject, training was performed in 10–15 experimental days, with one 20–30 min session performed each day. Intervals between training sessions were 1–4 days.

A visual cue provided the subject with feedback regarding the mental task recognition: the central circle turned green if the classifier recognized the task in agreement with the given command, or remained white if the signal was not recognized. The EEG was registered with 30 electrodes distributed over the head in accordance with the standard international 10–20 system. EEG signals were filtered from 5–30 Hz. We used a Bayesian approach for EEG pattern classifying. The activity sources most relevant for BCI functioning were identified using an independent component analysis (ICA). Classification accuracy was measured with Cohen's kappa, a parameter conventionally used in BCI studies (Kohavi and Provost, 1998). A kappa of 1 indicates perfect recognition, whereas a kappa of 0 indicates random recognition.

fMRI

fMRI was conducted using a Magnetom Avanto 1.5-T MRI system (Siemens, Germany). Standard axial T2-weighted turbo-spin echo imaging was performed initially to rule out pathological changes in brain tissue [repetition time (TR), 4000 ms; echo time (TE), 106 ms; section thickness, 5.0 mm; matrix, 230 × 230 mm; imaging time, 2 min 2 s]. Anatomical data were obtained with sagittal T1-weighted gradient echo imaging with isometric voxels (Ò1 multiplanar reconstruction: TR, 1940 ms; TE, 3.1 ms; TI, 1100 ms; section thickness, 1.0 mm; matrix, 256 × 256 mm; imaging time, 4 min 23 s). During the fMRI experiment, subjects performed the same task that was performed during the BCI training sessions, but without feedback. For each subject, three sets of functional data were obtained representing different conditions, including rest (8 replicates) and right or left hand movement imagery (4 replicates each). The imaging mode used was axial T2* gradient echo (TR, 3800 ms; TE, 50 ms; matrix, 192 × 192 mm, section thickness, 3 mm) with fat suppression and correction for motion. The imaging time was 6 min 10 s.

The data analysis was performed in the MATLAB (Mathworks, Natick, MA, USA) environment using the statistical package for processing in SPM8 (Welcome Trust Center of Neuroimaging, London, UK). The first step of analysis corrected head movement artifacts. Next, the functional data were translated to Montreal Neurological Institute (MNI) coordinates (i.e., normalization). Standard MNI coordinates, which are used in the SPM8 package, were developed and adopted by the International Consortium for Brain Mapping. In the next step, the normalized data were smoothed. This step was followed by a classic analysis that used generalized linear models. The results from each subject were used in the group analysis to identify areas showing task-specific activity.

nTMS

Neurophysiological investigation was performed using nTMS with the NBS eXimia Nexstim apparatus (Finland).It includes 70 mm figure-eight-shaped BiPulse Nexstim coil, with a maximal magnetic field strength of 199 V/m and a magnetic impulse duration of 280 μs. The coil was placed anteromedially at a 45° angle from the midline. The stimulated hemisphere was not the same for all the subjects and was chosen randomly.

As a first step, all subjects underwent an MRI investigation on a Magnetom Symphony 1.5 T scanner (Siemens, Germany) using a T1 multiplanar reconstruction regime (MPR); the data were loaded into the NBS eXimia Nexstim system to obtain subjects' individual 3D brain models. Following that, real anatomical entities were matched to their MRI representations.

The MEPs were recorded using a standard EMG machine (Nexstim, EMD, Finland) and surface electrodes. MEPs were recorded by placing 0.6 cm^2 EMG electrodes on the target muscle being mapped [abductor pollicis brevis (APB), flexor carpi ulnaris (FCU), and extensor carpi radialis (ECR)] which were positioned according to the atlas of Leis and Trapani (2000), according to the belly–tendon principle. The ground electrode was placed on the

right clavicle or on the upper third of the right forearm. We then determined the resting motor threshold (MT), defined as the lowest stimulation intensity allowing evocation of motor responses 0.50 mV peak to peak amplitude in 5/10 trials with the patient at rest (Rossini et al., 1994). Resting MT was measured in present (%) of the maximum intensity of the magnetic stimulator (1,5 Tesla). Evoked motor responses (EMRs) and their amplitudes and latencies were recorded for each target muscle. Cortical motor representations were constructed from these observations.

In the first step of the experiment, the areas of interest (contralateral primary motor and premotor cortices) were stimulated with magnetic fields of 80–110 V/m to identify EMRs with amplitudes of 100–500 μV. The resting MT was determined for each site by the largest detected EMR amplitude. Cortical representations of the target muscles were mapped at 110% intensity of the determined resting MT. The mean EMR amplitudes and muscle motor representations were evaluated during cortical mapping.

In the second step of the experiment, the passive EMR threshold was determined and the motor representations were mapped while subjects imagined grasping with the contralateral hand. The motor representations were mapped using stimulus intensities as in the first step. The hand was positioned on the armrest in the neutral position of the radiocarpal joint.

Statistical analysis of quantifiable data was performed using a repeated measures analysis of variance (ANOVA) and Newman-Keuls *post-hoc* test using the Statistica 6.0 software package (StatSoft, 2003). The data are presented as the median and 25–75% quartiles. Differences were considered significant at $p < 0.05$.

RESULTS

SUBJECTS

Eleven volunteers (mean age, 36 years; age range, 24–68 years; 7 men, 4 women) participated in the study. Subjects in group 1 ($n = 5$) underwent 10 to 15 sessions of BCI-supported training that were each 20–30 min in duration. The training course was followed by fMRI and nTMS examinations. Subjects in group 2 ($n = 6$) were tested without performing preliminary training sessions.

BCI TRAINING

The achieved accuracy rates (median Cohen's kappa) were 0.46 [0.45; 0.52]. BCI control for all subjects was achieved with sensorimotor rhythm modulation. MI was accompanied with desynchronization of mu and low beta rhythms (i.e., event-related desynchronization) (Pfurtscheller and Lopes da Silva, 1999). This signal was a recognizable command for the BCI.

FUNCTIONAL MRI

In BCI-trained subjects, MI was accompanied by activity in the contralateral somatosensory (Brodmann area 3), primary motor (Brodmann area 4), and premotor cortical areas. Activity also was observed in the bilateral supplementary motor cortex (Brodmann area 6), contralateral ventral lateral nucleus of thalamus, and ipsilateral cerebellum ($p < 0.0005$; **Figure 1**).

For BCI-naïve subjects, activity was observed in the contralateral somatosensory (Brodmann area 3) and premotor cortical areas, as well as the supplementary motor cortex (Brodmann area 6) bilaterally. Other activated areas included the contralateral ventral lateral nucleus of the thalamus, ipsilateral cerebellum, contralateral Brodmann area 9, and bilateral Brodmann areas 40 and 13 ($p < 0.0005$). The primary motor cortex was not activated in untrained subjects (**Figure 2**). The areas of activation including the somatosensory, premotor, and supplementary motor areas observed during MI were significantly larger in BCI-naïve subjects than in BCI-trained subjects ($p < 0.01$).

nTMS

In BCI-trained subjects, the passive MT for the motor cortex decreased by 6–18% (median change was 17%) during MI compared to the rest condition. In BCI-naïve subjects, the threshold change during MI compared to rest were not significant and were inconsistent among subjects. The threshold decreased by 1–8% in three subjects, insignificantly increased in two subjects, and was unchanged in one subject. The MT changes were statistically significant only for BCI-trained subjects ($p < 0.01$, **Table 1**).

For APB, the median change in motor response during MI compared to rest condition was 63% in BCI-trained subjects, and 11% in BCI-naïve subjects. For ECR, the change was 150% in BCI-trained subjects and 1% in BCI-naïve subjects. In BCI-trained subjects, the responses in APB and ECR (mean EMR) during MI were significantly higher during MI compared to the rest condition (APB, $p = 0.03$; ECR, $p = 0.01$). In BCI-naïve subjects, the differences in EMR were not significant (APB, $p = 0.24$; ECR, $p = 0.23$, **Table 1**).

We did not observe statistically significant increases in mean EMR amplitude in FCU for either group (**Table 1**). The median change in motor response was 78% in BCI-trained subjects

and 12% in BCI-naïve subjects. Moreover, in BCI-trained subjects, stimulation induced EMRs that were larger during MI than at rest, which was not observed in BCI-naïve subjects (**Figure 3**). A comparison of nTMS and fMRI maps revealed partial overlap of motor areas detected by these two methods (**Figure 4**).

DISCUSSION

The activation and excitability of the motor cortex during MI is different in BCI-trained and BCI-naïve subjects, and this difference can be detected with a combination of fMRI and nTMS.

MI AND ACTIVATION OF MOTOR STRUCTURES

The fMRI analysis revealed the same brain areas were active during MI for both groups. These areas included the contralateral somatosensory, contralateral premotor, supplementary motor cortex bilaterally, contralateral ventral lateral nucleus of thalamus, and ipsilateral cerebellum. Similar activation patterns were described in other fMRI-based MI studies (Jeannerod, 2001; Neuper et al., 2005; Sharma et al., 2006; Dickstein and Deutsch, 2007; Mulder, 2007).

In the literature, there is a debate regarding what role the primary motor cortex plays in MI, as some studies failed to observe its activation (Parsons et al., 1995; Hanakawa et al., 2003; Meister et al., 2004; de Lange et al., 2005). In our study, primary motor cortex activation was observed only in BCI-trained subjects. Therefore, we suppose primary motor cortex is involved in MI in individuals who can "successfully" imagine a movement, or who have been trained to do so (e.g., BCI-supported training).

The somatosensory, premotor, and supplementary motor cortical areas were activated during MI, and were larger on fMRI in BCI-naïve subjects. This is in agreement with the principles implying localization of new or skilled movements.

In BCI-naïve subjects, we observed bilateral activation of Brodmann area 40, the complex associative cortex. This region plays a central role in developing cognitive strategies and motor programs, and its activation was described in several previous MI studies (Gerardin et al., 2000; Lafleur et al., 2002; Jackson

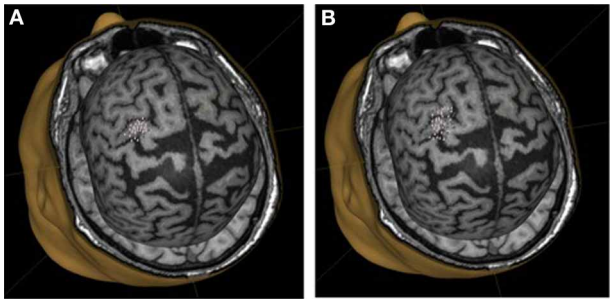

FIGURE 3 | Motor representation of target muscles in a BCI-trained subject. (A), background mapping; **(B)**, mapping during motor imagery.

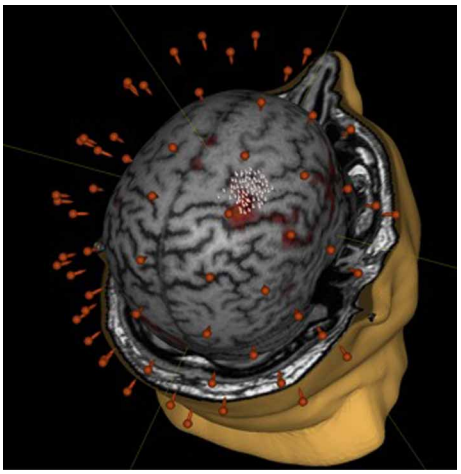

FIGURE 4 | Comparison of mapping results obtained during motor imagery in a BCI-trained subject by using fMRI (fist clenching imagery task) and nTMS.

et al., 2003). This associative area was reported to be activated predominantly in the left hemisphere during complex motor performed by right-handed individuals (Gerardin et al., 2000). In addition, the dorsolateral prefrontal cortex (Brodmann area 9) was active in BCI-naïve subjects. This associative area represents the highest level of motor planning and regulation, and plays an important role in sensory and mnemonic information integration and working memory processes (Derrfuss et al., 2004). Right and left insula activation can be associated with cognitive control, task coordination, and working memory involvement (Derrfuss et al., 2004). It should be noted that BCI-trained subjects did not show significant activity in the associative areas.

MI AND CORTICOSPINAL EXCITABILITY

Our nTMS findings indicate that MI is generally associated with a decrease in the evoked response threshold, an increase in the EMR amplitude, and an expansion of evoked response areas against the background of decreased excitation thresholds. Together, these changes reflect increased motor cortex excitability during MI. These changes are increased with MI training and often do not occur in untrained individuals. Our results are in agreement with the findings of other studies using classical TMS (without MRI navigation) (Fadiga et al., 1999; Hashimoto and Rothwell, 1999; Vargas et al., 2004; Cicinelli et al., 2006; Stinear et al., 2006).

nTMS AND INVESTIGATION OF MI

Pichiorri et al. (2011) used TMS to assess the neuroplastic changes associated with MI-based BCI training. In that study, 10 healthy volunteers participated in 6–8 40-min BCI sessions. The training resulted in a significant increase in motor cortex excitability, and enhanced EMRs in target muscles during MI (Pichiorri et al., 2011). The TMS used in those studies was not navigated using MRI or fMRI data. In contrast to conventional TMS, nTMS allows local and precise stimulation based on an individual's MRI data (Chervyakov et al., 2013). This technique makes it possible to assess cortical excitability with a high spatial (2 mm) and temporal resolution. In the present study, we obtained similar results in terms of EMR, but we used both nTMS and fMRI. nTMS allowed us to map target muscle representations during MI for each subject based on MRI and fMRI data.

nTMS can be used to evaluate the dynamics of neuroplastic processes accompanying MI. MI mapping is most commonly performed with fMRI. In this case, the indirect measure of brain activity is the BOLD signal. The main advantage of fMRI is its high spatial resolution of approximately 1 mm (deCharms et al., 2004). However, the temporal resolution of this technique is relatively low, reaching 1–2 s. In addition, the physiological slowing of the hemodynamic response ranges from 3–6 s (Weiskopf et al., 2004). Most fMRI-based studies of MI do not involve EMG activity. In contrast, TMS provides a high temporal and spatial resolution. Surface EMG recording during TMS mapping makes it possible to control for the lack of muscle control during MI. Moreover, this mapping technique is based on directed and selective cortex stimulation, whereas in fMRI mapping, brain activity is evaluated based on an indirect signal.

COMPARISON OF fMRI AND nTMS MOTOR REPRESENTATION MAPS

The activity foci determined by the group analysis of fMRI data were in agreement with previously published data from other MI studies (Jeannerod, 2001; Neuper et al., 2005; Sharma et al., 2006; Dickstein and Deutsch, 2007; Mulder, 2007; Pichiorri et al., 2011). The discrepancy between the results for motor area mapping obtained using the two techniques (fMRI and nTMS) can be explained by the fact that TMS has a direct and selective effect on corticospinal pathways, whereas fMRI reflects BOLD signal changes associated with task performance (i.e., MI). A large study aimed at comparing these two neuroimaging techniques showed the distance between motor areas identified by fMRI and nTMS ranged from 0–21.7 mm (3.70 ± 4.85 mm) (Neuvonen and Niskanen, 2009).

MI TRAINING AND ITS CLINICAL APPLICATION IN NEUROLOGICAL REHABILITATION

Changes in EMR amplitudes and cortical representations were mainly associated with a decrease in motor thresholds in individuals who had undergone MI training in a similar task. The EMR threshold reflects motor cortical excitability and was shown to be an informative parameter in several neurological diseases (Nikitin and Kurenkov, 2003). Our results suggest that MI training has

a significant effect on cortical motor representations, which is probably comparable to that of actual motor training. Therefore, MI can be recommended as a rehabilitation practice in patients with severe motor deficiencies resulting from central nervous system injury.

To conclude, although the number of participants in this experiment was small, the results suggest the possibility of appropriate and optimal neuroplasticity control using BCI training. The considerations discussed above also suggest that nTMS is a highly promising method for investigating neurological plasticity. Nevertheless, further combined TMS-MRI-fMRI studies are required to determine its optimal application sites.

A salient feature of human motor skill learning is the ability to exploit similarities across related tasks. In biological motor control, it has been hypothesized that muscle synergies, coherent activations of groups of muscles, allow for exploiting shared knowledge. Recent studies have shown that a rich set of complex motor skills can be generated by a combination of a small number of muscle synergies. In robotics, dynamic movement primitives are commonly used for motor skill learning. This machine learning approach implements a stable attractor system that facilitates learning and it can be used in high-dimensional continuous spaces. However, it does not allow for reusing shared knowledge, i.e., for each task an individual set of parameters has to be learned. We propose a novel movement primitive representation that employs parametrized basis functions, which combines the benefits of muscle synergies and dynamic movement primitives. For each task a superposition of synergies modulates a stable attractor system. This approach leads to a compact representation of multiple motor skills and at the same time enables efficient learning in high-dimensional continuous systems. The movement representation supports discrete and rhythmic movements and in particular includes the dynamic movement primitive approach as a special case. We demonstrate the feasibility of the movement representation in three multi-task learning simulated scenarios. First, the characteristics of the proposed representation are illustrated in a point-mass task. Second, in complex humanoid walking experiments, multiple walking patterns with different step heights are learned robustly and efficiently. Finally, in a multi-directional reaching task simulated with a musculoskeletal model of the human arm, we show how the proposed movement primitives can be used to learn appropriate muscle excitation patterns and to generalize effectively to new reaching skills.

Keywords: dynamic movement primitives, muscle synergies, reinforcement learning, motor control, musculoskeletal model

1. INTRODUCTION

Reinforcement Learning of motor skills in robotics is considered to be very challenging due to the high-dimensional continuous state and action spaces. In many studies it has been shown that learning can be facilitated by the use of movement primitives (Schaal et al., 2003; Rückert et al., 2013). Movement primitives are parametrized representations of elementary movements, where typically for each motor skill a small set of parameters is tuned or learned. However, many motor control tasks are related and could be learned more effectively by exploiting shared knowledge.

This is a well-known concept in motor neuroscience, where muscle synergies or coherent activations of groups of muscles (d'Avella et al., 2003; d'Avella and Bizzi, 2005; Bizzi et al., 2008) have been proposed to simplify the control problem of complex musculoskeletal systems. In analyzing muscle activation recordings it has been demonstrated that by combining only few muscle activation patterns multiple task instances of natural motor behaviors, e.g., fast reaching movements of humans (d'Avella et al., 2006), primate grasping movements (Overduin et al., 2008), or walking patterns of infants, toddlers, and adults (Dominici et al., 2011) could be efficiently modeled. One important finding of theses studies is that the dimensionality of the motor control problem can be drastically reduced by reusing common knowledge of related tasks, i.e., grasping objects at different locations using a linear combination of shared muscle synergies. While this has been demonstrated in biological data analysis, only few robotic applications exist that use this shared task knowledge (Chhabra and Jacobs, 2006; Alessandro et al., 2012). These methods demonstrate the advantages of shared synergies in learning robotic tasks. However, different procedures were applied to obtain a parametric description of synergies, i.e., in Chhabra and Jacobs (2006) a variant of non-negative matrix factorization (d'Avella et al., 2003) was used given a set of pre-computed trajectories and in Alessandro et al. (2012) the synergies were extracted from dynamic responses of a robot system with random initialization. In contrast, we propose to learn the synergies representation

in a reinforcement learning framework, where task-specific and task-invariant parameters in a multi-task learning setting are learned simultaneously.

In robotics the most widely used approach for motor skill learning are Dynamic Movement Primitives (DMPs) (Schaal et al., 2003; Ijspeert et al., 2013). This approach uses parametrized dynamical systems to determine a movement trajectory and has several benefits. First, as it is a model-free approach, there is no need to learn the typically non-linear, high-dimensional dynamic forward model of a robot (However, this is not the case when inverse dynamics controller are used to compute the control commands). Second, it provides a linear policy parametrization which can be used for imitation learning and policy search (Kober and Peters, 2011). The complexity of the trajectory can be scaled by the number of parameters (Schaal et al., 2003) and one can adapt meta-parameters of the movement such as the movement speed or the goal state (Pastor et al., 2009; Kober et al., 2010). Finally, the dynamical system is constructed such that the system is stable. This simplifies learning since even without modulating the dynamical system the movement trajectory is always attracted by a known (or learned) goal state. However, this parametrization does not allow for reusing shared knowledge, as proposed by the experimental findings studying complex musculoskeletal systems (d'Avella et al., 2003; Bizzi et al., 2008; d'Avella and Pai, 2010). Thus, typically for each motor task an individual movement parametrization has to be learned.

In this paper we propose to use a superposition of learned basis functions or synergies to modulate the stable attractor system of DMPs. This allows for reusing shared knowledge for learning multiple related tasks simultaneously while preserving the benefits of the dynamical systems, i.e., the stability in learning complex motor behavior. The synergies and their activation in time are learned from scratch in a standard reinforcement learning setup. Note that imitation learning could also be applied to implement an initial guess for the synergies, e.g., by using decomposition strategies discussed in d'Avella and Tresch (2001). However, this is beyond the scope of this paper. Moreover, our approach is like the DMPs applicable to discrete and rhythmic movements and allows for modeling time-varying synergies (d'Avella et al., 2006). We therefore denote our approach *DMPSynergies*. By using for each task a combination of individual, temporally fixed, basis functions DMPs can be modeled as special case of this approach. The benefit of the common prior knowledge is even more drastic when generalizing to new motor tasks given the previously learned basis functions. Thus, for simpler synergies only the weights for the linear combination have to be acquired and for time-varying synergies additionally the time-shift parameters need to be learned. This is demonstrated on a complex walking task and on reaching task using an arm actuated by muscles.

As in previous studies on DMPs (Meier et al., 2011; Mülling et al., 2013) we want to go beyond basic motor skills learning. However, in contrast to those studies that use a library of primitives for sequencing elementary movements (Meier et al., 2011) or mixing basic skills (Mülling et al., 2013), we implement the common shared knowledge among multiple tasks as prior in a hierarchical structure. On the lower level task related parameters, i.e., amplitude scaling weights or time-shift parameters are used to modulate a linear superposition of learned basis functions, the shared higher level knowledge. This has the promising feature that by combining just a small number of synergies diverse motor skills can be generated.

In the Materials and Methods, we will first briefly introduce DMPs (Schaal et al., 2003; Ijspeert et al., 2013) as we build on this approach. We then extend DMPs to allow for reusing shared task knowledge in the form of parametrized synergies. The advantage of the shared knowledge is evaluated in the Results on three multi-task learning scenarios. First, a simple via-point task is used to demonstrate the characteristics of the proposed representation. Then, rhythmic movements are learned in a dynamic 5-link planar biped walker environment. Finally, a musculoskeletal model of a human arm is used to evaluate our primitives on a muscle actuated system learning discrete reaching movements to multiple targets.

2. MATERIALS AND METHODS

2.1. DYNAMIC MOVEMENT PRIMITIVES

DMPs generate multi-dimensional trajectories by the use of non-linear differential equations (simple damped spring models) (Schaal et al., 2003). The basic idea is to use for each degree-of-freedom (DoF), or more precisely for each actuator, a globally stable, linear dynamical system of the form

$$\tau\dot{z} = \alpha_z(\beta_z(g - y^*) - z) + f, \quad \tau\dot{y}^* = z, \tag{1}$$

which is modulated by a learnable non-linear function f. The final position of a movement is denoted by g and the variables y^* and $\dot{y}^*$ represent the desired state in i.e., joint angles and joint velocities. The time constants α and β are usually pre-defined. The temporal scaling factor τ can be used for de- or accelerating the movement execution as needed. Finally z denotes an internal variable of the dynamical system. For each DoF an individual function f is used which is different for discrete and rhythmic movements.

For discrete movements the function f only depends on the phase s, which is an abstraction of time and was introduced to scale the movement duration (Schaal et al., 2003). The function $f(s)$ is constructed of the weighted sum of N Gaussian basis functions Ψ_n

$$f(s) = \frac{\sum_{n=1}^{N} \Psi_n(s) w_n s}{\sum_{n'=1}^{N} \Psi_{n'}(s)}, \tag{2}$$

where for discrete movements these Gaussian basis functions are

$$\Psi_n(s) = \exp\left(-\frac{1}{2h_n^2}(s - \mu_n)^2\right), \quad \tau\dot{s} = -\alpha_s s.$$

Only the weights w_n are parameters of the primitive which can modulate the shape of the movement. The centers or means $\mu_n \in [0, 1]$ specify at which phase of the movement the basis function becomes active. They are typically equally spaced in the range of s and not modified during learning. The bandwidth of the basis functions is given by h_n^2 and is typically chosen such that the Gaussians overlap.

For rhythmic movements periodic activation functions are used (Ijspeert et al., 2002). The non-linear function f reads

$$f(\phi) = \frac{\sum_{n=1}^{N} \Psi_n(\phi) w_n}{\sum_{n'=1}^{N} \Psi_{n'}(\phi)}, \quad (3)$$

where the periodic phase angle is denoted by $\phi \in [0, 2\pi]$. In Ijspeert et al. (2002) additionally a scalar variable was used to scale the amplitude of the oscillator, which was omitted for simplicity. The basis functions are given by

$$\Psi_n(\phi) = \exp(h_n(\cos(\phi - \mu_n) - 1)), \quad \tau\dot{\phi} = 1,$$

which implement von Mises basis functions. Note that for the periodic basis functions the trajectory in Equation 1 oscillates around the attractor point or goal state g.

Integrating the dynamical systems in Equation 1 for each DoF results into a desired trajectory $\langle \mathbf{y}_t^*, \dot{\mathbf{y}}_t^* \rangle$ of the joint angles. To follow this trajectory, in the most simple case a linear feedback controller is subsequently used to generate appropriate control commands denoted by $\mathbf{u}_t$:

$$\mathbf{u}_t = \text{diag}(\mathbf{k}_{\text{pos}})(\mathbf{y}_t^* - \mathbf{y}_t) + \text{diag}(\mathbf{k}_{\text{vel}})(\dot{\mathbf{y}}_t^* - \dot{\mathbf{y}}_t). \quad (4)$$

For each actuator the linear weights $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_D]$ as well as the control gains $\mathbf{k}_{\text{pos}}$ and $\mathbf{k}_{\text{vel}}$ have to be specified, i.e., $\boldsymbol{\theta} = [\mathbf{W}, \mathbf{k}_{\text{pos}}, \mathbf{k}_{\text{vel}}]$. This results into $ND + 2D$ parameters for the movement representation, where D denotes the number of actuators or muscles of a system. The simulated trajectory is denoted by $\langle \mathbf{y}_t, \dot{\mathbf{y}}_t \rangle$.

In multi-task learning we want to learn $k = 1..K$ tasks simultaneously. For very simply tasks, such as the via-point experiments described below, it could be sufficient to adapt the goal state g. However, this is usually not the case for more complex motor skill learning tasks in robotics. With DMPs typically for each motor skill an individual movement parametrization $\boldsymbol{\theta}_k$ has to be learned. However, if we assume similarities among these tasks the learning problem could potentially be simplified by reusing shared knowledge. Inspired by experimental findings in biology (d'Avella et al., 2003; Bizzi et al., 2008; d'Avella and Pai, 2010) we extend these DMPs. Only the parametrization for the non-linear function $f(s)$ for discrete movements or $f(\phi)$ for rhythmic movement changes. The dynamical system in Equation 1 and the linear feedback controller in Equation 4 remains the same.

2.2. DYNAMIC MOVEMENT PRIMITIVES WITH SHARED SYNERGIES (DMPSynergies)

For learning the kth task, we propose to use a linear combination of temporal flexible basis functions or synergies to parametrize the non-linear function $f(s)$ in Equation 2 or for rhythmic movements $f(\phi)$ in Equation 3:

$$f(s, k) = \sum_{m=1}^{M} \beta_{m,k} \Lambda\left(s, \boldsymbol{\theta}_m, \Delta s_{m,k}\right) s, \quad (5)$$

$$f(\phi, k) = \sum_{m=1}^{M} \beta_{m,k} \Omega\left(\phi, \boldsymbol{\theta}_m, \Delta s_{m,k}\right), \quad (6)$$

where s denotes the phase variable which is only used for discrete movements. As with DMPs (Ψ_n in Equation 2) the functions $\Lambda(.)$ and $\Omega(.)$ are different for discrete and rhythmic movements.

All K tasks share $m = 1..M$ synergies which are parametrized via the vector $\boldsymbol{\theta}_m$. Solely the weights $\beta_{m,k}$ and the time-shift $\Delta s_{m,k}$ are individual parameters for each task. The basic concept of the model is sketched in **Figure 1** for a one-dimensional discrete movement.

The complexity of each synergy is controlled by the number of Gaussians for discrete movements or by the number of von Mises basis functions for rhythmic patterns. We denote this number by N, where we parametrize in both cases the amplitude, the mean and the bandwidth. Thus, each synergy is represented by a parameter vector $\boldsymbol{\theta}_m = [a_{m,1}, \mu_{m,1}, h_{m,1}, \ldots, a_{m,N}, \mu_{m,N}, h_{m,N}]$.

For discrete movements the function $\Lambda(.)$ reads

$$\Lambda\left(s, \boldsymbol{\theta}_m, \Delta s_{m,k}\right) = \sum_{n=1}^{N} a_{m,n} \exp\left(-\frac{1}{2{h_{m,n}}^2}\left(s - \mu_{m,n} + \Delta s_{m,k}\right)^2\right). \quad (7)$$

For rhythmic movements a superposition of von Mises basis functions is used

$$\Omega\left(\phi, \boldsymbol{\theta}_m, \Delta s_{m,k}\right) = \sum_{n=1}^{N} a_{m,n} \exp\left(h_{m,n} \cos\left(\phi - \mu_{m,n} + \Delta s_{m,k}\right) - 1\right). \quad (8)$$

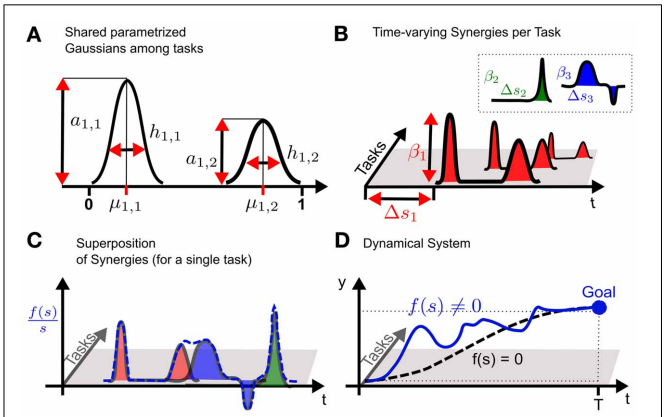

FIGURE 1 | Conceptual idea of using shared synergies in dynamical systems. (A) A synergy is constructed by a superposition of parametrized Gaussians. The parameters are the amplitude $a_{m,n}$, the mean $\mu_{m,n}$ and the bandwidth $h_{m,n}$. In the example two Gaussians ($n = 1..2$) are used to model the first $m = 1$ synergy. **(B)** For each task only the activation β_m of a synergy is learned. Time-varying synergies additionally implement a time-shift Δs_m. The key concept is that multiple tasks share the same parametrized synergies shown in **(A)**, which represent task related common knowledge. **(C)** For each task the non-linear function $f(s)$ is given by the weighted sum of the (time-shifted) synergies. Shown is a normalized version of $f(s)$ to illustrate the effects of the superposition also at the end of the movement, which would usually converge toward zero. **(D)** Finally, the non-linear function $f(s)$ is used to modulate a dynamical system. The unperturbed system with $f(s) = 0$ is denoted by the dashed line which is *attracted* by the goal state that is indicated by the large dot.

DMPs (Schaal et al., 2003) can be modeled as a special case of this formulation. For DMPs using $n = 1..N$ basis functions the mean $\mu_{m,n}$ and the bandwidth $h_{m,n}$ of the basis functions are fixed as discussed in Section 2.1. Solely the $n = 1..N$ amplitudes or weights $a_{m,n}$ are learned. By fixing these parameters and by modeling the non-linear function $f(s)$ for discrete movements or $f(\phi)$ for rhythmic movements using a single ($M = 1$) synergy our representation can be used to implement DMPs.

2.2.1. Multi-dimensional systems

For multi-dimensional systems for each actuator $d = 1..D$ an individual dynamical system in Equation 1 and hence an individual function $f(s, k)$ in Equation 5 or $f(\phi, k)$ in Equation 6 is used (Schaal et al., 2003). The phase variable s or ϕ is shared among all DoF (Note that $k = 1..K$ denotes the task.).

Extending our notation for multi-dimensional systems the non-linear function $f(s, k)$ in Equation 5 can be written as

$$\underbrace{f(s,d,k)}_{1\times 1} = \sum_{m=1}^{M} \underbrace{\beta_{m,k,d}}_{1\times 1} \underbrace{\Lambda\left(s, \boldsymbol{\theta}_{m,d}, \Delta s_{m,k,d}\right) s}_{1\times 1}.$$

Depending on the dimension d different weights $\beta_{m,k,d}$, policy vectors $\boldsymbol{\theta}_{m,d}$ and time-shift parameters $\Delta s_{m,k,d}$ are used. Note that the policy vector $\boldsymbol{\theta}_{m,d}$ is task-independent. Interestingly, when implementing additionally dimension-independent policy vectors, i.e., $\boldsymbol{\theta}_m$ anechoic mixing coefficients (Giese et al., 2009) can be modeled.

Here, we only discuss discrete movement representations, however, the reformulation procedure applies also for rhythmic movement parametrizations. Let us also define a vector notation of $\mathbf{f}(s, k)$

$$\underbrace{\mathbf{f}(s,k)}_{1\times D} = \sum_{m=1}^{M} \underbrace{\boldsymbol{\beta}_{m,k}}_{1\times D} \circ \underbrace{\mathbf{w}_m\left(s, \boldsymbol{\theta}_{m,1..D}, \Delta s_{m,k,d}\right)}_{1\times D}, \tag{9}$$

where the symbol $\circ$ denotes the Hadamard product, the element-wise multiplication of vectors. The synergy vectors are specified by

$$\begin{aligned}\mathbf{w}_m\left(s, \boldsymbol{\theta}_{m,1..D}, \Delta s_{m,k,d}\right) = \big[&\Lambda\left(s, \boldsymbol{\theta}_{m,1}, \Delta s_{m,k,1}\right) s,\\ &\Lambda\left(s, \boldsymbol{\theta}_{m,2}, \Delta s_{m,k,2}\right) s, \ldots,\\ &\Lambda\left(s, \boldsymbol{\theta}_{m,D}, \Delta s_{m,k,D}\right) s\big].\end{aligned}$$

This vector notation is used in the following to compare to existing synergies representations (d'Avella et al., 2003, 2006).

2.3. MUSCULOSKELETAL MODELS AND MUSCLE SYNERGIES

We also use the proposed movement representation, the DMPSynergies, to generate muscle excitation patters. These patterns are applied as input in a forward simulation of a musculoskeletal model. A schematic overview of such a simulation is shown in **Figure 2**. We briefly discuss all processes involved.

Muscle synergies for generating muscle excitation patterns are used as input in forward dynamics simulations. In our simulation experiments we evaluate time-varying synergies (d'Avella et al., 2006), which are a particular instance of the DMPSynergies, i.e., the weights $\beta_{m,k}$ and time-shift parameters $\Delta s_{m,k}$ in Equation 9 are independent of the dimension d. Thus, for discrete movements in multi-dimensional systems $f(s, k)$ reads

$$\underbrace{\mathbf{f}(s,k)}_{1\times D} = \sum_{m=1}^{M} \underbrace{\beta_{m,k}}_{1\times 1} \underbrace{\mathbf{w}_m\left(s + \Delta s_{m,k}, \boldsymbol{\theta}_{m,1..D}, 0\right)}_{1\times D}, \tag{10}$$

where $\beta_{m,k}$ is a scalar and the time-shift parameter $\Delta s_{m,k}$ is directly added to the phase variable s. This allows for a comparison to e.g., the formulation of time-varying synergies given in d'Avella et al. (2006), where

$$\mathbf{x}(t,k) = \sum_{m=1}^{M} a_m^k \mathbf{v}_m\left(t - t_m^k\right).$$

Shared synergies are represented by time-dependent vectors $\mathbf{v}_m(t - t_m^k)$, where in contrast to the proposed DMPSynergies a minor difference is the sign of the time-shift parameter t_m^k.

In this formulation of time-varying synergies (d'Avella et al., 2006) only the time-invariant combination coefficients a_m^k are task-dependent, whereas the vector $\mathbf{v}_m$ is task-independent. However, by using task, spatial or temporal (in)variant implementations of the mixing coefficients a or the basis vectors $\mathbf{v}$ other representations of synergies (d'Avella et al., 2003; Ivanenko et al., 2004; Giese et al., 2009) can be also implemented.

Activation dynamics model the effect of the delayed force generating process in muscles, as they are not capable of generating force instantaneously. Typically, for each muscle a first order differential equation is used, i.e., $\dot{a} = (f(s,k)^2 - f(s,k)a)/\tau_{\text{rise}} + (f(s,k) - a)/\tau_{\text{fall}}$ (Zajac, 1989).

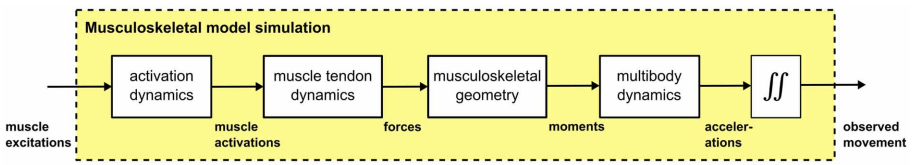

FIGURE 2 | Forward simulation of musculoskeletal models. Muscle excitation patterns are used as input, which result in a delayed muscle activity response (activation dynamics). Muscle forces are the result of simulated muscle tendon dynamics, which are typically approximated by a Hill-type contractile element in series with tendon. These muscle forces are used to compute moments of force considering the musculoskeletal geometry. A physics engine is finally used to simulate multibody dynamics which are numerically integrated to generate movement trajectories.

Here, $f(s, k)$ denotes the generated muscle excitation signal using e.g., the proposed DMPSynergies. The actual muscle activation is denoted by a, which is a function of the rise time constant τ_{rise} and the fall time constant τ_{fall}. For our evaluations we implemented $\tau_{\text{rise}} = 10\,\text{ms}$ and $\tau_{\text{fall}} = 40\,\text{ms}$ (Winters and Stark, 1985).

Muscle tendon dynamics describe the complex and non-linear force generation properties of muscles. For an approximation a variety of models exist (Zajac, 1989). In these models a muscle is approximated by a number of musculotendinous units, each of which is implemented by a Hill-type contractile element in series with tendon. Characteristic properties of muscles are the optimal fiber length L_0^M, the maximum isometric force F_0^M, and the muscle pennation angle α, which are shown in **Table A5** in the appendix for the investigated model of a human arm. The tendon dynamics in this musculoskeletal model were approximated by the muscle model proposed in Schutte et al. (1993).

Musculoskeletal geometry represents the path of a muscle from its origin to its insertion that can be implemented as a series of straight-line path segments, which pass through a series of via points (Delp et al., 2007). To simulate how muscles wrap over underlying bone and musculature wrapping surfaces i.e., cylinders, spheres and ellipsoids are implemented, where this model is based on the upper extremity model discussed in Holzbaur et al. (2005). A detailed description of the implemented musculoskeletal geometry is given in the supplement (in form of a simulation model file, .osim).

Multibody dynamics are simulated by the physics simulation application OpenSim (Delp et al., 2007; Seth et al., 2011). It is an open source software that already implements a variety of muscle models (Zajac, 1989) and a large number musculoskeletal models are freely available. In our experiments the computational time needed to simulate a movement with a duration of e.g., 500 ms takes between 10 and 20 s (OpenSim implements numerical integrators with an adaptive time step) on a standard computer (3 GHz and 4 GB memory). However, we exploited parallel computing techniques for policy search, which resulted in a gain of factor 10. Alternatively, the muscle dynamics could be approximated via regression methods to speed-up the simulations (Chadwick et al., 2009).

2.4. LEARNING WITH MOVEMENT PRIMITIVES

We denote the parametrization of a movement primitive by a policy vector $\boldsymbol{\theta}$. A widely used approach in robotics to learn these parameters is episodic reinforcement learning (Kober and Peters, 2011), which is outlined in **Figure 3A**. A policy search method is used to improve the movement primitive's representation $\boldsymbol{\theta}$ assuming a given objective or reward function $C(\tau) \in \mathbb{R}^1$. Throughout this manuscript $C(\tau)$ denotes a cost value that is equivalent to the negative reward in classical reinforcement learning (Sutton and Barto, 1998). It indicates the quality of an executed movement. A trajectory $\tau = \langle \mathbf{y}_{1:T}, \mathbf{u}_{1:T-1} \rangle$ is specified by the simulated joint angles $\mathbf{y}$ and the applied controls (torques) $\mathbf{u}$, where T denotes the number of time steps. We want to find a movement primitive's parameter vector $\boldsymbol{\theta}^* = \text{argmin}_{\boldsymbol{\theta}} J(\boldsymbol{\theta})$ which minimizes the expected costs $J(\boldsymbol{\theta}) = \mathbb{E}[C(\tau)|\boldsymbol{\theta}]$. We assume that we can evaluate the expected costs $J(\boldsymbol{\theta})$ for a given parameter vector $\boldsymbol{\theta}$ by performing roll-outs (samples) on the real or simulated system. In other words each movement trajectory is quantified by a single scalar reward $C(\tau)$, which can be used by an optimization method to improve the best guess of the movement policy $\boldsymbol{\theta}$.

For learning or optimizing the policy parameters $\boldsymbol{\theta}$ a variety of policy search algorithms exist in the motor control literature. Examples are the REINFORCE (Williams, 1992), the episodic Natural Actor Critic (Peters and Schaal, 2008), the Power (Kober and Peters, 2011) or the PI^2 (Theodorou et al., 2010) algorithm, which are reviewed in Kober and Peters (2011). Alternatively, standard optimization tools such as the 2nd order stochastic search methods (Hansen et al., 2003; Wierstra et al.,

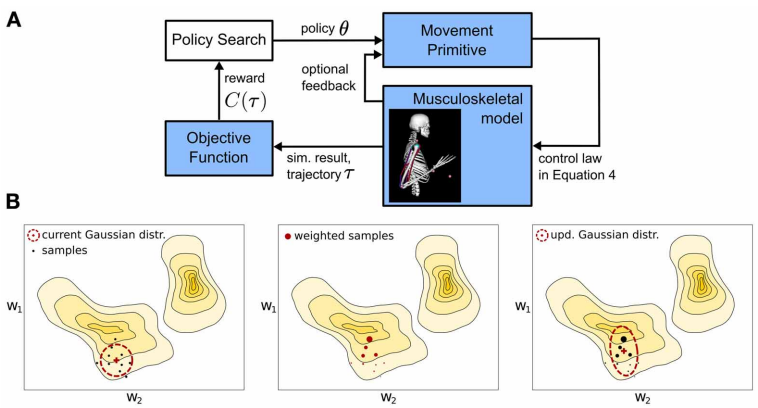

FIGURE 3 | Overview of the learning framework. (A) A parametrized policy $\boldsymbol{\theta}$ modulates the output of a movement primitive that is used to generate a movement trajectory τ. The quality of the movement trajectory is indicated by a sparse reward signal $C(\tau)$ which is used for policy search to improve the parameters of the movement primitive. For a single iteration the implemented policy search method - Covariance Matrix Adaptation (CMA) (Hansen et al., 2003) is sketched in **(B)**. The parameter space is approximated using a multivariate Gaussian distribution denoted by the ellipses, which is updated (from left to right) using second order statistics of roll-outs or samples that are denoted by the large dots (see text for details).

2008; Sehnke et al., 2010) can be used for policy search. These machine learning tools make no assumptions on a specific form of a policy and typically have just a single parameter to tune, the initial exploration rate. We therefore use the stochastic search method Covariance Matrix Adaptation (CMA) (Hansen et al., 2003) for learning the policy parameters in our experiments.

Roughly, CMA is an iterative procedure that locally approximates the function $C(\tau(\boldsymbol{\theta}))$ by a multivariate Gaussian distribution, which is denoted by the ellipse in the sketch in **Figure 3B**. From left to right a single optimization step for a two-dimensional policy vector $\boldsymbol{\theta} = [w_1, w_2]$ is shown. The colored regions denote the unknown optimization landscape, where solid lines depict equal $C(\tau)$ values. From the current Gaussian distribution, denoted by the ellipse in the left panel, CMA generates a number of samples, denoted by the black dots, evaluates the samples (the size of the dots in the center panel is proportional to their $C(\tau)$ values), computes second order statistics of those samples that reduced $C(\tau)$ and uses these to update the Gaussian search distribution, which is shown in right panel. For algorithmic details we refer to Hansen et al. (2003).

Note that for most interesting robotic tasks the unknown optimization landscape that is also sketched in **Figure 3B** is multimodal and policy search might converge to a local optimum. Thus, the result of learning is sensitive to the initial policy parameters $\boldsymbol{\theta}$ and for evaluating the convergence rate of different policy search methods multiple initial configurations should be considered (Kober and Peters, 2011). However, in this manuscript we evaluate the characteristics of movement primitive representations and put less emphasis on a particular policy search method. As we will demonstrate in our experiments CMA is robust in terms of converging to "good" solutions given the initial values of the evaluated movement primitive representations listed in the appendix.

In our experiments we compare single task learning with DMPs to learning multiple tasks simultaneously with DMPSynergies. With DMPs for each task $k = 1..K$ an individual policy vector $\boldsymbol{\theta}_k$ is learned, where the objective function used in policy search takes the task index as additional argument, i.e., $C(\tau, k)$. For learning multiple tasks simultaneously with DMPSynergies the policy vector $\boldsymbol{\theta}$ encodes all K task specific parameters $\beta_{m,k}$ and $\Delta s_{m,k}$, and all shared parameters denoted by θ_m in Equation 5 or Equation 6. The objective function is the sum of the individual task dependent costs $C(\tau) = \sum_{k=1}^{K} C(\tau, k)$.

3. RESULTS

We evaluated the proposed movement representation, the DMPSynergies, with simulations using three multi-task learning scenarios. A simple via-point task was used to illustrate the characteristics of the proposed movement representation. A challenging robotic learning task was used to generate rhythmic walking patterns for multiple step heights. Discrete reaching movements were learned using a musculoskeletal model of a human arm with eleven muscles.

3.1. VIA-POINT REACHING TASK WITH A SIMPLE TOY MODEL

The goal of this simple multi-task learning problem is to pass through $k = 1..5$ via-points ($\text{vp}_k \in \{0.2, 0.1, 0, -0.1, -0.2\}$), denoted by the large dots in **Figure 4A** and navigate to the goal state g at 1. We used a point mass system (1 kg), where the state at time t is given by the position y_t and the velocity $\dot{y}_t$. The applied controls u_t shown in **Figure 4B** are computed using the linear feedback control law with $k_{pos} = 400$ and $k_{vel} = 15$ specified in Equation 4. The finite time horizon is given by $T = 50$. For the dynamical system in Equation 1 we used the parameters $\alpha_z = 2$, $\beta_z = 0.9$ and $\tau = 0.1$. Further parameter settings used for policy search are summarized in **Table A1** in the appendix.

This task is specified by the objective function

$$C(k) = 10^5 \left(y_{t_{\text{vp}_k}} - \text{vp}_k\right)^2 + 10^4 \left(\dot{y}_T^2 + 10\left(y_T - g\right)^2\right) + 5 \cdot 10^{-4} \sum_{t=1}^{T} u_t.$$

The first two terms punish deviations from the via-point vp_k and the goal state g, where $y_{t_{\text{vp}_k}}$ denotes the position of the state at the time index of the kth via-point. The last term punishes high energy consumption, where u_t denotes the applied acceleration. Note that for simplicity we did not introduce the variable τ denoting the movement trajectory in $C(\tau, k)$ in Subsection 2.4. We always add a Gaussian noise term with a standard deviation of $\sigma = 0.5$ to the control action to simulate motor noise.

We used a single synergy ($M = 1$) with $N = 2$ Gaussians to model the shared prior knowledge. The learning curve is shown in **Figure 4C**, where we compare to single-task learning using DMPs with $N = 8$ Gaussian basis functions. For the via-point task 8 Gaussians were optimal with respect to the convergence rate, where we evaluated representations using $N = 2..20$ Gaussians (not shown). Additionally, we compare to an incremental learning setup (DMP inc.) in **Figure 4C**, where the DMP representation is always initialized with the best learned solution from the previous task. On the x-axis the number of samples or trajectory evaluations on the point mass system is plotted. As it can be seen the proposed approach can benefit from the shared knowledge and has a faster overall learning performance.

In this experiment, for each task we fixed the time-shift $\Delta s_k = 0$ and only learned the $k = 1..5$ weights β_k in Equation 5 (Note that the synergy index m was omitted as only a single synergy was used). For each of the $N = 2$ Gaussians we learned the mean μ, the bandwidth h and the amplitude a in Equation 7. Thus, in total $5 + 2 \times 3 = 11$ parameters were learned. In contrast with DMPs 8 Gaussian amplitudes were optimized.

The β values of the DMPSynergies representation for the five via-points are shown in **Figure 4D** for 10 runs. New motor skills can be generated without re-learning via a simple linear interpolation. The resulting trajectories are shown in **Figure 4E**. However, this is only the case in the simple via-point task. For more complex tasks these β values have to be learned.

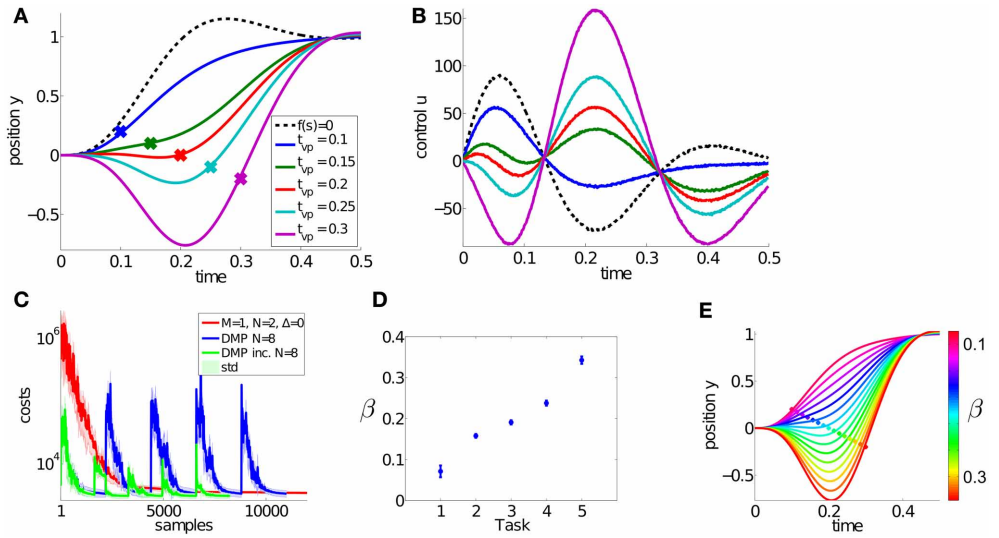

FIGURE 4 | Results for the dynamic via-point task. The goal of this simple multi-task learning problem is to pass through five via-points, denoted by the large dots in **(A)** and navigate to the target state at 1. The corresponding controls (accelerations) of this dynamical system are shown in **(B)**. These five trajectories are simultaneously learned using DMPSynergies with a single synergy ($M = 1$) represented by $N = 2$ Gaussians. We compare to dynamic movement primitives (DMPs) with $N = 8$ Gaussians and to an incremental variant of DMPs in **(C)**. For the DMP approaches each task (via-point) has to be learned separately. Thus, the two learning curves have five peaks. In contrast with DMPSynergies we could learn these five tasks at once, which resulted in faster overall convergence. The plot in **(D)** illustrates the mean and the standard deviation of the learned β values for the DMPSynergy approach. Via interpolating β and by reusing the learned synergy new motor skills can be generated without re-learning. This is illustrated in **(E)**, where $\beta \in [0.07, 0.34]$.

3.2. DYNAMIC BIPED WALKER TASK

To evaluate the DMPSynergies on a multi-dimensional robotic task we learned multiple walking patterns using a 5 degree-of-freedom (DoF) dynamic biped robot model, which is shown in **Figure 5A**. We demonstrate that by exploiting the shared knowledge among multiple walking gaits, solutions could be found more robustly and more efficiently in terms of learning speed compared to single task learning. Further, the shared synergies could be used to generalize new skills. The model is only as complex as required to study difficulties like limb coordination, effective underactuation, hybrid dynamics or static instabilities. More details on the design and challenges can be found in Westervelt et al. (2004).

The 10-dimensional state $\mathbf{q}_t = [q_{1:5}, \dot{q}_{1:5}]$ of the robot is given by the hip angles (q_1 and q_2), the knee angles (q_3 and q_4), a reference angle to the ground (q_5), and the corresponding velocities $\dot{q}_{1:5}$. Only the hip and the knee angles are actuated. Thus, 4 dynamical systems in Equation 1 are used to generate desired trajectories for the linear feedback controller in Equation 4. A phase resetting strategy is implemented to facilitate learning (Nakanishi et al., 2004). At each impact of the swing leg the phase ϕ in Equation 8 is set to zero. This increases the stability of the robot as the gait cycle duration is implicitly given by the impact time.

The initial state $\mathbf{q}_1 \in \mathbb{R}^{10}$, the goal state $\mathbf{g}$ and the control gains in Equation 4 were optimized in advance for a desired step height of $r^* = 0.2$ m to simplify learning. The resulting values are shown in **Table A2** in the appendix. For rhythmic movements the goal state $\mathbf{g} \in \mathbb{R}^5$ models an attractor point which is only specified for joint angles and not for velocities in Equation 1. As for the via-point reaching task, Gaussian noise with $\sigma = 1$ is added to the simulated controls. For Equation 1 we used the parameters $\alpha_z = 2$, $\beta_z = 0.5$ and $\tau = 0.06$. The initial parameter values and the applied ranges used for policy search are shown in **Table A3** in the appendix.

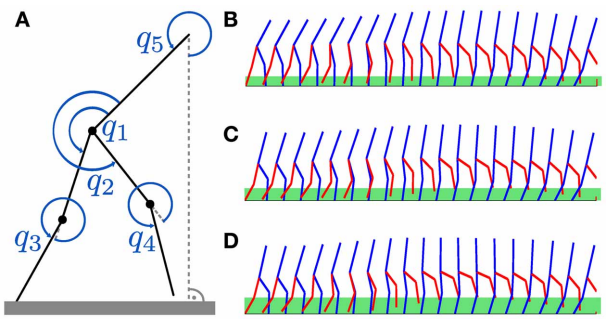

FIGURE 5 | Dynamic biped walker model. (A) For the walker model, only the hip angles q_1, q_2 and the knee angles q_3, q_4 are actuated. The reference angle to the flat ground is denoted by q_5. In this multi-task learning experiment we want to learn walking patterns for different step heights. Examples for step heights of 0.15, 0.25, and 0.3 m for a single step are shown in **(B–D)**. These patterns were learned using the proposed movement primitives with shared synergies ($M = 2$ and $N = 3$). The green bars in **(B–D)** denote the true (maximum) step heights, which are 0.19, 0.24, and 0.31 m.

In this multi-task learning experiment we want to learn walking patterns for different desired step heights: $r_k^* \in \{0.15, 0.2, 0.25, 0.3\}$ m. Example patterns for step heights of 0.15, 0.25 and 0.3 m are shown in **Figures 5B–D**, where the green

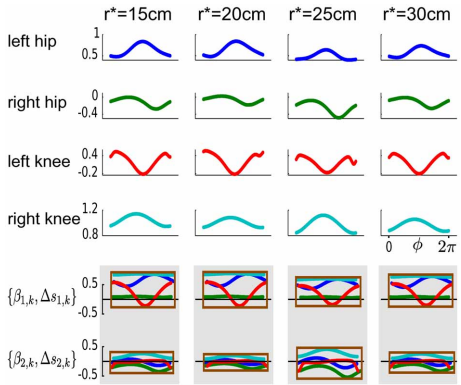

FIGURE 6 | Learned non-linear functions $f(\phi, k)$ for the walker task. The learned non-linear functions $f(\phi, k)$ are illustrated in the first four rows. The four task instances, i.e., the desired step heights are shown from left to right. For each actuator (left hip, right hip, left knee, and right knee) an individual function $f(\phi, k)$ is used that is generated by combining two learned synergies shown in the last two rows. These synergies are shared among multiple task instances and can be scaled and shifted in time (via $\beta_{m,k}$ and $\Delta s_{m,k}$). This is indicated by the enclosing rectangles, where the color of the synergies is used to distinguish the four actuators of the walker model.

Table 1 | Achieved costs for the walker task, where the standard deviation is denoted by the symbol ±.

Setup	Δ	C_{mean}	Best learned r [m]	#
$M = 2$	0	-20.3 ± 1.2	0.21, 0.21, 0.27, 0.27	56
$N = 2$	1	-20.8 ± 0.9	0.19, 0.23, 0.28, 0.26	88
$M = 2$	0	-21.4 ± 0.4	0.22, 0.24, 0.23, 0.26	80
$N = 3$	1	-20.5 ± 1.4	0.22, 0.22, 0.26, 0.28	112
$M = 3$	0	-19.0 ± 2.3	0.17, 0.19, 0.2, 0.26	84
$N = 2$	1	-19.6 ± 1.9	0.19, 0.22, 0.19, 0.2	132
$DMP_{N=4}$		-13.1 ± 0.8	0.17, 0.17, 0.23, 0.28	64
$DMP_{N=8}$		-14.8 ± 1.4	0.15, 0.2, 0.23, 0.29	128
DMP inc.$_{N=4}$		-19.2 ± 0.6	0.15, 0.20, 0.22, 0.3	64
DMP inc.$_{N=8}$		-18.8 ± 0.5	0.18, 0.19, 0.31, 0.26	128

In the second column the symbol **Δ** *denotes if additionally 16 M time-shift variables* **Δ*s*** *are learned. The total number of parameters is denoted by the symbol #, where e.g., for the representation in the 1st row 4 M = 8 task related weights and 3 · M · N · 4 = 48 shared parameters were optimized. The best results with the lowest costs denoted by C_{mean} are highlighted in gray shading.*

bars denote the maximum step heights during a single step (0.19, 0.24 and 0.31 m).

The objective function for a single walking task is given by the distance travelled in the sagittal plane, the duration of the simulation and deviations from the desired step height r_k^* with $k = 1..4$:

$$C(k) = -0.6(x_T - x_1) + 0.2(5 - T \cdot \Delta t) + 50 \sum_{i=1}^{S} (r_i - r_k^*)^2, \tag{11}$$

where x denotes the x-coordinate of the hip, S the number of steps and r_i the maximal step height during the ith step. We used a time step $\Delta t = 2$ ms. The time horizon $T \in [1, 5000]$ is given by the last valid state of the robot, where the biped does not violate the joint angle constraints specified by $\mathbf{q}_{\min}$ and $\mathbf{q}_{\max}$ in **Table A2** in the appendix.

With the proposed DMPSynergies the non-linear function $f(\phi, k)$ in Equation 6 is generated by combining a set of learned synergies that are shared among multiple task instances, i.e., the four ($k = 1..4$) desired step heights. This combination mechanism is illustrated for a representation using $M = 2$ synergies modeled by $N = 3$ Gaussians in **Figure 6**. For each actuator (left hip, right hip, left knee, and right knee) an individual function $f(\phi, k)$ is generated, which is subsequently used to modulate an attractor system shown in Equation 1 to compute the desired movement trajectories. The shared synergies shown in the last two rows in **Figure 6** can be scaled and shifted in time. This is indicated by the enclosing rectangles. Note that the color of the synergies is used to distinguish the four actuators of the walker model.

We evaluated different movement primitive representations with increasing complexity compared to single-task learning using DMPs with $N = 4$ and $N = 8$ Gaussians. The average final costs C_{mean} after learning over 10 runs are shown in **Table 1**. In the most simple representation we used $M = 2$ synergies modeled by $N = 2$ Gaussians. More complex representations implementing time-varying synergies are denoted by the symbol $\Delta = 1$ in **Table 1**. Here, additionally the time-shifts $\Delta s_{1:M}$ were learned for all synergies and all actuators. However, the final learning performance did not outperform the representation with fixed time-shifts (i.e., $M = 2$, $N = 3$ and $\Delta = 0$: -21.4 ± 0.4 compared to $M = 2$, $N = 3$ and $\Delta = 1$: -20.5 ± 1.4). This can be also seen in **Figure 7**, where we plot the learning curve for synergies with $\Delta s_{1:M} = 0$ in **Figure 7A** and the results for time-varying synergies in **Figure 7B**.

The average final cost value of the DMP representation is higher (i.e., $DMP_{N=8}$: -14.8 ± 1.4) compared to the best costs achieved with shared synergies ($M = 2$, $N = 3$ and $\Delta = 0$: -21.4 ± 0.4). This holds also for an incremental learning setup (e.g., DMP inc.$_{N=4}$: -19.2 ± 0.6), where DMPs were initialized with the best result from the previous task.

The joint angle trajectories of the left hip and knee joint for the DMPSynergy representation using $M = 2$ synergies modeled by $N = 3$ Gaussians and $\Delta = 1$ are illustrated in **Figure 8**. The average step heights were $r \in \{0.22, 0.22, 0.26, 0.28\}$, which do not match the desired step heights $r^* \in \{0.15, 0.2, 0.25, 0.3\}$. The reason for this is that the objective function in Equation 11 is designed to prefer correct multi-step walking movements over exact matches of the step heights since learning to walk is already a complex learning problem (approximately 90% of the costs are determined by the travelled distance and only 5% are caused by the distance to the desired step heights). However, for the different desired step heights the shape of the trajectories as well as the moment of the impact vary. The moments of impact are denoted by arrows in **Figure 8**.

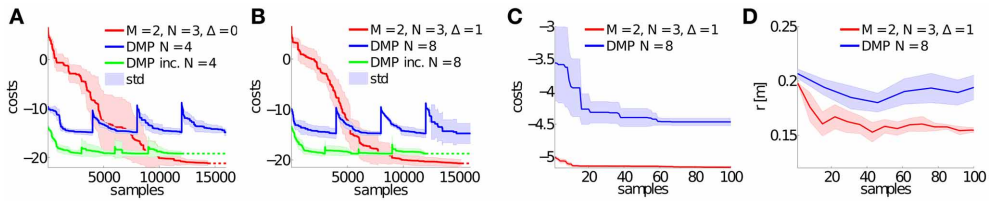

FIGURE 7 | Learning curves for the biped walker task. This figure illustrates the learning performance over 10 runs of the proposed approach using $M = 2$ synergies with $N = 3$ Gaussian basis functions. In **(A)** the time-shift variables $\Delta\mathbf{s}$ are not learned and set to zero. Whereas, in **(B)** also these $\Delta\mathbf{s}$ variables are adapted during learning. We compare to the dynamic movement primitives (DMP) with $N = 4$ Gaussians in **(A)** and to DMPs with $N = 8$ Gaussians in **(B)**. *DMP inc.* denotes an incremental learning setup, where DMPs were initialized with the best result from the previous task. Generalizing to a new step height ($r^* = 0.1$ m) is shown in **(C)**, where we applied the best learned policy for DMPSynergies from **(B)** and only optimized the weights $\beta_{1:2}$ for the two (fixed) synergies. The corresponding average step height over all steps is shown in **(D)**. We compare to DMPs with $N = 8$ Gaussians.

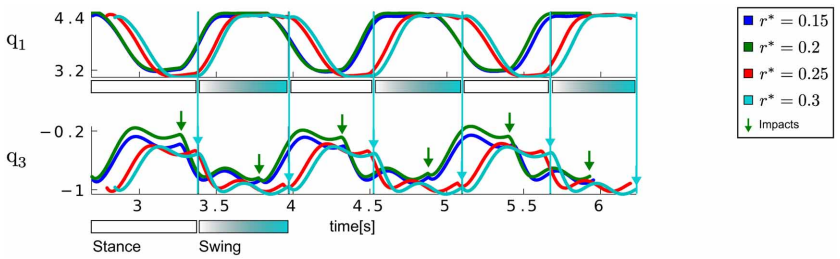

FIGURE 8 | Results for the biped walker task. This figure illustrates the (initially) left hip angle denoted by q_1 and the left knee angle (q_3) for the multi-task learning scenario. Shown are the best learned trajectories using the proposed approach (with $M = 2$, $N = 3$ and $\Delta = 1$) for the desired step heights of $r^* \in \{0.15, 0.2, 0.25, 0.3\}$. The true step heights of the learned walking patterns are $0.22 \pm 0.07, 0.22 \pm 0.08, 0.26 \pm 0.08, 0.28 \pm 0.08$. The points in time of the ground contacts are denoted by large arrows for desired step heights of 0.25 m and 0.3 m. For the later additionally the duration of the stance and the swing phases are illustrated by large boxes.

While generalizing to new motor skills was straightforward for the simple via-point task, for the walking tasks a linear interpolation turns out to be ineffective. We therefore demonstrate in **Figures 7C,D** how a new walking pattern for a desired step height of $r^* = 0.1$ m can be learned be reusing the previously learned prior knowledge (taking the best solution for $r^* = 0.25$ m) for $M = 2$ synergies modeled by $N = 3$ Gaussians and $\Delta = 1$. Only the weights $\beta_{1:M}$ are optimized in this experiment, keeping the learned time-shifts fixed. The costs in **Figure 7C** and the average step height r in **Figure 7D** demonstrate the advantage of using a fixed prior, where we compare to DMPs with $N = 8$ Gaussians.

3.3. MULTI-DIRECTIONAL REACHING TASK WITH A MUSCULOSKELETAL MODEL OF THE HUMAN ARM

A simplified model of a human arm based on the model by Holzbaur et al. (2005) was used to learn six reaching tasks simultaneously. The shoulder and the elbow joint were modeled by hinge joints. Thus, only movements in the sagittal plane were possible. The initial arm configuration and the six target locations (with a distance of 15cm to a marker placed on the radial stylion) are shown in **Figure 9A**. A learned example movement is illustrated in **Figure 9B**, where the cylinders, the spheres and the ellipsoids denote wrapping surfaces discussed in Subsection 2.3.

We focused on fast reaching movements of 500 ms duration ($T = 500$ and $\Delta t = 1$ ms) that can be implemented in an open-loop control scheme. Note that with our approach also closed-loop systems with feedback could be implemented, as discussed below. Thus, the learnable non-linear function $\mathbf{f}(s, k)$ in Equation 10 is directly used as input to the system in form of muscle excitation patterns. The parameter settings for learning are shown in **Table A4** in the appendix.

For learning the reaching tasks we evaluated the Euclidean distance of a marker $\mathbf{v}_k(t)$ placed on the radial stylion to a given target $\mathbf{g}_k$, where $k = 1..6$ denotes the task index. Additionally, large muscle excitations signals are punished:

$$C(k) = \sum_{k=1}^{6} 3 \cdot \frac{1}{T} \sum_{t=1}^{T} \|\mathbf{g}_k - \mathbf{v}_k(t)\| + 10^{-3} \int_{s=0}^{1} \mathbf{f}(s,k)^T \mathbf{f}(s,k) \mathrm{d}s, \tag{12}$$

where $\|.\|$ denotes the Euclidean distance between the marker $\mathbf{v}_k(t)$ and the target $\mathbf{g}_k$ at time t.

We evaluated five movement representations, defined in Equation 10, with an increasing number of shared synergies, i.e., $M = \{1, 2, 3, 4, 5\}$. Each synergy is represented by a single ($N = 1$) Gaussian. For each target and for each synergy the task-specific parameters $\beta_{k,m}$ and $\Delta s_{k,m}$ are learned. The number of task-specific and the number of task-invariant or shared parameters is shown in **Table 2**.

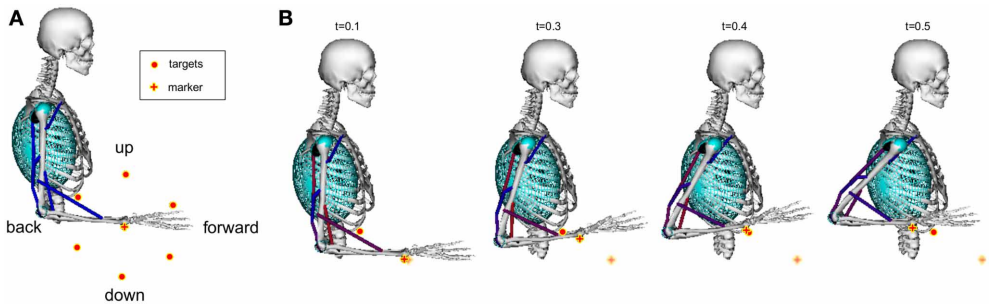

FIGURE 9 | Musculoskeletal model for learning reaching tasks. A model of a human arm with eleven muscles shown in **Table A5** in the appendix was used to learn six reaching skills in the sagittal plane **(A)**. As reward signal we encoded the distance to a marker placed on the radial stylion (denoted by the *plus* symbol) and punished large muscle excitation signals. Targets are denoted by large dots. We focused on fast reaching skills of 500 ms duration, where an example movement is shown in **(B)**. To simulate how muscles wrap over underlying bone and musculature wrapping surfaces are implemented as cylinders, spheres and ellipsoids (Holzbaur et al., 2005).

Table 2 | Details of the evaluated parametrizations and achieved costs for the reaching task.

No. of synergies	C_{mean}	$\#_K$	$\#_M$	Total
$M = 1$	2.38 ± 0.05	12	33	45
$M = 2$	1.52 ± 0.12	24	66	90
$M = 3$	1.15 ± 0.12	36	99	135
$M = 4$	1.15 ± 0.05	48	132	180
$M = 5$	1.17 ± 0.05	60	165	225

M denotes the number of implemented synergies, C_{mean} the final cost values, and the symbol $\pm$ the standard deviation. We use $\#_K$ to denote the number of task-specific parameters ($6 \cdot M$) and $\#_M$ to denote the number of task-invariant or shared parameters ($3 \cdot 11 \cdot M$).

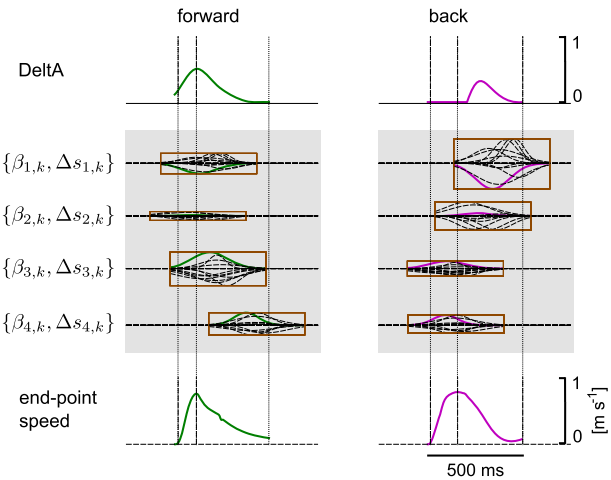

FIGURE 10 | Synergy combination mechanism. We hypothesize that a muscle excitation signal can be generated by combining a small number of learned synergies. Here, we illustrate this combination process for the deltoid anterior (DeltA) with four synergies for two movement directions. For the two movement directions different combination coefficients $\beta_{m,k}$ and different time-shift parameters $\Delta s_{m,k}$ were learned. The synergies are represented by a single parametrized Gaussian, where the corresponding basis function for DeltA is denoted by a bold line in the enclosing rectangles.

We hypothesized that a muscle excitation signal can be generated by combining a small number of learned synergies. An example for the anterior deltoid muscle (DeltA) is shown in **Figure 10** for two movement directions. Here, DMPSynergies with $M = 4$ synergies were used to generate the muscle excitation patterns. The muscle excitation patterns for all six movement directions and all eleven muscles are shown in **Figure 11**. Two observations can be made: first, as our objective function in Equation 12 punishes large muscle excitation signals a sparse representation of multiple motor skills is learned. Second, the learned muscle patterns partially show the typical triphasic behavior of human movement (Angel, 1975; Hallett et al., 1975; Berardelli et al., 1996; Chiovetto et al., 2010), where individual muscles (e.g., DeltA, PectClav and BRA in the first column in **Figure 11**) become activated at the onset of the movement, shortly before the velocity peak to decelerate, and finally, multiple muscles co-contract at the target location. These three events are denoted by the labels 1, 2, and 3 in the last row in **Figure 11**, where a threshold of 2 cm s^{-1} was used to determine the movement onset and the termination of the movement.

Comparing all five movement representations ($M = \{1, 2, 3, 4, 5\}$), we found that at least three synergies were necessary to accomplish all reaching tasks. This is shown in **Figure 12A**, where with only one ($M = 1$) or two synergies ($M = 2$) not all targets can be reached. Shown are the marker trajectories of three independent learning sessions (out of ten runs). Note that similar findings were obtained in analyzing human arm reaching movements, where four to five synergies were observed (d'Avella et al., 2006). The corresponding learning curves for all five movement representations are shown in **Figure 12B**, where the parametrizations with $M = 3..5$ synergies perform equal. This is also reflected in the final costs shown in **Table 2** (rows 3..5). As an example the marker trajectories and the tangential velocity profiles for the representation using $M = 4$ synergies are illustrated in **Figure 12C**. As we evaluated an open-loop control scheme these marker trajectories did not exactly terminate at the target location (after the limited number of episodes for learning). However, by increasing the number of episodes or by adding feedback the terminal accuracy could be improved.

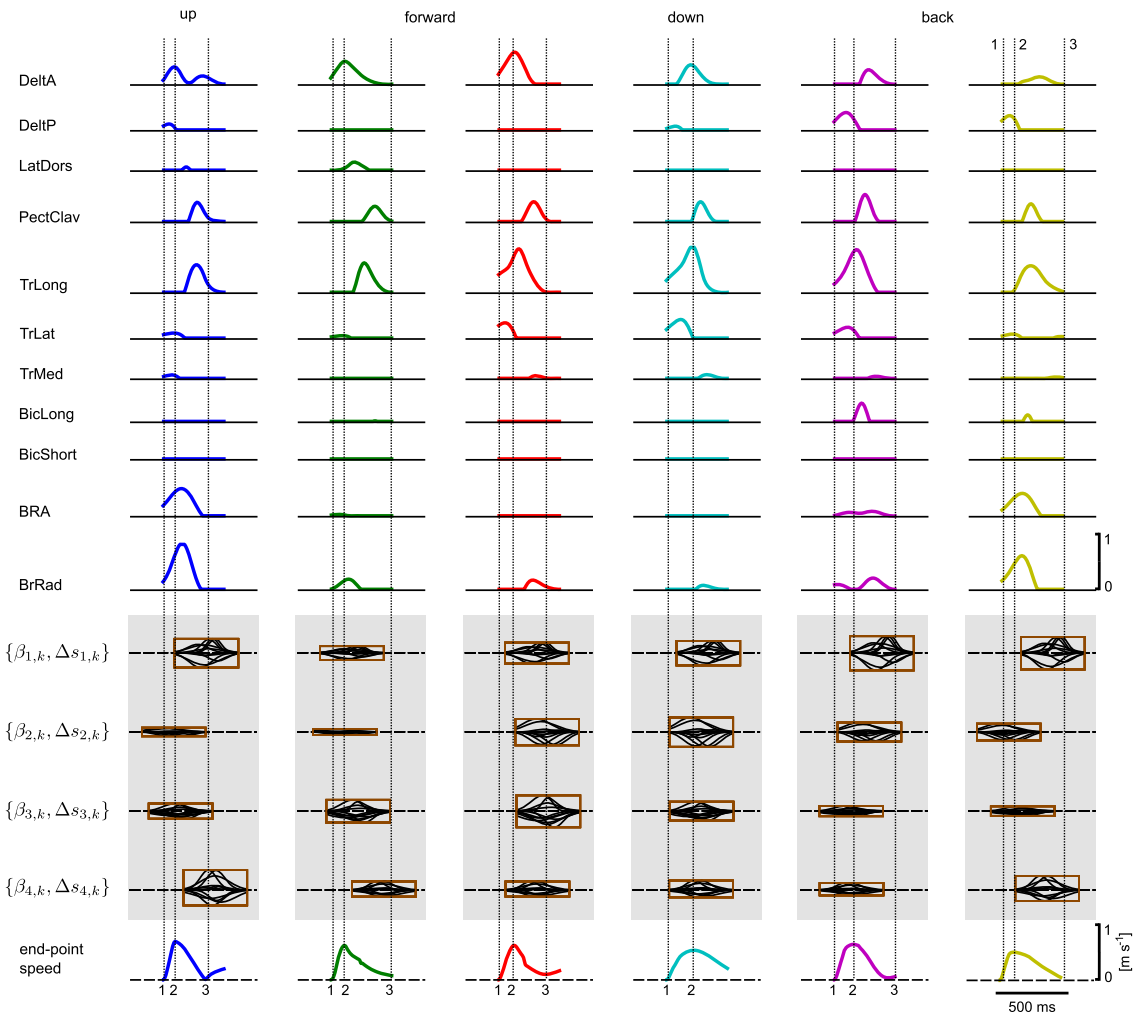

FIGURE 11 | Learned muscle excitation patterns. Shown are the muscle excitation patterns for all six targets (from left to right) and for all muscles (rows one to eleven). In the last row the tangential velocity profiles of the marker placed on the radial stylion is illustrated (see text for details).

For testing the generalization ability of DMPSynergies we rotated all six targets by 30 degrees and only re-learned the task-specific coefficients, i.e., the mixing coefficients $\beta_{m,k}$ and the time-shift parameters $\Delta s_{m,k}$. Interim solutions with a movement representation implementing $M = 4$ synergies are shown in **Figure 13A**. Note that, as we evaluated an open-loop controller, the rotated targets were unknown to the controller. Solely the objective function in Equation 12 quantifies deviations from the targets. After 15 episodes a first trend toward the new targets was visible, however, most of the trajectories (three learned solutions are illustrated) ended at the original targets. The corresponding learning curves for DMPSynergies with three ($M = 3$) and four ($M = 4$) synergies are shown in **Figure 13B**. The learning curve for the unperturbed scenario from the previous experiment is denoted by the dashed line ($M = 4$ orig.). Note that in both - the unperturbed and the perturbed experiments $K = 6$ reaching movements were learned, which demonstrates the benefit of the shared learned knowledge when generalizing new skills. For a comparison the blue line denoted by DMP $N = 4$ illustrates the convergence rate of single task learning with DMPs, where DMPSynergies ($M = 4$ orig.) can compete in terms of learning speed.

4. DISCUSSION

We proposed a movement representation based on learned parametrized synergies (DMPSynergies) that can be linearly combined and shifted in time. These learned synergies are shared among multiple task instances significantly facilitating learning of motor control policies. This was demonstrated on simulated robotic and on musculoskeletal systems. Below we discuss the significance and the implication of our findings with respect to robotics and biological motor control.

4.1. EXPLOITING SHARED SYNERGIES FOR MOTOR SKILL LEARNING IN ROBOTICS

For motor skill learning in robotics a common strategy is to use parametrized elementary movements or movement primitives (Kober and Peters, 2011). In this paper we proposed

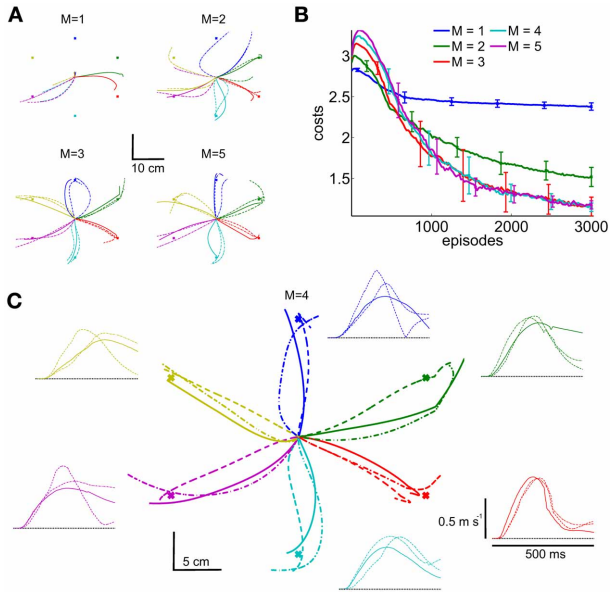

FIGURE 12 | Learning multi-directional reaching movements. We evaluated five movement representations with an increasing number of shared synergies, i.e., $M = \{1, 2, 3, 4, 5\}$. The resulting trajectories of the marker placed on the radial stylion are shown in **(A,C)**, where with less than three synergies not all targets can be reached. Illustrated are three independent learning results. In **(B)** we illustrate the average learning curves over 10 runs for these movement representations. For the representation using $M = 4$ synergies shown in **(C)** additionally the tangential velocity profiles are illustrated.

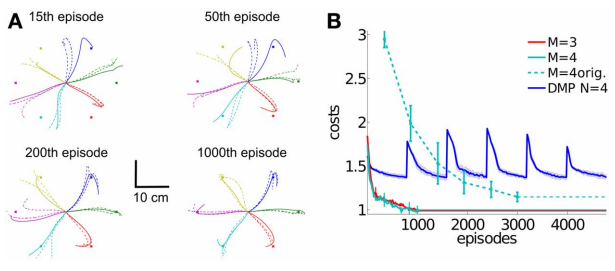

FIGURE 13 | Generalization to new reaching directions. For testing the generalization ability of the proposed DMPSynergies we fix the learned shared synergies and only adapt the task-specific parameters, i.e., the mixing coefficients $\beta_{m,k}$ and the time-shift parameters $\Delta s_{m,k}$. The $K = 6$ targets were rotated by 30 degrees, where in **(A)** the marker trajectories after 15, 50, 200, and 1000 episodes for a movement representation with $M = 4$ synergies are shown. In **(B)** we show the averaged learning curves for DMPSynergies with three and four synergies over 10 runs ($M = 3$ and $M = 4$). The learning curve for the unperturbed scenario from the previous experiment is denoted by the dashed line ($M = 4$ orig.). For a comparison the blue line denoted by DMP $N = 4$ illustrates the convergence rate of single task learning.

a generalization of the most widely used movement primitive representation in robotics, dynamic movement primitives (DMPs) (Schaal et al., 2003; Ijspeert et al., 2013). DMPs evaluate parametrized dynamical systems to generate trajectories. The dynamical system is constructed such that the system is stable. This movement representation has many advantages. It is a model-free approach, partially explaining its popularity in robotics as model learning in high-dimensional stochastic robotics systems is challenging. Further, its stable attractor system facilitates learning and DMPs can represent both rhythmic and discrete movements. Meta parameters can be used for adapting the movement speed or the goal state. Finally, the movement representation depends linearly on the policy parametrization, i.e., the learnable function f depends linearly on the parameters $\boldsymbol{\theta}$ of the movement primitive: $f(s) = \boldsymbol{\Phi}(s)^T\boldsymbol{\theta}$, where s is the time or phase variable. As a result, imitation learning for DMPs is straightforward, as this can simply be done by performing linear regression (Schaal et al., 2003). However, for each task k an individual set of parameters $\boldsymbol{\theta}_k$ has to be learned, which unnecessarily complicates learning of a large number of related motor skills. In contrast we proposed a generalization that allows for reusing shared knowledge among multiple related motor skills, i.e., the parameter vector $\boldsymbol{\theta}$ is task-invariant.

In particular, we replaced the non-linear modulation function $f(.)$ in DMPs by a hierarchical function approximator. On the lower level task related parameters (amplitude scaling weights and time-shift parameters) are used to modulate a linear superposition of basis functions. These basis functions encode shared higher level knowledge and are modeled by a mixture of Gaussians. With the proposed DMPSynergies representation discrete and rhythmic movements can be generated. By using Gaussians at the higher level DMPs can be implemented as special case. However, the DMPSynergies can compete with DMPs in terms of learning efficiency while allowing for learning multiple motor skills simultaneously.

This was demonstrated in two robotic multi-task learning scenarios, where we showed that, with the DMPSynergies, good policies could be found more reliably, i.e., local minima with high cost values were more often avoided, more efficiently (fewer samples were needed), and new skills could be generalized by exploiting the previously learned shared knowledge. A simple via-point task was used to demonstrate the characteristics of the approach, where the proposed movement representation could be used to generalize new movement trajectories by applying a linear interpolation on the synergy's weights β. In a second robotic task, a biped walker task, the hierarchical representation was used to learn walking patterns with multiple step heights. In this complex reinforcement learning task, it was shown that better solutions were found more reliably by exploiting the learned shared knowledge, which is a strong feature of a movement representation. While also with the classical DMP approach high quality movement gaits were learned, on average the achieved costs were higher compared to the proposed hierarchical synergies representation, i.e., -19.2 ± 0.6 for DMPs with 4 Gaussians (and with incremental learning) compared to -21.4 ± 0.4 when using $M = 2$ synergies with $N = 3$ Gaussians (where the time-shift parameters were fixed and set to zero, $\Delta = 0$). In this experiment 10,000 samples were needed to learn 4 walking gaits simultaneously, where the DMPSynergies approach can compete with DMPs (15,000 samples). Additionally, we demonstrated in a generalization experiment that walking patterns for an unknown step height ($r^* = 0.1$ m) could be learned

with 100 samples by exploiting the previously learned prior knowledge.

While DMPs (Schaal et al., 2003; Ijspeert et al., 2013) are most closely related to our shared synergies approach, there exist a few other approaches (Chhabra and Jacobs, 2006; Alessandro et al., 2012) also implement shared knowledge. In Chhabra and Jacobs (2006) a variant of non-negative matrix factorization (d'Avella et al., 2003) was used to compute the synergies given a set of trajectories created by applying stochastic optimal control methods (Li and Todorov, 2004). In Alessandro et al. (2012) an exploration phase was introduced to compute the dynamic responses of a robot system with random initialization. After a reduction phase, where a small number of proto-tasks were executed, a reduced set of dynamic responses was used to compute the synergies matrix by solving a linear system of equations. We proposed an alternative for learning the synergies and their combination parameters, where all unknowns are learned in a reinforcement learning setting from a single sparse reward signal. Moreover, for robotic tasks we embed the synergies approach in stable dynamical systems like in DMPs. This combines the benefits of DMPs and muscle synergies, namely the efficient learning ability of DMPs in high-dimensional systems and the hierarchical representation of movements that can be used for multi-task learning.

As with DMPs the complexity of the DMPSynergies representation can be scaled by the number of combined synergies or the number of implemented Gaussians modeling these synergies. However, as the trajectories generated with our representation depend non-linearly on the policy parameters (in contrast to DMPs) more sophisticated decomposition strategies like for example d'Avella and Tresch (2001); Chiovetto et al. (2013) are needed for imitation learning. With such approaches the extracted synergies could be implemented as initial solutions in our learning framework.

4.2. LEARNED SHARED SYNERGIES FOR BIOLOGICAL MOVEMENT GENERATION

The idea of reusing shared knowledge for movement generation is a well-known concept in biological motor control. Muscle activation patterns recorded during multiple task instances of natural motor behavior, i.e., fast reaching movements of humans (d'Avella et al., 2006), primate grasping movements (Overduin et al., 2008), or walking patterns (Dominici et al., 2011), could be efficiently modeled by combining only few muscle activation patterns. In particular, time-varying muscle synergies (d'Avella et al., 2003; Bizzi et al., 2008) were proposed to be a compact representation of muscle activation patterns. The key idea of this approach is that muscle activation patterns are linear sums of simpler, elemental functions or synergies. Each muscle synergy can be shifted in time and scaled with a linear factor to construct a large variety of activation patterns. In this manuscript we proposed a generative model to represent and learn time-varying synergies (d'Avella et al., 2006).

The proposed framework allows for studying the concept of muscle synergies from a generative perspective in contrast to the analytical approach, where muscle synergies are identified from observed data. Applying such a generative approach to a musculoskeletal model, we could provide a proof-of-concept of the feasibility of a low-dimensional controller based on shared synergies and a demonstration of its learning efficiency. Moreover, we could ask different question, i.e., how does performance scale with the complexity of the movement representation, how sparse is the encoding of the muscle patterns to solve particular tasks, and how well does the learned representation generalize to new movements? We addressed these questions in a multi-directional reaching task, where we investigated a musculoskeletal model of the upper limb with 11 muscles. Motor skills for 6 reaching directions were learned within 3000 episodes and by exploiting the learned shared synergies movements for rotated target directions can be generalized 3 times faster (**Figure 13**). We found that a minimum of three synergies were necessary to solve the task (**Figure 12B**). In our objective function large muscle excitation signals were punished, which resulted in a sparse representation of muscle excitation patterns. This sparse representation illustrated in **Figure 11** shows similarities to observed electromyographic activity recorded in related human reaching tasks (d'Avella et al., 2006), i.e., triphasic muscle patterns, where some of the muscles contributed at the movement onset, some at point of the maximum tangential velocity, and some at the end of the movement to co-contract. However, sensor feedback might be an important modulation signal to make this effect more pronounced.

The model was designed to capture salient features of human musculoskeletal system, such as muscle activation dynamics, Hill-type musculotendinous units, realistic geometry. However, to reduce the computational effort needed to simulate a movement we made a few simplifying assumptions. First, a limited number of muscles (11) were implemented, where simplified wrapping objects and muscle paths were modeled. Further, we implemented the shoulder and the elbow joint as hinge joints. Thus, only reaching movements in the sagittal plane could be performed. Finally, we focused on fast reaching movements in an open-loop control scheme. This was a valid assumption for comparing to human data for fast reaching movements (d'Avella et al., 2006). However, our proposed learning and control framework also allows for implementing closed-loop controllers, i.e., when introducing an inverse kinematics model $\mathbf{\Psi} \in \mathbb{R}^{Dx3}$ in Equation 1, i.e., $\tau\dot{\mathbf{z}} = \mathbf{\Psi}(\alpha_z(\beta_z(\mathbf{g} - \mathbf{y}^*) - \mathbf{z})) + \mathbf{f}$, where D denotes the number of actuators and we assumed that the goal state $\mathbf{g}$ lives in a three-dimensional Cartesian space. The inverse kinematics model $\mathbf{\Psi}$ maps the feedback error signal into the muscle pattern space and modulates the learned muscle excitation basis $\mathbf{f} \in \mathbb{R}^D$. With such closed-loop systems we might better understand the contribution of feedback to muscle control in biological movement generation (Lockhart and Ting, 2007).

Musculoskeletal models have been used before to investigate movement generation with muscle synergies (Berniker et al., 2009; Neptune et al., 2009; McKay and Ting, 2012). Berniker and colleagues used model-order reduction techniques to identify synergies as a low-dimensional representation of a non-linear system's input/output dynamics and optimal control to find the activations of these synergies necessary to produce a range of movements. They found that such a set of synergies was capable of producing effective control of reaching movements with

a musculoskeletal model of a frog limb and that it was possible to build a relatively simple controller whose overall performance was close to that of the system's full-dimensional non-linear controller. Neptune and colleagues generated muscle-actuated forward dynamics simulations of normal walking using muscle synergies identified from human experimental data using non-negative matrix factorization as the muscle control inputs. The simulation indicated that a simple neural control strategy involving five muscle synergies was sufficient to perform the basic sub-tasks of walking. McKay and Ting, studying an unrestrained balance task in cats, used a static quadrupedal musculoskeletal model of standing balance to identify patterns of muscle activity that produced forces and moments at the center of mass (CoM) necessary to maintain balance in response to postural perturbations. CoM control could be accomplished with a small number of muscle synergies identified from experimental data, suggesting that muscle synergies can achieve similar kinetics to the optimal solution, but with increased control effort compared to individual muscle control. In line with these simulation studies, we also found that a small number of muscle synergies was sufficient to perform multiple reaching tasks in a forward dynamic simulation of a musculoskeletal model. However, we did not use experimental data or model-order reduction techniques to identify muscle synergies. In our framework, both synergy structural parameters and synergy combination parameters were found with reinforcement learning, supporting the generality of the solutions identified. Moreover, we were able to test the generalization ability of the synergies in the same framework by optimizing only the task-specific synergy combination parameters.

The proposed reinforcement learning framework with movement primitives relates to optimal control approaches in the biological motor control literature (Delp et al., 2007; Erdemir et al., 2007). In these simulation studies muscle patterns are parametrized by e.g., bang-bang (on-off) controls, constant control values, or control vectors approximated with polynomials [see Table 2 in Erdemir et al. (2007) for an overview of different control strategies]. However, to the best of our knowledge non of these approaches implemented shared synergies as control signal representation for learning multiple task instances simultaneously. Even with complex representations, e.g., with $M = 5$ synergies learning 225 parameters converged within 3000 episodes, which is a promising feature of the proposed approach for studies on more complex musculoskeletal models.

In this manuscript we demonstrated how time-varying synergies (d'Avella et al., 2006) can be implemented and learned from scratch. Interestingly, by adding an additional constraint on the movement representation, i.e., by using a single policy vector for all actuators anechoic mixing coefficients (Giese et al., 2009) can be implemented. However, in general any synergy representation such as synchronous synergies (Ivanenko et al., 2004; Dominici et al., 2011) used for locomotion can be learned. Thus, we do not argue for a particular synergy representation. Our representation was motivated to extend the widely used DMPs (Schaal et al., 2003) for exploiting shared task-invariant knowledge for motor skill learning in robotics.

5. CONCLUSION

We proposed a movement primitive representation implementing shared knowledge in form of learned synergies. The representation competes with the state-of-the-art, it can implement DMPs (Schaal et al., 2003) as a special case, and it allows for an efficient generalization to new skills. Importantly, shared knowledge simplifies policy search in high-dimensional spaces, which was demonstrated in a dynamic biped walking task. Further, the proposed learned synergies are a compact representation of high-dimensional muscle excitation patterns, which allows us to implement reinforcement learning in musculoskeletal systems. In such frameworks muscle patterns are learned from scratch using a sparse reward signal, where we could investigate how muscles and muscle synergies contribute to a specific task, how complex a task-invariant representation must be, and how well the learned synergies generalize to changes in the environment. In a multi-directional arm reaching experiment we provided first insights to these questions. In future research the proposed movement generation and learning framework will be used to study feedback signals and feedback delays, imitation learning from biological data and the effect of simulated muscle surgeries.

APPENDIX

For the via-point task the parameter settings for learning are shown in **Table A1**. Initial parameter values and parameter settings for policy search for the biped walker task are shown in **Table A2** and in **Table A3**. In **Table A4** we list the learning settings for the multi-directional reaching task using a musculoskeletal model of a human arm. The implemented muscles and their characteristic parameters are shown in **Table A5**.

Table A1 | Parameter settings for the discrete via-point task.

Parameter	Range	Initial value
a, (w)	$\in [-5, 5]$	$a^0 = 0$
μ, (μ)	$\in [0, 1]$	μ^0 spaced linearly in $[0, 1]$
h, (h)	$\in [0.01, 1]$	$h^0 = 0.1$
β	$\in [0, 100]$	$\beta^0 = 1$

In brackets are the variable names for the dynamic movement primitives, which are used for comparison.

Table A2 | Biped walker setting of pre-optimized quantities.

Variable	Value
q_1	[3.5, 4.4, −0.07, −0.5, −0.7, −1.5, −0.6, −1.0, 0.3, −0.4]
g	[2.8, 4.5, −0.3, −1.8]
k_{pos}	[632.5, 885.6, 463.4, 643.7]
k_{vel}	[14.5, 13.2, 38.6, 40.6]
q_{min}	[2.8, 2.8, −2.6, −2.6, −1.04]
q_{max}	[4.7, 4.7, 0, 0, 1.0]

Table A3 | Policy search parameter settings for the rhythmic walking task.

Parameter	Range	Initial value
a, (w)	$\in [-2, 2]$	$a^0 = 0$
μ, (μ)	$\in [0.8\mu^0, 1.2\mu^0]$	μ^0 spaced linearly in $[0, 2\pi]$
h, (h)	$\in [0.1, 10]$	$h^0 = 1$
β	$\in [0, 2]$	$\beta^0 = 1$
Δs	$\in [0, 0.5]$	$\Delta s^0 = 0$

In brackets are the variable names for the dynamic movement primitives.

Table A4 | Parameter settings for the multi-directional reaching task.

Parameter	Range	Initial value
a	$\in [-1, 1]$	$a^0 = 0.5$
μ	$\in [0.3, 0.7]$	μ^0 spaced linearly in $[0.3, 0.7]$
h	$\in 8[10^{-5}, 10^{-3}]$	$h^0 = 8 \cdot 10^{-4}$
β	$\in [0, 1]$	$\beta^0 = 1$
Δs	$\in [-0.2, 0.2]$	$\Delta s^0 = 0$

Table A5 | Characteristic muscle parameters of an upper limb model taken from Garner and Pandy (2001).

	L_0^M [cm]	L_s^T [cm]	F_0^M [N]	α [rad]
Anterior deltoid (DeltA)	14.68	**9.3** (1.64)	277.48	0
Posterior deltoid (DeltP)	17.02	5.93	567.15	0
Latissimus dorsi-thoracic (LatDors)	34.87	14.75	173.43	0
Pectoralis major-clav (PectClav)	22.65	0.45	342.46	0
Triceps brachii-long (TrLong)	15.24	**25.05** (19.05)	629.21	0.26
Triceps brachii-lateral (TrLat)	6.17	19.64	1268.87	0.26
Triceps brachii-medial (TrMed)	4.9	**18.19** (12.19)	619.67	0.26
Biceps-long (BicLong)	15.36	**32.93** (22.93)	392.91	0.17
Biceps-short (BicShort)	13.07	**26.98** (22.98)	461.76	0.17
Brachialis (BRA)	10.28	**9.75** (1.75)	853	0.17
Brachioradialis (BrRad)	27.03	6.04	101.58	0.08

The tendon slack length is denoted by L_s^T, the maximum isometric force by F_0^M, the optimal fiber length by L_0^M, and the muscle pennation angle by α. To increase the reachable space, we adapted the tendon slack length L_s^T of a small number of muscles (bold numbers vs. the original values in brackets).

Human locomotion has been described as being generated by an impulsive (burst-like) excitation of groups of musculotendon units, with timing dependent on the biomechanical goal of the task. Despite this view being supported by many experimental observations on specific locomotion tasks, it is still unknown if the same impulsive controller (i.e., a low-dimensional set of time-delayed excitation primitives) can be used as input drive for large musculoskeletal models across different human locomotion tasks. For this purpose, we extracted, with non-negative matrix factorization, five non-negative factors from a large sample of muscle electromyograms in two healthy subjects during four motor tasks. These included walking, running, sidestepping, and crossover cutting maneuvers. The extracted non-negative factors were then averaged and parameterized to obtain task-generic Gaussian-shaped impulsive excitation curves or primitives. These were used to drive a subject-specific musculoskeletal model of the human lower extremity. Results showed that the same set of five impulsive excitation primitives could be used to predict the dynamics of 34 musculotendon units and the resulting hip, knee and ankle joint moments (i.e., $NRMSE = 0.18 \pm 0.08$, and $R^2 = 0.73 \pm 0.22$ across all tasks and subjects) without substantial loss of accuracy with respect to using experimental electromyograms (i.e., $NRMSE = 0.16 \pm 0.07$, and $R^2 = 0.78 \pm 0.18$ across all tasks and subjects). Results support the hypothesis that biomechanically different motor tasks might share similar neuromuscular control strategies. This might have implications in neurorehabilitation technologies such as human-machine interfaces for the torque-driven, proportional control of powered prostheses and orthoses. In this, device control commands (i.e., predicted joint torque) could be derived without direct experimental data but relying on simple parameterized Gaussian-shaped curves, thus decreasing the input drive complexity and the number of needed sensors.

Keywords: EMG-driven modeling, musculoskeletal modeling, lower extremity, multiple degrees of freedom, muscle dynamics, muscle synergy

INTRODUCTION

Human movement is the result of the coordinated excitation of musculotendon units (MTUs), which actuate multiple joints in the upper and lower extremities. Because of the inherent redundant nature of the human neuromuscular system, multiple MTU excitation patterns can result in the same joint moment, position, and motion (Tax et al., 1990; Buchanan and Lloyd, 1995). When performing a motor task, the neural drive to MTUs defines the specific excitation patterns among the many possible solutions. Understanding the mechanisms underlying an individual's excitation patterns is an open question in current movement neuroscience and biomechanics. This is fundamental for understanding human locomotion and for the development of novel neurorehabilitation technologies.

The neural drive, or excitation, to MTUs is ultimately determined by action potential trains generated from pools of alpha motor neurons that innervate specific MTUs (Farina and Negro, 2012). Surface electromyography (EMG) indirectly reflects the neural excitation to MTUs and can be easily recorded during human movement. For this reason, EMG signals recorded from the major lower extremity muscle groups have been used to directly drive open-loop forward dynamics simulations using models that are accurate, physiological, and anatomical representations of the human neuromusculoskeletal system (Lloyd and Besier, 2003; Sartori et al., 2012a,c).

It has been shown that the multi-muscular EMG patterns observed during motor behaviors have a lower dimensionality with respect to the number of muscles and associated MTUs (D'Avella et al., 2003; Bizzi et al., 2008). Therefore, the EMG excitation patterns can be expressed using a low-dimensional set of MTU excitation primitives (XPs). In human locomotion, the XPs have been consistently observed to be sequential and minimally overlapped impulses (burst-like) of excitation (Ivanenko et al., 2004, 2006; Cheung et al., 2005; Bizzi et al., 2008). Therefore, human locomotion has been interpreted as being generated by an impulsive excitation of groups of MTUs, with the timing

dependent on the biomechanical goal of the task (Ivanenko et al., 2005). The association between XP timing and task performance was also particularly evident in (Oliveira et al., 2013).

Based on this experimental evidence, in this study we propose the use of a low-dimensional set of single-impulse, Gaussian-shaped XPs to drive a physiologically accurate, subject-specific musculoskeletal model of the human lower extremity (Sartori et al., 2012a). Within the musculoskeletal model, the XPs operate as an impulsive controller, where the onset of an XP corresponds to the recruitment of the associated muscles and MTUs.

Although the use of single-impulse, Gaussian-shaped curves was previously supported by experimental evidence from human locomotion studies (Ivanenko et al., 2006), this current study is not focussed on any speculation on the physiological nature of human locomotion excitation patterns. Rather, the use of single-impulse curves in this study has the purpose of exploiting actual primitives of excitations having simple mathematical formalizations. The combination of these single-impulse curves allows generation of more complex multi-impulse excitation inputs and MTU recruitment patterns that might emerge from human locomotion tasks, which have been often observed in the literature (Davis and Vaughan, 1993; Ivanenko et al., 2006; Clark et al., 2010).

Previous studies have used low-dimensional sets of multi-impulse curves within musculoskeletal models of the human lower extremity for the purpose of assessing the mechanical role of muscles during human locomotion (Neptune et al., 2009; McGowan et al., 2010; Allen and Neptune, 2012). Furthermore, other studies assessed and explored the conceptual idea of muscle synergies in relation to the biomechanics of human and animal movement (Zajac et al., 2002; McKay and Ting, 2008; Fregly et al., 2012b; Kutch and Valero-Cuevas, 2012; Ting et al., 2012).

The present study, however, addresses a number of questions that have not been considered in the current literature. One main hypothesis is that a low-dimensional controller of single-impulse XPs could be designed to be generic to subjects and motor tasks, but sufficiently selective to drive a subject-specific musculoskeletal model of the human lower extremity. This would allow coordinating large groups of MTUs and subsequently predicting joint moments about multiple degrees of freedom (DOFs) in the lower extremity during a variety of motor tasks that are substantially different to each other. It is also hypothesized that the use of a *subject-generic, task-generic, low-dimensional* XP set, as opposed to a *subject-specific, task-specific, high-dimensional* EMG set, does not lead to substantial loss of joint moment prediction accuracy in the driven musculoskeletal model. This view would pose the problem of how to differentiate the model's outputs across movements, since the same impulsive controller is used as input drive across different tasks and subjects. In this scenario, it is hypothesized that the model's outputs (i.e., MTU forces and resulting joint moments) are differentiated across movements by the experimental joint kinematics input to the model. This is subsequently used to estimate somatosensory information such as the instantaneous MTU kinematics (Sartori et al., 2012c) and update the MTU force and resulting joint moment estimates (see Methods Section) (Lloyd and Besier, 2003; Sartori et al., 2012a). It is worth noting that the experimental joint kinematics input might, in fact, differ from the kinematics that would be obtained by converting the model's predicted joint moments into joint position. Therefore, within our methodology, the experimental joint kinematics operates as an error correction factor that accounts for somatosensory information (i.e., MTU kinematics) and compensates for the static behavior and simplified structure of the generic XP-based controller. Therefore, prediction discrepancies are not compensated for by a task-specific, subject-specific impulsive controller but rather by joint kinematics information.

Addressing these questions not only would offer further indirect evidence of the theoretical correctness of the human locomotion control scheme previously proposed in the literature (Ivanenko et al., 2005, 2007; Lacquaniti et al., 2012), but would also support the hypothesis that a variety of human locomotion tasks, substantially different from each other, may share a similar neuromuscular control scheme of impulsive nature. Finally, it would provide a novel musculoskeletal model of human locomotion that (1) could be operated in an open-loop forward dynamics way without using numerical optimization to match the experimental joint moments, (2) could be therefore executed at low computational cost (see Results Section), and (3) could produce movement-specific joint moment estimates even if driven by subject-generic and task-generic XPs.

The main advantage of the proposed approach is that, once an XP set has been defined, no EMG recordings are needed for the model operation. This might have substantial implications in the development of novel neurorehabilitation technologies. In this scenario, our proposed XP-driven musculoskeletal model can be operated at low computational costs for the real-time prediction of an individual's neuromusculoskeletal dynamics and for the subsequent development of neuromuscular human-machine interfaces for powered prostheses and orthoses control. In this, MTU activation and joint moments can be predicted in real-time solely from the low-dimensional XP set and three-dimensional joint kinematics without loss of accuracy with respect to using EMG signals. This would substantially decrease the input drive complexity as well as the number of needed sensors on the wearable robot, thus increasing the system robustness.

In this paper, the proposed XP-driven modeling methodology is presented and validated with a direct comparison to the previously presented EMG-driven modeling method (Lloyd and Besier, 2003; Sartori et al., 2012a).

MATERIALS AND METHODS

The procedure comprised four steps: (1) collecting human movement data using motion capture technology, (2) modeling and simulating the recorded human movement, (3) determining a low-dimensional set of XPs, and (4) calibrating and executing the musculoskeletal model of the human lower extremity.

HUMAN MOVEMENT DATA COLLECTION

Two healthy men (age: 28 and 26 years, height: 183 and 167 cm, mass: 67 and 73 kg) volunteered for this investigation and gave their informed, written consent. The project was approved by the Human Research Ethics committee at the University of Western Australia.

The motion data acquired from the two subjects were static anatomical trials, functional calibration trails, and the actual dynamic gait trials. During all trials, the three-dimensional location of retro-reflective markers placed on the subjects' body was recorded (250 Hz) using a 12-camera motion capture system (Vicon, Oxford, UK). During the dynamic trials, ground reaction forces (GRFs) and EMG signals were collected (2000 Hz) synchronously with the marker trajectories using an in-ground force plate (AMTI, Watertown, USA), and bipolar electrodes with a telemetered EMG system (Noraxon, Scottsdale, USA), respectively.

The dynamic trials were eight repetitions of four motor tasks including fast walking (FW, 1.3 ± 0.25 m/s), running (RN, 2.5 ± 0.5 m/s), sidestepping (SS, 2.0 ± 0.35 m/s), and crossover (CO, 1.9 ± 0.15 m/s) cutting maneuvers. Each trial included the full stance phase of gait of the subjects' right leg. The CO and SS tasks were straight running with change of direction to the right and left respectively. In these, the direction change was performed by having the right leg in contact with the floor and going through the full stance phase. In all tasks, velocities were measured by tracking the speed of the trunk markers during the stance phase. The four motor tasks were chosen because (1) they required the production of large joint moments about the six considered DOFs including: hip flexion-extension (HipFE), hip adduction-abduction (HipAA), hip internal-external rotation (HipROT), knee flexion extension (KneeFE), ankle plantar-dorsi flexion (AnkleFE), and ankle subtalar flexion (AnkleSF), and (2) because they reflected different MTU recruitment strategies and contraction dynamics. This permitted us to investigate whether the proposed methodology could use a simple XP set to predict joint moments produced about the six considered DOFs while accounting for different MTU operation strategies.

EMG data were collected from 16 muscle groups including: hip adductors (add), gluteus maximus (gmax), gluteus medius (gmed), gracilis (gra), tensor fasciae latae (tfl), lateral hamstrings (latham), medial hamstrings (medham), sartorius (sar), rectus femoris (recfem), vastus medialis (vasmed), vastus lateralis (vaslat), gastrocnemius medialis (gasmed), gastrocnemius lateralis (gaslat), peroneus group (per), soleus (sol), and tibialis anterior (tibant). Both GRFs and marker trajectories were low-pass filtered with a fourth-order Butterworth filter. Cut-off frequencies (between 2 and 8 Hz) were determined by a trial-specific residual analysis (Winter, 2004). EMGs were processed by band-pass filtering (30–450 Hz), then full-wave rectifying, and low-pass filtering (6 Hz).

From the collected dynamic trials, two distinct datasets were created; one for the calibration of the musculoskeletal model and the other for the validation. For each subject, the calibration dataset included two repeated trials of the four motor tasks (i.e. FW, RN, SS, and CO). A different dataset was used to validate the calibrated musculoskeletal model on each subject and included six repeated novel trials for the four considered motor tasks. None of the trials in the validation dataset were included in the calibration dataset. Therefore, there was no common data between the two datasets.

MOVEMENT MODELING

Using the software OpenSim [1] (Delp et al., 2007), a generic model of the human musculoskeletal geometry[2] was scaled to match the individual subject's anthropometry. This was done based on the experimentally measured marker positions recorded from the static standing poses, and the location of the hip, knee and ankle joint centers as well as knee flexion-extension axis determined using the functional calibration trials (Besier et al., 2003b). During the scaling process, virtual markers were created and placed on the musculoskeletal geometry model based on the position of the experimental markers. The OpenSim Inverse Kinematics (IK) algorithm (Delp et al., 2007) solved for joint angles that minimized the least-squared error between experimental and virtual markers. The joint moments that needed to track the IK-generated angles were obtained using Inverse Dynamics (ID) and Residual Reduction Analysis (RRA) (Delp et al., 2007). The joint moments produced by this pathway were called "the experimental" moments. The alternative pathway to estimate joint moments was by the XP-driven and EMG-driven models (Sartori et al., 2012a).

The estimates produced by our proposed methodology can be directly compared to previously proposed works in the literature (Besier et al., 2009; Winby et al., 2009; Krishnaswamy et al., 2011; Sartori et al., 2012a,b; Hamner and Delp, 2013). Furthermore, **Figure A1** compares our derived experimental joint moments to those available in the literature (Winter, 1983, 2004; Liu et al., 2008; Hamner et al., 2010). The normalized root mean squared error and correlation coefficients assumed values that ranged between 0.1–0.3 and 0.89–0.98 respectively (see Validation Procedure Section). During walking, our derived experimental joint moments had peak values of comparable magnitude between the hip extension in the early stance and the ankle plantar flexion in the late stance. This differed to what reported in (Winter, 2004; Liu et al., 2008) in which the peak hip extension moment was smaller than the peak ankle plantar flexion moment. However, it is worth stressing the fact that the use of an ankle joint with oblique axes, like that used in our proposed work, directly coupled ankle plantar-dorsi flexion with ankle subtalar flexion (Kirby, 2001; Yamaguchi et al., 2009). The effect of this coupling on the ankle plantar-dorsi flexion moments is less pronounced in ankle joint models with orthogonal axes (Winter, 2004) or in models in which the ankle subtalar flexion is constrained to the anatomical neutral position (Liu et al., 2008).

MUSCLE EXCITATION PRIMITIVE

To identify the muscle XPs, a two-step process was used based on a previously described non-negative matrix factorization (NNMF) technique (Lee and Seung, 2001). First, the muscle-specific EMG linear envelopes were normalized in time and with respect to the peak processed EMG values obtained from all trials (Ivanenko et al., 2004; Gizzi et al., 2011). In this way, each muscle for each trial and motor task was equally represented in the final muscle

[1] OpenSim release 2.2.0 available from: https://simtk.org/home/opensim
[2] Available from: https://simtk.org/home/nmblmodels/

weighting computation and results reflected only changes in timing. The normalized linear envelopes computed from all dynamic trials in the validation dataset collected from the two subjects were then combined into an $m \times n$ matrix, where m indicates the number of muscles and n the number of trial frames × number of trials × number of subjects. That is, each row was associated to a muscle, which concatenated the muscle's EMG data from all trials and subjects. The NNMF was then applied to the $m \times n$ matrix with a number of non-negative factors identified together with their associated weightings (see Results Section). The extracted, experimental non-negative factors were linearly combined with their associated weightings to produce an $m \times n$ matrix of reconstructed EMGs and then compared to the original EMG matrix. The agreement between the two matrices was then quantified by least squares errors. The NNMF was then iterated within an optimization procedure by adjusting the non-negative factors until they minimized the least squared error between experimental and reconstructed EMG data. In this procedure the dimensionality of the non-negative factor set was increased until the accuracy of the reconstructed EMG data exceeded a predefined threshold. This was assessed by means of the Variation Accounted For (VAF) index, which was defined as VAF = 1 – SSE/TSS, where SSE (sum of squared errors) represented the unexplained variation and TSS (total sum of squares) was the total variation of the EMG data. A minimal VAF value of 80% was the threshold to be exceeded in this study to consider the reconstruction quality as satisfactory (Gizzi et al., 2011). This resulted in a matrix of five non-negative factors (i.e. $5 \times n$ non-negative factor matrix) that accounted for 89% of the variability in the EMG data. In this, each muscle group had five associated weighting factors. These determined how much each of the five non-negative factors contributed to the excitation of a specific muscle group. The weightings were then normalized to the highest weighting value: $\bar{W}_{j,i} = \frac{W_{j,i}}{\max(W_{1,i}, W_{2,i}, W_{3,i}, W_{4,i}, W_{5,i})}$, where $W_{j,i}$represented the j^{th} weighting ($1 \leq j \leq 5$) for the i^{th} muscle group ($1 \leq i \leq 16$), whereas $\bar{W}_{j,i}$ was the resulting normalized weighting (i.e., $0 \leq \bar{W}_{j,i} \leq 1$).

In the second step, from the $5 \times n$ non-negative factor matrix, each non-negative factor that was associated to a specific trial and subject was isolated based on the frames associated to the specific trial. This allowed removing the discontinuities existing between two adjacent non-negative factors. Then, the extracted trial-specific non-negative factors were averaged across trials. The five trial-averaged non-negative factors were then fitted with five Gaussian-shaped single-impulse curves (see Results Section), which represented the XPs that were used to drive the proposed XP-driven musculoskeletal model:

$$g(t) = h \cdot e^{-\frac{(t-b)^2}{2 \cdot c^2}} - s \quad (1)$$

where t is the time frame and h, b, c, and s were the function parameters defining the Gaussian curve peak height, the position of the center of the peak, the width of the curve bell, and the vertical shift respectively. The function parameters were identified using a simulated annealing optimization algorithm (Goffe et al., 1994) that minimized the root mean squared error with respect to each of the five average non-negative factors.

MUSCULOSKELETAL MODELING

The XP-driven musculoskeletal model (**Figure 1**) was developed from our previously described EMG-driven model of the human lower extremity (Lloyd and Besier, 2003; Winby et al., 2009; Sartori et al., 2012a,c). The following of this section provides a description of the XP-driven modeling workflow as well as a description of the model components.

In the proposed *XP-driven modeling workflow*, a five-dimensional impulsive controller (i.e. made of five XPs, **Figure 2**) defined, a priori, an initial recruitment scheme for 34 MTUs in the human lower extremity. The properties of the recruitment scheme were preserved across subjects and motor tasks including the relative position and peak amplitude of one XP with respect to another and the MTUs recruited by each XP. The five XPs were only time-scaled (i.e. stretched or compressed) to match the length of the stance phase across movements. A closed-loop calibration step (**Figure 1E**, also see below in this section) was then performed to identify a number of musculoskeletal model parameters, which varied non-linearly across subjects because of anatomical and physiological differences (Sartori et al., 2012a). In this step, the impulsive controller was further refined to determine a finer mapping between the low-dimensional set of XPs and the high-dimensional set of MTU-specific activations (**Figure 1B**) that best described the MTU-specific activation strategies across the four selected tasks.

The calibrated XP-driven model was then validated on the same motor tasks selected for calibration (i.e. FW, RN, SS, and CO) but using a novel set of trials (see the Human movement data collection Section). During the validation step, the calibrated XP-driven model operated as an open-loop predictive system, which did not use numerical optimization to track the experimental joint moments, and therefore operated at low computational cost (see Results Section). The MTU-specific activations and the resulting joint moments were directly determined as a function of the five XPs and the three-dimensional joint kinematics, i.e. there was no need to record further EMG data.

The proposed model's structure comprised five main components (**Figure 1**): Musculotendon Kinematics, Musculotendon Excitation-to-Activation, Musculotendon Dynamics, Moment Computation, and Model Calibration.

The *Musculotendon Kinematics component* (**Figure 1A**) used MTU-specific multidimensional spline functions to produce instantaneous estimates of MTU length ℓ^{mt}, and three-dimensional moment arms r as a function of joint angles (Sartori et al., 2012c)[3].

The *Musculotendon Excitation-to-Activation component* (**Figure 1B**) mapped the five XPs into the 34 MTU-specific activations. The five XPs were initially associated to the 16 muscle groups from which the EMG data were recorded. In this, if a muscle group had an associated weighting factor greater than 0.4 on one of the five XPs, then the muscle group was considered to be associated to that specific XP that defined its initial excitation (Neptune et al., 2009). With respect to (Neptune et al., 2009),

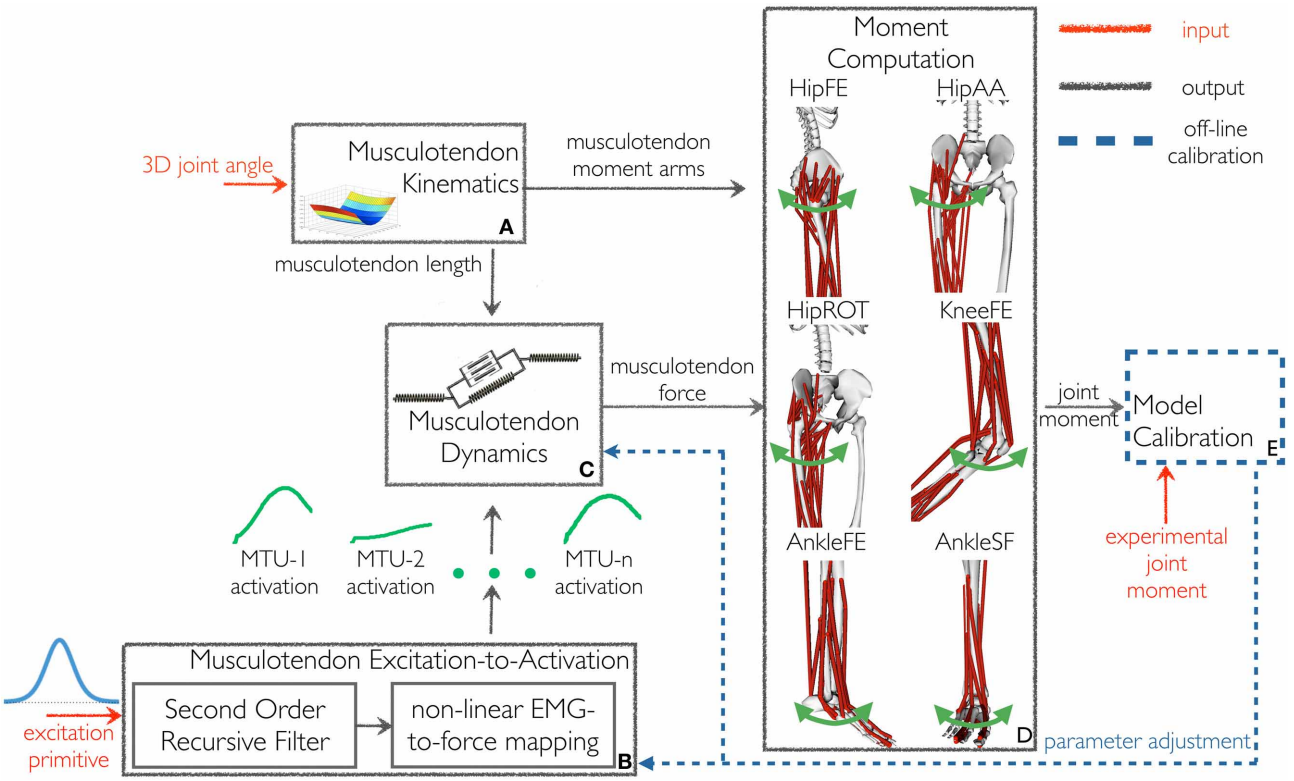

FIGURE 1 | The schematic structure of the excitation primitive (XP)-driven musculoskeletal model. It comprises five components: **(A)** Musculotendon Kinematics, **(B)** Musculotendon Excitation-to-Activation, **(C)** Musculotendon Dynamics, **(D)** Moment Computation, and **(E)** Model Calibration. The XP-driven model is initially calibrated using the Model Calibration component. After calibration the model is operated in open-loop. The Musculotendon Excitation-to-Activation component is used to map the initial five-dimensional XP set to the 34 individual MTU activations. Subsequently, MTU force and the resulting moments are determined as a function of MTU activation and experimental three-dimensional musculotendon kinematics (i.e., calculated using Inverse Kinematics), without tracking experimental joint moments. Joint moments are predicted with respect to six degrees of freedom: hip flexion-extension (HipFE), hip adduction-abduction (HipAA), hip internal-external rotation (HipROT), knee flexion-extension (KneeFE), ankle plantar-dorsi flexion (AnkleFE), and ankle subtalar-flexion (AnkleSF).

our proposed cut-off criterion differed in the fact that weightings and primitives were extracted from the matrix concatenating all EMG linear envelopes from all subjects and trials (see Muscle Excitation Primitive Section). Therefore, NNMF generated a single set of weightings that applied to all subjects' trials. In (Neptune et al., 2009), NNMF was individually applied to each subject. This created subject-specific weightings, which were then averaged prior to the application of the 0.4 cut-off criterion. In our proposed methodology, if a muscle group had more than one associated XP, then the average across the XPs was calculated and used as the muscle group initial excitation. Muscle weightings allowed arranging muscles groups into seven modules (see second test results in Results Section). A module included all muscle groups with a weighting greater than or equal to 0.4 on the same XP. All MTUs from all muscle groups within a module received the same initial XP. The XPs were also assigned to MTUs for which experimental EMG data could not be recorded and included the gluteus minimus, iliacus, psoas, and vastus intermedius. In this allocation, two MTUs that shared the same innervation and contributed to the same mechanical action were assumed to be in the same module and have therefore the same initial XP (Kahle and Frotscher, 2002; Ivanenko et al., 2006). Therefore, the XP that was assigned to both the rectus femoris and the sartorius (module 2 in **Figure 2A**) was also assigned to the iliacus and psoas. The vastus medialis and vastus lateralis XP (module 3 in **Figure 2A**) was assigned to the vastus intermedius, and the gluteus medius XP to the gluteus minimus (also module 3 in **Figure 2A**). These assignments were motivated by anatomical and functional information on the MTUs, assuming that the dimensionality computed from a smaller set of MTUs could be applied to the entire set. Furthermore, if the XPs were the reflection of the spinal circuitry dynamics then the XPs must apply to all lower extremity MTUs whether or not experimental EMGs were available for a specific MTU. This mapping enabled us to use the low dimensional set of XPs to excite a larger number of MTUs than those for which experimental EMG data were available. It is worth noting that this mapping is, in general, not entirely described by the muscle group weightings extracted from the available experimental EMG data using NNMF. This is because experimental EMGs do not directly reflect the activity of deeply located MTUs. For this reason, muscle group weightings were not used to linearly combine XPs together. This allowed us

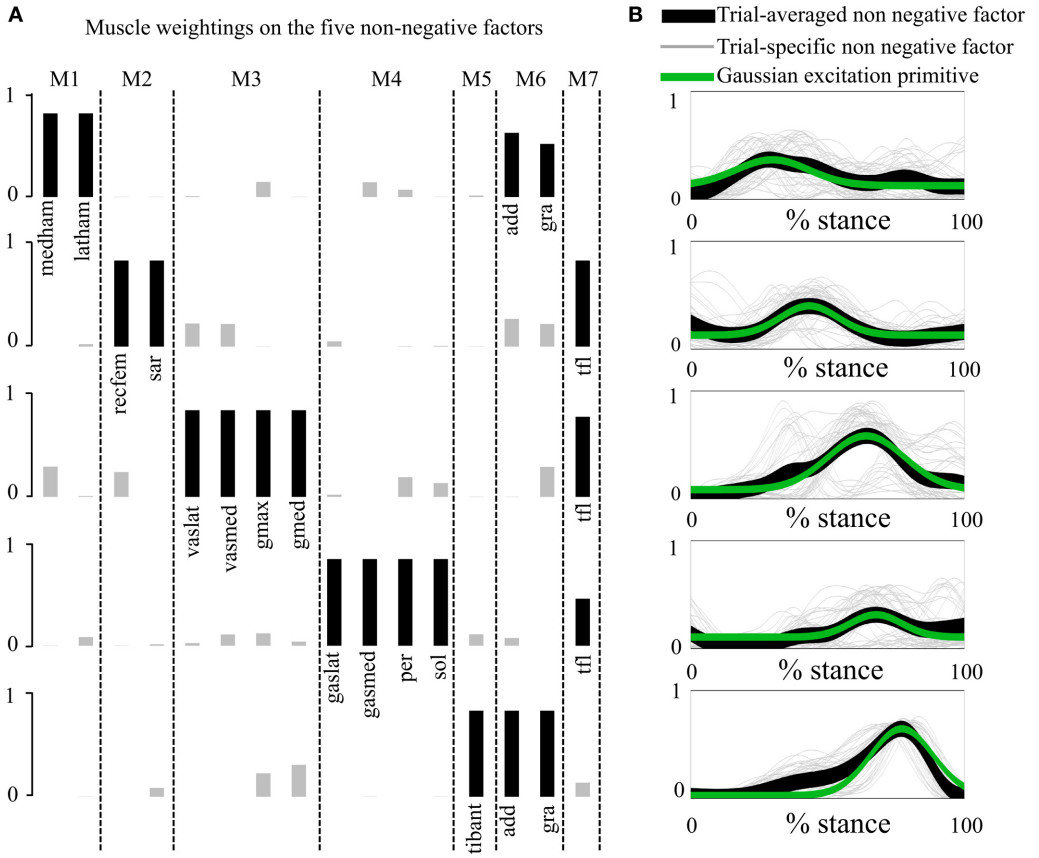

FIGURE 2 | Non-negative factors, muscle weightings, muscle modules, and associated parameterized Gaussian excitation primitives (XPs). (A) Muscle modules (i.e., M1–M7) show how the weightings (i.e., black and gray bars) of the XPs contribute to the excitation of groups of muscles. Black bars show the weightings with a value greater than 0.4. **(B)** The five non-negative factors extracted from each motor trial (trial-specific non-negative factors) are averaged across trials (trial-averaged non-negative factors), which enabled parameterized Gaussian excitation primitives (XPs) to be created. The reported data are from the stance phase with 0% being heel-strike and 100% toe-off events.

to account for the impulsive nature of the MTU recruitment. The transformation from the XP (i.e. applied to a group of MTUs) to the MTU-specific activation (i.e., applied to a single MTU only) is discussed below.

Each XP that was assigned to a group of MTUs was processed by a critically damped second order recursive filter, which simulated the individual MTU twitch response to the initial XP excitation (Thelen et al., 1994; Lloyd and Besier, 2003):

$$u(t) = \alpha \cdot x(t-d) - \beta_1 u(t-1) - \beta_2 u(t-2) \qquad (2)$$

where $x(t)$ was the XP at time t, $u(t)$ was the MTU-specific post-processed XP, α was the MTU-specific gain coefficient, and β_1, and β_2 were the MTU-specific recursive filtering coefficients. The term d was the electromechanical delay. This was set to 10ms based on previously reported experimental results (Nordez et al., 2009) and it was treated as a global parameter as previously suggested (Heine et al., 2003).

The resulting $u(t)$ signal was then further processed using the non-linear transfer function in Equation 3 (Lloyd and Besier, 2003; Buchanan et al., 2004). This accounted for the non-linearity between the MTU excitation and force, reflecting the saturation at high levels of the motor unit recruitment in generating force (Lloyd and Besier, 2003; Buchanan et al., 2004; Farina and Negro, 2012):

$$a(t) = \frac{e^{Au(t)} - 1}{e^{A} - 1} \qquad (3)$$

where A was the non-linear shape factor, which was constrained to $-3 < A < 0$, with 0 being a linear relationship (Lloyd and Besier, 2003). The resulting MTU-specific activation, $a(t)$, represented the ultimate control input to the MTU contractile component. Note that this transformation adjusted the timing (Equation 2) and shape (Equations 2 and 3) of the XPs for each MTU individually. This is important to account for the different activation timing emerging from different motor tasks (Ivanenko et al., 2005).

In the *EMG-driven model*, the EMG linear envelopes were directly used to drive the musculoskeletal model. As previously described, EMG linear envelopes were normalized with respect to the peak processed EMG values obtained from the entire set of recorded trials (Sartori et al., 2012a,b). In this scenario, a dedicated EMG linear envelope was associated with each muscle group

individually, with all MTUs within a muscle group receiving the same EMG pattern (Sartori et al., 2012a). This accounted for the different excitation dynamics across muscle groups as opposed to when using XPs, which excited multiple muscle groups simultaneously. Therefore, the excitation-to-activation transformation (Equations 2 and 3) could be treated as a global transformation that applied equally to all MTUs. That is, the same values for the filtering coefficients and the shape factor were used for all MTUs in the model. In this context, the deeply located iliacus and psoas MTUs were not driven by EMG signals. As a result, only their passive force contribution was modeled using the Musculotendon Dynamics component (**Figure 1C**, see below) by setting the MTU activation to zero (Sartori et al., 2012a).

In the *Musculotendon Dynamics component* (**Figure 1C**), each MTU was modeled as a Hill-type muscle model. In this, the muscle fibers had generic force-velocity $f(v^m)$, force-length passive $f_P(l^m)$, and active $f_A(l^m)$ curves, which were normalized to maximum isometric muscle force ($F^{\max}$), optimal fiber length, and maximum muscle contraction velocity (Zajac, 1989). The tendon dynamics was modeled using a non-linear force-strain function $f(\varepsilon)$ normalized to $F^{\max}$ (Zajac, 1989). Using biomechanical parameters from (Delp et al., 1990; Lloyd and Buchanan, 1996, 2001), the MTU force F^{mt} was calculated as a function of $a(t)$, fiber length l^m and fiber contraction velocity v^m:

$$\begin{aligned} F^{mt} &= F^t = F^m \cos(\phi(t)) \\ &= \left[a(t) f_A(l^m) f(v^m) + f_P(l^m)\right] F^{\max} \cos(\phi(t)) \end{aligned} \quad (4)$$

where F^t and F^m were the tendon and fiber force, and $\varphi(t)$ the pennation angle. During the process of MTU force estimation, l^m and v^m were determined at each time point while ensuring equilibrium between F^t and F^m in Equation 4 (Lloyd and Besier, 2003).

The Moment Computation component (**Figure 1D**) estimated the joint moments M_X as the sum of the product of r_X and F^{mt}, for each X DOF, i.e.,HipFE, HipAA, HipROT, KneeFE, AnkleFE, and AnkleSF.

The *Model Calibration component* (**Figure 1E**) determined the values for a set of parameters that vary non-linearly across subjects and cannot be determined experimentally or from literature (Winby et al., 2008). Parameters were varied within predefined boundaries to ensure MTUs always operated within their physiological range (Lloyd and Besier, 2003). Parameters were adjusted using a simulated annealing algorithm (Goffe et al., 1994) until the objective function $f_E = (E_{\text{HipFE}} + E_{\text{HipAA}} + E_{\text{HipROT}} + E_{\text{KneeFE}} + E_{\text{AnkleFE}} + E_{\text{AnkleSF}})$ was minimized equally for each DOF. Each DOF error term (E_{HipFE}, E_{HipAA}, E_{HipROT}, E_{KneeFE}, E_{AnkleFE}, E_{AnkleSF}) was the sum of the root mean square differences between the predicted and experimental joint moments calculated over the eight calibration trials recorded for a specific subject.

During calibration, two MTU-specific activation-filtering coefficients in the Musculotendon Excitation-to-Activation component (**Figure 1B**) were adjusted, while being constrained to realize a stable positive solution and a critically damped impulsive response for the recursive filter (Equation 2) (Lloyd and Besier, 2003). In this, the two adjusted parameters determined the final value of α, β_1, and β_2 in Equation 2. The MTU-specific global shape factor parameter A (Equation 3) was also altered between -3 and 0 to account for the non-linear EMG-to-force relationship (Lloyd and Besier, 2003; Buchanan et al., 2004; Winby et al., 2009).

In the Musculotendon Dynamics component, 11 muscle strength coefficients were calibrated to scale the MTU-specific $F^{\max}$ to match the person's strength, while maintaining the force generating capacity across MTUs. Strength coefficients were varied between 0.5 to 2 and gathered MTUs in 11 groups according to their functional action including uniarticular hip flexors, uniarticular hip extensors, hip adductors, hip abductors, uniarticular knee flexors, uniarticular knee extensors, uniarticular ankle plantar flexors, uniarticular ankle dorsi flexors, biarticular quadriceps, biarticular hamstrings, and biarticular calf muscles. Muscle tendon slack length l_s^t, and optimal fiber length l_O^m were also adjusted so that l_s^t = initial value $\pm$ 5% and l_O^m = initial value $\pm$ 2.5% with initial values obtained using the methodology presented in (Winby et al., 2008).

VALIDATION PROCEDURE

The validation comprised four tests to assess the XP-driven model prediction ability and to compare it to the EMG-driven model prediction ability. Furthermore, one additional test was performed to assess the XP-driven model computation time.

In the four prediction tests, the subject-specific calibrated XP-driven and EMG-driven models were operated in open-loop, (i.e. without using optimization to track the experimentally recorded joint moments) on each individual motor trial performed by each subject. In this, both the XP-driven and EMG-driven models predicted $a(t)$, and M_X solely using the parameterized XPs, or experimental EMGs respectively, and the three-dimensional joint angles. The models' outputs were then time-normalized using a cubic spline and the similarity between the predicted and the experimental variables was quantified using the coefficient of determination R^2 (i.e., square of the Pearson product moment correlation coefficient) and the normalized root mean squared deviation *NRMSD*:

$$NRMSD = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(\hat{X}_i - X_i\right)^2}}{\max(\hat{X}, X) - \min(\hat{X}, X)} \quad (5)$$

where X and $\hat{X}$ referred to the two variables being compared, which were (1) the predicted and experimental joint moments, (2) the $a(t)$ produced using the EMG-driven model and the XP-driven model, or (3) the experimental and parameterized XP curves. Furthermore, N referred to the number of points in the considered curves. In our proposed study, these metrics identified acceptable results for values of *NRMSD* and R^2 being $0.0 \leq NMRSD \leq 0.3$ and $0.7 \leq R^2 \leq 1.0$. This criterion was based on the results previously proposed in the literature that used EMG-driven methodologies (Besier et al., 2003a; Lloyd and Besier, 2003; Buchanan et al., 2004, 2005; Winby et al., 2009; Manal et al., 2011; Shao et al., 2011).

For the only purpose of displaying results in a concise way, in some cases, the time-normalized models outputs from the same

motor task were averaged across trials and/or across subjects. This produced ensemble average curves for the predicted $a(t)$, and M_X as well as for the matching experimental joint moments $\hat{M}_X$.

The *first test* examined the five non-negative factors that were extracted from the experimental EMG data as well as the five XPs that were parameterized using Equation 1. The agreement between the j^{th} experimental non-negative factor (g^j_{exp}, $1 \leq j \leq 5$) and the corresponding j^{th} parameterized XP curve (g^j_{par}, $1 \leq j \leq 5$) was then quantified using the R^2 and the *NRMSD* coefficients. Furthermore, for the i^{th} muscle group ($1 \leq i \leq 16$), the value of the five associated normalized weightings $\bar{W}_{j,\,i}$ ($1 \leq j \leq 5$) was analyzed. If $\bar{W}_{j,\,i}$ was greater than 0.4, then the j^{th} XP was associated to the i^{th} muscle group. Because EMG linear envelopes were normalized to the peak processed EMG values on a trial basis, it was expected that the amplitude of the final XPs did not affect the final muscle weighting distribution based on the employed 0.4 cut-off criterion. However, in order to assess this directly, an additional set of weightings was computed. In this, the weighting factors $W_{j,\,i}$ (with $1 \leq j \leq 5$, and $1 \leq i \leq 16$) extracted from NNMF were first multiplied by the amplitude peak of the associated XP and then normalized as previously described in the Muscle Excitation Primitive Section. The two muscle weighting sets were then directly compared.

The *second test* assessed whether the MTU activations (i.e. resulting from the XP-to-activation mapping, Equations 2 and 3) predicted by the XP-driven model were similar to the MTU activations predicted by the EMG-driven model. Because the XP-driven model was calibrated on an individual to best match the variety of MTU and joint dynamics observed over all four calibration tasks (i.e., FW, RN, SS, and CO), it was expected that the MTU activations resulting from this task-generic XP-to-activation mapping well matched the EMG-driven MTU activations on average over the four motor tasks. However, because the XP-to-activation mapping was preserved across tasks, it was expected a lesser favorable matching with EMG-driven MTU activations across each individual trial.

The *third test* compared the joint moment prediction accuracy of the XP-driven and EMG-driven models. This assessed whether our proposed methodology could use a task-generic XP-to-activation mapping to predict task-specific joint moments simultaneously produced about the six considered DOFs.

The *fourth test* assessed whether the XP-driven musculoskeletal model was able to reproduce the similar variability observed in the joint moments predicted by the EMG-driven model as well as in the joint moments experimentally recorded. This question arises from the consideration that our proposed model is driven by the same set of XPs, which are only scaled in time to match the length of the trial-specific stance phase. A positive outcome of this test would give further confidence that the use of a subject-generic, task-generic, and low-dimensional XP set would not decrease the ability of the musculoskeletal model to produce movement-specific outputs and would not imply substantial loss of predictive ability with respect to using EMG recordings as an input to the model. Furthermore, this would imply that the predicted joint moment variability was the direct reflection of the predicted MTU kinematics which is the only model input that varies across trials as a function of the three-dimensional joint angles. Finally, this would support the hypothesis that dynamically different movements could emerge from the same locomotion program decoded in the spinal circuitries. For this purpose, we calculated and compared the standard deviation curves extracted from the joint moments predicted using the XPs and the EMG data as well as from those experimentally recorded.

In the *fifth test* the XP-driven musculoskeletal model calibration and execution time were examined. Calibration time was calculated as the time needed to calibrate the model on the eight calibration trials of each subject. Execution time was calculated as the average time needed to repeatedly compute one time point from all DOF joint moments 1000 times. Tests were performed on an 8 GB RAM Intel i7 CPU. If fast execution times were obtained from this test, it would imply the possibility of applying our proposed methodology for the on-line control of powered prostheses and orthoses.

RESULTS

In the *first test* (**Figures 2**, **A2**, **Tables 1**, **A1**), the five experimentally extracted non-negative factors, and muscle group weightings accounted for the 89% of the experimental EMG data variability. Muscle groups were apportioned into seven modules according to the dominant weightings (**Table 1**). The NNMF (**Figure 2A**) revealed that the non-negative factor 1 was mostly responsible for the excitation of add ($W_1 = 0.77$), medham ($W_1 = 1$), latham ($W_1 = 0.64$), and gra ($W_1 = 1$). For the remaining muscle groups W_1 ranged from 10^{-5} to 0.17. The non-negative factor 2 was mostly responsible for the excitation of recfem ($W_2 = 1$), sar ($W_2 = 1$), and tfl ($W_2 = 1$). For the remaining muscle groups W_2 ranged from 10^{-5} to 0.26. The non-negative factor 3 was mostly responsible for the excitation of gmax ($W_3 = 1$), gmed ($W_3 = 1$), tfl ($W_3 = 0.92$), vaslat ($W_3 = 1$), and vasmed ($W_3 = 1$). For the remaining muscle groups W_3 ranged from 10^{-5} to 0.33. The non-negative factor 4 was mostly responsible for the excitation of gaslat ($W_4 = 1$), gasmed ($W_4 = 1$), per ($W_4 = 1$), sol ($W_4 = 1$), and tfl ($W_4 = 0.55$). For the remaining muscle groups W_4 ranged from 10^{-5} to 0.13. The non-negative factor 5 was mostly responsible for the excitation of add ($W_5 = 1$), gra ($W_5 = 1$), and tibant ($W_5 = 1$). For the remaining muscle groups W_5 ranged from 10^{-5} to 0.3. The only muscle groups that received excitation from more than one XP were add, gra, and tfl. The alternative muscle weighting set, which we computed accounting for the XP peak amplitude (see Muscle Excitation Primitive Section), resulted in the same XP-to-MTU distribution that was obtained from the muscle weighting set that did not account for the XP peak amplitude. **Figure A2** and **Table A1** directly compare the values from the two muscle weighting sets. The parameterized XPs well fitted the experimental non-negative factors with R^2 values ranging from 0.74 to 0.94, and *NRMSD* values ranging from 0.0003 to 0.25 (**Figure 2B**). **Table 1** also summarizes how the five parameterized XPs were assigned to the 16 muscle groups and to the MTUs within and how these were apportioned into the seven muscle modules.

In the *second test* (**Figures 3**, **4**, **Table A2**) the MTU-specific activations predicted by the XP-driven model closely matched the activations predicted using the EMG-driven model on average on all subjects and tasks (**Figure 3**). For this analysis the iliacus

Table 1 | Muscle modules and their allocated excitation primitives (XP) to the 16 muscle groups and associated musculotendon units.

Muscle modules and excitation primitives (XP) used	Muscle groupings in the modules	Musculotendon units
Module 1 using XP1:	medial hamstrings	biceps femoris short head (bfsh), biceps femoris long head (bflh)
	lateral hamstrings	semimembranosus (semimem), semitendinosus (semiten)
Module 2 using XP2:	rectus femoris	recfem
	sartorius	sar
	No experimental EMG	psoas
	No experimental EMG	illiacus
Module 3 using XP3:	gluteus maximus	gmax1, gmax2, gmax3
	gluteus medius	gmed1, gmed2, gmed3,
	No experimental EMG	gluteus minimus (gmin1, gmin2, gmin3)
	vastus lateralis	vaslat
	vastus medialis	vasmed
	No experimental EMG	vastus intermedius (vasint)
Module 4 using XP4:	gastrocnemius lateralis	gaslat
	gastrocnemius medialis	gasmed
	peroneus	peroneus longus (perlong), peroneus brevis (perbrev), peroneus tertis (perter)
	soleus	sol
Module 5 using XP5:	tibialis anterior	tibant
Module 6 using (XP1+XP5)/2:	hip adductors	adductor magnus (addmag1, addmag2, addmag3), adductor longus (addlong), adductor brevis (addbrev)
	gracilis	gra
Module 7 using (XP2+XP3+XP4)/3:	tensor fasciae latae	tfl

and psoas MTUs were not considered due to lack of experimental EMG data available. The R^2 coefficient on the average MTU activations assumed values below 0.7 (i.e. between 0.07 and 0.67) for six MTUs only. For the remaining 26 MTUs, the R^2 coefficient assumed higher values that ranged from 0.8 and 0.99. Similarly, the *NRMSD* coefficient on the average MTU activations assumed values above 0.3 (i.e. from 0.31 to 0.45) for five MTUs only. For the remaining 27 MTUs the *NRMSD* coefficient assumed smaller values that ranged between 0.057 and 0.25. **Table A2** reports the detailed values from all MTUs for the R^2 and *NRMSD* coefficients averaged across trials and subjects (i.e. results depicted in **Figure 3**). The proposed XP-driven model was also able to predict the activation of deeply located MTUs such as psoas and iliacus for which experimental EMG data were not available. In this, the ability of the XP-driven model to match, on average, the EMG-dependent MTU activation generated on the four motor tasks gives further confidence that the XP-dependent activations predicted for the deeply located MTUs may also be a reliable reflection of their average physiological behavior. However, further experimental validation is needed in this context. **Figure 3** also shows that the XP-driven MTU activations assumed smaller variability (i.e. standard deviation range) with respect to the EMG-driven MTU activations. This is because of the use of a task-generic XP-to-activation mapping, which does not allow reproducing the whole range of the task-specific MTU activation patterns observed when using EMG data as input to the model. In this scenario, **Figure 4** depicts the specific case of a representative MTU, i.e. the peroneus brevis. For this, R^2 ranged from 0.58 to 0.98 while *NRMSD* ranged from 0.12 to 0.46 across subjects and tasks. Similar results were found for all remaining MTUs. **Table A2** also reports the subject-specific R^2 and *NRMSD* values for all MTUs averaged across all trials within each motor task and for each subject individually.

In the *third test* (**Figure 5**, **Tables A3**, **A4**), the XP-driven model predicted joint moments produced about the six lower extremity DOFs during the four motor tasks with comparable performance to the EMG-driven model (**Figure 5**). The *NRMSD* coefficient between predicted and experimental joint moments ranged from 0.048 and 0.46 when the EMG-driven model was used, whereas it ranged from 0.082 and 0.42 when the XP-driven model was employed. The R^2 coefficient between predicted and experimental joint moments ranged from 0.2 to 0.99 when the EMG-driven model was used, while it ranged from 0.3 to 0.98 when the XP-driven model was used. **Table A3** reports the full range of subject-specific and task-specific R^2 and *NRMSD* values observed between the XP-driven model predictions and the experimental measurements. **Table A4** reports the full range of subject-specific and task-specific R^2 and *NRMSD* values between

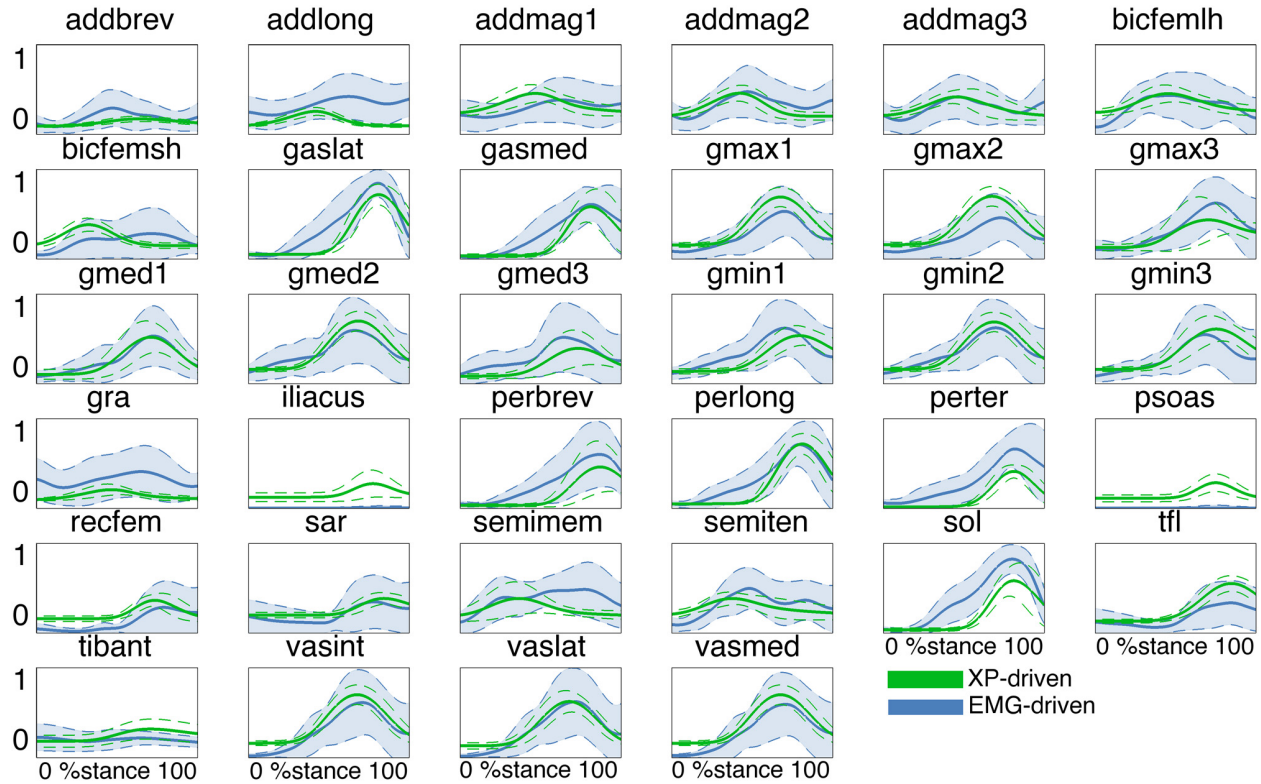

FIGURE 3 | Predicted musculotendon unit (MTU) activations. The ensemble average (filled lines) and standard deviation (dotted lines) activation curves are depicted for the 34 MTUs included in the musculoskeletal model. Data are averaged across all trials and subjects. MTU names are defined as in **Table 1**. MTU activations are reported both from the estimates obtained from XP-driven and EMG-driven musculoskeletal models. The reported data are from the stance phase with 0% being heel-strike and 100% toe-off events.

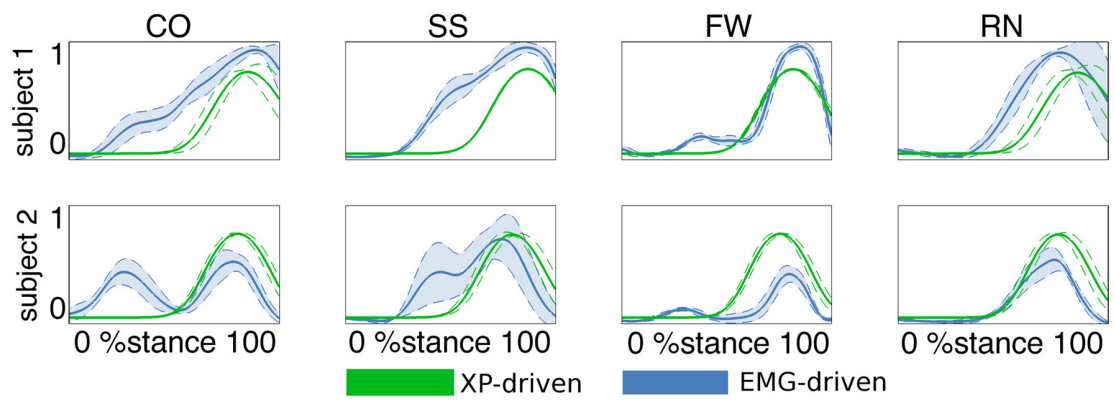

FIGURE 4 | Predicted musculotendon unit (MTU) activations. The ensemble average (filled lines) and standard deviation (dotted lines) activation curves are depicted for the peroneus brevis MTU. Data are averaged across all trials within each motor task performed by the two subjects individually. Motor tasks included fast walking (FW), running (RN), crossover (CO), and sidestepping (SS) cutting maneuvers. Activations are reported both from the estimates obtained from XP-driven and EMG-driven musculoskeletal models. The reported data are from the stance phase with 0% being heel-strike and 100% toe-off events.

the EMG-driven model prediction and the experimental measurements. The weakest prediction accuracy was observed both in the XP-driven and EMG-driven models for the moments about HipAA during FW and to the moments about AnkleSF during CO and SS.

In the *fourth test* (**Figures 5**, **6**, **Table 2**), the upper and lower standard deviations (SDs) of the joint moments predicted using the XP-driven model assumed similar values to those predicted using the EMG-driven model and to those experimentally recorded. **Figure 5** displays joint moment standard deviations

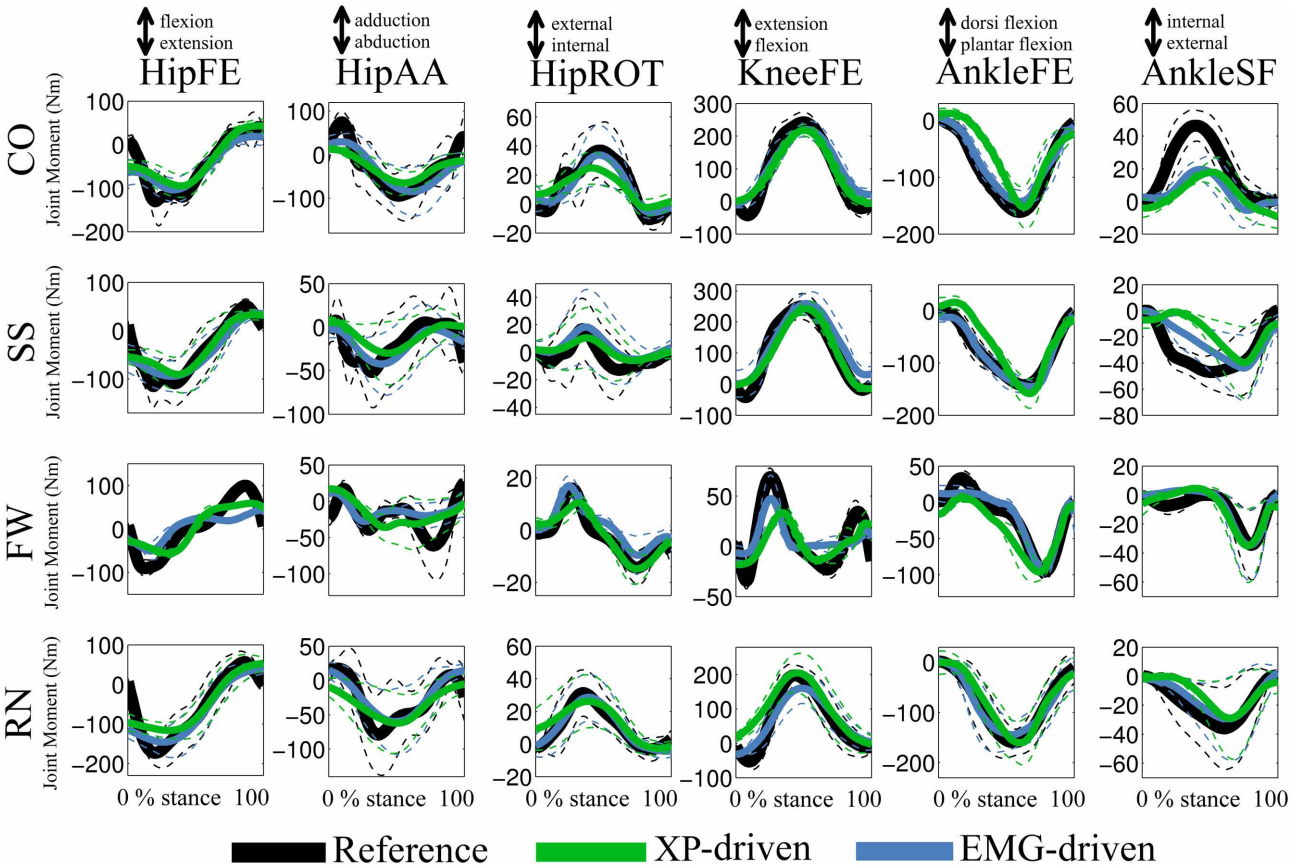

FIGURE 5 | Predicted and experimental joint moments. The ensemble average (filled lines) and standard deviations (dotted lines) curves are depicted for the predicted (i.e. XP-driven and EMG-driven) and experimental (i.e., Reference) joint moments about six degrees of freedom (DOFs) including: hip flexion-extension (HipFE), hip adduction-abduction (HipAA), hip internal-external rotation (HipROT), knee flexion-extension (KneeFE), ankle plantar-dorsi flexion (AnkleFE), and ankle subtalar-flexion (AnkleSF). Results are shown for four motor tasks including: fast walking (FW), running (RN), side-stepping (SS), and cross-over (CO) cutting maneuvers. The reported data are from the stance phase with 0% being heel-strike and 100% toe-off events.

task-wise, resulting from averaging across the subjects' performed trials within each specific task. **Figure 6** and **Table 2** report joint moment standard deviations subject-wise, resulting from averaging across all trials and tasks performed by each subject individually.

The SD similarity observed between the XP-driven and the EMG-driven model estimates was within acceptable ranges. The R^2 coefficients were always greater than 0.65 whereas the *RMSD* coefficients where always less than 0.26, about all DOFs, both across motor tasks (**Figure 5**) and subjects (**Figure 6** and **Table 2**), and both for the upper and lower SDs. This gives further confidence that the use of our proposed XP-driven model can reproduce similar output variability both across subjects and tasks with respect to the use of experimental EMG recordings as an input to the musculoskeletal model.

Across tasks (**Figure 5**), the SD similarity observed between the XP-driven model estimates and the experimental data, had less favorable R^2 and *RMSD* values that were observed about the AnkleSF during CO (i.e. $R^2 = 0.53$ and $RMSD = 0.4$, upper SD) and SS (i.e. $R^2 = 0.01$ and $RMSD = 0.5$, upper SD), and during FW about HipAA (i.e. $R^2 = 0.26$ and $RMSD = 0.36$, lower SD), and KneeFE (i.e. $R^2 = 0.38$ and $RMSD = 0.22$, upper SD). In the remaining cases, the R^2 coefficients were always greater than 0.7 whereas the *RMSD* coefficients where always less than 0.21.

Across individuals (**Figure 6** and **Table 2**), subject 1's R^2 and *RMSD* coefficients were always greater than 0.69 and always less than 0.31, respectively. Less favorable values were obtained for subject 2 about AnkleSF (i.e. $R^2 = 0.13$ and $RMSD = 0.48$, lower SD) and HipAA (i.e. $R^2 = 0.12$ lower SD and $RMSD = 0.31$ upper SD). This may also explain the less favorable results from CO, SS, and FW about the same DOFs obtained when analyzing data task-wise (**Figure 5**). In the remaining cases, the R^2 coefficients were always greater than 0.73 whereas the *RMSD* coefficients where always less than 0.19.

The *fifth test* revealed that the average calibration time for the XP-driven model was 21 h and 24 min. However, the calibrated open-loop models executed fast. The average open-loop execution time was 20.32 ± 0.2 ms.

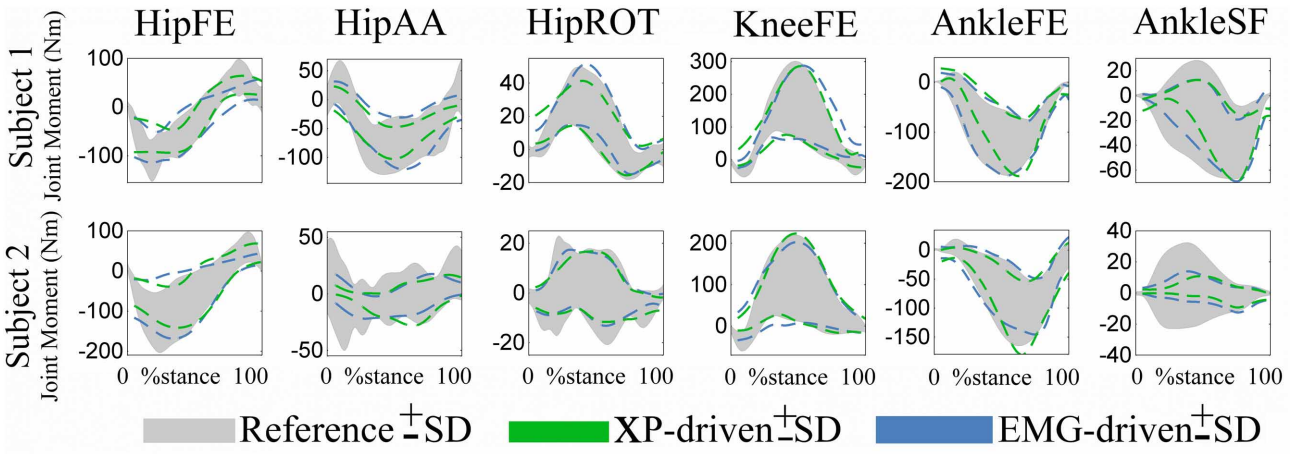

FIGURE 6 | Predicted and experimental standard deviations (SDs). Upper and lower SDs are reported subject-wise resulting from averaging across motor tasks. SDs are reported for the experimental joint moments (i.e., Reference, shaded area) about 6 degrees of freedom (DOFs) including: hip flexion-extension (HipFE), hip adduction-abduction (HipAA), hip internal-external rotation (HipROT), knee flexion-extension (KneeFE), ankle plantar-dorsi flexion (AnkleFE), and ankle subtalar-flexion (AnkleSF). The SDs are also shown for same joint moments predicted by the XP-driven and EMG-driven musculoskeletal models (i.e., dotted lines). The data are averaged across all trials and tasks. The data are reported from the two subjects over the stance phase, with 0% being heel-strike and 100% toe-off events.

Table 2 | Coefficients of determination (R^2) and the normalized root mean squared deviation (*NRMSD*) between the standard deviations *(SD)* of the joint moments measured experimentally and those predicted by the parameterized XP-driven model.

	Subject 1				Subject 2			
	Upper *SD*		Lower *SD*		Upper *SD*		Lower *SD*	
	R^2	NRMSD	R^2	NRMSD	R^2	NRMSD	R^2	NRMSD
HipFE	0.93	0.11	0.88	0.15	0.89	0.13	0.91	0.16
HipAA	0.86	0.24	0.92	0.21	0.63	0.31	0.12	0.21
HipROT	0.93	0.15	0.96	0.12	0.89	0.18	0.75	0.19
KneeFE	0.98	0.08	0.95	0.13	0.99	0.06	0.76	0.19
AnkleFE	0.96	0.12	0.89	0.19	0.95	0.12	0.96	0.08
AnkleSF	0.95	0.24	0.69	0.31	0.73	0.36	0.13	0.48

DISCUSSION

Despite previous works used low-dimensional sets of impulsive curves to drive musculoskeletal models of the human lower extremity (Neptune et al., 2009; McGowan et al., 2010; Allen and Neptune, 2012), our proposed study combined muscle modularity with musculoskeletal modeling with the aim to address a number of novel questions. Our proposed study showed that one single low-dimensional set of single-impulse excitation primitives, or XPs, could be found to best fit the variety of muscle recruitment and excitation patterns observed from two subjects performing motor tasks biomechanically different from each other (i.e. FW, RN, SS, and CO). Once an XP set was defined, no further EMG recordings were needed for the model operation. The XP set determined the structure of a task-generic impulsive controller, which could be preserved across all tasks and subjects. The simplified structure of the task-generic impulsive controller was compensated by combination with movement-specific estimates of MTU kinematics. This allowed producing movement-specific estimates of MTU force and joint moment with no loss of accuracy with respect to those derived from experimental EMG data.

The application of the NNMF algorithm to the EMG data set showed that each XP excited one specific subset of muscle groups (**Figures 2**, **A2**, **Tables 1**, **A1**). The only groups that were excited by more than one XP were the hip adductors, the gracilis, and the tensor fasciae latae. This scheme of recruitment was determined based on a 0.4 cut-off criterion on the muscle weightings (see the Musculoskeletal Modeling Section) and was preserved across subjects and motor tasks, where the XPs were only scaled to match the stance phase length of each individual motor trial.

The XP-driven musculoskeletal model internal parameters were then calibrated to match the physiological characteristics of each subject recruited in the study (see Methods Section). This also allowed defining a finer non-linear mapping from the initial XPs to the 34 MTU-specific activations. The nature of this mapping represented a best fit of the variety of MTU excitation

patterns observed during the four considered tasks and was specific to an individual. This was subsequently applied without further variations during the model validation step (i.e. model open-loop operation). It is worth stressing the fact that, in the context of muscle synergies, the XP-to-activation transformation (Equations 1, 2, and 3) reflects the weightings on the XPs (**Figure 2A**) because it allows for changes in the amplitude level and in the time shifting for a specific XP being refined on a specific MTU. One benefit of the XP-to-activation transformation is that it accounts for the dynamics of muscles (i.e. excitation, activation, and force) and joint (i.e. joint moment) as well as for the demand of the motor tasks being used for calibration. These factors are not accounted for by previously proposed dimensionality reduction methodologies that operate on EMG recording only. These include NNMF, principal component analysis, independent component analysis, or factor analysis.

During validation, the calibrated model was operated in open-loop on a set of novel trials that were not used during the calibration. However, the novel set of validation trials comprised the same motor tasks used for calibration (i.e. FW, RN, SS, and CO). In this process, the proposed model was driven by the five XPs and by the three-dimensional joint kinematics. In this, numerical optimization was not employed and experimental EMG data were not used as input.

Results demonstrated the proposed XP-to-activation transformation (Equations 1, 2, and 3) could properly solve for the neuromuscular redundancy by predicting a specific MTU activation solution (among the several possible ones) that well reflected a best fit of the different EMG-based MTU activation strategies observed during the four selected tasks (**Figures 3**, **4**, **Table A2**). This result gains further importance if we consider that MTUs were driven by a set of Gaussian-shaped curves that were not linearly combined according to the muscle weightings (**Figure 2** and **Table 1**). This proves that a subject-generic, task-generic, low-dimensional impulsive controller that recruits groups of MTUs with timing dependent on the stance phase can predict physiological MTU activation patterns that reflect subject-specific, task-specific EMG recordings of higher-dimensionality.

Results also showed that the proposed XP-driven model was able to predict joint moments that matched those experimentally measured from the six selected lower extremity DOFs with comparable accuracy to that associated to the EMG-driven model (**Figure 5**, **Tables A3**, **A4**). The ability of matching joint moments produced during different motor tasks implied that the proposed methodology was able to account for the different MTU activation strategies and contractile conditions associated to each motor task.

Furthermore, results showed that, although the excitation patterns driving the model (i.e. XPs) were the same across tasks (**Figures 3**, **4**), the patterns of predicted joint moments varied across trials and this variability was in agreement with the variability observed both in the experimentally measured joint moments as well as in the joint moments predicted from EMG data (**Figures 5**, **6**, **Table 2**). In this, the task-generic excitation patterns were continuously modulated by the movement-specific estimates of MTU kinematics (i.e. MTU length and moment arms, **Figure 1A**) derived from the experimental joint kinematics input (Sartori et al., 2012c). This modulation process took place both in the Musculotendon Dynamics component (**Figure 1C**) and in the Moment Computation component (**Figure 1D**). The Musculotendon Dynamics component combined MTU activation with MTU length to compute MTU force (Equation 4). The MTU force was then combined with the MTU moment arms to compute MTU moment. Therefore, the computation of MTU force and moment could be seen as a transformation of the task-generic MTU activation that accounted for movement-specific MTU kinematics, thus resulting in movement-specific estimates of joint moments (i.e. summation of MTU moments about a specific joint and DOF). This allowed compensating for the static behavior and for the simplified structure of the single XP-based controller.

Previous studies proposed analyses of muscles modularity using NNMF during locomotion tasks including walking (Ivanenko et al., 2005), running, and sidestepping cutting maneuvers (Oliveira et al., 2013). In these studies, five non-negative factors were identified and extracted. These reflected the recruitment of muscles in the lower and upper extremities. Our proposed study identified the same number of non-negative factors with respect to those in the literature (Ivanenko et al., 2005; Oliveira et al., 2013). However, our study only analyzed lower extremity muscles and solely during the stance phase. Furthermore, our extracted set of non-negative factors and weightings reflected the dynamics of four motor tasks simultaneously (i.e. FW, RN, SS, and CO) whereas the previously proposed studies (Ivanenko et al., 2005; Oliveira et al., 2013) analyzed a specific motor task individually, thus generating a task-specific set of non-negative factors and weightings. These differences were reflected in dissimilarities in the timing of the maximum peak amplitude observed across non-negative factors as well as in the distribution of weightings across muscles. Our extracted non-negative factors had maximum peaks localized from about 20% to 80% of the stance phase (**Figure 2**). The non-negative factors reported by (Ivanenko et al., 2005) during walking had the maximum peaks distributed from about 5% to the end of the stance phase. However, the non-negative factors 1 and 5 reflected the recruitment of trunk and arm muscles and their associated peaks were in the transition from the swing to the stance phase. Higher similarity in the maximum peak timing was observed in the inner non-negative factors including non-negative factor 2 (at about 45% and 55% in our study and in Ivanenko's et al. respectively), and non-negative factor 3 (at about 70% in both studies). A similar scenario was observed in Oliveira et al. (2013) during sidestepping, where non-negative factors had the maximum peaks distributed throughout the entire stance phase, with non-negative factors 1 and 5 reflecting the recruitment of the trunk muscles and implementing the transition across the stance and swing phase. In this, higher similarity in the maximum peak timing was observed in the inner non-negative factors that most reflected the recruitment of lower extremity muscles. These included non-negative factor 2 in our study and non-negative factor 3 in Oliveira et al. (2013) both at about 45% of stance. Furthermore, it also included non-negative factor 3 in our study and non-negative factor 4 in Oliveira et al. (2013) at about 70% and 65% respectively. The non-negative factors reported by Oliveira et al. (2013) during running had the

maximum peaks distributed throughout the entire stance phase. In these, the recruitment of the trunk muscles was reflected by all five non-negative factors. The best similarity in the maximum peak timing was observed in the non-negative factors that most accounted for the recruitment of lower extremity muscles. These included non-negative factor 1 (at about 20% in both studies). Furthermore, it also included non-negative factor 3 in our study and non-negative factor 2 in Oliveira et al. (2013) at about 70 and 65% of stance respectively.

Future work is needed to further improve our proposed methodology. Experimental results showed that the trial-specific non-negative factors extracted from the different motor tasks had peaks that were substantially shifted in time depending on the nature of the task. This was especially evident in the third non-negative factor (**Figure 2B**). While the timing of the peaks for the trial-specific factors extracted from RN, SS, and CO was consistent, the timing of the peak for the trial-specific factors extracted from FW was anticipated by 30%. Future work is needed to allow adjusting the peak timing, magnitude, and bell width of the parameterized XPs during the model execution to implement the transition across tasks (i.e., RN, CO, and SS). Furthermore, the XP-to-activation transformation (Equations 1, 2 and 3) will be modulated across tasks thus allowing better representing the dynamics of individual movements. Moreover, the parameterized XPs could be, in the future, further modulated in time and amplitude based on biomechanical events triggering appropriate muscle reflexes to allow for adaptation to different gait dynamics and terrains.

The joint moment prediction accuracy tests (**Figure 5** and **Tables A3**, **A4**) revealed that both the XP-driven and the EMG-driven models could not predict a substantial moment contribution about AnkleSF during the CO and SS cutting maneuvers tasks and about HipAA during FW. This may be explained by the fact that the MTUs currently included in the model, with AnkleSF and HipAA moment arms, accounted for the 80 and the 86% respectively of the total physiological cross sectional area. Future work should therefore include additional MTUs crossing the hip and ankle joints. The MTUs in the model with moment arms about the remaining four DOFs accounted for more than the 90% of the total physiological cross sectional area.

Our proposed methodology predicted joint moments during the stance phase only. The main reason for this was that calibration included trials of running, as well as sidestepping and crossover cutting maneuvers. For these motor tasks the swing phase occurred partially, or totally, out of the motion capture volume. Therefore there was an incomplete swing phase data available for calibration across trials. The second, although much lesser reason, was that joint moments were estimated using inverse dynamics, which strongly relies on the magnitude of GRFs (Delp et al., 2007). During the swing phase of locomotion, the GRFs are zero, which means the inverse dynamics calculations become highly sensitive to segmental inertial parameters that are difficult to measure *in vivo*. These include the segment mass, the location of the segment center of mass, and the mass moment of inertia (Lanovaz and Clayton, 2001; Delp et al., 2007), which were only scaled linearly to the subject's size (Delp et al., 2007). Inverse dynamics measurements of joint moments during the swing phase may therefore not be reliable and we preferred not to use these for the model calibration and for the subsequent validation step. Future work will focus on (1) using better methods for extracting subject-specific segmental parameters (i.e. using MRI), and (2) predicting joint kinematics, rather than joint moments, using full forward dynamics models (Barrett et al., 2007) or non-parametric methods such as Bayesian filtering (Ko and Fox, 2009). This will allow extending the analyses presented in this study to the whole gait cycle thus increasing the applicability of our proposed methodology.

The present results showed that our proposed methodology could predict MTU forces and joint moments within the range of DOFs, tasks, and gait cycle phases (i.e. stance phase) on which the model was calibrated. However, how the model extrapolates outside the range of these DOFs, tasks, and gait cycle phases is currently not know. Furthermore, it is not known whether or not new ranges of DOFs, tasks, and gait cycle phases would require updating the Gaussian curves in the impulsive controller accordingly. This requires an extensive and structured research, which was beyond the scope of this study. However, this will be important to be determined as the size of the calibration data set also affects the speed at which calibration can occur. Indeed, our proposed XP-driven model relies upon an off-line calibration procedure that is time consuming. On the other hand, the model execution was observed to be fast, i.e. in the order of 20ms per time frame. Future work should focus on the design of more efficient calibration algorithms. The use of MTU models that do not require an explicit integration of the MTU dynamics equations could considerably speed up the calibration process without loss of joint moment prediction accuracy as it was shown in Sartori et al. (2012b).

This work presented a study on two subjects only. Therefore, it may not be completely generalizable. However, the proposed XP-driven musculoskeletal model was scaled and then calibrated to the actual subjects to account for the subject-specific (1) anthropometry, (2) XP-to-activation mapping, and (3) MTU intrinsic properties. This allows our methods to be applied across individuals without relying on the existence of specific anthropomorphic models, while accounting for the individual's muscle activation patterns across multiple DOFs. This represents an improvement in current state of the art methodologies were the recruited subjects were chosen to be of similar build of the anatomical model (Lloyd and Besier, 2003; Martelli et al., 2011). However, a more general model validation across a larger number of individuals will be the subject of future work.

It is important noting that the aim of our proposed work was not that of addressing all limitations associated to excitation-driven modeling in one single study. Our aim was to demonstrate that a single impulsive controller could be used as input drive to large musculoskeletal models operating in open-loop across different motor tasks with no loss of accuracy with respect to using experimental EMGs. This supports the hypothesis that biomechanically different movements could emerge from the same locomotion program decoded in the spinal circuitries.

The proposed XP-driven model may have direct implications in the development of rehabilitation technologies. The proposed

methodology could be, in the future, further extended to create generic XP sets descriptive of larger populations of subjects and motor tasks. Also, additional XP sets could be specifically created for different patient populations thus describing MTU recruitment patterns typically observed in different neurological or orthopedic conditions. This will give the potential possibility of extrapolating the generic XP-based impulsive controller to novel subjects (within a specific population) without needing to record further EMG data.

The ability of our proposed XP-driven model to predict physiological MTU activations and joint moments, will allow obtaining accurate predictions of the user's effort during dynamic movement. This will allow determining how muscles contribute to modulate joint compliance in locomotion (Rapoport et al., 2003; Cronin et al., 2011; Heitmann et al., 2011; Pfeifer et al., 2012). It will allow determining the heat released by muscles and the resulting metabolic energy consumption during movement (Sawicki and Ferris, 2009; Bisi et al., 2011; Krishnaswamy et al., 2011; Farris and Sawicki, 2012). Furthermore, it will allow determining the magnitude of reaction forces in the lower extremity joints (Winby et al., 2009; Lin et al., 2010; Fregly et al., 2012a; Modenese and Phillips, 2012; Manal and Buchanan, 2013). The ability of determining these variables will enable a number of applications in the field of neurorehabilitation technologies including (1) the design of powered prostheses that modulate joint compliance according to that modulated in the subject's contralateral leg, (2) the design of powered orthoses that can effectively reduce the energy consumption during locomotion, and (3) the monitoring and prevention of orthopedic conditions such as osteoporosis and osteoarthritis. In these scenarios, the proposed XP-driven model would only need direct recordings of joint angles and estimates of the gait cycle percentage as input. This would allow decreasing the input drive complexity and the number of needed sensors, thus increasing the robustness of the system with respect to the case requiring real measurements of EMG data.

The availability of the proposed methodology will facilitate the transition toward the design of human-inspired devices that can effectively embody the dynamics of the human neuromuscular control of movement without relying on explicit representations of task-specific control models.

ACKNOWLEDGMENTS

GLOSSARY

LIST OF ACRONYMS AND SYMBOLS SORTED WITH RESPECT TO ORDER OF APPEARANCE IN THE TEXT

MTU	Musculotendon units
EMG	Electromyography
XPs	Excitation primitives
DOFs	Degrees of freedom
FW	Fast walking
RN	Running
SS	Sidestepping cutting maneuvers
CO	Crossover cutting maneuvers
GRFs	Ground reaction forces
HipFE	Hip flexion-extension
HipAA	Hip adduction-abduction
HipROT	Hip internal-external rotation
KneeFE	Knee flexion-extension
AnkleFE	Ankle plantar-dorsi flexion
AnkleSF	Ankle subtalar flexion
add	Hip adductors
gmax	Gluteus maximus
gmed	Gluteus medius
gra	Gracilis
tfl	Tensor fasciae latae
latham	Lateral hamstrings
medham	Medial hamstrings
sar	Sartorius
recfem	Rectus femoris
vasmed	Vastus medialis
vaslat	Vastus lateralis
gasmed	Gastrocnemius medialis
gaslat	Gastrocnemius lateralis
per	Peroneus group
sol	Soleus
tibant	Tibialis anterior
IK	Inverse kinematics
ID	Inverse dynamics
RRA	Residual reduction analysis
NNMF	Non-negative matrix factorization
m	Number of muscles
n	The number of trial frames × number of trials × number of subjects
VAF	Variation accounted for
SSE	Sum of squared errors
TSS	Total sum of squares
$W_{j,i}$	Muscle weighting
$\bar{W}_{j,i}$	Normalized muscle weighting
t	Time
h	Gaussian curve peak height
b	Position of the center of the peak
c	Width of the curve bell
s	Vertical shift
$g(t)$	Fitted Gaussian curve
ℓ^{mt}	Musculotendon unit length
r	Musculotendon unit moment arm
$x(t)$	EMG linear envelope
$u(t)$	EMG linear envelope processed by recursive filter
α, β_1, β_2	Recursive filter coefficients
d	Electromechanical delay
$a(t)$	Musculotendon unit activation
A	Shape factor
$f(v^m)$	Fiber force-velocity relationship
$f_A(l^m)$	Fiber active force-length relationship
$f_P(l^m)$	Fiber passive force-length relationship
F^{max}	Maximal isometric force
$f(\epsilon)$	Tendon force-strain relationship
v^m	Fiber contraction velocity
l^m	Fiber length
F^{mt}	Musculotendon unit force
F^t	Tendon force
F^m	Fiber force
$\varphi(t)$	Pennation angle
M_X, with X = (HipFE, HipAA, HipROT, KneeFE, AnkleFE, AnkleSF)	Predicted joint moment with respect to the degree of freedom X
f_E	Calibration objective function
E_X, with X = (HipFE, HipAA, HipROT, KneeFE, AnkleFE, AnkleSF)	Error term with respect to the degree of freedom X
l_s^t	Tendon slack length
l_O^m	Optimal fiber length
R^2	Square of the Pearson product moment correlation coefficient
$NRMSD$	Normalized root mean squared deviation
N	Number of frames in a specific curve
$\hat{M}_X$, with X = (HipFE, HipAA, HipROT, KneeFE, AnkleFE, AnkleSF)	Experimental joint moment with respect to the degree of freedom X
g^j_{exp}	Experimental Gaussian curve
g^j_{par}	Parameterized Gaussian curve
SD	Standard deviation

APPENDIX

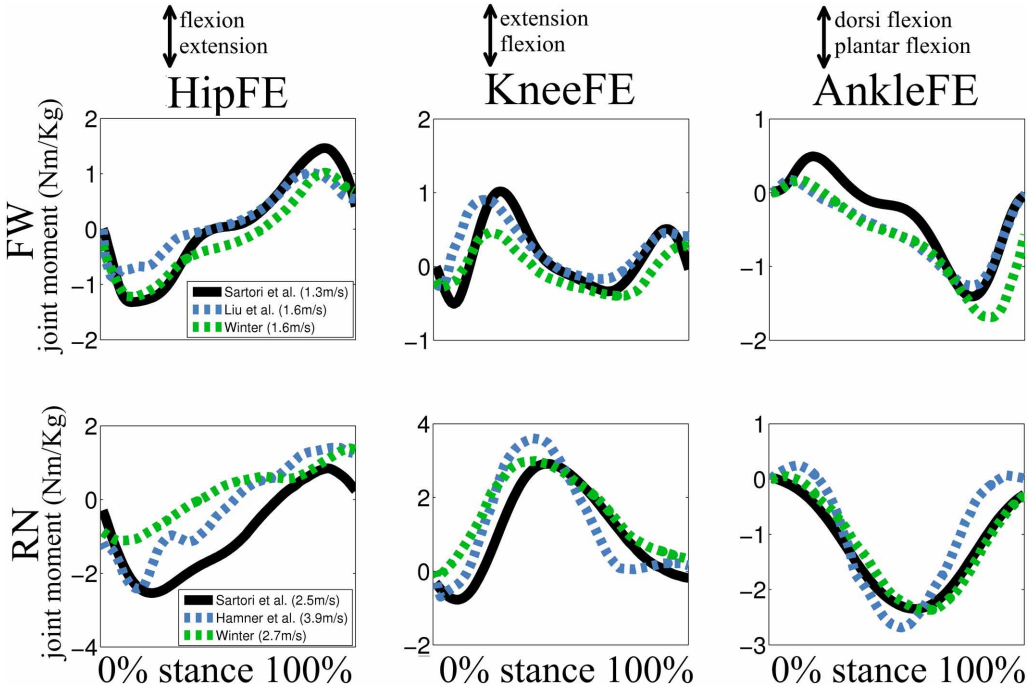

FIGURE A1 | Experimental joint moments. Ensemble average curves are depicted for joint moment derived about three degrees of freedom (DOFs) including: hip flexion-extension (HipFE), knee flexion-extension (KneeFE), and ankle plantar-dorsi flexion (AnkleFE) during fast walking (FW) and running (RN). Joint moment derived in our study (Sartori et al., see Methods Section) were compared to data from (Winter, 1983, 2004; Liu et al., 2008; Hamner et al., 2010). The reported data are from the stance phase with 0% being heel-strike and 100% toe-off events.

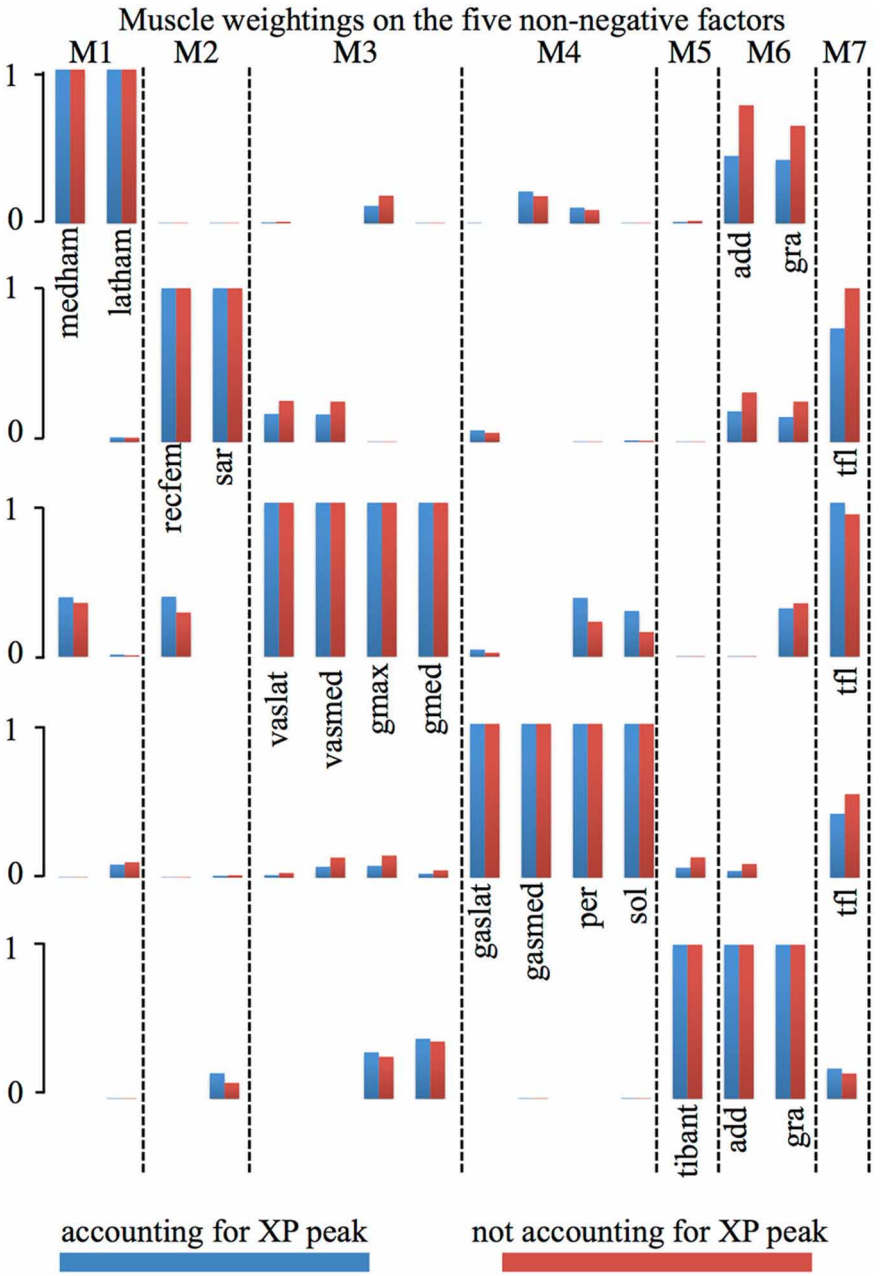

FIGURE A2 | Muscle weightings comparison. Muscle weightings directly extracted from the non-negative matrix factorization algorithm (i.e., not accounting for XP peak, **Figure 2A**) are directly compared to those computed accounting for the excitation primitive (XP) peak amplitude (accounting for XP peak). Also see **Table A1**.

Table A1 | Comparison of muscle weightings normalized with and without accounting for the excitation primitive (XP) peak.

	Not accounting for XP peak					Accounting for XP peak				
	***XP*1**	***XP*2**	***XP*3**	***XP*4**	***XP*5**	***XP*1**	***XP*2**	***XP*3**	***XP*4**	***XP*5**

Analyses of experimental data acquired from humans and other vertebrates have suggested that motor commands may emerge from the combination of a limited set of modules. While many studies have focused on physiological aspects of this modularity, in this paper we propose an investigation of its theoretical foundations. We consider the problem of controlling a planar kinematic chain, and we restrict the admissible actuations to linear combinations of a small set of torque profiles (i.e., motor synergies). This scheme is equivalent to the time-varying synergy model, and it is formalized by means of the dynamic response decomposition (DRD). DRD is a general method to generate open-loop controllers for a dynamical system to solve desired tasks, and it can also be used to synthesize effective motor synergies. We show that a control architecture based on synergies can greatly reduce the dimensionality of the control problem, while keeping a good performance level. Our results suggest that in order to realize an effective and low-dimensional controller, synergies should embed features of both the desired tasks and the system dynamics. These characteristics can be achieved by defining synergies as solutions to a representative set of task instances. The required number of synergies increases with the complexity of the desired tasks. However, a possible strategy to keep the number of synergies low is to construct solutions to complex tasks by concatenating synergy-based actuations associated to simple point-to-point movements, with a limited loss of performance. Ultimately, this work supports the feasibility of controlling a non-linear dynamical systems by linear combinations of basic actuations, and illustrates the fundamental relationship between synergies, desired tasks and system dynamics.

Keywords: muscle synergies, number of synergies, system dynamics, kinematic strokes, kinematic chain

1. INTRODUCTION

Richness, flexibility, and adaptability characterize the generation of movements in many animal species. During the last century these features have fascinated many scientists, who started to investigate the possible mechanisms underlying the observed motor performance. Although many questions remain open, today there is a large consensus that motor skills may arise from a modular and hierarchical organization of the movement system (Kargo and Giszter, 2000a,b; Hart and Giszter, 2004; Ting and McKay, 2007; Bizzi et al., 2008; Kargo and Giszter, 2008; d'Avella and Pai, 2010). This idea was initially introduced by Bernstein (1967) in the context of motor redundancy, and it has then evolved into different, yet related, concepts (Flash and Hochner, 2005; Giszter et al., 2010). The common denominator of these ideas is that motor actions emerge from the combination of a limited set of modules. This strategy would reduce the number of variables to be controlled, and therefore it might simplify motor control and learning.

One of the proposed forms of modularity are the so-called muscle synergies, coordinated activations of groups of muscles (Tresch et al., 1999; Saltiel et al., 2001; d'Avella et al., 2003). Hypothetically, the central nervous system (CNS) encodes a parsimonious set of synergies and combines them in a task-dependent fashion to generate appropriate motor commands. This hypothesis is typically evaluated by analyzing the spatio-temporal regularities of electromyographic signals (EMG) recorded from a group of subjects. Decomposition-based techniques, such as principal component analysis (PCA) or non-negative matrix factorization (NMF), are used to extract the components that best reconstruct the recorded dataset. In many cases these components (i.e., synergies) appear very similar across different experimental conditions, and therefore they are regarded as an indirect evidence of the hypothesized neural modularity. This methodology has been successful in explaining muscle contractions across a wide range of complex tasks (e.g. running, walking, keeping balance, reaching and other combined movements) in humans (Ivanenko et al., 2005; Cappellini et al., 2006; d'Avella et al., 2006, 2008, 2011; Torres-Oviedo and Ting, 2007, 2010), in frogs (Giszter et al., 1993; Mussa-Ivaldi et al., 1994; Kargo and Giszter, 2000b, 2008; Mussa-Ivaldi and Bizzi, 2000), cats (Ting and Macpherson, 2005; Torres-Oviedo et al., 2006), monkeys (Overduin et al., 2008, 2012), and other species (Dominici et al., 2011). However, the

results are often descriptive in nature and they do not offer a principled investigation of the hypothesized synergy-based control strategy (Alessandro et al., 2013).

The implementation of muscle synergies within the CNS is currently under investigation (Bizzi and Cheung, 2013). Recently, Hart and Giszter (2010) have provided direct evidence that dedicated sets of spinal interneurons are associated to the temporal activations of synchronous synergies in frogs. Experiments with monkeys (Overduin et al., 2012) and humans (Cheung et al., 2009b; Clark et al., 2010) suggest that synergies may be organized in the spinal cord and in the cortico-spinal divergent connectivity, and that the motor cortex modulates their recruitment. For visually guided tasks, time-varying synergies might be represented also at the cortical level; their spatial structure might derive from divergent corticospinal connectivity or from spinally organized modules, and their temporal characteristic may originate from the activation dynamics of the motor cortex (d'Avella et al., 2006, 2008, 2011).

While these studies focus on physiological aspects of the muscle synergy hypothesis, very little research addresses the theoretical foundation of the proposed modular controller. Which synergies should be employed to execute the desired motor tasks? How many synergies are needed? How does the dynamics of the system to be controlled affect the synergy-set? Is there a relation between the desired tasks and these elementary control modules? Addressing these theoretical questions would certainly provide a better understanding of the muscle synergy hypothesis, and might eventually lead to a computational model to explain the experimental data. In this paper we analyze these aspects from the perspective of controlling an idealized arm. We formulate control signals for a planar kinematic chain as linear combinations of a small set of predefines actuations (i.e., synergies) in accordance with the model of time-varying synergies (d'Avella et al., 2003). For this purpose we propose the dynamic response decomposition (DRD), a general tool to find the open-loop controllers that enable a dynamical system to solve desired tasks (Alessandro et al., 2012; Carbajal, 2012). Our method initially solves the task in state variables by interpolation; then, it identifies the combination of synergies (i.e., actuation) that leads to the closest kinematic trajectory to the computed interpolant. Additionally we propose a procedure to synthesize a limited set of effective synergies. In this manuscript we apply the DRD to point-to-point reaching tasks, and to via-point movements. Within the latter class of tasks we analyze two specific scenarios: (1) moving to a desired target and coming back to the initial posture (i.e., reversal task) and (2) reaching a desired location, passing though a given via-point (i.e., via-point reaching). Our theoretical analysis is independent of the biological implementation details of muscle synergies; i.e., we employ a kinematic chain instead of a biologically plausible musculoskeletal model, and DRD is currently not proposed as a model of the CNS mechanisms underlying muscle synergies. However, we believe that our results have a general validity as they interpret the fundamental problem of controlling a non-linear dynamical system by means of a modular synergy-based controller.

Reversal and via-point reaching movements can be subdivided in two distinct kinematic phases: from the initial to the intermediate point, and from the intermediate to the final point. A possible strategy to solve these tasks is therefore to concatenate the actuations associated to the two phases; each actuation is in turn realized as a combination of synergies. This idea is related to another form of modularity, the composition of movements into sequences of kinematic primitives, or strokes (Flash et al., 1992; Novak et al., 2003). While this segmentation explains a vast amount of experimental data, there is no consensus on whether such strokes effectively reflect a segmented control strategy (Fishbach et al., 2005, 2007). Alternatively they could just emerge as a result of a possible trajectory optimization (Dagmar and Schaal, 1999), or even be artifacts of the data analysis. In these latter cases the actuation could be computed in its entirety without concatenation. In this manuscript we analyze both strategies: the concatenation of simple synergy-based control signals, and the computation of a synergy-based actuation for the whole task. This investigation provides some computational insights on the advantages and the disadvantages of these two approaches, and it offers a proof of concept on how muscle synergies and kinematic modularity might be integrated into a unified framework.

This paper is organized as follows. In section 2 we introduce the mathematical formulation of DRD, the method that we employ throughout the paper to synthesize synergies and to compute task solutions. Section 3 presents the results obtained for reversal and via-point reaching tasks. Such results are further discussed in section 4, where we additionally summarize and speculate on important aspects of the muscle synergy hypothesis that are highlighted by DRD; finally we provide some concluding remarks.

2. METHODS

In this section we introduce the mathematical details of the dynamic response decomposition (DRD). After some definitions, we present the core element of the method: a general procedure to compute actuations that solve generic reaching tasks (see section 2.1). Subsequently, in section 2.2, we show how DRD can be used for the synthesis of a set of synergies.

Let us consider a differential equation modeling a physical system

$$\mathcal{D}\left(\boldsymbol{q}(t)\right) = \boldsymbol{u}(t),$$

where $\mathcal{D}$ is a differential operator, $\boldsymbol{q}(t)$ represents the time-evolution of the configuration variables (their derivatives with respect to time are $\dot{\boldsymbol{q}}(t)$), and $\boldsymbol{u}(t)$ is the actuation applied. Inspired by the hypothesis of muscle synergies, we formulate the actuation as a linear combination of predefined motor co-activation patterns:

$$\boldsymbol{u}(t) = \sum_{i=1}^{N_\phi} \phi_i(t) b_i := \boldsymbol{\Phi}(t)\boldsymbol{b}, \tag{1}$$

where the N_ϕ functions $\phi_i(t) \in \boldsymbol{\Phi}$ are called *motor synergies*, and are modulated by the weighting coefficients b_i. The notation $\boldsymbol{\Phi}(t)$ describes a formal matrix where each column is a different synergy, and the column vector $\boldsymbol{b}$ encapsulates the weighting coefficients. If we consider a time discretization, $\boldsymbol{\Phi}(t)$ becomes a

N dim($\boldsymbol{q}$)-by-N_ϕ matrix, where N is the number of time steps and dim($\boldsymbol{q}$) is the dimensionality of the configuration space. Equation (1) is essentially equivalent to the model of time-varying synergies (d'Avella et al., 2003), however, in this paper we neglect the possibility to modulate the onset time of each synergy.

We define *dynamic responses* (DR) of the set of synergies the responses $\boldsymbol{\theta}_i(t) \in \boldsymbol{\Theta}$ of the system to each synergy (i.e., forward dynamics):

$$\mathcal{D}(\boldsymbol{\theta}_i(t)) = \phi_i(t) \qquad i = 1...N_\phi. \tag{2}$$

with initial conditions chosen arbitrarily.

2.1. THE DYNAMIC RESPONSES DECOMPOSITION

A generic reaching task consists in reaching a final state $\left(\boldsymbol{q}_T, \dot{\boldsymbol{q}}_T\right)$ from an initial state $\left(\boldsymbol{q}_0, \dot{\boldsymbol{q}}_0\right)$ in a given amount of time T satisfying intermediate constraints called via-points. In the case of a single via-point defined at time t_v, the task can be formalized as follows:

$$\begin{aligned} \boldsymbol{q}(0) &\doteq \boldsymbol{q}_0, \qquad \dot{\boldsymbol{q}}(0) \doteq \dot{\boldsymbol{q}}_0, \\ \boldsymbol{q}(t_v) &\doteq \boldsymbol{q}_v, \qquad \dot{\boldsymbol{q}}(t_v) \doteq \dot{\boldsymbol{q}}_v, \\ \boldsymbol{q}(T) &\doteq \boldsymbol{q}_T, \qquad \dot{\boldsymbol{q}}(T) \doteq \dot{\boldsymbol{q}}_T, \end{aligned} \tag{3}$$

where $\doteq$ indicates a prescribed value, i.e., a point constraint. Depending on the desired task, more or less requirements can be imposed. For example a simple point-to-point reaching task consists only of the constraints defined at $t = 0$ and $t = T$. Furthermore, one could formulate via-point tasks without prescribing any velocity. This would define a class of tasks where the system is free to traverse the desired positions with any velocity. In addition, it is also possible to constrain higher order time derivatives of the configuration vector, e.g. acceleration, jerk, etc.

Controlling a system to perform a given task amounts to finding the actuation $\boldsymbol{u}(t)$ that leads to an evolution of the system-variables that fulfills the point constraints (Equation 3). Specifically, assuming that the synergies are known, the goal is to identify the appropriate synergy combination coefficients $\boldsymbol{b}$. The DRD procedure consists of, first, solving the problem in kinematic space (i.e., finding an appropriate $\boldsymbol{q}(t)$), and then computing the corresponding actuation. From the kinematic point of view, solving the task can be seen as an interpolation problem; i.e., a set of functions is used to generate a trajectory $\boldsymbol{q}(t)$ that interpolates the points $\{\boldsymbol{q}_k(t_k), \dot{\boldsymbol{q}}_k(t_k)\}_{k=0,v,T}$ associated to the task-constraints (Equation 3); the idea is not to track a desired trajectory defined *a priori*, but to find any trajectory that passes through the points defined by the task. To build this interpolant one could employ orthonormal polynomials, trigonometric or Gaussian functions, to mention just a few possibilities. One of the most salient properties of DRD is that it employs the dynamic responses of the synergies (given by Equation 2), that is:

$$\boldsymbol{q}(t) = \sum_{i=1}^{N_\theta} \boldsymbol{\theta}_i(t) a_i := \boldsymbol{\Theta}(t)\boldsymbol{a}. \tag{4}$$

The quality of the DRs as building blocks for the interpolation was evaluated in our previous works on planar kinematic chains (Alessandro et al., 2012) and other dynamical systems (Carbajal, 2012). As we mentioned before, if time is discretized, $\boldsymbol{\Theta}(t)$ becomes a N dim($\boldsymbol{q}$)-by-N_θ matrix, where N_θ is the number of dynamic responses. The vector of combination coefficients $\boldsymbol{a}$ is chosen such that the task constraints are satisfied, obtaining one out of the myriad of possible trajectories that solve the task. Specifically, this vector is computed by solving the following linear system of equations:

$$\begin{pmatrix} \boldsymbol{\theta}_1(0) & \dots & \boldsymbol{\theta}_{N_\theta}(0) \\ \boldsymbol{\theta}_1(t_v) & \dots & \boldsymbol{\theta}_{N_\theta}(t_v) \\ \boldsymbol{\theta}_1(T) & \dots & \boldsymbol{\theta}_{N_\theta}(T) \\ \dot{\boldsymbol{\theta}}_1(0) & \dots & \dot{\boldsymbol{\theta}}_{N_\theta}(0) \\ \dot{\boldsymbol{\theta}}_1(t_v) & \dots & \dot{\boldsymbol{\theta}}_{N_\theta}(t_v) \\ \dot{\boldsymbol{\theta}}_1(T) & \dots & \dot{\boldsymbol{\theta}}_{N_\theta}(T) \end{pmatrix} \boldsymbol{a} = M\boldsymbol{a} = \begin{pmatrix} \boldsymbol{q}_0 \\ \boldsymbol{q}_v \\ \boldsymbol{q}_T \\ \dot{\boldsymbol{q}}_0 \\ \dot{\boldsymbol{q}}_v \\ \dot{\boldsymbol{q}}_T \end{pmatrix} = P. \tag{5}$$

The matrix M in the left-hand side is called *alternant matrix*; the solvability of the problem depends on its rank. If the matrix has full row rank, any point constraint can be solved. Otherwise, the possibility to find an exact solution (as opposed to an approximation) becomes strictly dependent on the specific task. According to the Rouché-Capelli theorem, if the rank of the alternant matrix (not necessarily equal to number of rows) is equal to the rank of the augmented matrix $[M|P]$, where P is the vector of point constraints, the specific problem can be solved exactly. Section 3 presents some examples. These observations, and their implications for the hypothesis of muscle synergies, are further discussed in section 4.

Once a kinematic solution has been found (as a linear combination of DRs), the corresponding actuation $\tilde{\boldsymbol{u}}(t)$ can be obtained by applying the differential operator (i.e., inverse dynamics);

$$\mathcal{D}\left(\boldsymbol{\Theta}(t)\boldsymbol{a}\right) = \tilde{\boldsymbol{u}}(t).$$

Finally, the vector $\boldsymbol{b}$ can be computed by projecting $\tilde{\boldsymbol{u}}(t)$ onto the linear span of the synergy set $\boldsymbol{\Phi}$. If $\tilde{\boldsymbol{u}}(t)$ does not belong to the linear span of $\boldsymbol{\Phi}$, the solution can only be approximated in terms of a defined norm (e.g. Euclidean):

$$\boldsymbol{b} = \arg\min_{\boldsymbol{b}} ||\tilde{\boldsymbol{u}}(t) - \boldsymbol{\Phi}(t)\boldsymbol{b}||. \tag{6}$$

When time is discretized, all functions of time become vectors and this problem can be solved explicitly using the psuedo-inverse of the matrix $\boldsymbol{\Phi}(t)$,

$$\boldsymbol{\Phi}^+\tilde{\boldsymbol{u}} = \boldsymbol{\Phi}^+\mathcal{D}\left(\boldsymbol{\Theta}\boldsymbol{a}\right) = \boldsymbol{b}. \tag{7}$$

This equation highlights the mapping between the kinematic combination coefficients $\boldsymbol{a}$ (kinematic solution) and the synergy combination coefficients $\boldsymbol{b}$ (dynamic solution):

$$\mathcal{F} = \boldsymbol{\Phi}^+ \circ \mathcal{D} \circ \boldsymbol{\Theta}, \tag{8}$$

where $\circ$ denotes composition. Generically, this operator represents a non-linear mapping $\mathcal{F} : \mathbb{R}^{N_\theta} \to \mathbb{R}^{N_\phi}$, and it will be discussed in section 4.3.

To assess the quality of the solution we define the following measures:

Interpolation error: measures the quality of the interpolant $\boldsymbol{\Theta}(t)\boldsymbol{a}$ with respect to the task-constraints.

$$\begin{gathered} \mathrm{err}_I = \sqrt{\sum_{k\in K} e_{IPk}^2 + e_{IVk}^2} \\ e_{IPk} = ||\boldsymbol{q}_k - \boldsymbol{\Theta}(t_k)\boldsymbol{a}|| \qquad e_{IVk} = ||\dot{\boldsymbol{q}}_k - \dot{\boldsymbol{\Theta}}(t_k)\boldsymbol{a}|| \\ K = \{0, \nu_1, \ldots, \nu_n, T\} \end{gathered} \tag{9}$$

where $||\cdot||$ denotes the Euclidean norm, and the difference between angles are mapped to the interval $(-\pi, \pi]$. The subindex k identifies the point constraint, i.e., $k = 0$ for the initial condition, $k = \nu_i$ for the i-th via-point, and $k = T$ for the final condition. In this work we consider tasks with a single or with no via-points, i.e., $K = \{0, \nu, T\}$ and $K = \{0, T\}$, respectively (the latter case corresponding to simple point-to-point tasks). Note that err_I is not a tracking error with respect to a predefined trajectory, but a measure of the distance between $\boldsymbol{\Theta}(t)\boldsymbol{a}$ and the points $\{\boldsymbol{q}_k(t_k), \dot{\boldsymbol{q}}_k(t_k)\}$ defined by the tasks.

Projection error: measures the distance between the actuation $\tilde{\boldsymbol{u}}(t)$, that solves the task, and the control signal obtained by the linear combination of the synergies $\boldsymbol{\Phi}$

$$\mathrm{err}_P = \sqrt{\int_0^T ||\tilde{\boldsymbol{u}}(t) - \boldsymbol{\Phi}(t)\boldsymbol{b}||^2 \mathrm{d}t}. \tag{10}$$

This error represents the loss caused by projecting the actuation $\tilde{\boldsymbol{u}}(t)$ onto the linear span of the synergies, and is zero only when the calculated actuation is an element of this span.

Forward dynamics error: measures the quality of the trajectory $\tilde{\boldsymbol{q}}(t, \boldsymbol{b})$, obtained by applying the actuation $\boldsymbol{\Phi}(t)\boldsymbol{b}$ to the dynamical system (i.e., forward dynamics), with respect to the task constraints

$$\begin{gathered} \mathrm{err}_F = \sqrt{\sum_{k\in K} e_{FPk}^2 + e_{FVk}^2} \\ e_{FPk} = ||\boldsymbol{q}_k - \tilde{\boldsymbol{q}}(t_k, \boldsymbol{b})|| \qquad e_{FVk} = ||\dot{\boldsymbol{q}}_k - \dot{\tilde{\boldsymbol{q}}}(t_k, \boldsymbol{b})|| \\ K = \{0, \nu_1, \ldots, \nu_n, T\} \end{gathered} \tag{11}$$

Similarly to the interpolation error, err_F is not a tracking error with respect to a desired trajectory, but a measure of the distance between $\tilde{\boldsymbol{q}}(t, \boldsymbol{b})$ and the points defining the tasks. Replacing $\tilde{\boldsymbol{q}}$, $\dot{\tilde{\boldsymbol{q}}}$, $\boldsymbol{q}_k$ and $\dot{\boldsymbol{q}}_k$ with their corresponding end-effector values provides the *forward dynamics error of the end-effector*.

Note that the quantities err_I and err_F provide a cumulative evaluation of the DRD solution with respect to all the task-constraints. Mathematically, they represent the Euclidean distance between the DRD solution and the points characterizing the task. Since these errors are defined as a sum over quantities with different units, it could be hard to interpret them from a physical point of view. To overcome this problem, we present our results in two ways. On one hand, we present them in terms of error measures above, which provide a cumulative assessment of the results simplifying the explanation. On the other hand, we report the results in terms of the quantities e_{IPk}, e_{IVk}, e_{FPk}, e_{FVk}, which represent interpolation and forward dynamics errors with respect to position and velocity constraints independently, and therefore are susceptible to a physical interpretation. These quantities will be normalized by factors that provide references to the obtained results, and that will be defined in the next sections.

2.2. SYNTHESIS AND DEVELOPMENT OF SYNERGIES

The synthesis of synergies is carried out in two phases: exploration and reduction. The exploration phase consists in actuating the system with an extensive set of motor signals $\boldsymbol{\Phi}_0$ to obtain the corresponding DRs $\boldsymbol{\Theta}_0$. The reduction phase consists in solving a small set of tasks (that we call proto-tasks, and are defined as a set of point constraints) in kinematic space, and then computing the corresponding actuations. The elements of the set $\boldsymbol{\Theta}_0$ are used to interpolate the proto-tasks as described in Equations (4) and (5); the obtained trajectories are taken as the elements of the reduced set $\boldsymbol{\Theta}$. Finally, the synergy set $\boldsymbol{\Phi}$ is computed by applying relation (Equation 2), i.e., inverse dynamics, to these kinematic trajectories. As a result, there will be as many synergies as the number of proto-tasks (i.e., $N_\phi = N_\theta$).

In a nutshell, the synthesized synergies are the actuations solving the proto-tasks. A legitimate question is: "how do we choose the proto-tasks?" In principle, the DRD method does not impose any restriction. However, in order to obtain satisfactory performance, synergies should be able to approximate the desired actuations. Since the control signals corresponding to similar tasks are likely to be characterized by similar features, a reasonable choice is that the proto-tasks belong to class of the desired tasks (e.g. reversal, via-point reaching). In such a case, the synthesized synergies are actuations solving instances of the desired class of tasks, and therefore they embed the characteristic features of the desired control signals. Thus, we expect that appropriate linear combinations of these synergies are able to approximate the other actuations belonging to the desired set. In general, the more similar the proto-tasks are to the tasks to be solved (in terms of Equation 3), the better the performance of the corresponding synergies. Section 3.4 provides some examples and addresses these issues in detail.

Two other aspects that directly influence the quality of the synergy-based controller are the number of proto-tasks and their particular instances. To obtain good performance in a wide variety of tasks, the constraints defining the proto-tasks should cover relevant regions of the state space. Clearly, an increasing number of (different) proto-tasks corresponds to a gradual improvement of the overall performance. However, it also systematically expands the synergy-set, thus affecting the dimensionality of the controller. In order to tackle this trade-off, we propose a procedure that parsimoniously adds a new proto-task only when and where it is needed: if the performance in a desired task is not satisfactory, we add a new proto-task in one of the regions of the state-space with the highest projection error. In other words, the new proto-task is the task with the worst approximated actuation. Note that the procedure to evaluate the projection error in the entire

workspace does not involve any actual task execution nor forward dynamics integration, and therefore it is relatively light in calculation.

3. RESULTS

We apply the methodology described in section 2 to a simulated planar kinematic chain modeling a human arm [see (Hollerbach and Flash, 1982) for model details]. In the exploration phase, we employ an extensive set of motor signals $\mathbf{\Phi}_0$ to actuate the arm model and generate the corresponding dynamic responses $\mathbf{\Theta}_0$. The nature of these signals has a marginal role and it does not affect the quality of the obtained results (Alessandro et al., 2012; Carbajal, 2012). Here we use a set of 90 low-pass filtered uniformly random signals (butterworth with cutoff frequency of 0.314 rad). We test the performance of the method on three classes of tasks: point-to-point (section 3.1), reversal (section 3.2), and via-point-reaching (section 3.3).

3.1. POINT-TO-POINT TASKS

A point-to-point reaching task consists in reaching a final state from an initial state in a given amount of time. Thus, a task instance is specified by four two-dimensional point constraints: initial and final joint angles and velocities. In this section we restrict our analysis to the subclass of tasks that are characterized by the initial position $\boldsymbol{q}_c$ (red cross in **Figure 1**), and that impose initial and final velocities equal to zero, i.e., $\dot{\boldsymbol{q}}_T = \dot{\boldsymbol{q}}_0 = 0$. The only unspecified constraints are the joint-coordinates of the target; i.e., since the kinematic chain has two degrees of freedom (DoF) there are two free task-parameters. Essentially the arm is required to start from the configuration $\boldsymbol{q}_c$ and reach a desired target with zero velocity. Note that the velocity constraints are added just to restrict the class of desired tasks, and therefore to simplify the explanations throughout the paper. The method is mathematically general, and therefore can also be used to solve tasks in which these constraints are not imposed.

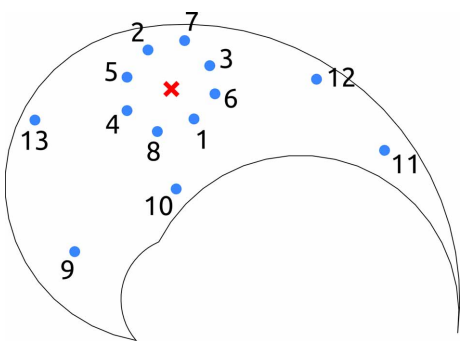

FIGURE 1 | Salient points of the testing-tasks in end-effector space. The solid line delimits the workspace of the kinematic chain. For point-to-point testing tasks, the red cross represents the initial position of the arm, and the blue dots indicate the final targets. For reversal tasks, the red cross represents the initial and final position of the arm, and the blue dots illustrate the intermediate targets. Finally, for the via-point reaching tasks the red cross indicates the location of the via-point, and the blue dots represent the initial and the final positions of the arm. In the text, the joint configuration vector corresponding to the red cross is referred as $\boldsymbol{q}_c$.

After the reduction phase the linear system in Equation (5) becomes:

$$\begin{pmatrix} \boldsymbol{q}_c & \dots & \boldsymbol{q}_c \\ \boldsymbol{\theta}_1(T) & \dots & \boldsymbol{\theta}_{N_\theta}(T) \\ 0 & \dots & 0 \\ 0 & \dots & 0 \end{pmatrix} \boldsymbol{a} = \begin{pmatrix} \boldsymbol{q}_c \\ \boldsymbol{q}_T \\ 0 \\ 0 \end{pmatrix}, \tag{12}$$

where $\boldsymbol{\theta}$ are the reduced DRs, and $\boldsymbol{q}_T$ is the target posture (that uniquely defines a desired task instance as $\boldsymbol{q}_c$ is a fixed value). Since each element is a two-dimensional column vector, the extended matrix consists of four non-zero rows; the first two rows consist of repetitions of the same numerical values (the components of $\boldsymbol{q}_c$). As a result, an exact kinematic solution is guaranteed if the rank of the alternant matrix is equal to 3; i.e., there should be at least three linearly independent columns. This poses a lower bound on the minimum required number of DRs and therefore of synergies. However, a higher number of synergies might be necessary to achieve satisfactory approximations of the desired actuations, and ultimately to fulfill the task requirements.

Notice that in order to obtain the alternant matrix described in Equation (13), the proto-tasks should belong to the same class of the desired tasks (i.e., point-to-point, starting at $\boldsymbol{q}_c$). Additionally, the exploration DRs $\mathbf{\Theta}_0$ should be able to generate kinematic solutions that fulfills all the constraints of the proto-tasks (i.e., zero interpolation error). As it was shown by Carbajal (2012), for systems with non-linear dynamics this is likely to happen as the 8-by-90 alternant matrix, built from the exploration DRs, most probably contains more than eight linearly independent columns. Thus any point-to-point task could be solved.

Figure 2A shows the distribution of the projection error for an increasing number of synergies, and exemplifies the proposed procedure to incrementally add new proto-tasks. Initially, two targets are chosen randomly (top left panel); subsequent targets are added in the regions characterized by higher projection error. As it can be seen, the introduction of new proto-tasks leads to better performance on wider regions of the space, and eventually the actuations needed to solve any point-to-point task can be reasonably approximated ($\text{err}_P < 10^{-2}$ Nm with seven synergies). The bottom right panel shows the distribution of the forward dynamics error of the end-effector obtained with seven proto-tasks. Comparing this panel with the bottom center one (projection error with seven proto-tasks), it can be seen that the forward dynamics error reproduces the distribution of the projection error, rendering the latter a good estimate of the relative forward performance across tasks. However, it is important to stress that, due to the non-linearity of the dynamical system, the projection error serves only as an heuristic estimate of the actual error made when executing the task.

Figure 2B shows the trend of the average projection error (across the targets distributed in the workspace) as a function of the number of proto-tasks. Depending on the precision required, more or less proto-tasks can be used. Here we employ seven proto-tasks to obtain an average projection error $< 10^{-2}$ Nm. This means that the actuations to solve any point-to-point task

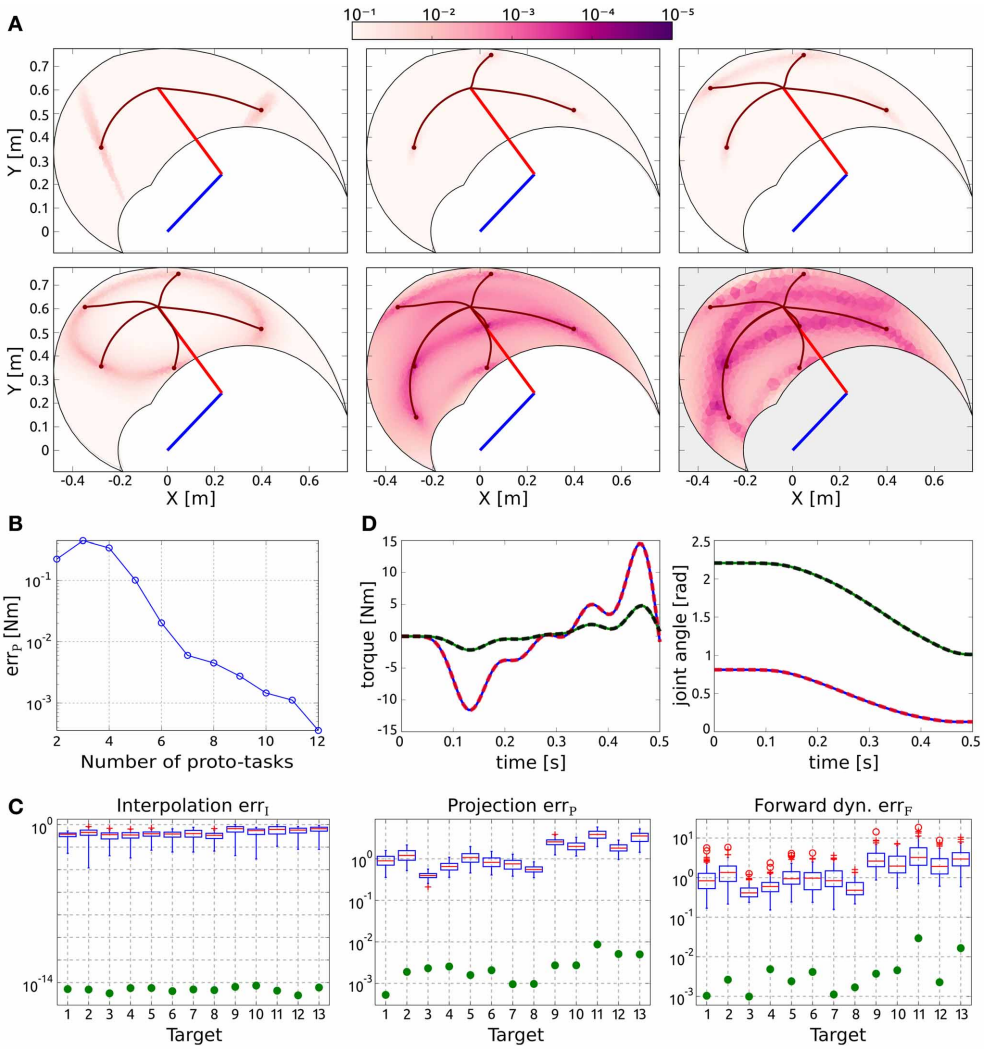

FIGURE 2 | Results of point-to-point tasks. (A) Selection of proto-tasks based on projection error. Each panel shows the kinematic chain in its initial posture (straight segments), and the distribution of the projection error over the end-effector space (colored region). The color of each point indicates the projection error produced to reach a target in that position. The bottom right panel shows the distribution of the forward dynamics error of the end-effector using seven proto-tasks (seven synergies). **(B)** Average projection error (across targets distributed in the workspace) as a function of the number of synergies. **(C)** Evaluation of the reduction phase for the testing point-to-point tasks. Comparison between the synthesized synergies (filled circles) and subsets randomly selected from the exploration-actuations (box-plots). **(D)** Actuation that solves the task (continuous lines) and projected (dashed lines) torque, and interpolated (continuous lines) and executed (dashed lines) joint trajectories for the tasks with the highest projection error (i.e., target 11).

(starting at $\boldsymbol{q}_c$) can be approximated by combining only seven synergies. The average forward dynamics error err_F using seven synergies amounts to $\approx 10^{-2}$. These results show that a set of "good" synergies can drastically reduce the dimensionality of the controller, while maintaining satisfactory performance. Note that the controller has to "choose" the values of two joint-torques at each time-step, thus its dimensionality is much higher than the number of DoF of the system (in fact it is infinite dimensional if we consider actuations as continuous vector-valued functions of time). Hence, seven synergies contribute a dimensionality reduction even if the system has two DoF (Alessandro et al., 2013).

To further demonstrate that the reduction phase is not trivial, we compare the errors resulting from the set of seven synthesized synergies, with the errors corresponding to 100 random subsets of size seven drawn from the exploration signals. The testing point-to-point tasks are identified by the 13 targets depicted in **Figure 1**. **Figure 2C** shows that the errors of the random subsets (box-plots) are always orders of magnitude higher than the errors of the synergies resulting from the reduction phase (filled circles). The seven reduced DRs lead to an alternant matrix with rank equal to 3, therefore any point-to-point constrain-vector of this class can be interpolated exactly. As a result, in contrast to the case of random DRs, the obtained

interpolation error is negligible for all the testing tasks ($\text{err}_I \simeq 10^{-15} \sim 0$). In terms of projection and forward dynamics error, the reduced synergies perform about 2–3 orders of magnitude better than any random subset. Additionally, they lead to high task performance (forward dynamics errors in the range $[10^{-3}, 10^{-2}]$), yet greatly reducing the dimensionality of the controller.

Figure 2D exemplifies these results for the testing tasks characterized by the highest projection error (target 11). The difference between the torque that solves the task $\tilde{\boldsymbol{u}}(t)$ (continuous lines) and that obtained as a linear combination of synergies $\boldsymbol{\Phi b}$ (dashed lines) is negligible. Similarly, there is negligible difference between the kinematic solution obtained as a linear combination of DRs (continuous lines) and the trajectory resulting from the projected actuation (dashed lines).

A more detailed evaluation of the obtained results is summarized in **Table 1**, which presents the normalized values of interpolation and forward dynamics errors for each task-constraint separately at the target points (i.e., $k = T$, see Equations 9 and 11). The errors in position (e_{IPT} and e_{FPT}) are normalized to $||\boldsymbol{e}_{PM}|| = 5.02$ rad, where $\boldsymbol{e}_{PM}$ is a vector containing the angular ranges of the two joints (therefore encoding the maximum position error possible); the errors in velocity (e_{IVT} and e_{FVT}) are normalized to $||\boldsymbol{e}_{VM}|| = 5.70$ rad/s, where $\boldsymbol{e}_{VM}$ contains the peak angular velocities of the two joints across the kinematic solutions to the 13 testing tasks. As it can be seen, the very satisfactory maximum normalized values are 3.62×10^{-4} (i.e., 0.0002 rad, task 12) for position, and 5.13×10^{-3} (0.03 rad/s, task 11) for velocity forward dynamics errors.

Table 1 | Normalized interpolation (int) and forward dynamics (fwd. dyn.) errors for each task-constraint of the testing point-to-point tasks.

Task	int_T ($\times 10^{-16}$)		fwd. dyn._T ($\times 10^{-4}$)	
	Pos	Vel	Pos	Vel
1	1.77	2.91	0.23	1.80
2	0.99	3.77	1.14	4.50
3	0.99	0.75	1.34	1.27
4	4.51	0.97	0.96	8.45
5	3.78	2.45	0.22	4.20
6	0.91	1.70	0.64	7.23
7	1.59	3.66	0.48	1.91
8	1.76	2.41	0.86	2.87
9	5.59	2.02	1.13	6.47
10	4.53	6.56	1.05	7.93
11	0	2.98	3.38	51.3
12	0.88	0.25	3.62	2.38
13	2.21	5.39	1.37	28.9

The normalization factors are $||\boldsymbol{e}_{PM}|| = 5.02$ rad and $||\boldsymbol{e}_{VM}|| = 5.70$ rad/s for position and velocity errors, respectively; the rationale behind these factors is discussed in section 3.1. The errors are evaluated at the time of the target constraint T. The expressions pos and vel identify position and velocity constraints, respectively.

3.2. REVERSAL TASKS

A reversal task consists in reaching a desired target and coming back to the initial position. The tasks considered in this subsection are characterized by zero velocity at the time of the constraints, i.e., $\dot{\boldsymbol{q}}(0) = \dot{\boldsymbol{q}}(t_v) = \dot{\boldsymbol{q}}(T) = 0$, and by the initial (and final) posture placed in the center of the operational space, i.e., $\boldsymbol{q}(0) = \boldsymbol{q}(T) = \boldsymbol{q}_c$ (red cross in **Figure 1**). Thus, the only free task-parameters are the joint-coordinates of the intermediate target (two parameters). In other words, the agent is required to reach a certain location with zero velocity (i.e., the via-point), and return to its initial posture. These reversal tasks have relevance as they resemble the motion performed for carrying objects to and from the agent, e.g. reaching for food and bringing it to the mouth, or picking up a salient object and moving it closer for examination.

After the reduction phase, the linear system of Equation (5) becomes:

$$\begin{pmatrix} \boldsymbol{q}_c & \cdots & \boldsymbol{q}_c \\ \boldsymbol{\theta}_1(t_v) & \ldots & \boldsymbol{\theta}_{N_\theta}(t_v) \\ \boldsymbol{q}_c & \cdots & \boldsymbol{q}_c \\ 0 & \ldots & 0 \\ 0 & \ldots & 0 \\ 0 & \ldots & 0 \end{pmatrix} \boldsymbol{a} = \begin{pmatrix} \boldsymbol{q}_c \\ \boldsymbol{q}_v \\ \boldsymbol{q}_c \\ 0 \\ 0 \\ 0 \end{pmatrix}. \tag{13}$$

where $\boldsymbol{\theta}$ are the reduced DRs, and $\boldsymbol{q}_v$ is the intermediate desired position (that uniquely defines the specific task instance). For the same rationale discussed in section 3.1, to guarantee the existence of an exact kinematic solution for any reversal task belonging to this class, the rank of the alternant matrix, and therefore the minimal number of DRs, should be equal to 3. However, the number of synergies required to obtain satisfactory values of projection and forward dynamics errors might be higher.

Like in the case of point-to-point movements, proto-tasks belong to same class of the desired tasks (i.e., reversal, $\boldsymbol{q}_0 = \boldsymbol{q}_T = \boldsymbol{q}_c$), and they are added incrementally. Since the position of the desired intermediate target is the only unknown, the newly added proto-task is identified by placing the via-point in the region of the operational space with the highest projection error. As shown in **Figure 3A**, this strategy aims at decreasing the projection error over the entire configuration space, such that eventually the actuations necessary to solve any reversal task can be approximated satisfactorily. In particular, eight synergies are enough to obtain an average projection error $\text{err}_P < 10^{-2}$ Nm (see **Figure 3B**, blue line), and an average forward dynamics error of $\approx 10^{-2}$.

The reduced synergies are compared to 100 subsets of 8 actuations, randomly chosen from the exploration motor signals. The testing reversal tasks are identified by the 13 intermediate targets depicted in **Figure 1**. The results shown in **Figure 3C** provide additional evidence that the reduction phase identify effective synergies: the mean errors of the random subsets (boxplot) are orders of magnitude higher than those corresponding to the reduced synergies (filled circles), and the forward dynamics errors lie in the range $[10^{-3}, 10^{-2}]$, meaning that the 13 approximated actuations lead to good task performance. **Figure 3D** depicts the DRD solution of the task with highest projection error (target 11). The difference between computed and projected torques, as well

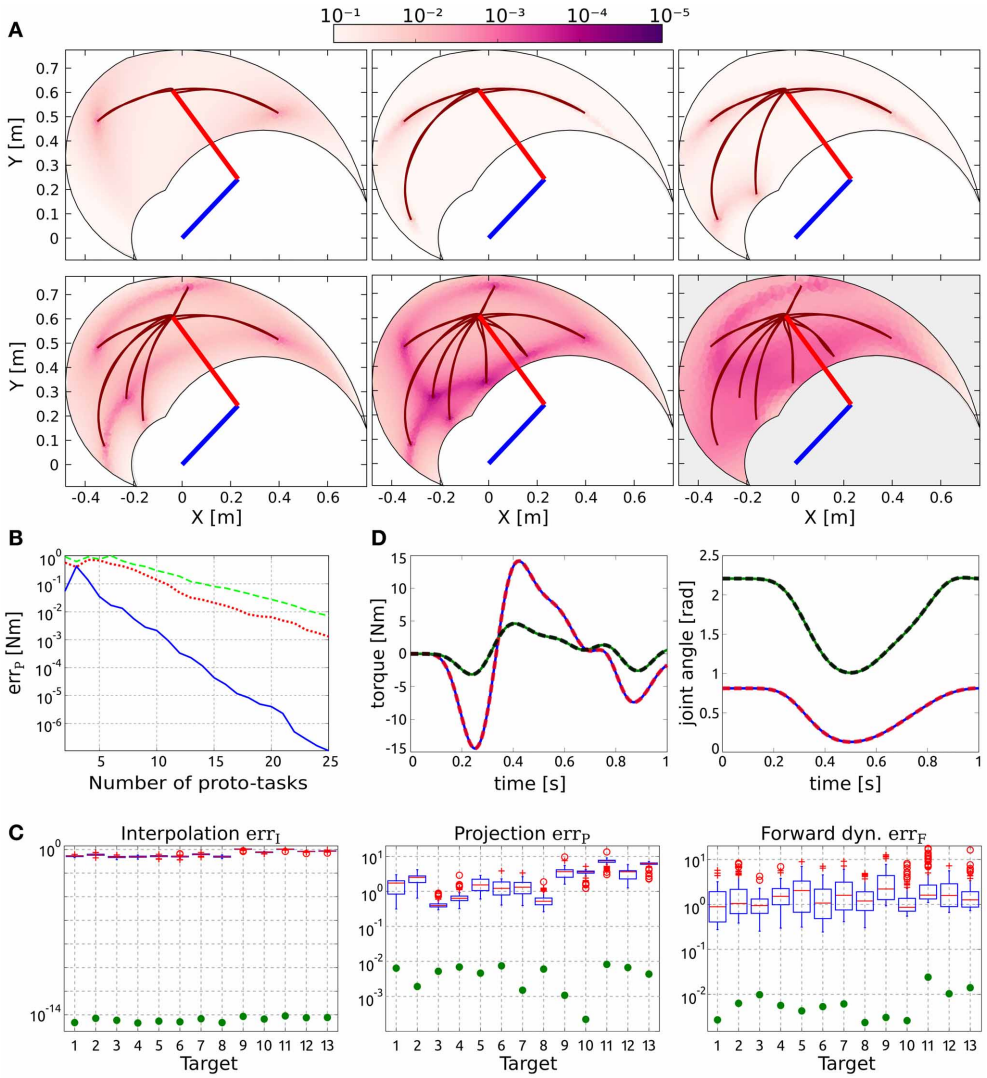

FIGURE 3 | Results of reversal tasks. (A) Selection of proto-tasks based on projection error. Each panel shows the kinematic chain in its initial posture (straight segments), and the distribution of the projection error over the end-effector space (colored region). The color of each point indicates the projection error produced to reach that position and to go back to the initial posture. The bottom right panel shows the distribution of the forward dynamics error of the end-effector using eight proto-tasks (eight synergies). **(B)** Averaged projection error as a function of the number of proto-tasks for increasingly general classes of via-point tasks. The least general tasks are reversal motions (blue continuous line), characterized by two free task-parameters (i.e., configuration of the intermediate target). An increase in generality consists in fixing only the initial posture, while intermediate target and final position represents free task-parameters (red dotted line). Finally the most general class (green dashed line) does not fix any posture (six free task-parameters). The number of synergies required to achieve the same error increases with the generality of the class of tasks. These results are discussed in section 3.4. **(C)** Evaluation of the reduction phase for the testing reversal tasks. Comparison between the synthesized synergies (filled circles) and subsets randomly selected from the exploration-actuations (box-plots). **(D)** Actuation that solves the task (continuous lines) and projected (dashed lines) torque, and interpolated (continuous lines) and executed (dashed lines) joint trajectories for the tasks with the highest projection error (i.e., target 11).

as the difference between computed and executed trajectories are negligible, showing the quality of the synthesized synergies.

The values of the normalized interpolation and forward dynamics error for each task constraints are summarized in **Table 2**. The normalization factors, computed as in section 3.1, are $||\boldsymbol{e}_{PM}|| = 5.02$ rad, and $||\boldsymbol{e}_{VM}|| = 8.20$ rad/s, for position and velocity errors, respectively. The maximum normalized values of the errors are 1×10^{-3} (i.e., 0.005 rad, task 12, $k = T$) for position, and 2.5×10^{-3} (0.02 rad/s, task 11, $k = T$) for velocity forward dynamics errors.

3.2.1. Concatenation of point-to-point actuations

Reversal tasks are composed by two kinematically different phases: from the initial point to the target (center-out), and from the target back to the initial position (out-center). Therefore, it should be possible to generate suitable control signals by

Table 2 | Normalized interpolation (int) and forward dynamics (fwd. dyn.) errors for each task-constraint of the testing reversal tasks.

Task	int_v ($\times 10^{-16}$)		fwd. dyn._v ($\times 10^{-4}$)		int_T ($\times 10^{-16}$)		fwd. dyn._T ($\times 10^{-4}$)	
	Pos	Vel	Pos	Vel	Pos	Vel	Pos	Vel
1	1.82	0.86	0.63	0.98	1.78	1.90	4.62	1.31
2	4.42	2.79	0.27	1.25	4.29	3.14	2.76	7.40
3	2.74	1.52	1.18	2.16	3.96	2.13	8.29	10.55
4	1.77	0.20	0.63	0.38	0.66	1.69	5.93	5.82
5	0.99	1.58	0.91	1.47	0.66	2.63	4.13	4.29
6	1.78	0.29	0.80	0.83	2.74	2.24	7.00	4.77
7	2.21	3.15	0.91	1.71	3.45	3.04	3.88	6.83
8	1.98	1.02	0.50	0.57	1.98	0.39	4.08	1.26
9	0.99	1.79	0.46	2.30	6.38	6.50	0.67	2.90
10	0.75	3.21	0.13	2.23	2.43	3.23	1.43	2.08
11	0.46	1.58	1.51	14.05	5.93	7.73	3.92	25.60
12	0.88	2.45	1.44	9.53	4.17	4.74	10.02	5.34
13	1.33	2.23	1.45	2.25	2.69	6.06	5.75	16.55

The normalization factors are $||\boldsymbol{e}_{PM}|| = 5.02$ rad and $||\boldsymbol{e}_{VM}|| = 8.20$ rad/s for position and velocity errors, respectively. The errors are evaluated at the via-point ($k = v$) and at the final point $k = T$. The expressions pos and vel identify position and velocity constraints, respectively.

concatenating the actuations associated to the individual point-to-point tasks. Each of these subtasks are solved by means of DRD. In the following we explore this possibility, and we compare the obtained solutions to the results of applying DRD to the entire reversal tasks.

In order to produce a meaningful solution from the concatenation, at the beginning of the out-center movement all the system variables (positions, velocities and accelerations) should match the values obtained at the end of the center-out phase. This condition can be enforced by imposing additional constraints on the acceleration of the joints. Here we prescribe zero velocity and acceleration at the end of the center-out tasks, at the beginning of the out-center, as well as at the target-point of the reversal tasks. Clearly, any other value would represent an equally suitable choice. Additionally, we assign zero velocity at the beginning and at the end of the reversal movements. Formally, the tasks are defined as follows:

Center-out

$$\begin{aligned} &\boldsymbol{q}(0) = \boldsymbol{q}_c, \quad \dot{\boldsymbol{q}}(0) = 0, \\ &\boldsymbol{q}(t_v) = \boldsymbol{q}_v, \quad \dot{\boldsymbol{q}}(t_v) = 0, \quad \ddot{\boldsymbol{q}}(t_v) = 0 \end{aligned} \tag{14}$$

Out-center

$$\begin{aligned} &\boldsymbol{q}(t_v) = \boldsymbol{q}_v, \quad \dot{\boldsymbol{q}}(t_v) = 0, \quad \ddot{\boldsymbol{q}}(t_v) = 0, \\ &\boldsymbol{q}(T) = \boldsymbol{q}_c, \quad \dot{\boldsymbol{q}}(T) = 0 \end{aligned} \tag{15}$$

Reversal

$$\begin{aligned} &\boldsymbol{q}(0) = \boldsymbol{q}_c, \quad \dot{\boldsymbol{q}}(0) = 0, \\ &\boldsymbol{q}(t_v) = \boldsymbol{q}_v, \quad \dot{\boldsymbol{q}}(t_v) = 0, \quad \ddot{\boldsymbol{q}}(t_v) = 0, \\ &\boldsymbol{q}(T) = \boldsymbol{q}_c, \quad \dot{\boldsymbol{q}}(T) = 0. \end{aligned} \tag{16}$$

The synthesis of the synergies for each class of tasks follows the same procedure described in section 2.2 and exemplified in **Figure 3A**. We choose the number of synergies for the point-to-point (six synergies) and for the reversal tasks (seven synergies) in order to achieve comparable average projection errors across the 13 testing targets (0.011 for center-out, 0.014 for out-center, 0.016 for reversal tasks as computed by DRD, and 0.013 for the concatenation of DRD point-to-point solutions). The individual projection errors are depicted in **Figure 4A**. For the targets 1–8, 10, and 13, the actuations provided by the concatenation of point-to-point DRD solutions are better suited than those computed by applying DRD to the entire tasks. However, the forward dynamics errors do not always follow the same relation (**Figure 4B**). As an example, for the targets 2–7, the entire DRD solution performs better than the concatenation of the point-to-point actuations. The relation is, however, kept for targets 1, 8, 10, 11, and 12. Although these results might seem counter intuitive, they can be explained by analyzing the forward dynamics errors of the single center-out and the out-center tasks. It can be noticed that when the error of the entire DRD reversal solution is lower than any of the point-to-point errors, the former solution is preferable to the concatenation-based trajectory (targets 2–7, 9, 11–13). On the other hand, when the forward errors of both point-to-point tasks are lower than the error of the entire reversal solution, concatenation seems to be a better strategy (targets 1, 8, 10). In most of the cases, the forward error of the concatenation err_{Fcoc} is almost close to the "sum" of the single point-to-point errors, err_{Fco} and err_{Foc}. In order to conform to the definition of the error (see Equation 11), this sum is computed as $\text{err}_{\text{Fcoc}} = \sqrt{\text{err}_{\text{Fco}}^2 + \text{err}_{\text{Foc}}^2}$.

The relation between the forward error of the concatenation and the forward errors of the individual point-to-point DRD solutions is, in reality, far from trivial. The scenario is depicted schematically in **Figure 5**, where the red line represents a possible solution to a reversal task. Trivially, in the first part of the movement the trajectory obtained from the concatenation strategy (dashed line) corresponds to the DRD solution to the center-out task (dashed green). The actuation

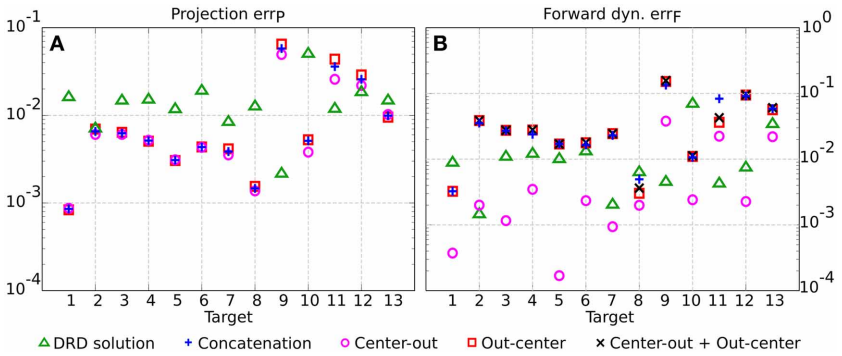

FIGURE 4 | Comparison between the DRD solutions to the entire testing reversal tasks (green triangles) and the concatenation of DRD point-to-point solutions (blue crosses) in terms of projection (A) and forward dynamics errors (B). The plot also indicates the performance of the individual center-out (magenta circles) and out-center tasks (red squares), and the sum of their corresponding errors (black Xs).

corresponding to the out-center task is then applied. Since the first submotion is affected by errors (i.e., forward error of the center-out task, $e_{co}(t_{vp})$), the system does not lie in the initial conditions associated to the out-center task (yellow line). This initial error propagates over the course of the movement according to the dynamical properties of the system (dashed blue line), and affects the state at the end of the motion. The resultant final error $e_{coc}(T)$ is in general different from the forward error of the DRD out-center solution $e_{oc}(T)$. As a result, the overall forward error of the concatenation can be higher (e.g. target 11) or lower (e.g. target 9) than the "sum" of the point-to-point errors. In theory, due to this effect, applying DRD to the entire task could lead to better performance than concatenating DRD point-to-point actuations even if the error of the entire solution is higher than both the errors of center-out and out-center tasks. Such a scenario is, however, not very likely if the error associated to center-out task is very low (as in our examples).

In general terms, none of the two methods seems to be better than the other, however, the following conclusions can be drawn. The concatenation-based solution accumulates the errors of the single movement phases. Furthermore, this strategy requires additional conditions on the kinematic variables to enable the compatibility between the two point-to-point trajectories. On the other hand, the application of DRD to the entire reversal task requires the definition of adequate proto-tasks. If these details are not available (the class of desired tasks is too general, see section 3.4), the concatenation method might be a viable alternative. **Table 3**, summarizes the results of this and the next sections.

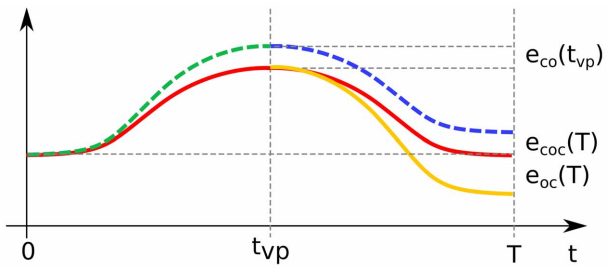

FIGURE 5 | Schematic representation of the concatenation of DRD point-to-point solutions. The red line represents a possible exact solution to a reversal task. The first part of the concatenation-based trajectory (until the time of the via-point t_{vp}) corresponds to the individual center-out solution (dashed green line), which is affected by the forward dynamics error $e_{co}(t_{vp})$. This error propagates over the course of the second submovement (dashed blue line), leading to the final error $e_{coc}(T)$. The latter is in general different from the final forward dynamics error $e_{oc}(T)$ of the individual out-center movement (orange continuous line).

Table 3 | Mean projection errors obtained for the testing instances of reversal and via-point reaching tasks using N_ϕ synergies.

	Reversal		Via-point reaching	
	Error ($\times 10^{-2}$ Nm)	N_ϕ	Error ($\times 10^{-2}$ Nm)	N_ϕ

2nd phase	1.4	6	1.4	6
Concatenation	1.3	12	1.5	12
DRD	1.6	7	1.3	17

See text for more details.

3.3. VIA-POINT REACHING

In this section we show the performance of DRD to solve via-point reaching tasks. These motions require the agent to reach a desired final position, passing through a given via-point. Specifically, in this section we set the via-point to be the center of the operational space $\boldsymbol{q}_c$ (red cross in **Figure 1**), and the initial, intermediate, and final velocities to be equal to zero. The joint-coordinates of initial and final postures, $\boldsymbol{q}_0$ and $\boldsymbol{q}_T$, represent the free task-parameters as they can be chosen arbitrarily to instantiate specific tasks (four parameters). Finally, we prescribe acceleration equal to zero at the via-point. As described in the previous section, this enables us to generate meaningful task solutions by concatenating the actuations corresponding to the two phases of the movement.

Formally, the desired class of tasks can be described as follows:

$$\begin{aligned} &\boldsymbol{q}(0) = \boldsymbol{q}_0, && \dot{\boldsymbol{q}}(0) = 0, && \\ &\boldsymbol{q}(t_v) = \boldsymbol{q}_c, && \dot{\boldsymbol{q}}(t_v) = 0, && \ddot{\boldsymbol{q}}(t_v) = 0 \\ &\boldsymbol{q}(T) = \boldsymbol{q}_T, && \dot{\boldsymbol{q}}(T) = 0. && \end{aligned} \tag{17}$$

The synergies are synthesized as described in section 2.2. Since the parameters $\boldsymbol{q}_0$ and $\boldsymbol{q}_T$ can be chosen arbitrarily, the parameter space is four-dimensional. This condition does not affect the general procedure; i.e., proto-tasks are sequentially added in the point of the space characterized by the highest projection error. **Figure 6A** depicts the averaged projection error (across the targets distributed in the parameter space) as a function of the number of synergies.

The synthesized synergies are tested on 18 tasks, the initial and final positions of which are drawn from the targets in **Figure 1**. **Figure 6B** reports the errors obtained by using 17 reduced synergies (upward green triangles), and the performance of 100 sets of size 17 drawn from the exploration signals (box-plots). The interpolation errors corresponding to the synthesized synergies are lower than, but comparable to, the mean errors of the random sets ($\approx 10^{-14}$). This is not surprising since 17 random signals are likely to produce an alternant matrix with full row-rank, thus any desired constraint vector can be obtained with negligible interpolation error. However, it is interesting to notice that the information added by the reduction phase leads to lower interpolation errors. In relation to projection and forward dynamics errors, the synthesized synergies perform about two orders of magnitude better than the random signals, providing further evidence that the reduction phase is a valuable procedure. **Figure 6C** shows the DRD solution of the via-point reaching task with the highest projection error (starting at point 10 and arriving at point 5). Similarly to point-to-point and reversal movements, the difference between computed and projected actuations, and the difference between interpolated and executed trajectories are negligible.

The detailed values of normalized interpolation and forward dynamics errors are summarized in **Table 4**. Similarly to the position and velocity errors, the acceleration errors are defined as $e_{IAk} = ||\ddot{\boldsymbol{q}}_k - \ddot{\boldsymbol{\Theta}}(t_k)\boldsymbol{a}||$ and $e_{FAk} = ||\ddot{\boldsymbol{q}}_k - \ddot{\tilde{\boldsymbol{q}}}(t_k, \boldsymbol{b})||$ (interpolation and forward dynamics, respectively). The normalization factors, computed as in section 3.1, are $||\boldsymbol{e}_{PM}|| = 5.02$ rad, and $||\boldsymbol{e}_{VM}|| = 7.05$ rad/s, for position and velocity errors, respectively; the errors in acceleration are normalized to $||\boldsymbol{e}_{AM}|| = 61.5$ rad/s^2, where $\boldsymbol{e}_{AM}$ contains the peak angular accelerations of the two joints across the kinematic solutions to the testing tasks. The maximum normalized values of the errors are 4.2×10^{-3} (i.e., 0.021 rad, task 10-3, $k = T$) for position, 6.4×10^{-3} (0.046 rad/s, task 13-1, $k = T$) for velocity, and 2.03×10^{-6} (1.2×10^{-4} rad/s^2, task 2-8, $k = v$) for acceleration forward dynamics errors.

Finally, we compare the use of DRD for solving the entire tasks, to the concatenation of individual DRD point-to-point solutions. In the same vein of the reversal tasks, the considered via-point reaching movements can be composed of an initial out-center motion (from $\boldsymbol{q}_0$ to $\boldsymbol{q}_c$), followed by a center-out movement (from $\boldsymbol{q}_c$ to $\boldsymbol{q}_T$). The number of synergies is chosen to obtain a comparable mean projection error across the 18 testing tasks. We used six synergies for both out-center and center-out tasks, and 17 synergies for via-point reaching, leading to the following average errors: 0.012 Nm for center-out, 0.014 Nm for out-center, 0.013 Nm for via-point reaching as solved by DRD, and 0.015 Nm for the concatenation. **Table 3** summarizes these results.

The yellow downward triangles in **Figure 6B** indicate the performance of the concatenation strategy. In line with the rationale in section 3.2.1, this method accumulates the errors of the sequential point-to-point solutions, resulting in higher values of forward dynamics and interpolation error. From the point of view of dimensionality reduction, the concatenation strategy might be convenient as the number of synergies reduces from 17 to 12 (six for each movement phase) with a small loss of performance (see **Table 3**).

3.4. TASK GENERALITY AND NUMBER OF SYNERGIES

The obtained results show that via-point reaching tasks require a higher number of synergies than reversal tasks. To achieve a mean projection error $<10^{-2}$ Nm, via-point reaching needs at least 17 synergies, and the reversal tasks at least 7. In this section, we provide a plausible interpretation of this difference, accompanied by additional results to support our rationale.

For the sake of clarity let us first define the *generality* of a class of tasks as the number of its free task-parameters. As discussed above, the desired class of tasks can be defined by imposing certain values to the state variables and their derivatives. For example, the reversal tasks presented in section 3.2 impose zero velocities, and additionally fix initial and final postures to a specific point of the configuration space, $\boldsymbol{q}_c$. Although they are essentially via-point tasks, each instance is defined only by the position of the desired intermediate target. Thus the generality of this class of task is 2 as the target is specified by two values (i.e., its joint-coordinates). Via-point reaching tasks, as defined in section 3.3, fix the position of the via-point to $\boldsymbol{q}_c$, and impose initial, intermediate and final velocities equal to zero; each task instance is therefore defined by the desired initial and final postures, thus the generality of this class of tasks is 4.

The lower the generality of the desired class of tasks, the lower the variability of the control signals. This observation is exemplified in **Figure 7**, which shows the actuations associated to the reversal (panel **A**) and the via-point reaching testing tasks (panel **B**). As expected, the actuations in panel **A** are more regular than those in panel **B**. Quantitatively, the mean correlations between the (absolute values of the) control signals of the shoulder are 0.97 and 0.67 for reversal and via-point reaching, respectively, and the correlations between the actuations of the elbow are 0.70 and 0.53. The regularities that can be observed in the first phase of the via-point reaching movements are simply due to the fact that groups of testing tasks are characterized by the same initial position (see the abscissas label of **Figure 6B**). If this was not the case, the corresponding mean correlation values would be even lower.

The number of required synergies is strictly related to the previous observations. Since the proto-tasks belong to the desired class of tasks (see section 2.2), the reduced synergies are elements of the set of desired actuation. If the desired control signals are

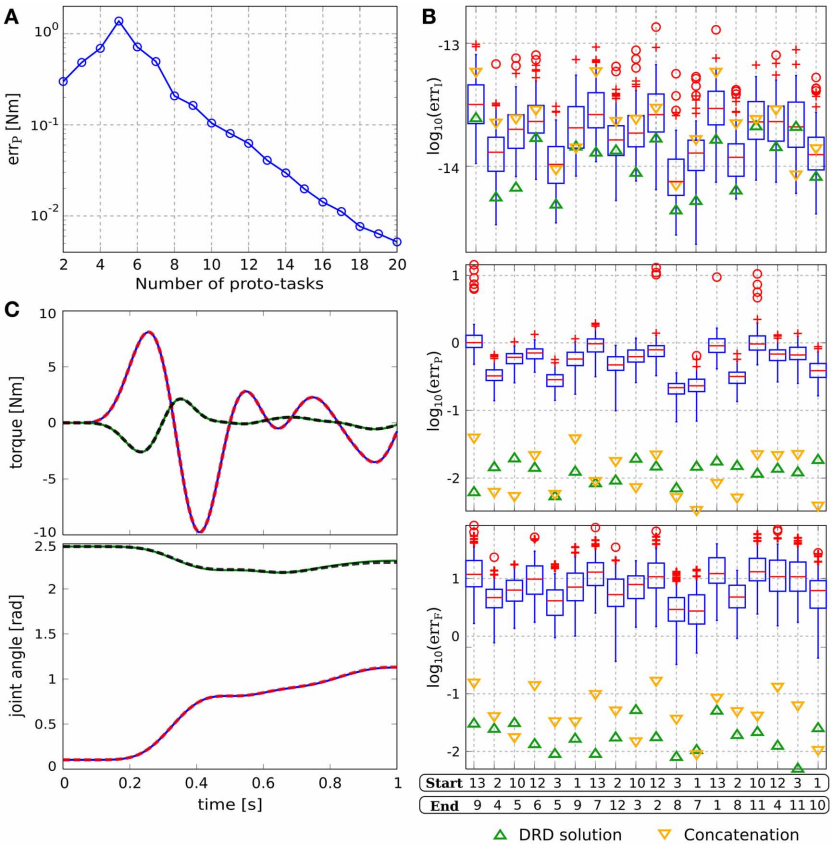

FIGURE 6 | Results of via-point reaching tasks. (A) Average projection error (across via-point reaching tasks with initial and final positions distributed in the workspace) as a function of the number of synergies. **(B)** Evaluation of the reduction phase for 18 testing via-point reaching tasks; "Start" and "End" indicate the indexes of the initial and final points, respectively (see **Figure 1**). The plots also present the errors obtained by concatenating individual out-center and center-out DRD solutions (yellow downward triangles). **(C)** Actuation that solves the task (continuous lines) and projected (dashed lines) torque, and interpolated (continuous lines) and executed (dashed lines) joint trajectories for the tasks with the highest projection error (i.e., Start 10, End 5).

characterized by a low degree of variability (e.g. reversal case), their essential features can be captured by a handful of elements. Otherwise, a higher number of synergies is required.

To further test the validity of our rationale, we consider three increasingly more general classes of tasks. The first class (a) consists of the reversal tasks described in section 3.2, in which the only free task-parameters are the joint-coordinates of the via-point. The second one (b) fixes only the initial position, while via-point and final posture can be chosen arbitrarily. Finally, the third class of tasks (c) does not impose any fixed posture. **Figure 3B** shows the trends of the average projection errors as a function of the number of synergies for the three cases (blue continuous, red dotted, and green dashed lines, respectively). As expected, the number of synergies that are needed to obtain a certain degree of performance increases with the generality of the class of tasks. The projection error is meaningful only if the kinematic solution fulfills the task constraints, thus the trends in **Figure 3B** should be considered starting from the minimum number of proto-tasks that guarantees this condition (i.e., three, five, and six synergies). The oscillations that can be observed for a smaller number of synergies can therefore be ignored as they are not representative of task performance in any way.

The effectiveness of the reduction phase is strictly related to the generality of the desired class of tasks. Very general classes lead to weakly correlated control signals. Thus, the reduction phase becomes less useful, and the synthesized synergies will embed regularities that are solely due to the dynamics of the system. Additionally, in order to obtain good performance in all the desired tasks, a large number of synergies will be required. As a direct consequence, the performance of the synthesized synergies will approach the performance of generic actuations. To illustrate this concept we compare the synergies synthesized for each of the previous classes of tasks with random sets of exploration actuations. The latter control signals are not generated through the process of reduction, and therefore they are not expected to embed any information about the tasks to be solved. We choose the minimum number of synergies that guarantees a mean projection error $<10^{-2}$ Nm, i.e., 8, 18, and 24 for classes (a), (b), and (c), respectively (see **Figure 3B**). Then we use these groups of synergies to solve the 13 reversal testing tasks. **Figure 8** depicts the

Table 4 | Normalized interpolation (int) and forward dynamics (fwd. dyn.) errors for each task-constraint of the testing via-point reaching tasks.

The normalization factors are $||e_{PM}|| = 5.02$ rad, $||e_{VM}|| = 7.05$ rad/s and $||e_{AM}|| = 61.5$ rad/s^2 for position, velocity and acceleration errors, respectively. The errors are evaluated at the via-point ($k = v$) and at the final point $k = T$. The expressions pos, vel, and acc identify position, velocity, and acceleration constraints, respectively.

difference between the mean projection errors obtained by using the random sets e_{ri}, and the projection errors corresponding to the three sets of synergies e_{si} (i.e., $I_i = e_{ri} - e_{si}$ for each class i). As expected, this difference reduces for increasingly more general tasks.

4. DISCUSSION

We performed an analysis of the muscle synergy hypothesis from a computational perspective; i.e., the control of a planar kinematic chain through linear combinations of a limited set of torque profiles (motor synergies). We proposed the DRD as a tool to generate appropriate synergy-based controllers and to synthesize an effective set of synergies; such a tool has been tested to solve point-to-point and via-point tasks. DRD generates a kinematic solution by combining the dynamic responses of the synergies, and it employs inverse dynamics to compute the corresponding actuation; this control signal is finally approximated by a linear combination of synergies. The problem of finding a kinematic solution is therefore reduced to a simple interpolation, and the associated combination of synergies is obtained by projection. The quality of the obtained controller (and ultimately the task performance) depends on the set of synergies used.

Although our approach involves many assumptions and simplifications, we believe that it highlights important theoretical aspects of the muscle synergy hypothesis. First, we have provided direct evidence to the possibility of controlling a non-linear dynamical system by linear combinations of a parsimonious set of basic actuations; these scheme can result in good performance across many instances of the desired class of tasks. Hence, we support the paradigm of muscle synergies as a possible CNS principle to simplify motor control and learning. Furthermore, our results suggest that, in order to realize an effective and low-dimensional controller, synergies should embed features of the system dynamics and the desired class of tasks. Within the DRD, the information on the system dynamics is captured by the DRs (i.e., trajectories of the system variables under the actuation of each synergy), and that on the desired class of tasks is obtained by means of the reduction procedure (i.e., solving a representative set of proto-tasks). The beneficial effect of this approach is visible from two perspectives: at the kinematic level, it leads to an alternant matrix that can generate the desired constraint vectors (see Equations 12 and 13); at the actuation level, it provides samples of the desired control signals (see **Figure 7**). As a result, the obtained synergies over-perform hundreds of arbitrary choices of basic controllers taken from the exploration motor signals.

The number of required synergies to achieve a given performance depends on the generality of the desired class of tasks (i.e., number of free task-parameters); general tasks (e.g. via-point reaching) require more synergies than highly specific ones (e.g. reversal). These considerations further confirm that synergies are strictly tailored to the class of tasks to be solved. The mathematical formulation of DRD shows a clear non-linear relationship between kinematic and actuation modularity, that is directly intertwined to the dynamics of the system. Our analysis on the concatenation of synergy-based controllers to solve via-point tasks is directly related to the notion of kinematic primitives (Flash et al., 1992), and it represents a control scheme that, for the

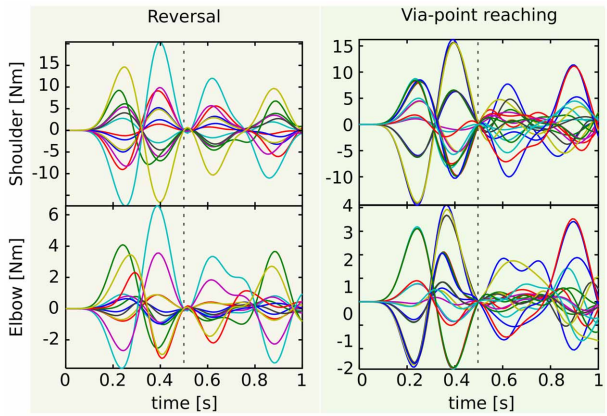

FIGURE 7 | Actuations corresponding to the testing reversal and via-point reaching tasks. Since the via-point task is more general, the corresponding control signals **(right)** are less correlated than the reversal ones **(left)**. This is particularly visible in the second phase of the movement (after the dashed vertical line that marks the time of the via-point). See text for more details and for the values of the correlation.

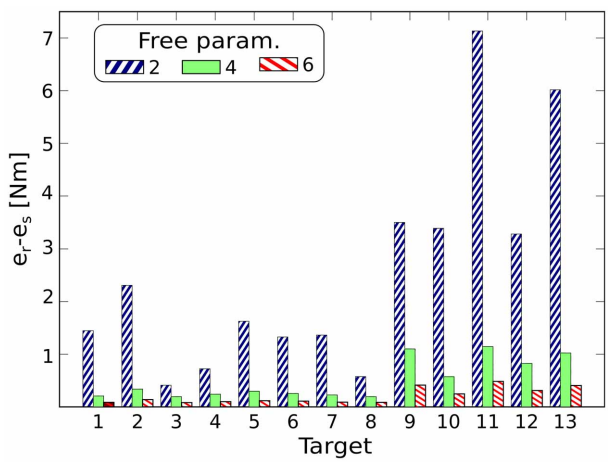

FIGURE 8 | Difference between the mean projection errors obtained by using the random sets, e_{ri}, and the projection errors corresponding to three sets of synergies, e_{si} (i.e., $l_i = e_{ri} - e_{si}$ for each set i), for solving the reversal testing tasks. The sets of synergies correspond to increasingly more general classes of tasks; i.e., two, four, and six free task-parameters (right diagonal blue, green, and left diagonal red bars, respectively). This difference reduces for increasingly more general tasks, showing that the effectiveness of the reduction phase decreases as the actuations become less regular.

first time, integrates this form of modularity together with muscle synergies. The obtained results show that the concatenation method accumulates the errors of the individual submotions. On the other hand, the application of DRD to the entire via-point task requires the definition of well specified proto-tasks. If the class of task is too general, concatenation could be a viable strategy to keep the number of synergies low (see **Table 3**).

The usage of a kinematic chain rather than a muscle-driven skeletal model is a simplification in our work that is worth discussing. This simplification implies the definition of control signals (and therefore synergies) in the space of joint torques, and not in muscle activation space. In a musculoskeletal system, the non-linear relation between torques and kinematic variables is complemented by the additional non-linear dynamics that translates muscle activations into joint torques. The total mapping between muscle activations and kinematic variables is non-trivial. The chain of the two non-linear relations might either compensate each other, resulting in overall milder non-linearities, or form an even stronger one. A more detailed model could also bring into play other effects, for example the preflex dynamical properties of muscles, which might themselves correct mild external disturbances, stabilizing the overall system. In any case, our mathematical framework aims at capturing the fundamental theoretical problem behind the muscle synergy hypothesis; i.e., the possibility of controlling the output variables of a non-linear dynamical system (i.e., kinematic chain or musculoskeletal model) by means of a linear input strategy (i.e., linear combination of torque or muscle synergies). Thus, although muscle synergies may emerge from the interaction between neural as well as biomechanical constraints (Ting and McKay, 2007), we believe that the findings of this work (see section 4.1) are qualitatively valid also for realistic musculoskeletal models. Nevertheless, quantitative details such as the obtained number of synergies and their waveforms are strongly intertwined to the dynamical system used. We intend to evaluate DRD in more biologically plausible systems in future developments of our work. In what follows we are going to discuss our work in relation to the current debate on muscle synergies (sections 4.1 and 4.2), and to the field of robotics (section 4.3).

4.1. COMPUTATIONAL INSIGHTS ON THE MUSCLE SYNERGY HYPOTHESIS

Many studies in experimental neuroscience analyze the validity of the muscle synergy hypothesis solely in terms of the accuracy in approximating recorded EMG signals (d'Avella et al., 2003; d'Avella and Bizzi, 2005; Torres-Oviedo and Ting, 2007; Cheung et al., 2009a; Torres-Oviedo and Ting, 2010). This measure is equivalent to our projection error, and it does not explicitly quantifies the quality of the synergy-based controller. The introduction of complementary measures, similar to the forward dynamics error, would provide a direct evaluation of task performance, and therefore they could shed new lights on the hypothetical modularity of the CNS (Alessandro et al., 2013; Delis et al., 2013).

In this vein, some researchers introduced the concept of functional synergies, i.e., the components of an extended dataset that includes muscle activations as well as measurements of task variables (e.g. joint angles, end-limb force) (Torres-Oviedo et al., 2006; Chvatal et al., 2011). As a result, each component consists of two elements: a pattern of muscle contractions, and the corresponding evolution of the task variables. Such an approach is not too different from the idea behind DRD: synergies are associated to their DRs (i.e., biomechanical functionalities), which are linearly combined to obtain the kinematic solution of the task. However, the identification of functional synergies by means of non-negative matrix factorization (NMF), implies that muscle synergies and their biomechanical functionalities are scaled

by the same coefficients. This contrasts with our theoretical results, which show a non-linear relationship (the mapping $\mathcal{F}$, see Equation 8) between the mixing weights of the synergies and those of the DRs. Ideally, one should go beyond the use of NMF, and develop novel techniques that do not impose a linear mapping between the two sets of coefficients.

The mapping $\mathcal{F}$ points out a fundamental non-linear relationship between kinematic and actuation modularity. More generally, this result applies to any groups of variables that are related to each other by a non-linear differential operator like $\mathcal{D}$ (e.g. kinematic and muscle variables, muscle excitation and activation, neural and muscle activation). However, linear forms of modularity have been investigated both at the kinematic (Berret et al., 2009) and at the muscle activation level (d'Avella et al., 2006). Our result suggests that these modularities cannot coexist; i.e., if one level of variables is bounded to a linear set (e.g. kinematic variables in our work), the other level of variables can at most be approximated linearly, but they intrinsically belong to a non-linear space (e.g. torque). Alternatively, additional processes might linearize the system dynamics as suggested by Berniker et al. (2009) and Nori (2005).

The fact that synergies and DRs are related through the dynamics of the system has another important implication. Since the former are feasible kinematic solutions to the proto-tasks, the obtained synergies can always be realized as actuations. The same cannot be said, in general, for synergies identified from numerical analyses of biomechanical data. Though some studies have verified the feasibility of the extracted synergies as actuations (Neptune et al., 2009; McGowan et al., 2010; Allen and Neptune, 2012), biomechanical constraints are not explicitly included in the extraction algorithms. Additionally, Equation (2) provides an automatic way to cope with smooth variations of the agent morphology. That is, both the synergies and their dynamic responses evolve together with the body. In line with Nori (2005), these considerations highlight the importance of the body in the hypothetical modularization of the CNS.

The mathematical formulation of DRD, and in particular the system of linear equations (5), shows a clear relation between the minimum number of synergies and the difficulty of the task. To guarantee the existence of a kinematic solution, the alternant matrix should be full-row rank. In other words, the minimum number of proto-tasks, and therefore of synergies, should correspond to the dimensionality of the task-constraint vector. For a two-DoF kinematic chain, general via-point tasks consist of three position and three velocity constraints (each of them is two-dimensional); thus, at least 12 DRs are required to be able to solve any task in kinematic space. A highly specified class of tasks reduces the minimum number of required synergies. For example, point-to-point and reversal tasks, that are characterized by two free task-parameters (i.e., location of the target), require three DRs (instead of 12); for via-point reaching this number increases to 5 (see section 3). Note that these bounds are solely based on kinematic considerations; since the dynamical system is non-linear, they do not necessarily guarantee low values of projection and forward dynamics error. In fact, as shown in section 3, the number of synergies that is required to obtain satisfactory performance is certainly higher than the theoretical kinematic-based estimation. However, this number still follows the principle that more general tasks require a higher number of synergies (see **Figure 3B** and section 3.4).

Our method to synthesize synergies might be interpreted from a developmental perspective. Initially, the agent explores its sensory-motor system employing a variety of actuations. Later, it attempts to solve the first tasks (proto-tasks), perhaps obtaining weak performance as the exploration phase may not have produced enough responses yet (see the box-plots in **Figures 2C**, **3C**, and **Figure 6B**). If the agent finds an acceptable solution to a proto-task, such a solution is used to generate a new synergy (populating the set $\mathbf{\Phi}$), otherwise it continues with the exploration. The failure to solve important tasks for its survival, could motivate the agent to include additional proto-tasks; **Figures 2A**, **3A** illustrate this mechanism. The development of the synergy-set incrementally improves the overall abilities of the agent. Alternatively, existing proto-tasks could be modified. It has to be clear that we are not arguing in any way that this procedure resembles the mechanisms involved in the motor development of biological organisms. It is, however, interesting that our procedure facilitates the autonomous generation of new synergies, and the possible adaptation of the existing ones to cope with the changes in the body dynamics (see Equation 2). These features are in line with the recent findings by Dominici et al. (2011). An alternative strategy for synergy development (not implemented in this paper) might be the concatenation of movement chunks. If the agent has already developed the synergies to solve point-to-point tasks, via-point proto-tasks could be solved by the concatenation of point-to-point actuations. As shown in **Figures 4B**, **6B** the results might not be as good as if the solution were computed *ad hoc* (i.e., for the entire via-point proto-tasks). However, inspired by Sosnik et al. (2004) and Rohrer et al. (2004), one could imagine that such solutions might improve with practice, eventually leading to appropriate via-point modules.

The concatenation of point-to-point control signals to solve via-point tasks is based on the observation that movements can be composed by sequences of kinematic strokes, or submovements. The relation between this form of planning modularity (Morasso and Mussa-Ivaldi, 1982) and muscle synergies is still under debate. Possibly, as implemented in our formulation, each kinematic stroke translates into a combination of time-varying synergies, and therefore the final movement plan corresponds to a sequence of mixing patterns. This strategy would be in line with the hypothesis of an intermittent controller that sequentially initiates discrete movement primitives (Fishbach et al., 2005; Loram et al., 2010; Squeri et al., 2010; Karniel, 2013). Submovements might be combined in time succession (Soechting and Terzuolo, 1987; Meyer et al., 1988), or based on the vectorial summation of overlapping preplanned trajectories (Flash and Henis, 1991; Henis and Flash, 1995; Novak et al., 2003; Roitman et al., 2004; Pasalar et al., 2005). In this manuscript we have exemplified the former approach; the analysis of the latter by means of DRD is non-trivial, and it is therefore left for future work. As shown by recent experimental studies (d'Avella et al., 2011), such a strategy might enable reusing synergies underlying point-to-point kinematic trajectories to generate more complex trajectories involved in reaching a jumping target. Finally, it is important to notice that

the kinematic solution to a via-point task appears to be composed of different movement-chunks even when it is obtained from a single composition of highly specified synergies. This observation supports the idea that strokes could just emerge as a result of the trajectory optimization (Dagmar and Schaal, 1999) or even be data analysis artifacts.

Our work analyzes the theoretical aspects, rather than the implementation details, of the muscle synergy hypothesis. As such DRD does not represent a model of the neural substrates involved in muscle synergies, and we do not claim that DRD is somehow implemented within the CNS. In fact, the biological mechanisms involved in muscle synergies are probably very different from the mathematical techniques used in this paper. For example, in our method synergies can be obtained simply by computing the solution to the proto-tasks; on the contrary, the biological process of synergy development is very likely to be incremental, and it spans several years of development (Dominici et al., 2011). However, some of the functionalities of DRD are not biologically implausible. The computation of a kinematic solution to a task (see Equation 8) can be regarded as a form of kinematic planning, and can be performed by means of a recurrent neural network (Cichocki and Unbehauen, 1992a,b) that computes the DRs mixing weights $\boldsymbol{a}$. Interestingly, DRD suggests that, although muscle synergies are defined at the motor command level (i.e., muscle activation), they could also be related to kinematic planning, and that the planning process might be carried out by exploiting knowledge of the system dynamics (in our framework embedded in the DRs). The non-linear function $\mathcal{F}$ is a mapping between two finite dimensional sets of variables (the DR weights, expression of the planned trajectory, and the synergy weighting coefficients $\boldsymbol{b}$), therefore it can be encoded by means of a feedforward neural network. Conceptually, this function represents the neural pathways between the cortical areas related to planning (Buneo and Andersen, 2006) and the neural substrate where synergies are supposedly located; the outputs of this function represent the descending neural commands that modulate synergy recruitments (Ivanenko et al., 2003; Torres-Oviedo et al., 2006; Ting, 2007; Ting and McKay, 2007; Torres-Oviedo and Ting, 2010). As a matter of fact, $\mathcal{F}$ is a compact form of inverse dynamical model. Thus, its hypothetical neural implementation may involve the primary motor cortex (M1), which is know to be related to dynamical features of the movements (and in particular to inverse dynamics) (Kalaska, 2009), and the cerebellum, which is supposedly involved in the neural representation of internal models (Kawato, 1999; Diedrichsen et al., 2005; Bursztyn et al., 2006). These considerations are supported by the recent hypothesis suggesting that muscle synergies might be organized both at the spinal (Hart and Giszter, 2010) and at the cortical level (Overduin et al., 2012); their spatial structure might derive from divergent corticospinal connectivity or from spinally organized modules, and their temporal characteristic may originate from the dynamics of the recurrent connections of the motor cortex (d'Avella et al., 2006).

4.2. COMPARISON WITH OTHER COMPUTATIONAL STUDIES

While many studies try to validate or falsify the hypothesis of muscle synergies, only a few researchers have focused on developing and testing control architectures based on this concept. Some of these works aim at proposing novel techniques for robot control, other intend to analyze the hypothesized modularity from a computational point of view. Our work falls into the second category; in this section we briefly compare it to similar contributions, in particular to those studies that provide a possible interpretation of muscle synergies. The reader is referred to Alessandro et al. (2013) for a more comprehensive review.

Inspired by the original work by Mussa-Ivaldi (1997), Nori and Frezza (2005) developed a control architecture for non-linear systems based on the idea of spinal force fields (Giszter et al., 1993; Mussa-Ivaldi et al., 1994; Mussa-Ivaldi and Bizzi, 2000; Nori, 2005). Relying on the technique of feedback linearization, the method yields a set of synergies that is able to generate a complete repertoire of movements (i.e., the system can reach any arbitrary state in an arbitrary amount of time). Thus, the authors interpreted muscle synergies as a basis of the entire control action space. Berniker et al. (2009) defines synergies as the smallest set of input vectors that influences the output of a reduced-order model of the agent, and that minimally restrict the commands useful to solve the desired tasks. Practically, this set is found by optimizing the synergies against a representative dataset of desired sensory-motor signals. Similarly, Todorov and Ghahramani (2003) employ an unsupervised learning procedure to identify muscle synergies from a collection of sensory-motor data, which is obtained by actuating the robot with random signals. Their work proposes that synergies are a constituent part of an inverse model of the sensory-motor system. Another interpretation is given by Marques et al. (2012), who suggest that synergies solely reflect the biomechanical constraints of the agent.

Similar computational approaches have also been used to test whether a given model of muscle synergies (or more generally, a primitive-based controller) is competent to reproduce experimental observations. The comparison between simulated and experimental data is often performed both at the kinematic and at the muscle activation level. Furthermore, the role of biomechanical constraints is explicitly taken into account. Hence, employing biologically plausible models of the musculoskeletal apparatus becomes necessary. Kargo et al. (2010) have demonstrated that the model of premotor drives accounts for the kinematic trajectories and the isometric force fields observed in frog wiping reflexive behaviors (Kargo and Giszter, 2008). In particular they have showed that realistic wiping trajectories can be obtained simply by modulating the amplitudes and the phase-shifts of the activation pulses, without altering the muscle activation balance of each synchronous synergy. Similar studies have been carried out in the context of human walking (Neptune et al., 2009; McGowan et al., 2010; Allen and Neptune, 2012) and balancing in cats (McKay and Ting, 2008, 2012).

Unlike all those studies, the work presented herein does not aim at reproducing experimental data, rather it provides a theoretical investigation of motor synergies. As discussed in section 3.4, our work suggests that synergies can be obtained by solving well defined control problems. Similar ideas have already been proposed (Chhabra and Jacobs, 2008; Todorov, 2009; Alessandro and Nori, 2012; Thomas and Barto, 2012). However, these studies do not investigate which class of problems are best suited for this

purpose. In this manuscript we show that these problems (i.e., proto-tasks) should belong to the same class of the desired tasks; this would lead to a compact set of synergies that capture features of the system dynamics and the desired class of tasks, and therefore result in good task performance. Additionally we show a clear relation between the number of synergies and two characteristics of the task: generality (i.e., number of free task parameters), and difficulty (i.e., number of constraints). Further, we propose a possible integration scheme between kinematic stroke and muscle synergies; to the best of our knowledge no other synthetic study has tested this idea.

4.3. THE DRD METHOD AND ITS RELEVANCE TO ROBOTICS

In robotics an active field of research focuses on novel mechanisms to generate trajectories (e.g. kinematic patterns or motor commands) and to learn their representations from given samples. The frameworks of Dynamic Movement Primitives (DMPs) (Ijspeert et al., 2013) and Stable Estimator of Dynamical Systems (SEDS) (Khansari-Zadeh and Billard, 2011) have recently received particular attention for their stability and invariance properties. Both methods encode desired trajectories in the attractor landscapes of appropriately tuned autonomous dynamical systems. While in DMPs this is obtained by modifying the dynamics of a well known system by mean of a learned forcing term, SEDS employs Gaussian mixture models (GMM) to identify the desired attractor landscape from scratch. Also the DRD can be interpreted as a method to generate kinematic trajectories and control signals. The former are obtained by linearly combining the DRs (i.e., kinematic solutions to the proto-tasks), and the latter by linearly combining the synergies (i.e., projections of the actuations that solve the proto-tasks onto the synergy-span). A quantitative comparison between our method and dynamical system-based architectures is out of the scope of this paper, however, the following considerations can be made.

DMPs and SEDS employ advanced machine-learning techniques to learn a representation of externally provided desired trajectories (e.g. via imitation learning). In contrast, DRD is not only limited to represent task solutions, but it also provides a strategy to self-generate them (i.e., planning). Given a set of constraints defining the task, DRD finds both a kinematic solution by interpolation, and the corresponding actuation by projection. As a result, no desired trajectory has to be provided externally nor any complex learning procedure is required, instead simple algebraic operations are used to solve the control problem. These features are possible mainly for two non-trivial results: (1) the dynamic responses of non-linear systems are good basis functions to build interpolant trajectories and (2) the actuations solving the proto-tasks (i.e., synergies) span a representative set of control signals.

In terms of generalization, the spatial invariance property of DMP can be exploited to generate only scaled versions of the learned movement kinematics (e.g. point-to-point reaching and reversal tasks). This is not the case for combinations of DRs, which, for example, can generate via-point reaching movements that share the same initial and intermediate points, but have different targets (see section 3.3). This kind of generalization could be obtained by shaping the dynamics of the DMPs by means of appropriate basis functions that capture common features of the desired tasks (Rückert and d'Avella, 2013). This idea is in spirit similar to solving proto-tasks, however, it requires a computationally intense learning phase if compared to our method to synthesize synergies. The same drawback is experienced by using SEDS. Furthermore, synergies embed essential features of the desired control signals, and therefore, unlike DMP and SEDS, DRD can generalize also at the actuation level.

The main disadvantage of DRD is its explicit time-indexing; as a result it does not provide an easy strategy to modulate the velocity of a given movement, and it leads to controllers that are not robust to time-perturbation. Moreover, at the current stage DRD does not provide proved stable controller, a feature that can be enjoyed in DMP and SEDS. These drawbacks could be avoided by encoding synergies and DRs by means of DMPs. In a similar vein, techniques based on mixture of DMPs have recently been proposed to improve generalization. Outstanding results have been obtained, however, each primitive has to be learned by demonstration (Muelling et al., 2010). Using DRD such primitives could be self-generated by means of the procedure to solve proto-tasks, and then they could be translated into dynamical systems. In conclusion, DRD and DMP could be combined into a unified powerful technique that inherit the advantages of both approaches, rendering the two methods more complementary than competitive.

In the DRD method, once the task is solved in kinematic space, the corresponding actuation can be computed using the explicit inverse dynamical model of the system (i.e., the differential operator $\mathcal{D}$). It might appear that there is no particular advantage in projecting this solution onto the linear span of the synergy set. However, the differential operator might be unknown or affected by errors; this is very often the case in robotics, where learning inverse models is still a hot topic of research (Nguyen-Tuong and Peters, 2011). A synergy-based controller would enable to compute the appropriate actuation by evaluating the mapping $\mathcal{F}$ on the vector $\boldsymbol{a}$, hence obtaining the synergy combinators $\boldsymbol{b}$. Since $\mathcal{F}$ is a mapping between two finite low-dimensional vector spaces, estimating this map may turn out to be easier than estimating the differential operator $\mathcal{D}$. In order to estimate the map $\mathcal{F}$, the input–output data generated during the exploration phase (i.e., $\boldsymbol{\Phi}_0$ and $\boldsymbol{\Theta}_0$) could be used as learning data-set. The obtained relation could be instrumental to estimate a first guess of the synergy set; $\mathcal{F}$ and $\boldsymbol{\Phi}$ could then be iteratively modified until convergence. Further work is required to test these ideas.

5. CONCLUSIONS

The current work analyzes the hypothesis of muscle synergies from a computational perspective; i.e., the control of a planar kinematic chain through linear combinations of a limited set of torque profiles (motor synergies). The proposed DRD is able to generate effective synergies, greatly reducing the dimensionality of the problem, while keeping a good performance level. In order to obtain good performance across a variety of task instances, synergies should capture the essential features of the tasks to be solved, and take the system dynamics into account. The number of required synergies increases with the generality of the desired class of tasks. Nevertheless, to keep the number

of synergies low, solutions to general tasks can be obtained by concatenating the synergy-based controllers associated to simple point-to-point movements with a limited degradation of task performance. Overall our work serves as a proof of concept for the notion of muscle synergies, showing that linear combinations of actuation modules can be used to control a non-linear dynamical system. This paper highlights the advantages and the limitations of this approach, and it draws attention to important aspects that are not easily accessible in experimental studies.

The future developments of this research point toward different directions. The relations between muscle synergies and kinematic submovements will be further investigated. In particular, we will analyze the idea of overlapping point-to-point strokes (Flash et al., 1992). Another interesting line of investigation is the validation of our method against biological data, paving the way toward a predictive model of the muscle synergy hypothesis. To this end, a first step will be the evaluation of DRD on realistic musculoskeletal models. From the theoretical point of view, we are currently studying the mathematical properties of the synergies synthesized by means of the reduction procedure. Finally, we plan to tackle the challenge of learning the mapping between kinematic and synergy coefficients.

The software used to produce all the results reported in this paper is available as a GNU Octave package under free and open source license[1]. The reader is encouraged to download, test, report bugs and submit improvements to the algorithm.

Biological movement generation combines three interesting aspects: its modular organization in movement primitives (MPs), its characteristics of stochastic optimality under perturbations, and its efficiency in terms of learning. A common approach to motor skill learning is to endow the primitives with dynamical systems. Here, the parameters of the primitive indirectly define the shape of a reference trajectory. We propose an alternative MP representation based on probabilistic inference in learned graphical models with new and interesting properties that complies with salient features of biological movement control. Instead of endowing the primitives with dynamical systems, we propose to endow MPs with an intrinsic probabilistic planning system, integrating the power of stochastic optimal control (SOC) methods within a MP. The parameterization of the primitive is a graphical model that represents the dynamics and intrinsic cost function such that inference in this graphical model yields the control policy. We parameterize the intrinsic cost function using task-relevant features, such as the importance of passing through certain via-points. The system dynamics as well as intrinsic cost function parameters are learned in a reinforcement learning (RL) setting. We evaluate our approach on a complex 4-link balancing task. Our experiments show that our movement representation facilitates learning significantly and leads to better generalization to new task settings without re-learning.

Keywords: movement primitives, motor planning, reinforcement learning, optimal control, graphical models

1. INTRODUCTION

Efficient motor skill learning in redundant stochastic systems is of fundamental interest for both, understanding biological motor systems as well as applications in robotics.

Let us first discuss three aspects of human and animal movement generation the combination of which is the motivation for our approach: (1) its modular organization in terms of movement primitives, (2) its variability and behavior under perturbations, and (3) the efficiency in *learning* such movement strategies.

First, concerning the movement primitives (MPs) in biological motor systems, the musculoskeletal apparatus is a high-dimensional redundant stochastic system and has many more degrees-of-freedom (DoF) than needed to perform a specific action (Bernstein, 1967). A classical hypothesis is that such redundancy is resolved by a combination of only a small number of functional units, namely MPs (d'Avella et al., 2003; Bizzi et al., 2008; d'Avella and Pai, 2010). In other terms, MPs can be understood as compact parameterizations of elementary movements which allows for an efficient abstraction of the high-dimensional continuous action spaces. This abstraction has been shown to facilitate learning of complex movement skills (d'Avella et al., 2003; Schaal et al., 2003; Neumann et al., 2009).

A second important aspect about biological movement are the characteristics of motor variability under perturbations or stochasticity. If humans perform the same task several times, the resulting movement trajectories vary considerably. Stochastic optimal control (SOC), besides its high relevance in engineering problems, has proven itself as an excellent computational theory of this effect (Todorov and Jordan, 2002; Trommershauser et al., 2005). An implication of SOC, the *minimum intervention principle*, states that we should only intervene in the system if it is necessary to fulfill the given task. If the task constraints are not violated it is inefficient to suppress the inherent noise in the stochastic system. The fact that biological movements account for such principles suggests that SOC principles are involved on the lowest level of movement generation.

These biological perspectives suggest that the third aspect, efficient motor skill learning, is facilitated by this combination of MPs with low level SOC principles. While existing MP methods have demonstated efficient learning of complex movement skills (d'Avella et al., 2003; Schaal et al., 2003; Neumann et al., 2009) they lack an integration of SOC principles *within* MPs. Instead, in current approaches the parameters of the MP compactly determine the shape of the desired trajectory either directly or indirectly. This trajectory is then followed by feedback control laws. An example for an indirect trajectory parameterization are the widely used Dynamic Movement Primitives (DMPs) (Schaal et al., 2003), which use parameterized dynamical systems to determine a movement trajectory. The idea of DMPs to endowing MPs with an intrinsic dynamical system has several benefits: they

provide a linear policy parameterization which can be used for imitation learning and policy search (Kober and Peters, 2011). The complexity of the trajectory can be scaled by the number of parameters (Schaal et al., 2003) and one can adapt meta-parameters of the movement such as the movement speed or the goal state of the movement (Pastor et al., 2009; Kober et al., 2010). Further, the dynamical system of a DMP is to some degree also reactive to perturbations by adapting the time progression of the canonical system depending on joint errors and thereby de- or accelerating the movement execution as needed (Ijspeert and Schaal, 2003; Schaal et al., 2003). However, the trajectory shape itself is fixed and non-reactive to the environment.

In our approach we aim to go beyond MPs that parameterize a fixed reference trajectory and instead truly integrate SOC principles within the MP. The general idea is to endow MPs with an intrinsic probabilistic planning system instead of an intrinsic dynamical system. Such a *Planning Movement Primitive* (PMP) can react to the environment by optimizing the trajectory for the specific current situation. The intrinsic probabilistic planning system is described as a graphical model that represents the SOC problem (Kappen et al., 2009; Toussaint, 2009). Training such a MP therefore amounts to learning a graphical model such that inference in the learned graphical model will generate an appropriate policy. This has several implications. First, this approach implies a different level of generalization compared to a dynamical system that generates a fixed (temporally flexible) reference trajectory. For instance, if the end effector target changes between training and testing phase, an intrinsic planning system will generalize to a new target without retraining. A system that directly encodes a trajectory would either have to be retrained or use heuristics to be adapted (Pastor et al., 2009). Second, this approach truly integrates SOC principles within the MP. The resulting policy follows the minimum intervention principle and is compliant compared to a feedback controller that aims to follow a reference trajectory.

As with DMPs, a PMP is trained in a standard RL setting. Instead of parameterizing the shape of the trajectory directly, a PMP has parameters that determine the intrinsic cost function of the intrinsic SOC system. While the reward function (typically) gives a single scalar reward for a whole movement, the learned intrinsic cost function is in the standard SOC form and defines task and control costs for every time-step of the movement. In other terms, training a PMP means to learn from a sparse reward signal an intrinsic cost function such that the SOC system will, with high probability, generate rewarded movements. Parallel to this learning of an intrinsic cost function, a PMP also exploits the data to learn an approximate model of the system dynamics. This approximate dynamics model is used by the intrinsic SOC system. Therefore, PMP learning combines model-based and model-free RL: it learns a model of the system dynamics while at the same time training PMP parameters based on the reward signal. It does not learn an approximate model of the reward function itself. We can exploit supervised learning methods such as Vijayakumar et al. (2005) and Nguyen-Tuong et al. (2008a,b) for learning the system dynamics and at the same time use policy search methods to adapt the PMP parameters that determine the intrinsic cost function. This two-fold learning strategy has the promising property of fully exploiting the data by also estimating the system dynamics instead of only adapting policy parameters.

As mentioned above, our approach is to represent the intrinsic SOC system as a graphical model, building on the recent work on Approximate Inference Control (AICO), (Toussaint, 2009). AICO generates the movement by performing inference in the graphical model that is defined by the system dynamics and the intrinsic cost function. Since we learn both from experience, all conditional probability distributions of this graphical model are learned in the RL setting. The output of the planner is a linear feedback controller for each time slice.

Our experiments show that by the use of task-relevant features, we can significantly facilitate learning and generalization of complex movement skills. Moreover, due to the intrinsic SOC planner, our MP representation implements the principles of optimal control, which allows to learn solutions of high quality which are not representable with traditional trajectory-based methods.

In the following section we review in more detail related previous work and the background on which our methods build. Section 3 then introduces the proposed PMP. In section 4 we evaluate the system on a one-dimensional via-point task and a complex dynamic humanoid balancing task and compare to DMPs. We conclude with a discussion in section 5.

2. RELATED WORK AND BACKGROUND

We review here the related work based on parameterized movement policies, policy search methods and SOC.

2.1. PARAMETERIZED MOVEMENT POLICIES

MPs are a parametric description of elementary movements (d'Avella et al., 2003; Schaal et al., 2003; Neumann et al., 2009). We will denote the parameter vector of a MP by $\boldsymbol{\theta}$ and the possibly stochastic policy of the primitive as $\pi(\mathbf{u}|\mathbf{x}, t; \boldsymbol{\theta})$, where $\mathbf{u}$ is the applied action and $\mathbf{x}$ denotes the state. The key idea of the term "primitive" is that several of these elementary movements can be combined not only sequentially but also simultaneously in time. However, in this paper, we want to concentrate on the parameterization of a single MP. Thus we only learn a single elementary movement. Using several MPs simultaneously is part of future work for our approach as well as for existing approaches such as Schaal et al. (2003) and Neumann et al. (2009).

Many types of MPs can be found in the literature. The currently most widely used movement representation for robot control are the DMPs (Schaal et al., 2003). DMPs evaluate parameterized dynamical systems to generate trajectories. The dynamical system is constructed such that the system is stable. In order to do so, a linear dynamical system is used which is modulated by a learnable non-linear function f. A great advantage of the DMP approach is that the function f depends linearly on the parameters $\boldsymbol{\theta}$ of the MP: $f(s) = \boldsymbol{\Phi}(s)^T\boldsymbol{\theta}$, where s is the time or phase variable. As a result, imitation learning for DMPs is straightforward, as this can simply be done by performing a linear regression (Schaal et al., 2003). Furthermore, it also allows the use of many well-established RL methods such as policy gradient methods (Peters and Schaal, 2008) or Policy Improvements by Path Integrals PI^2 (Theodorou et al., 2010). The complexity of the trajectory can be scaled by the number of features used for modeling f. We can

also adapt meta-parameters of the movement such as the movement speed or the goal state of the movement (Pastor et al., 2009; Kober et al., 2010). However, as the features $\mathbf{\Phi}(s)$ are fixed, the ability of the approach to extract task-relevant features is limited. Yet, the change of the desired trajectory due to the change of the meta-parameters is based on heuristics and does not consider task-relevant constraints. While the dynamical system of a DMP is to some degree reactive to the environment—namely by adapting the time progression of the canonical system depending on joint errors and thereby de- or accelerating the movement execution as needed (Ijspeert and Schaal, 2003; Schaal et al., 2003)—the trajectory shape itself is fixed and non-reactive to the environment. As the DMPs are the most common movement representation, we will use it as a baseline in our experiments. A more detailed discussion of the DMP approach can be found in the Appendix.

Another type of movement representation was introduced in Neumann et al. (2009) by the movement template framework. Movement templates are temporally extended, parameterized actions, such as sigmoidal torque, velocity or joint position profiles, which can be sequenced in time. This approach uses a more complex parameterization as the DMPs. For example, it also incorporates the duration of different phases, like an acceleration or deceleration phase. The division of a movement into single phases allows the use of RL methods to learn how to sequence these primitives. However, as the approach still directly specifies the shape of the trajectory, defining complex movements for high-dimensional systems is still complicated, which has restricted the use of movement templates to rather simple applications.

An interesting movement representation arizing from analysis of biological data are muscle synergies (d'Avella et al., 2003; Bizzi et al., 2008). They have been used to provide a compact representation of electromyographic muscle activation patterns. The key idea of this approach is that muscle activation patterns are linear sums of simpler, elemental patterns, called muscle synergies. Each muscle synergy can be shifted in time and scaled with a linear factor to construct the whole activation pattern. While the synergy approach has promising properties such as the linear superposition and the ability to share synergies between tasks, except for some smaller applications (Chhabra and Jacobs, 2006), these MPs have only been used for data analysis, and not for robot control.

All the so far presented MPs are inherently local approaches. The specified trajectory and hence the resulting policy are only valid for a local (typically small) neighborhood of our initial state. If we are in a new situation, it is likely that we need to re-estimate the parameters of the MP. The generation of the reference trajectory for these approaches is often an offline process and does not incorporate knowledge of the system dynamics, proprioceptive or other sensory feedback. Because the reference trajectory itself is usually created without any knowledge of the system model, the desired trajectory might not be applicable, and thus, the real trajectory of the robot might differ considerably from the specified trajectory.

There are only few movement representations which can also be used globally, i.e., for many different initial states of the systems. One such methods is the Stable Estimator of Dynamical Systems (Khansari-Zadeh and Billard, 2011) approach. However, this method has so far only been applied to imitation learning, using the approach for learning or improving new movement skills is not straight forward. We will therefore restrict our discussion to local movement representations.

Our PMP approach is, similar as the DMPs, a local approach. In a different situation, different abstract goals and features might be necessary to achieve a given task. However, as we extract task-relevant features and use them as parameters, the same parameters can be used in different situations as long as the task-relevant features do not change. As we will show, the valid region where the local MPs can still be applied is much larger for the given control tasks in comparison to trajectory-based methods.

2.2. POLICY SEARCH FOR MOVEMENT PRIMITIVES

Let $\mathbf{x}$ denote the state and $\mathbf{u}$ the control vector. A trajectory τ is defined as sequence of state control pairs, $\tau = \langle \mathbf{x}_{1:T}, \mathbf{u}_{1:T-1} \rangle$, where T is the length of the trajectory. Each trajectory has associated costs $C(\tau)$ (denoted as extrinsic cost), which can be an arbitrary function of the trajectory. It can, but need not be composed of the sum of intermediate costs during the trajectory. For example, it could be based on the minimum distance to a given point throughout the trajectory. We want to find a MP's parameter vector $\boldsymbol{\theta}^* = \text{argmin}_{\boldsymbol{\theta}} J(\boldsymbol{\theta})$ which minimizes the expected costs $J(\boldsymbol{\theta}) = \mathbb{E}[C(\tau)|\boldsymbol{\theta}]$. We assume that we can evaluate the expected costs $J(\boldsymbol{\theta})$ for a given parameter vector $\boldsymbol{\theta}$ by performing roll-outs on the real system.

In order to find $\boldsymbol{\theta}^*$ we can apply policy search methods. Here a huge variety of possible methods exists. Policy search methods can be coarsely divided into step-based exploration and episode-based exploration approaches. Step-based exploration approaches such as Peters and Schaal (2008), Kober and Peters (2011), and Theodorou et al. (2010) apply an exploration noise to the action of the agent at each time-step of the episode. Subsequently, the policy is updated such that the (noisy) trajectories with higher reward are more likely to be repeated. In order to do this update, step-based exploration techniques strictly rely on a policy which is linear in its parameters. This is true for the DMPs (Schaal et al., 2003). Currently, the most common policy search methods are step-based approaches, including the REINFORCE (Williams, 1992), the episodic Natural Actor Critic (Peters and Schaal, 2008), the PoWER (Kober and Peters, 2011), or the PI^2 (Theodorou et al., 2010) algorithm. This also explains partially the popularity of the DMP approach for motor skill learning because DMPs are, from those introduced above, the only representation which can be used for these step-based exploration methods (apart from very simple ones like linear controllers).

However, recent research has also intensified on episode-based exploration techniques that make no assumptions on a specific form of a policy (Hansen et al., 2003; Wierstra et al., 2008; Sehnke et al., 2010). These methods directly perturb the policy parameters $\boldsymbol{\theta}$ and then estimate the performance of the perturbed $\boldsymbol{\theta}$ parameters by performing roll-outs on the real system. During the episode no additional exploration is applied (i.e., a deterministic policy is used). The policy parameters are then updated in the estimated direction of increasing performance. Thus, these exploring methods do not depend on a specific form of parameterization of the policy. In addition, they allow the use of second order stochastic search methods that estimate correlations

between policy parameters (Hansen et al., 2003; Wierstra et al., 2008; Heidrich-Meisner and Igel, 2009b). This ability to apply correlated exploration in parameter-space is often beneficial in comparison to the uncorrelated exploration techniques applied by all step-based exploration methods, as we will demonstrate in the experimental section.

2.3. STOCHASTIC OPTIMAL CONTROL AND PROBABILISTIC INFERENCE FOR PLANNING

SOC methods such as Todorov and Li (2005), Kappen (2007), and Toussaint (2009) have been shown to be powerful methods for movement planning in high-dimensional robotic systems. The incremental Linear Quadratic Gaussian (iLQG) (Todorov and Li, 2005) algorithm is one of the most commonly used SOC algorithms. It uses Taylor expansions of the system dynamics and cost function to convert the non-linear control problem in a Linear dynamics, Quadratic costs and Gaussian noise system (LQG). The algorithm is iterative—the Taylor expansions are recalculated at the newly estimated optimal trajectory for the LQG system.

In Toussaint (2009), the SOC problem has been reformulated as inference problem in a graphical model, resulting in the AICO algorithm. The graphical model is given by a simple dynamic Bayesian network with states $\mathbf{x}_t$, actions $\mathbf{u}_t$ and task variables $\mathbf{g}^{[i]}$ (representing the costs) as nodes, see **Figure 1**. The dynamic Bayesian network is fully specified by conditional distributions encoded by the cost function and by the state transition model. If beliefs in the graphical model are approximated as Gaussian the resulting algorithm is very similar to iLQG. Gaussian message passing iteratively re-approximates local costs and transitions as LQG around the current mode of the belief within a time slice. A difference to iLQG is that AICO uses forward messages instead of a forward roll-out to determine the point of local LQG approximation and can iterate belief re-approximation with in a time slice until convergence, which may lead to faster overall convergence. For a more detailed discussion of the AICO algorithm with Gaussian message passing see section 3.5.

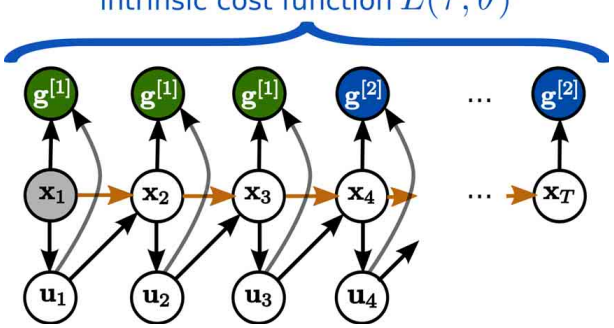

FIGURE 1 | Planning Movement Primitives are endowed with an intrinsic planning system, which performs inference in a *learned* graphical model. States are denoted by $\mathbf{x}_t$, controls by $\mathbf{u}_t$, and the time horizon is fixed to T time-steps. In this example the graphical model is used to infer the movement by conditioning on two abstract goals $\mathbf{g}^{[1]}$ and $\mathbf{g}^{[2]}$, which are specified in the *learned* intrinsic cost function $L(\tau;\boldsymbol{\theta})$.

Local planners have the advantage that they can be applied to high-dimensional dynamical systems, but the disadvantage of requiring a suitable initialization. Global planning (Kuffner and LaValle, 2000) on the other hand does not require an initial solution, however, they have much higher computational demands. Our motivation for using only a local planner as component of a PMP is related to the learning of an intrinsic cost function.

Existing planning approaches for robotics typically use handcrafted intrinsic cost functions and the dynamic model is either analytically given or learned from data (Mitrovic et al., 2010). PMPs use RL to train an intrinsic cost function for planning instead of trying to learn a model of the extrinsic reward directly. The reason is that a *local* planner often fails to directly solve realistically complex tasks by optimizing directly the extrinsic cost functions. From this perspective, PMPs learn to translate complex tasks to a simpler intrinsic cost function that can efficiently be optimized by a local planner. This learning is done by trial-and-error in the RL setting: the PMP essentially learns from experience which intrinsic cost function the local planner can cope with and uses it to generate good trajectories. Thereby, the RL of the intrinsic cost function can compensate the limitedness of the local planner.

3. MATERIALS AND METHODS

In this section we introduce the proposed PMPs, in particular the parameterization of the intrinsic cost function. The overall system will combine three components: (1) a regression method for learning the system dynamics, (2) a policy search method for finding the PMP parameters, and (3) a SOC planner for generating movements with the learned model and PMP parameters.

3.1. PROBLEM DEFINITION

We consider an unknown dynamical system of the form

$$\mathbf{x}_{t+1} = f_{\text{Dyn}}(\mathbf{u}_t, \mathbf{x}_t) + \boldsymbol{\epsilon}_t, \tag{1}$$

with state variable $\mathbf{x}_t$, controls $\mathbf{u}_t$ and Gaussian noise $\boldsymbol{\epsilon}_t \sim \mathcal{N}(0, \boldsymbol{\sigma})$. The agent has to realize a control policy $\pi : \mathbf{x}_t \mapsto \mathbf{u}_t$, which in our case will be a linear feedback controller for each time slice. The problem is to find a policy that minimizes the expected costs of a finite-horizon episodic task. That is, we assume there exists a cost function $C(\tau)$, where $\tau = (\mathbf{x}_{1:T}, \mathbf{u}_{1:T-1})$ is a roll-out of the agent controlling the system. We do not assume that the cost function $C(\tau)$ is analytically known or can be written as sum over individual costs for each time-step, i.e., $C(\tau) = \sum_t h_t(\mathbf{x}_t, \mathbf{u}_t)$. This would imply an enormous credit assignment problem with separate costs at each time-step. Thus more generally, we only get a single scalar reward $C(\tau)$ for the whole trajectory. The problem is to find $\text{argmin}_\pi \langle C(\tau) \rangle_\pi$.

The system dynamics f_{Dyn} as well as the cost function $C(\tau)$ are analytically unknown. Concerning the system dynamics we can estimate an approximate model of the systems dynamics from a set of roll-outs—as standard in model-based RL. However, concerning costs, we only receive the single scalar cost $C(\tau)$ after a roll-out indicating the quality or success of a movement. Note that $C(\tau)$ is a function of the whole trajectory, not only of the final state. Learning C from data would be an enormous task,

more complex than learning an immediate reward function $\mathbf{x}_t \mapsto \mathbf{r}_t$ as in standard model-based RL where $\mathbf{r}_t$ denotes the reward at time t.

Generally, approaches to learn $C(\tau)$ directly in a form useful for applying SOC methods seems an overly complex task and violates the maxim "never try to solve a problem more complex than the original." Therefore, our approach will not try to learn $C(\tau)$ from data but to employ RL to learn *some* intrinsic cost function that can efficiently be optimized by SOC methods and generates control policies that, by empiricism, minimizes $C(\tau)$.

3.2. PARAMETERIZATION OF PMP'S INTRINSIC COST FUNCTION

In PMPs the parameters $\boldsymbol{\theta}$ encode task-relevant abstract goals or features of the movement, which specify an intrinsic cost function

$$L(\tau; \boldsymbol{\theta}) := \sum_{t=0}^{T} l(\mathbf{x}_t, \mathbf{u}_t, t; \boldsymbol{\theta}) + c_p(\mathbf{x}_t, \mathbf{u}_t), \quad (2)$$

where l denotes the intermediate intrinsic cost function for every time-step and $c_p(\mathbf{x}_t, \mathbf{u}_t)$ is used to represent basic known task constraints, such as torque or joint limits. We will assume that such basic task constraints are part of our prior knowledge, thus c_p is given and not included in our parameterization. For the description of PMPs we will neglect the constraints c_p for simplicity. We will use a via-point representation for the intermediate intrinsic cost function $l(\mathbf{x}_t, \mathbf{u}_t, t; \boldsymbol{\theta})$. Therefore, parameter learning corresponds to extracting goals which are required to achieve a given task, such as passing through a via-point at a given time. As pointed out in the previous section, $L(\tau; \boldsymbol{\theta})$ is *not* meant to approximate $C(\tau)$. It provides a feasible cost function that empirically generates policies that minimize $C(\tau)$.

There are many ways to parameterize the intermediate intrinsic cost function l. In this paper we choose a simple via-point approach. However, in an ongoing study we additionally implemented a desired energy state of a pendulum on a cart, which simplifies the learning problem. The movement is decomposed in N shorter phases with duration $d^{[i]}, i = 1, .., N$. In each phase the cost function is assumed to be quadratic in the state and control vectors. In the ith phase ($t < d^{[1]}$ for $i = 1$ and $\sum_{j=1}^{i-1} d^{[i]} < t \leq \sum_{j=1}^{i} d^{[i]}$ for $i > 1$) we assume the intrinsic cost has the form:

$$l(\mathbf{x}_t, \mathbf{u}_t, t; \boldsymbol{\theta}) = (\mathbf{x}_t - \mathbf{g}^{[i]})^T \mathbf{R}^{[i]} (\mathbf{x}_t - \mathbf{g}^{[i]}) + \mathbf{u}_t^T \mathbf{H}^{[i]} \mathbf{u}_t. \quad (3)$$

It is parameterized by the via-point $\mathbf{g}^{[i]}$ in state space; by the precision vector $\mathbf{r}^{[i]}$ which determines $\mathbf{R}^{[i]} = \text{diag}(\exp \mathbf{r}^{[i]})$ and therefore how steep the potential is along each state dimension; and by the parameters $\mathbf{h}^{[i]}$ which determine $\mathbf{H}^{[i]} = \text{diag}(\exp \mathbf{h}^{[i]})$ and therefore the control costs along each control dimension. We represent the importance factors $\mathbf{r}^{[i]}$ and $\mathbf{h}^{[i]}$ both in log space as we are only interested in the relationship of these factors. At the end of each phase (at the via-point), we multiply the quadratic state costs by the factor $1/\Delta t$ where Δt is the time-step used for planning. This ensures that at the end of the phase the via-point is reached, while during the phase the movement is less constraint. With this representation, the parameters $\boldsymbol{\theta}$ of our PMPs are given by

$$\boldsymbol{\theta} = [d^{[1]}, \mathbf{g}^{[1]}, \mathbf{r}^{[1]}, \mathbf{h}^{[1]} \ldots d^{[N]}, \mathbf{g}^{[N]}, \mathbf{r}^{[N]}, \mathbf{h}^{[N]}]. \quad (4)$$

Cost functions of this type are commonly used—and hand-crafted—in control problems. They allow to specify a via-point, but also to determine whether only certain dimensions of the state need to be controlled to the via-point, and how this trades off with control cost. Instead of hand-designing such cost functions, our method will use a policy search method to learn these parameters of the intrinsic cost function. As for the DMPs we will assume that the desired final state at time index T is known, and thus $\mathbf{g}^{[N]}$ is fixed and not included in the parameters. Furthermore, since we consider finite-horizon episodic tasks the duration of the last phase is also fixed: $d^{[N]} = T - \sum_{i=1}^{N-1} d^{[i]}$. Still, the algorithm can choose the importance factors $\mathbf{r}^{[N]}$ and $\mathbf{h}^{[N]}$ of the final phase.

3.3. DYNAMIC MODEL LEARNING

PMPs are endowed with an intrinsic planning system. For planning we need to learn a model of the system dynamics f_{Dyn} in Equation (1). The planning algorithm can not interact with the real environment, it solely has to rely on the learned model. Only after the planning algorithm is finished, the resulting policy is executed on the real system and new data points $\langle [\mathbf{x}_t, \mathbf{u}_t], \dot{\mathbf{x}}_t \rangle$ are collected for learning the model.

Many types of function approximators can be applied in this context (Vijayakumar et al., 2005; Nguyen-Tuong et al., 2008a,b). We use the lazy learning technique Locally Weighted Regression (LWR) (Atkeson et al., 1997) as it is a very simple and effective approach. LWR is a memory-based, non-parametric approach, which fits a local linear model to the locally-weighted set of data points. For our experiments, the size of the data set was limited to 10^5 points implemented as a first-in-first-out queue buffer, because the computational demands of LWR drastically increase with the size of the data set. In particular we used a Gaussian kernel as distance function with the bandwidth parameters $h_\phi = 0.25$ for joint angles, $h_{\dot{\phi}} = 0.5$ for velocities, and $h_u = 0$ for controls[1]. For more details we refer to Chapter 4 in Atkeson et al. (1997).

3.4. POLICY SEARCH FOR PMP'S INTRINSIC COST FUNCTION

Model learning takes place simultaneously to learning the parameters $\boldsymbol{\theta}$ of the MP. In general this could lead to some instability. However, while the distribution $P(\mathbf{x}_t)$ depends on the policy and the data for model learning is certainly non-stationary, the conditional distribution $P(\mathbf{x}_{t+1}|\mathbf{u}_t, \mathbf{x}_t)$ is stationary. A local learning scheme as LWR behaves rather robust under such type of non-stationarity of the input distribution only. On the other hand, from the perspective of $\boldsymbol{\theta}$ optimization, the resulting policies may change and lead to different payoffs $C(\tau)$ even for the same parameters $\boldsymbol{\theta}$ due to the adaption of the learned system dynamics.

[1]The bandwidth parameter for controls is set to zero as the matrizes $\mathbf{A}$ and $\mathbf{B}$ in the linearized model, i.e., $\dot{\mathbf{x}} = \mathbf{A}(\mathbf{x})\mathbf{x} + \mathbf{B}(\mathbf{x})\mathbf{u}$ are independent on the controls $\mathbf{u}$.

Since the resulting control policies of our PMPs depend non-linearly on the parameters $\boldsymbol{\theta}$, step-based exploration techniques can not be used in our setup. Hence, we will use the second order stochastic search method CMA (Covariance Matrix Adaptation, Hansen et al. 2003) which makes no assumptions on the parameterization of the MP.

We employ the second order stochastic search method CMA to optimize the parameters $\boldsymbol{\theta}$ w.r.t. $C(\tau)$. The parameter space is approximated using a multivariate Gaussian distribution. Roughly, CMA is an iterative procedure that, from the current Gaussian distribution, generates a number of samples, evaluates the samples, computes second order statistics of those samples that reduced $C(\tau)$, and uses these to update the Gaussian search distribution. In each iteration, all parameter samples $\boldsymbol{\theta}$ use the same learned dynamic model to evaluate $C(\tau)$. Further, CMA includes an implicit forgetting in its update of the Gaussian distribution and therefore behaves robust under the non-stationarity introduced by adaptation of the system dynamics model.

We will compare our PMP approach to both, DMPs learned with CMA policy search and DMPs learned with the state of the art step-based method PI^2 (Theodorou et al., 2010). However, we focus in this work on the characteristics of the movement representation and place less emphasis on a specific policy search method.

Note that even if the learned model is only a rough approximation of the true dynamics, the policy search for parameters of the intrinsic cost function can compensate for an imprecise dynamics model: the policy search approach finds parameters $\boldsymbol{\theta}$ of the intrinsic cost function such that—even with a mediocre model—the resulting controller will lead to low extrinsic costs in the real system.

3.5. PROBABILISTIC PLANNING ALGORITHM

We use the probabilistic planning method AICO (Toussaint, 2009) as intrinsic planning algorithm. It offers the interpretation that a MP can be represented as graphical model and the movement itself is generated by inference in this graphical model.

The graphical model is fully determined by the learned system dynamics and the learned intrinsic cost function, see **Figure 1**. In order to transform the minimization of $L(\tau;\theta)$ into an inference problem, for each time-step an individual binary random variable z_t is introduced. This random variable indicates a reward event. Its probability is given by

$$P(z_t = 1|\mathbf{x}_t, \mathbf{u}_t, t) \propto \exp(-l(\mathbf{x}_t, \mathbf{u}_t, t; \boldsymbol{\theta})),$$

where $l(\mathbf{x}_t, \mathbf{u}_t, t; \boldsymbol{\theta})$ denotes the cost function for time-step t defined in Equation (3). AICO now assumes that a reward event $z_t = 1$ is observed at every time-step. Given that evidence, AICO calculates the posterior distribution $P(\mathbf{x}_{1:T}, \mathbf{u}_{1:T-1}|z_{1:T} = 1)$ over trajectories.

We will use the simplest version of AICO (Toussaint, 2009), where an extended Kalman smoothing approach is used to estimate the posterior distribution $P(\mathbf{x}_{1:T}, \mathbf{u}_{1:T-1}|z_{1:T} = 1)$. The extended Kalman smoothing approach uses Taylor expansions to linearize the system and subsequently uses Gaussian messages for belief propagation in a graphical model. Gaussian message passing iteratively re-approximates local costs and transitions as a LQG around the current mode of the belief within a time slice. For more details we refer to Toussaint (2009).

AICO is only a local optimization method and we have to provide an initial solution which is used for the first linearization. We will use the direct path (or the straight line) to the via-points $\mathbf{g}^{[i]}$ in Equation (3) as initial solution. Before learning the via-points $\mathbf{g}^{[i]}$ with $i = 1..N-1$ are set to the initial state $\mathbf{x}_1$. The final via-point is fixed and set to the desired final state $\mathbf{g}^{[N]} = \mathbf{x}_T$.

AICO provides us with a linear feedback controller for each time slice of the form

$$\mathbf{u}_t = \mathbf{O}_t\mathbf{x}_t + \mathbf{o}_t, \tag{5}$$

where $\mathbf{O}_t$ is the inferred feedback control gain matrix and $\mathbf{o}_t$ denotes the linear feedback controller term. This feedback control law is used as policy of the MP and is evaluated on a simulated or a real robot.

The original formulation of the AICO method (Toussaint, 2009) does not consider torque limits, which are important for many robotic experiments as well for the dynamic balancing experiments we consider in this paper. Therefore we extended the algorithm. This extension yields not only a modified form of the immediate cost function but also results in different update equations for the messages and finally different equations of the optimal feedback controller. A complete derivation of the extension including the resulting messages and the corresponding feedback controller is given in Rückert and Neumann (2012). Also the algorithm is listed in that work.

On overview of the interactions between policy search of the PMP's intrinsic cost function and the planning process using AICO is sketched in **Figure 2**. The learning framework is organized the following: given the parameters $\boldsymbol{\theta}$ from the policy search method CMA, AICO is initialized with an initial solution which is the direct path to the via-points. AICO is then used to optimize the parameterized intrinsic cost function $L(\tau;\theta)$ to estimate a linear feedback controller for each time-step, see Equation (5). The feedback controller is subsequently executed on the simulated or the real robot and the extrinsic cost $C(\tau)$ is evaluated. Based on this evidence CMA will update its distribution over the policy search space and computes a new parameter vector. Simultaneously we collect samples of the system dynamics $\langle[\mathbf{x}_t, \mathbf{u}_t], \dot{\mathbf{x}}_t\rangle$ while executing the MP. These samples are used to improve our learned dynamics model, which is used for planning.

4. RESULTS

We start our evaluation of the proposed PMP approach on a one-dimensional via-point task to illustrate basic characteristics. In order to demonstrate our approach on a more challenging dynamic robot task we choose a complex 4-link humanoid balancing task. At the end of this section we discuss an important issue: the computational time of PMPs for simulated and real world tasks.

In our experiments, we focus on investigating the optimality of the solution, the robustness to noise for learning, and the

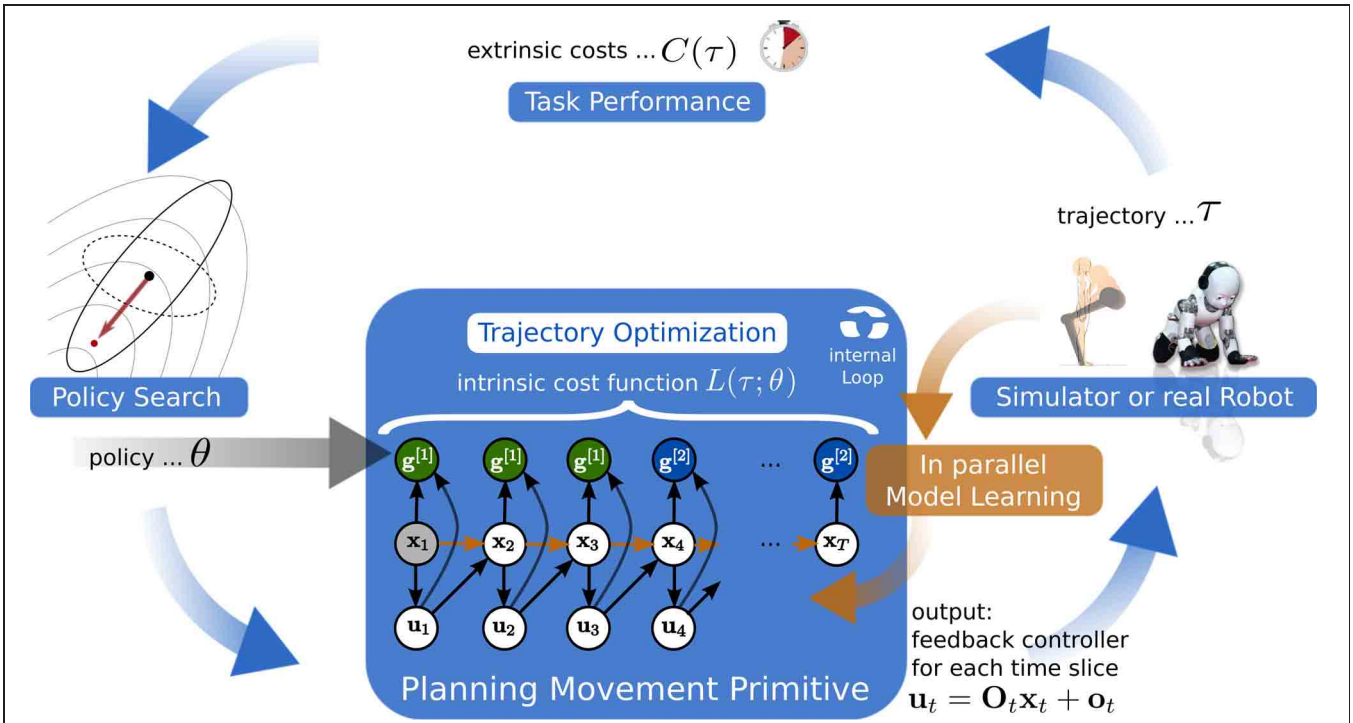

FIGURE 2 | We decompose motor skill learning into two different learning problems. At the highest level we learn parameters $\boldsymbol{\theta}$ of an intrinsic cost function $L(\tau; \boldsymbol{\theta})$ using policy search (model-free RL). Given parameters $\boldsymbol{\theta}$ the probabilistic planner at the lower level uses the intrinsic cost function $L(\tau; \boldsymbol{\theta})$ and the learned dynamics model to estimate a linear feedback controller for each time-step (model-based RL). The feedback controller is subsequently executed on the simulated or the real robot and the extrinsic cost $C(\tau)$ is evaluated. Based on this evidence the policy search method computes a new parameter vector. Simultaneously we collect samples of the system dynamics $\langle[\mathbf{x}_t, \mathbf{u}_t], \dot{\mathbf{x}}_t\rangle$ while executing the movement primitive. These samples are used to improve our learned dynamics model which is used for planning.

generalizability to different initial or final states. For the 4-link task we additionally demonstrate how model learning influences the learning performance.

For a comparison we take the commonly used DMPs as a baseline where we use the newest version of the DMPs (Pastor et al., 2009) as discussed in detail in Appendix A. As described above we use 2nd order stochastic search to learn the PMP and DMP parameters. In order to compare to a more commonly used policy search algorithm we additionally test the PI^2 algorithm (Theodorou et al., 2010) for learning the DMP parameters. For all experiments we empirically evaluate the optimal settings of the algorithms (such as the exploration rate of CMA and PI^2, the number of centers for the DMPs, or the number of via-points for the PMPs), which are listed in Appendix B.

4.1. ONE-DIMENSIONAL VIA-POINT TASK

In this task the agent has to control a one-dimensional point mass of 1 kg. The state at time t is denoted by $\mathbf{x}_t = [\phi_t, \dot{\phi}_t]^T$ and we directly control the acceleration u_t. The time horizon was limited to $T = 50$ time-steps, which corresponds to a simulation time of 0.5 s with a time-step of $\Delta t = 10$ ms. Starting at $\mathbf{x}_1 = [0, 0]^T$ the agent has to pass through a given via-point $g_v = -0.2$ at $t_v = 30$. The velocity of the point mass at the via-point is not specified and can have any value. The final target g_T was set to 1. The movement is shown in **Figure 3**. For this task we define the extrinsic cost function:

$$C(\tau) = 10^4(\dot{\phi}_T^2 + 10(g_T - \phi_T)^2) + 10^5(g_v - \phi_{t_{30}})^2 + 5 \cdot 10^{-3} \sum_{t=1}^{T} u_t^2.$$

The first two terms punish deviations from the target g_T and the via-point g_v, where $\phi_{t_{30}}$ denotes the first dimension of the state $\mathbf{x}_t = [\phi_t, \dot{\phi}_t]^T$ at time index 30. The target should be reached with zero velocity at $T = 50$. The last term punishes high energy consumption where u_t denotes the applied acceleration. The control action is noisy, we always add a Gaussian noise term with a standard deviation of $\sigma = 20$ to the control action. As this is a very simple task, we use it just to show different characteristics of the DMPs (using 10 Gaussians for that representation was optimal) and PMPs (apparently 2 via-points are sufficient for this task).

A quite similar task has been used in Todorov and Jordan (2002) to study human movement control. The experiments showed that humans were able to reach the given via-points with high accuracy, however, in between the via-points, the trial-to-trial variability was rather high. This is a well-known concept from optimal control, called the *minimum intervention principle*,

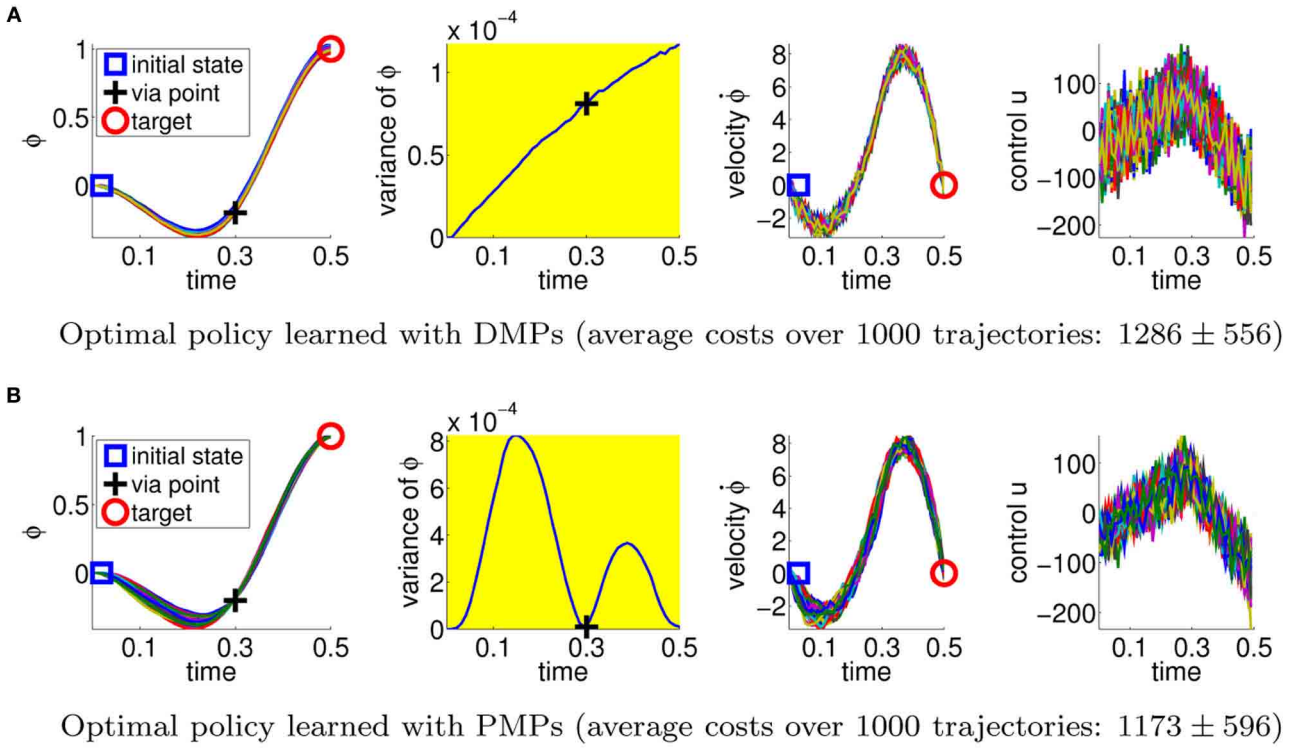

FIGURE 3 | This figure illustrates the best available policies for the DMPs and the PMPs for the via-point task. From left-to-right shown are the point mass trajectories, the variance of these trajectories, the velocity of the point mass, and the applied accelerations. The agent has to pass the via-point at $t_v = 0.3$ s and deal with the stochasticity of the system (Gaussian control noise with a variance of 20^2). The plots show 100 trajectories reproduced with the optimal parameters for the DMPs **(A)** and 100 trajectories with the (hand-crafted) optimal parameters for PMPs **(B)**. The PMP approach is able to reduce the variance of the movement if it is relevant for the task, while the DMPs can only suppress the noise in the system throughout the trajectory in order to get an acceptable score. This advantage is also reflected by the average costs over 1000 trajectories. The DMP solution achieved cost values of 1286 ± 556 whereas the PMP result was 1173 ± 596.

showing also that human movement control follows basic rules of optimal control.

4.1.1. Optimality of the solutions

We first estimate the quality of the *best available* policy with the DMP and the PMP approach. We therefore use the PMPs with two via-points and set the parameters $\boldsymbol{\theta}$ per hand. As we are using a linear system model and a simple extrinsic cost function, the PMP parameters can be directly obtained by looking at the extrinsic costs. As the PMPs use the AICO algorithm, which always produces optimal policies for LQG systems, the PMP solution is the optimal solution. We subsequently use the mean trajectory returned by AICO and use imitation learning to fit the DMP parameters. We also optimized the feedback controllers used for the DMPs [2]. In **Figure 3** we plotted 100 roll-outs of the DMP and PMP approach using this optimal policies. The second column illustrates the trial-to-trial variability of the trajectories. The optimal solution has minimum variance at the via-point and the target. As expected this solution is reproduced with the PMP approach, because the parameters of the PMPs are able to reflect the importance of passing through the via-point. The DMPs could not adapt the variance during the movement because the used (optimized) feedback controller uses constant controller gains. As we can see, the variance of the DMP trajectory is simply increasing with time.

Comparing the optimal solutions we find that PMPs, in contrast to DMPs, can naturally deal with the inherent noise in the system. This is also reflected by the average cost values over 1000 trajectories, 1286 ± 556 for the DMPs and 1173 ± 596 for the PMPs. The $\pm$ symbol always denotes the standard deviation. PMPs perform significantly better than DMPs (t-test: $p < 10^{-3}$).

4.1.2. Robustness to noise for learning

This advantage would not be very useful if we were not able to learn the optimal PMP parameters from experience. Next we test using CMA policy search to learn the parameters for the DMPs and the PMPs. In addition, in order to compare to a more commonly used policy search method, we also compare to the PI^2 approach (Theodorou et al., 2010) which we could only evaluate for the DMP approach. We evaluated the learning performance in the case of no control noise, **Figure 4A**, and in the case of control noise $\sigma = 20$, **Figure 4B** performing 15 runs.

[2]The control gains, i.e., the two scalars k_{pos} and k_{vel} of the linear feedback controller in Equation (7) in the Appendix are learned using a 2nd order stochastic search method.

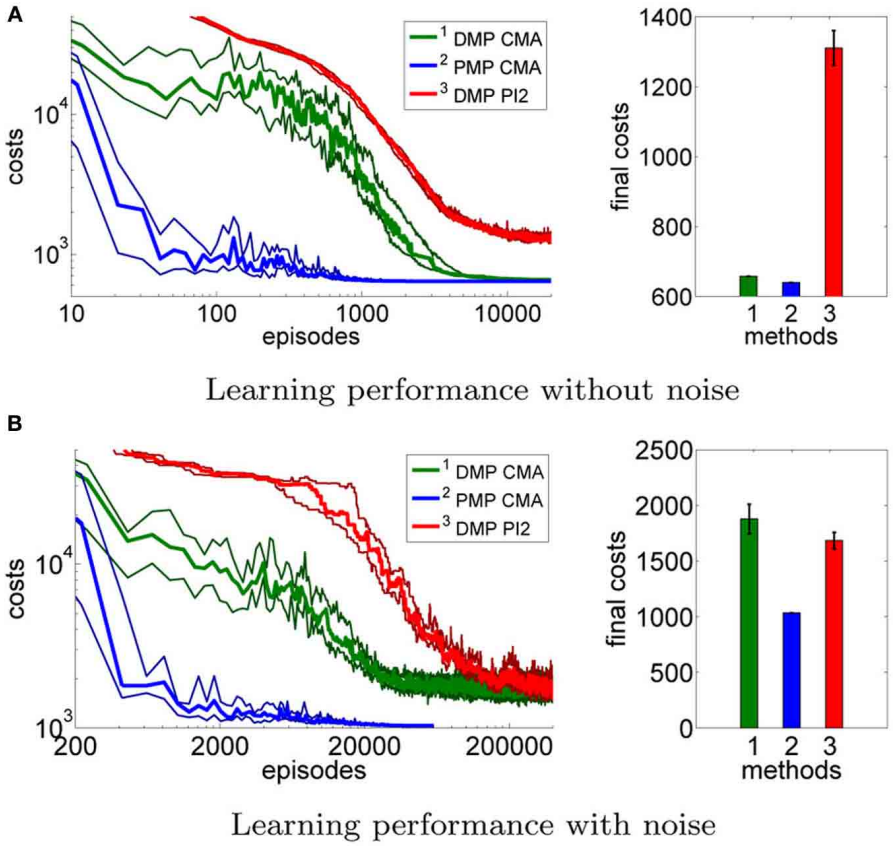

FIGURE 4 | This figure illustrates the learning performance of the two movement representations, DMPs and PMPs, for the one-dimensional via-point task. Illustrated are mean values and standard deviations over 15 runs after CMA policy search. In addition, we also compare to the PI^2 approach (Theodorou et al., 2010) which we could only evaluate for the DMP approach. Without noise the final costs of the two representations are similar if CMA policy search is used **(A)**. In the second example **(B)** we use zero-mean Gaussian noise with $\sigma = 20$ for the controls. In this setup we needed to average each performance evaluation for CMA over 20 roll-outs. For both setups the PMPs could considerably outperform the DMPs in terms of learning speed. For the noisy setup the PMPs could additionally produce policies of much higher quality as they can adapt the variance of the trajectories to the task constraints. PI^2 could not find as good solutions as the CMA policy search approach in both setups.

Without control noise the quality of the learned policy found by 2nd order search is similar for the DMPs (657.5 ± 0.18) and the PMPs (639.6 ± 0.01). PI^2 could not find as good solutions as the stochastic search approach. The reason for this is that PI^2 could not find the very large weight values which are needed for the last few centers of the DMPs in order to have exactly zero velocity at the final state (note that the weights of the DMPs are multiplied by the phase variable s which almost vanishes in the end of the movement and therefore these weight values have to be very high). Because CMA policy search uses second order information, such large parameter values are easily found. This comparison clearly shows that using 2nd order search for policy search is justified. If we compare the learning speed in terms of required episodes or roll-outs between DMPs and PMPs, we find an advantage for PMPs which could be learned an order of magnitude faster than the DMPs.

The second experiment (with control noise of $\sigma = 20$) was considerably harder to learn. Here, we needed to average each performance evaluation over 20 roll-outs. The use of more sophisticated extensions of CMA (Heidrich-Meisner and Igel, 2009a) which can deal with noisy performance evaluations and hence improve the learning speed of CMA policy search in the noisy setup is part of future work. In **Figure 4B** we find that the PMPs could be learned an order of magnitude faster than the DMPs. As expected from the earlier experiment, the PMPs could find clearly better solutions as the DMPs as they can adapt the variance of the trajectory to the task constraints. Again, PI^2 showed a worse performance than 2nd order search. Illustrated are mean values and standard deviations over 15 runs of learning (1034 ± 1.46 for the PMPs and 1876 ± 131 for the DMPs using CMA). To compare these results to the optimal costs we evaluated the best learned policies of both approaches and generated 1000 trajectories. The learned solution for the PMPs was similar to the hand-coded optimal solution, 1190 ± 584 versus costs of 1173 ± 596 for the optimal solution. DMPs achieved costs of 1478 ± 837, illustrating that, eventhough the DMPs are able to represent much better solutions with costs of 1286 ± 556 (see **Figure 3**), it is very hard to find this solution.

In **Table 1**, we show the mean and variance of the found parameters averaged over 15 runs for the first via-point in

Table 1 | Learned parameters using PMPs for the via-point task (1st via-point).

Scenario	$d^{[1]}$	$g^{[1]}$	$\log(\mathbf{r}^{[1]})$	$\log(\mathbf{h}^{[1]})$
Optimal	0.3	**−0.2**	[5, 0]	−2.3
No noise	0.29 ± 0.01	$\mathbf{-0.27} \pm 0.03$	$[4.08 \pm 4.18, -0.8 \pm -0.77]$	-3.05 ± -4
With noise	0.29 ± 0.01	$\mathbf{-0.23} \pm 0.05$	$[4.93 \pm 5.29, -0.31 \pm -0.12]$	-2.85 ± -3

The symbol ± denotes the standard deviation.

comparison to the optimal PMP parameters. We can see that the found parameters matched the optimal ones. Interestingly, in the experiment with no noise, the found parameters had a larger deviation from the optimal ones, especially for the first via-point $g^{[1]}$ in **Table 1**. The reason for this is the simple observation that without noise, we can choose many via-points which results in the same trajectory, whereas with noise we have to choose the correct via-point in order to reduce the variance of the trajectory at this point in time.

4.1.3. Generalizability to different task settings

Next, we investigate the ability of both approaches to adapt to different situations or to adapt to different priors. In the previous task, **Figure 3** the initial and the target state were assumed as prior knowledge. The movement was learned for the initial state $\phi_1 = 0$ and for the target state $\phi_T = 1$. We want to investigate if the same learned parameters can be re-used to generate different movements, e.g., used for different initial or target states.

For PMPs we use the new initial or final states denoted by $\mathbf{x}_1$ and $\mathbf{g}^{[N]}$ in the graphical model in **Figure 1** and re-plan the movement (using the same learned parameters). The change of the initial state or the target state is also allowed by the DMP framework. However, how the movement is generalized to these new situations is based on heuristics (Pastor et al., 2009) and does not consider any task constraints (in this example to pass through the via-point).

In **Figure 5** the learned policies are applied to reach different initial states $\phi_1 \in \{-0.6, -0.4, -0.2, 0, 0.2, 0.4, 0.6\}$ (**Figures 5A,B**) and different goal states $\phi_T \in \{1.5, 1.25, 1, 0.75, 0.5\}$ (**Figures 5C,D**). All plots show the mean trajectory. In order to change the initial or the target state of the movement we have to change the point attractor of the DMPs, which changes the complete trajectory. Due to this heuristic, the resulting DMP trajectories shown in **Figures 5A,C** do not pass through the via-point any more. Note that we use a modified version of the DMPs (Pastor et al., 2009) which has already been built for generalization to different initial or target points. The PMPs on the other hand still navigate through the learned via-point when changing the initial or the goal state as shown in **Figures 5B,D**.

4.1.4. Concluding summary

As we have seen the PMPs implement all principles of optimal control, which allows to learn solutions for stochastic systems of a quality which is not representable with traditional trajectory-based methods such as the DMPs. The optimal movement trajectory could be learned from scratch up to one order of magnitude faster compared to DMPs. This difference was even more visible in the stochastic case, where the DMPs needed more than 30, 000 episodes to find satisfactory solutions. In the setting with control noise the learned parameters matches the optimal ones because only by the use of noise the parameters are uniquely determined. Finally the PMPs could extract the task-relevant feature, the via-point. Even if the task changes—e.g., the initial or the final state are changed, the movement trajectory still passes through the learned via-point. The DMPs on the other hand heuristically scale the trajectory which offers no control for fulfilling task-relevant constraints.

With DMPs 12 parameters were learned, where we used 10 Gaussian kernels and optimized 2 control gains. For the PMPs 2 via-points were sufficient, where the last one was fixed. However, for both via-points we could specify 3 importance weights. Thus, in total $8 = 2 + 3 + 3$ parameters were learned.

4.2. DYNAMIC HUMANOID BALANCING TASK

In order to assess the PMPs on a more complex task, we evaluate the PMP and DMP approach[3] on a dynamic non-linear balancing task (Atkeson and Stephens, 2007). The robot gets pushed with a specific force F and has to keep balance. The push results in an immediate change of the joint velocities. The motor torques are limited, which makes direct counter-balancing of the force unfeasible. The optimal strategy is therefore to perform a fast bending movement and subsequently return to the upright position, see **Figure 6**. This is a very non-linear control problem, applying any type of (linear) balancing control or local optimal control algorithm such as AICO with the extrinsic cost function fails. Thus, we have to use a parametric movement representation. Like in the previous experiment, we take the DMP (Schaal et al., 2003) approach as a baseline.

We use a 4-link robot as a simplistic model of a humanoid (70 kg, 2 m) (Atkeson and Stephens, 2007). The eight-dimensional state $\mathbf{x}_t$ is composed of the arm, the hip, the knee and the ankle positions and their velocities. Table 1 in Rückert and Neumann (2012) shows the initial velocities (resulting from the force F which always acts at the shoulder of the robot) and the valid joint angle range for the task. In all experiments the applied force was $F = 25$Ns. If one of the joints leaves the valid range the robot is considered to be fallen. Additionally to the joint limits, the controls are limited to the intervals $[\pm 250, \pm 500, \pm 500, \pm 70]$ Nm (arm, hip, knee, and ankle). For more details we refer to Atkeson and Stephens (2007).

[3] For PMPs again 2 via-points were optimal. DMPs performed best when using 10 Gaussian kernels per dimension.

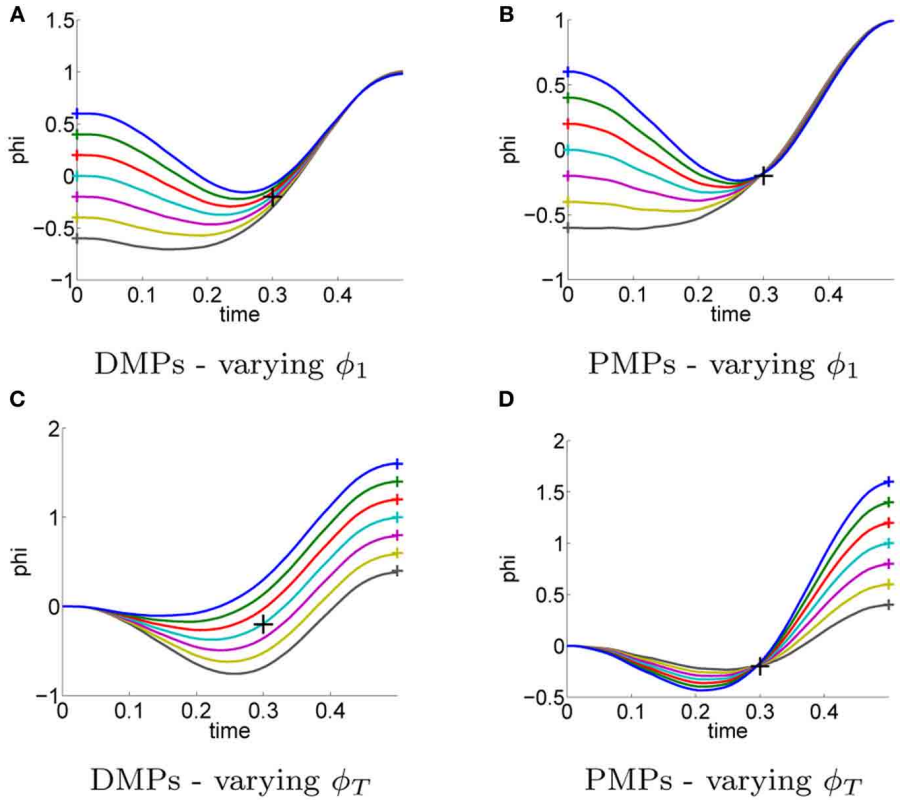

FIGURE 5 | For the previous task illustrated in Figure 3 the movement was learned for a single initial state $\phi_1 = 0$ and a single target state $\phi_T = 1$. The initial and the target state were assumed as prior knowledge. In this experiment we evaluated the generalization of the learned policies to different initial states $\phi_1 \in \{-0.6, -0.4, -0.2, 0, 0.2, 0.4, 0.6\}$ **(A–B)** and different target states $\phi_T \in \{1.5, 1.25, 1, 0.75, 0.5\}$ **(C–D)**. Always the same parameters $\boldsymbol{\theta}$ have been used, i.e., the parameters were not re-learned. Illustrated are the mean trajectories. The DMPs **(A,C)** are not aware of task-relevant features and hence do not pass through the via-point any more. **(B,D)** PMPs can adapt to varying initial or target states with small effects on passing through the learned via-point.

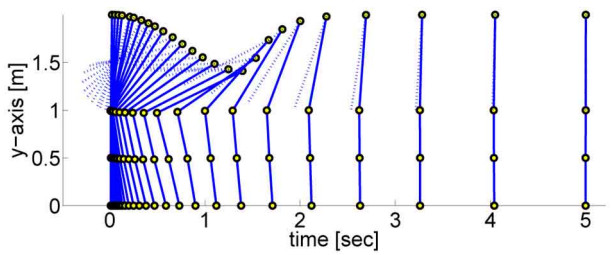

FIGURE 6 | This figure illustrates a dynamic balancing movement learned using the proposed Planning Movement Primitives. The 4-link robot modeling a humanoid (70 kg, 2 m) gets pushed from behind with a specific force ($F = 25$ Ns) and has to move such that it maintains balance. The optimal policy is to perform a fast bending movement and subsequently return to the upright robot posture. The circles denote the ankle, the knee, the hip, and the shoulder joint. The arm link is drawn as dotted line to differentiate it from the rest of the body.

Let t_s be the last time index where the robot has not fallen and let $\mathbf{x}_{t_s}$ be the last valid state. The final state or resting state (upright position with zero velocity) is denoted by $\mathbf{x}_r$. The movement was simulated for 5 s with a $\Delta t = 10$ ms resulting in $T = 500$ time-steps. As extrinsic cost function $C(\tau)$ we use:

$$C(\tau) = 20(t_s - T)^2 + (\mathbf{x}_{t_s} - \mathbf{x}_r)^T \mathbf{R}_E (\mathbf{x}_{t_s} - \mathbf{x}_r) + \sum_{t=1}^{t_s} \mathbf{u}_t^T \mathbf{H}_E \mathbf{u}_t. \quad (6)$$

The first term $(t_s - T)^2$ is a punishment term for falling over. If the robot falls over, this term typically dominates. The precision matrix $\mathbf{R}_E$ determines how costly it is not to reach $\mathbf{x}_r$. The diagonal elements of $\mathbf{R}_E$ are set to 10^3 for joint angles and to 10 for joint velocities. Controls are punished by $\mathbf{H}_E = 5 \cdot 10^{-6}\mathbf{I}$. Because of the term $(t_s - T)^2$ we cannot directly encode the extrinsic cost function as a sum of intermediate costs, which is usually required for SOC algorithms. But we can use PMPs to transform this reward signal into an intrinsic cost function for a local probabilistic planner.

4.2.1. Optimality of the solutions

We use additive zero-mean Gaussian noise with a standard deviation $\sigma = 10$. In contrast to the simple via-point task where

imitation learning was used to compare the trajectories shown in **Figure 3** are the policies for the 4-link task learned from scratch. **Figure 7** illustrates the best learned policies for DMPs (left column) and PMPs (right column). Shown are the joint angle trajectories (**Figures 7A,B**) and the variance of these trajectories (**Figures 7C,D**). The corresponding controls are illustrated in **Figure 8**. We evaluated 100 roll-outs of the best policies found by both approaches. While the DMPs cannot adapt the variance during the movement **Figure 7C**, the PMPs can exploit the power of SOC and are able to reduce the variance at the learned via-point (marked by crosses) **Figure 7D**. As the PMPs are able to control the variance of the trajectory, we can see that the variance of the movement is much higher compared to the DMPs (**Figures 7C,D**). Accuracy only matters at the via-points. We can also see that the arm trajectory has a high variance after the robot is close to a stable up-right posture **Figure 7B**, because it is not necessary to strictly control the arm in this phase. The best found policy of the DMPs had costs of 568 while the best result using PMPs was 307. This strongly suggests that it is advantageous to reduce the variance at certain points in time in order to improve the quality of the policy.

4.2.2. Robustness to noise for learning

Next, we again want to assess the learning speed of both approaches. We again used CMA policy search for the PMPs and DMPs as well as PI^2 for the DMP approach. The average over 20

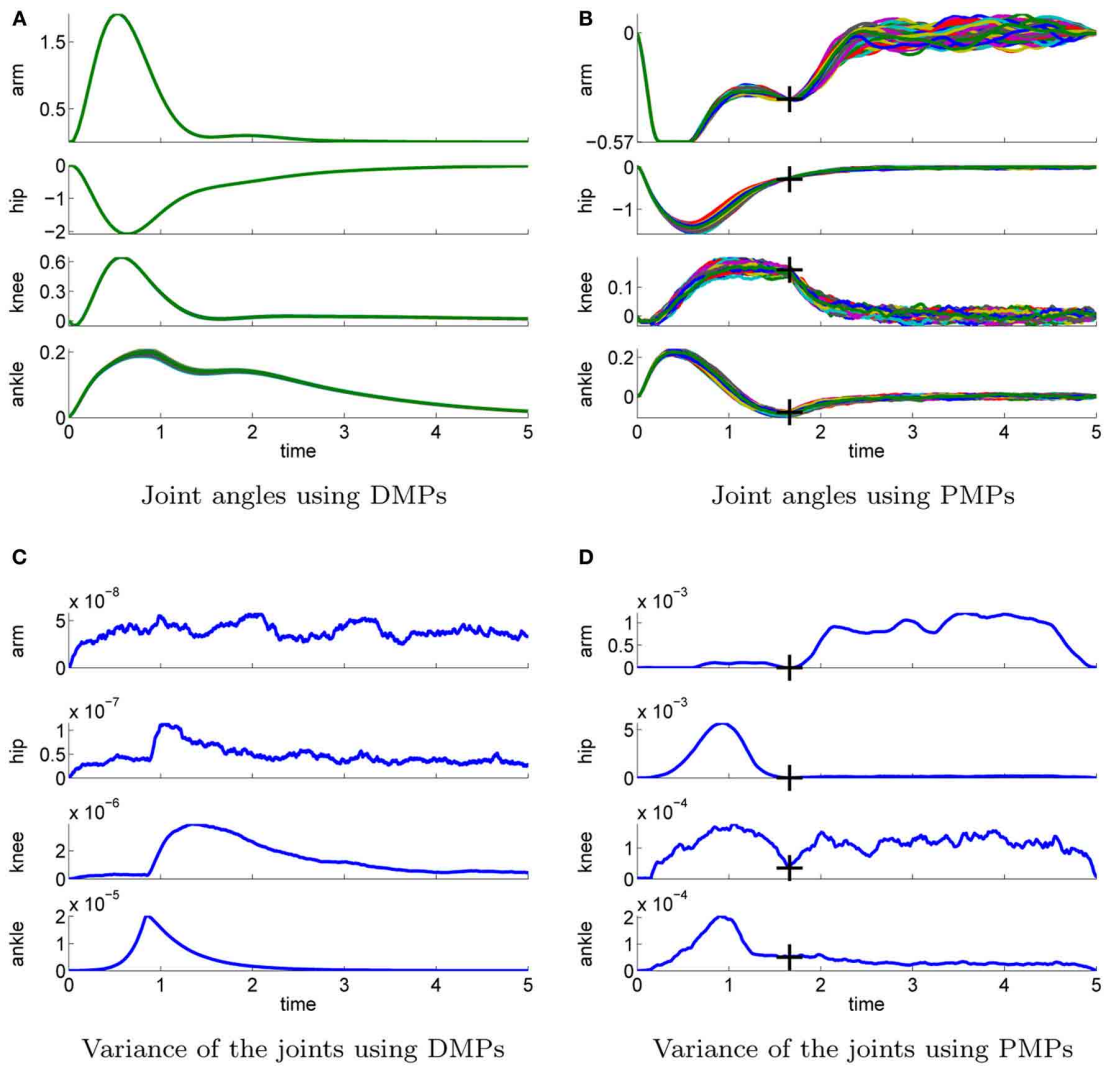

FIGURE 7 | This figure illustrates the best learned policies for the 4-link balancing task using DMPs (left column) and PMPs (right column). Shown are the joint angle trajectories **(A–B)** and the variance of these trajectories **(C–D)**. The applied controls are illustrated in **Figure 8**. We evaluated 100 roll-outs using the same parameter setting $\boldsymbol{\theta}$ for each approach. The controls were perturbed by zero-mean Gaussian noise with $\sigma = 10$ Ns. PMPs can exploit the power of stochastic optimal control and the system is only controlled if necessary, see the arm joint trajectories in **(B)**. The learned via-points are marked by crosses in **(B)** and **(C)**. For DMPs the variance of the joint trajectories **(C)** is determined by the learned controller gains of the inverse dynamics controller. As constant controller gains are used the variance can not be adapted during the movement and is smaller compared to **(D)**. For DMPs the best available policy achieved cost values of 568 whereas the best result using PMPs was 307.

runs of the learning curves are illustrated in **Figure 9**. Using the PMPs as movement representation, good policies could be found at least one order of magnitude faster compared to the trajectory-based DMP approach. The quality of the found policies was better for the PMP approach (mean values and standard deviations after learning: 993 ± 449 for the DMPs and 451 ± 212 for the PMPs). For the DMP approach we additionally evaluated PI^2 for policy search, however, PI^2 was not able to find good solutions—the robot always fell over.

4.2.3. Generalizability to different task settings

In the next step we again test the generalization to different initial or final states. More specific we investigate how well the approaches can adapt to different priors of the arm joint.

In the previous task the target was assumed to be known prior knowledge and the policy was learned for a final arm posture of $\phi_{T_{\text{arm}}} = 0$. We used this learned policy to generate movements to different final targets of the arm joint $\phi_{T_{\text{arm}}} \in \{3, 2.5, 2, 1.5, 1, 0.5, 0, -0.2, -0.4, -0.6\}$. We only change either the arm-position of the last via-point or the point attractor of the dynamical system. The results shown in **Figure 10** confirm the findings of the one-dimensional via-point task. The PMPs first move to the via-point, always maintaining the extracted task constraints, and afterward move the arm to the desired position while keeping balance. All desired target positions of the arm could be fulfilled. In contrast, the DMPs managed to keep balance only for few target positions. The valid range of the target arm position with DMPs was $\phi_{T_{\text{arm}}} \in [-0.2, 1]$. This shows the advantage of generalization while keeping task constraints versus generalization per using the DMP heuristics.

The ability of the two approaches to adapt to different initial states is illustrated in **Figure 11**. We used the learned policy for $\phi_{1_{\text{arm}}} = 0$ to generate movements using different initial states of the arm joint: $\phi_{1_{\text{arm}}} = \{1, 0.5, 0.2, 0, -0.2, -0.4, -0.6\}$. The push perturbing the robot results in an immediate change of the joint velocities, which are shown in **Table A5** in the Appendix for these different initial states. For the DMPs only the joint angles 0 and -0.2 resulted in successful policies. Whereas with PMPs the valid range of the initial arm position was $\phi_{1_{\text{arm}}} \in [-0.6, 0.5]$.

4.2.4. Model learning using PMPs

So far all experiments for the PMPs were performed using the known model of the system dynamics, these experiments are denoted by PMP in **Figure 12**. Note that also for the DMPs the known system model has been used for inverse dynamics control. Now we want to evaluate how model learning affects the performance of our approach. This can be seen in **Figure 12**. In the beginning of learning the extrinsic costs are larger compared to motor skill learning with a given analytic model. However, as the number of collected data-points $\langle [\mathbf{x}_t; \mathbf{u}_t], \dot{\mathbf{x}}_t \rangle$ increases the PMPs with model learning quickly catch up and converge finally to the same costs. The PMP representation with model learning in parallel considerably outperforms the trajectory-based DMP approach in learning speed and in the final costs.

4.2.5. Computational time

For our simulations we used a standard personal computer (2.6 Ghz, 8 Gb ram) with implementations of the algorithms in C++. For the 4-link pendulum the DMPs could generate the movement trajectory within less than 0.1 s. With the proposed PMPs it took less than 1 s (including model learning). The time horizon was 5 s and we used a time-step of $\Delta t = 10$ ms.

4.2.6. Concluding summary

In contrast to the via-point task the optimal solution for this dynamic balancing task is unknown. The comparison to the

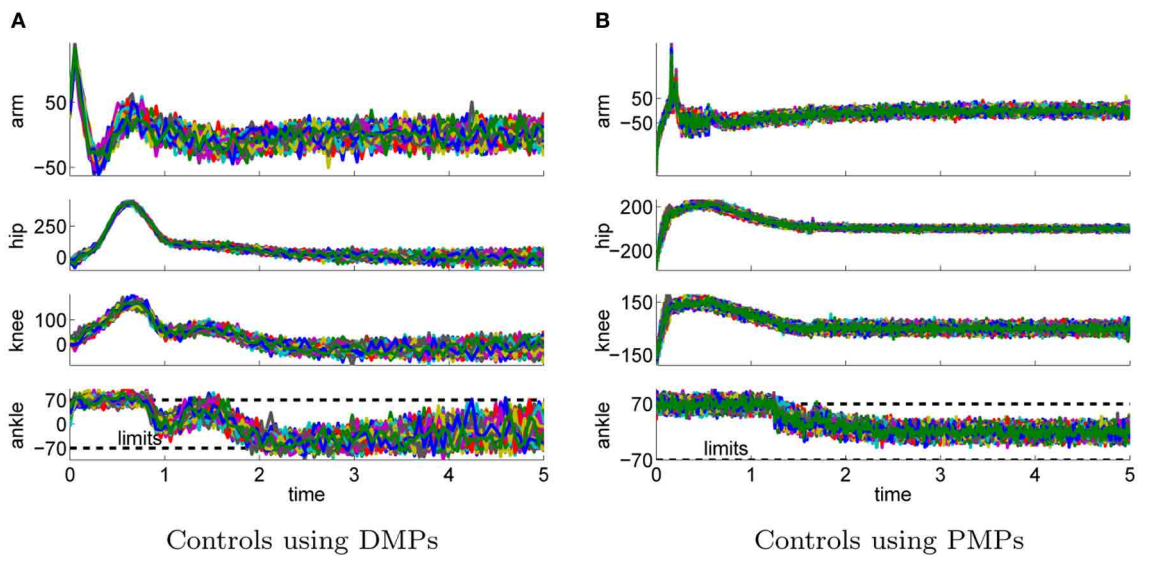

FIGURE 8 | This figure illustrates the controls of best learned policies for the 4-link balancing task using DMPs (A) and PMPs (B). The corresponding joint angle trajectories are shown in **Figure 7**. The controls were perturbed by zero-mean Gaussian noise with $\sigma = 10$ Nm. Shown are 100 roll-outs using the same parameter setting $\boldsymbol{\theta}$ for each approach. The dotted horizontal lines in the last row indicate the control constraints.

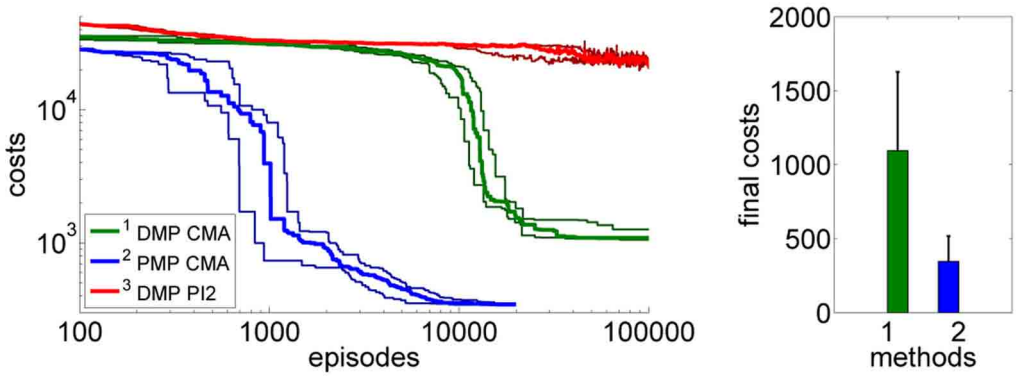

FIGURE 9 | The figure illustrates the learning performance of the two movement representations, DMPs and PMPs for the 4-link balancing task. Illustrated are mean values and standard deviations over 20 runs after CMA policy search. The controls (torques) are perturbed by zero-mean Gaussian noise with $\sigma = 10$ Nm. The PMPs are able to extract characteristic features of this task which is a specific posture during the bending movement, shown in **Figure 7B**. Using the proposed Planning Movement Primitives good policies could be found at least one order of magnitude faster compared to the trajectory-based DMP approach. Also, the quality of the best-found policy was considerably better for the PMP approach (993 ± 449 for the DMPs and 451 ± 212 for the PMPs). For the DMP approach we additionally evaluated PI^2 for policy search, which could not find as good solutions as the CMA policy search approach.

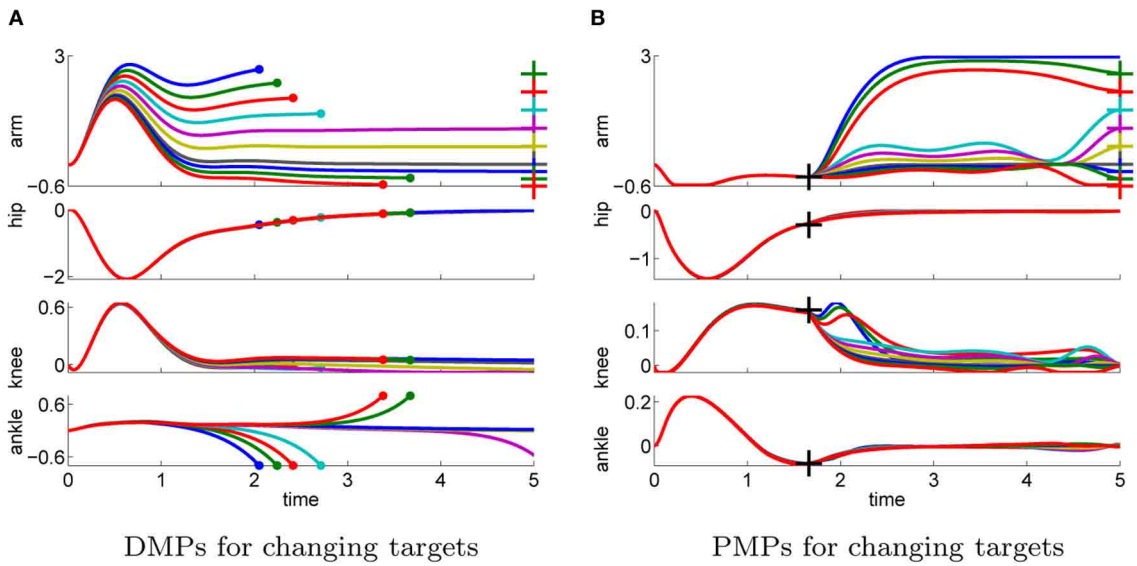

FIGURE 10 | This figure illustrates the joint angle trajectories (arm, hip, knee, and ankle) of a 4-link robot model during a balancing movement for different final targets of the arm joint (3, 2.5, 2, 1.5, 1, 0.5, 0, −0.2, −0.4, −0.6). The applied policies were learned for a final arm posture of $\phi_{\tau_{\text{arm}}} = 0$. **(A)** The valid range of the arm joint using DMPs is $\phi_{\tau_{\text{arm}}} \in [-0.2, 1]$. Large dots in the plot indicates that the robot has fallen. **(B)** PMPs could generate valid policies for all final arm configurations.

DMPs shows a similar result as for the via-point task. With the PMPs we could find movements of significantly higher quality compared to the DMPs and the motor skill could be learned up to one order of magnitude faster with PMPs. We again applied the same parameters to different initial or final states to demonstrate the generalization ability. Now we can see the advantage of the learned task-relevant features. While the PMPs still try to fulfill the extracted task-relevant constraints and therefore succeeded for almost all initial/final state configurations, the DMPs again just heuristically scale the trajectory, which results in the robot falling in almost all but the learned configurations. Finally we showed that the dynamic model could be learned in parallel for the 4-link balancing task.

For all balancing experiments shown in this section the robot was pushed with the specific force $F = 25$ Ns. We have performed the same evaluations for various forces and the results are basically the same. For example, a comparison of the learning performances using the negative force $F = -25$ Ns is shown in **Figure 13**. The executed movement of the best learned policy using PMPs is shown in **Figure 14**.

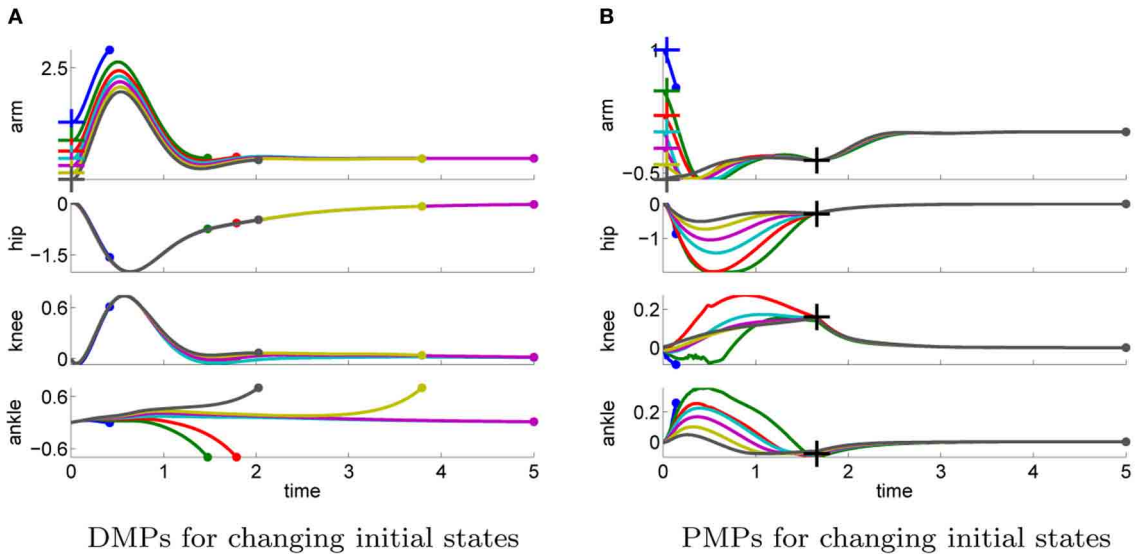

FIGURE 11 | This figure illustrates the joint angle trajectories (arm, hip, knee and ankle) of a 4-link robot model during a balancing movement for different initial states of the arm joint (1, 0.5, 0.2, 0, −0.2, −0.4, −0.6). The applied policies were learned for an initial arm posture of $\phi_{1_{\text{arm}}} = 0$. **(A)** The valid range of the arm joint using DMPs is $\phi_{1_{\text{arm}}} \in [-0.2, 0]$. Large dots in the plot indicates that the robot has fallen. **(B)** PMPs could generate valid policies for $\phi_{1_{\text{arm}}} \in [-0.6, 0.5]$.

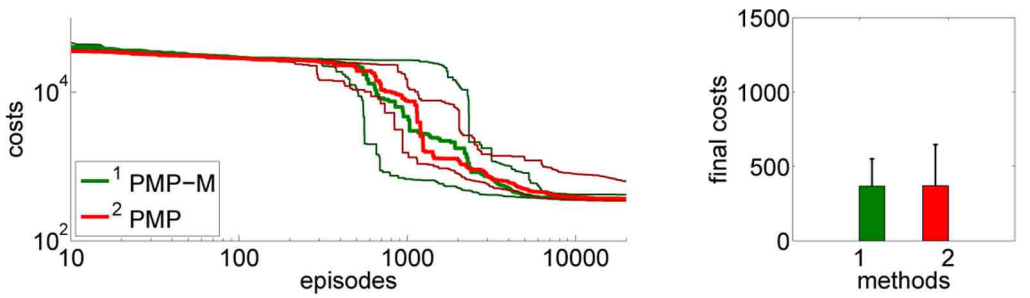

FIGURE 12 | This figure shows the influence of model learning on the 4-link balancing task. Illustrated are mean values and standard deviations over 20 runs. The learning performance with the given system model is denoted by PMP. Instead of using the given model we now want to learn the system model from data (as described in section 3.3), which is denoted by PMP-M. In the beginning of learning the extrinsic costs are larger compared to motor skill learning with a given analytic model. However, as the number of collected data-points $([\mathbf{x}_t; \mathbf{u}_t], \dot{\mathbf{x}}_t)$ increases the PMPs with model learning quickly catch up and converge finally to the same costs. The PMP representation with model learning in parallel considerably outperforms the trajectory-based DMP approach in learning speed and in the final costs.

In total 40 weights and 8 control gains were learned with DMPs. For PMPs we used 2 via-points where the second one was fixed. Thus, we learned 8 parameters specifying the first via-point and additionally 12 importance weights for each via-point. This results in 32 parameters.

5. DISCUSSION

In this paper we concentrated on three aspects of biological motor control, which are also interesting for robotic motor skill learning: (1) the modularity of the motor system, which makes it possible to represent high-dimensional action spaces in terms of lower-dimensional MPs, (2) its variability and behavior under stochasticity, and (3) the efficiency in learning movement strategies.

In order to achieve similar properties also for robotic motor skill learning we propose to exploit the power of SOC already at the level of the MP. Instead of endowing a MP with a dynamical system, like the DMPs (Schaal et al., 2003), we endow a MP with an intrinsic probabilistic planning system. The resulting MP is called PMP. For the dynamical systems approach the parameters of the MP indirectly define the shape of the trajectory. In our case, the parameters of the MP define the intrinsic cost function of a graphical model, which represents a SOC problem. Performing inference in this graphical model yields the controls for executing the movement.

Due to the use of the intrinsic planning system our representation complies with basic principles of SOC. For example, the PMPs are able to account for the motor variability often observed

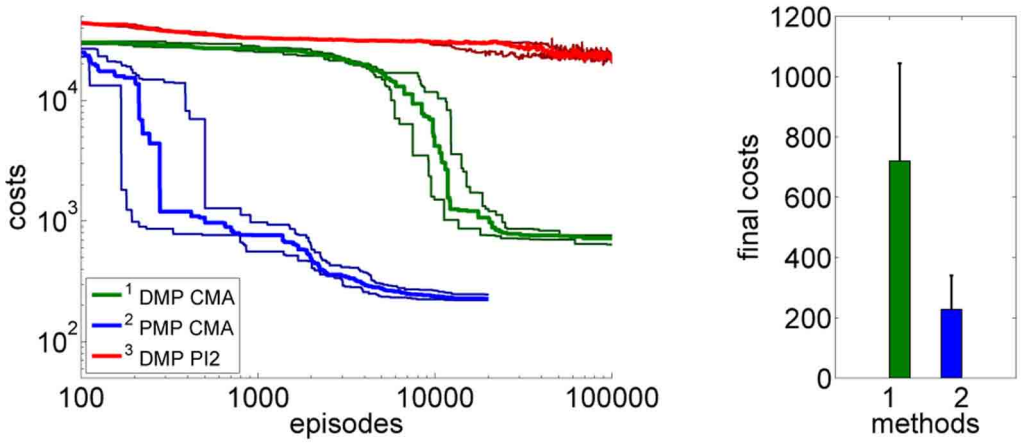

FIGURE 13 | This figure illustrates the learning performance of the two movement representations, DMPs and PMPs for the 4-link balancing task. But in contrast to the evaluations shown in the experimental section did we here apply a *negative* force F = −25 Ns. Illustrated are mean values and standard deviations over 20 runs after CMA policy search. The controls (torques) are perturbed by zero-mean Gaussian noise with $\sigma = 10$ Nm. Using the proposed Planning Movement Primitives good policies could be found at least one order of magnitude faster compared to the trajectory-based DMP approach. Also, the quality of the best-found policy was considerably better for the PMP approach (720 ± 323 for the DMPs and 227 ± 112 for the PMPs). For the DMP approach we additionally evaluated PI^2 for policy search which could not find good policies.

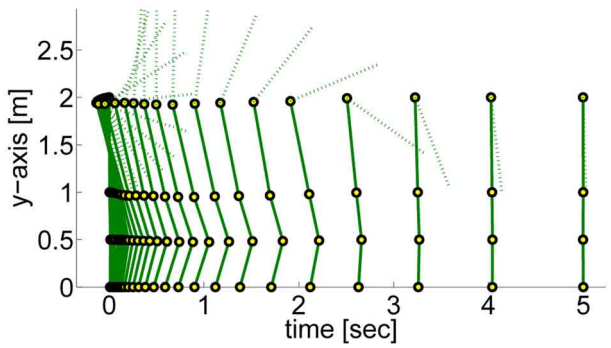

FIGURE 14 | This figure illustrates a dynamic balancing movement learned using the proposed Planning Movement Primitives. The 4-link robot modelling a humanoid (70 kg, 2 m) gets pushed with the specific force ($F = -25$ Ns) and has to move such that it maintains balance. The circles denote the ankle, the knee, the hip, and the shoulder joint.

in human motion. Instead of suppressing the noise of the system by following a single reference trajectory, the PMPs are able to learn to intervene the system only if it is necessary to fulfill a given task, also known as the minimum intervention principle (Todorov and Jordan, 2002). This allows a much higher variance in parts of the trajectory where less accuracy is needed. Current methods which rely on a reference trajectory are not able to reproduce these effects.

The parameters of PMPs encode learned task-relevant features of the movement, which are used to specify the intrinsic cost function for the MP's intrinsic planning system. Our experiments have shown that such a task-related parameterization facilitates learning and generalization of movement skills. Policies of higher quality could be found an order of magnitude faster than with the competing DMP approach. In addition, as confirmed by our experiments, the intrinsic planner also allows a wide generalization of the learned movement, such as generalization to different initial or goal positions. The DMPs on the other hand have to use heuristics for this generalization (Pastor et al., 2009), which had the consequence that the robot typically fell over in a new situation. In this case relearning is needed for the DMPs while the PMPs allow to reuse the learned parameters.

In traditional SOC methods (Todorov and Li, 2005; Kappen, 2007; Toussaint, 2009) the intrinsic cost function is typically hand-crafted. In contrast we learn the cost function from experience. We considered a general class of motor skill learning tasks where only a scalar reward is observed for the whole movement trajectory. Thus, with PMPs this external sparse reward signal is used to learn the intrinsic cost function. We applied the second order stochastic search method CMA (Hansen et al., 2003) for finding appropriate intrinsic cost functions. In this paper we focused on the representation of movements, and placed less emphasis on a specific policy search method. We want to point out again that our method does not depend on the used policy search method, any episode-based exploring policy search method can be used. We also do not want to argue for using episode-based exploring methods for policy search, however, as our experiments show, these methods provide useful alternatives to the more commonly used step-based approaches such as the PI^2 algorithm (Theodorou et al., 2010). Future work will concentrate on more grounded approaches for extracting immediate costs from a sparse reward signal. This can also be of interest for imitation learning, where we do not know the immediate costs used by the demonstrator, but often we can evaluate the demonstrators behavior by an external reward signal.

The planner requires to know the system dynamics, which we also learn from data. As shown by our experiments this can be done without significant loss of performance. Hence, our approach combines model-based and model-free RL. As in

model-based RL, we learn a system model to plan with. Model-free RL is used as method to search for appropriate intrinsic cost functions. We used the LWR (Atkeson et al., 1997) for learning the system dynamics as it is a very simple and effective approach. Future work will also concentrate on more complex robot models where more sophisticated methods like Vijayakumar et al. (2005), Nguyen-Tuong et al. (2008a), and Nguyen-Tuong et al. (2008b) could be applied for model learning.

In our experiments the number of phases was fixed ($N = 2$). It was assumed as prior knowledge and can model the complexity of the movement representation (Similarly, the complexity of DMPs can be scaled by the number of Gaussian activation functions). During our experiments we also evaluated the balancing task with up to $N = 5$ phases, but more than 2 phases did not improve the quality of the learned policy. One via-point on the other hand was not sufficient to describe the movement.

A promising topic for future investigation is the combination of primitives in order to achieve several tasks simultaneously. This is still a mostly unsolved problem for current movement representations. Because of the non-linear task demands and system dynamics a naive linear combination in trajectory space usually fails. Here, our PMPs offers new opportunities. New movements can be inferred by a linear combination of cost functions, which results in a non-linear combination of the policies for the single tasks.

APPENDIX

A. DYNAMIC MOVEMENT PRIMITIVES

The most prominent representation for movement primitives (MPs) used in robot control are the DMP (Schaal et al., 2003). We therefore used the DMPs as a baseline in our evaluations and will briefly review this approach in order to clarify differences to our work. For our experiments we implemented an extension of the original DMPs (Pastor et al., 2009), which considers an additional term in the dynamical system which facilitates generalization to different target states. For more details we refer to Schaal et al. (2003) and Pastor et al. (2009).

DMPs generate multi-dimensional trajectories by the use of non-linear differential equations. The basic idea is to a use for each degree-of-freedom (DoF) of the robot a globally stable, linear dynamical system which is modulated by learnable non-linear functions f :

$$\tau\dot{z} = \alpha_z\beta_z(g - y) - \alpha_z z - \alpha_z\beta_z(g - y_1)s + f, \tau\dot{y} = z,$$

where the desired final position of the joint is denoted by g and the initial position of the joint is denoted by y_1. The variables y and $\dot{y}$ denote a desired joint position and joint velocity, which represent our movement plan. The temporal scaling factor is denoted by τ and α_z and β_z are time constants. The non-linear function f directly modulates the derivative of the internal state variable z. Thus, f modulates the desired acceleration of the movement plan. s denotes the phase of the movement.

For each DoF of the robot an individual dynamical system, and hence an individual function f is used. The function f only depends on the phase s of a movement, which represents time, $\tau\dot{s} = -\alpha_s s$. The phase variable s is initially set to 1 and will converge to 0 for a proper choice of τ and α_s. With α_s we can modulate the desired movement speed. The function f is constructed of the weighted sum of K Gaussian basis functions Ψ_i

$$f(s) = \frac{\sum_{i=1}^{K} \Psi_i(s) w_i s}{\sum_{i=1}^{K} \Psi_i(s)}, \quad \Psi_i(s) = \exp(-\frac{1}{2\sigma_i^2}(s - c_i)^2).$$

As the phase variable s converges to zero also the influence of f vanishes with increasing time. Hence, the dynamical system is globally stable with g as point attractor.

In our setting, only the linear weights w_i are parameters of the primitive which can modulate the shape of the movement. The centers c_i specify at which phase of the movement the basis function becomes active and are typically equally spaced in the range of s and not modified during learning. The bandwidth of the basic functions is given by σ_i^2.

Integrating the dynamical systems for each DoF results into a desired trajectory $\langle \mathbf{y}_t, \dot{\mathbf{y}}_t \rangle$ of the joint angles. We will use an inverse dynamics controller to follow this trajectory (Peters et al., 2008). The inverse dynamics controller receives the desired accelerations $\ddot{\mathbf{q}}_{\text{des}}$ as input and outputs the control torques $\mathbf{u}$. In order to calculate the desired accelerations we use a simple decoupled linear PD-controller

$$\ddot{\mathbf{q}}_{\text{des}} = \text{diag}(\mathbf{k}_{\text{pos}})(\mathbf{y}_t - \mathbf{q}_t) + \text{diag}(\mathbf{k}_{\text{vel}})(\dot{\mathbf{y}}_t - \dot{\mathbf{q}}_t). \quad (7)$$

Unfortunately standard inverse dynamics control did not work in our setup because we had to deal with control limits of multi-dimensional systems. Thus, we had to use an inverse dynamics controller which also incorporates control constraints. For this reason we performed an iterative gradient ascent using the difference between the actual (using constrained controls) and the desired accelerations $\ddot{\mathbf{q}}_{\text{des}}$ as error function. This process was stopped after at most 25 iterations.

For our comparison, we will learn the linear weights $\mathbf{w}$ for each DoF as well as the controller gains $\mathbf{k}_{\text{pos}}$ and $\mathbf{k}_{\text{vel}}$, i.e., $\boldsymbol{\theta} = [\mathbf{w}_1, \ldots, \mathbf{w}_D, \mathbf{k}_{\text{pos}}, \mathbf{k}_{\text{vel}}]$. This results into $KD + 2D$ parameters for the movement representation, where D denotes the number of DoF of the robot.

B. TASK SETTINGS AND PARAMETERS

In this section the MP parameters and constants are specified for the one-dimensional via-point task and for the humanoid balancing task.

B.1 ONE-DIMENSIONAL VIA-POINT TASK

For the one-dimensional via-point task the parameters of the Dynamic Movement Primitives are listed in **Table A1**. The valid configuration space for the policy search algorithm is listed in **Table A2**. The CMA policy search algorithm has just one parameter, the exploration rate. Where the best exploration rate using DMPs for this task found was 0.05.

The limits of the parameterization of the Planning Movement Primitives (PMPs) (see Equation 4) is listed in **Table A3**. For the via-point task we choose $N = 2$, where the second via-point $g^{[N]} = g_T$ was given. The exploration rate was set to 0.1 in all experiments.

Table A1 | Via-point task: DMP movement primitive parameters.

K	α_s	α_z	β_z	τ
10	1	2	0.9	0.1

Table A2 | Via-point task: DMP policy search configuration parameters.

	w	$\mathbf{k}_{\text{pos}}$	$\mathbf{k}_{\text{vel}}$
Lower bound	−100	0	0
Upper bound	+100	100	100

Table A3 | Via-point task: PMP policy search configuration parameters with $i = 1,2$.

	$\mathbf{d}^{[1]}$	$\mathbf{g}^{[1]}$	$\mathbf{r}^{[i]}$	$\mathbf{h}^{[i]}$
Lower bound	0.05	−2	$[1, 10^{-6}]$	10^{-4}
Upper bound	0.4	+2	$[10^6, 10^4]$	10^{-2}

B.2 DYNAMIC HUMANOID BALANCING TASK

The DMP parameters for the balancing task are listed in **Table A4**. The policy search parameters are the same like for the via-point task, **Table A2**. The exploration rate was set to 0.1.

The PMPs were again evaluated with $N = 2$ via-points, where the second via-point $g^{[N]} = g_T$ (the up-right robot posture) was given and for the first via-point the valid joint angle configuration is shown in Table 1 in Rückert and Neumann (2012). The exploration rate was 0.1 and the policy search algorithm configuration is listed in **Table A5**.

In the generalization experiment we applied the same learned policy of the 4-link balancing task to different initial states. For different initial arm joint configurations the push modulated with F resulted in different initial joint velocities, which are shown in **Table A6**.

Table A4 | Balancing task: DMP movement primitive parameters.

K	α_s	α_z	β_z	τ
10	1	5	5	1

Table A5 | Balancing task: PMP policy search configuration parameters with $i = 1, 2$.

	$\mathbf{d}^{[1]}$	$\mathbf{r}^{[i]}$	$\mathbf{h}^{[i]}$
Lower bound	0.1	10^{-2} for angles and 10^{-4} for velocities	$10^{-9}\mathbf{1}$
Upper bound	4.6	10^{4} for angles and 10^{2} for velocities	$10^{-3}\mathbf{1}$

Vector $\mathbf{1}$ *denotes a 4-dimensional column vector, where all elements are equal to 1.*

Table A6 | Initial velocities (multiplied by $10^2/F$) for different initial states of the arm joint $\phi_{0_{\text{arm}}}$.

$\phi_{0_{\text{arm}}}$	Arm	Hip	Knee	Ankle
1	−2.39	7.56	−8.54	1.42
0.5	−3.61	6.12	−7.9	1.32
0.2	−4.15	5.29	−7.52	1.25
0	−4.27	5.09	−7.43	1.24
−0.2	−4.15	5.29	−7.52	1.25
−0.4	−3.82	5.8	−7.75	1.29
−0.6	−3.43	6.38	−8	1.34

A wide range of blind source separation methods have been used in motor control research for the extraction of movement primitives from EMG and kinematic data. Popular examples are principal component analysis (PCA), independent component analysis (ICA), anechoic demixing, and the time-varying synergy model (d'Avella and Tresch, 2002). However, choosing the parameters of these models, or indeed choosing the type of model, is often done in a heuristic fashion, driven by result expectations as much as by the data. We propose an objective criterion which allows to select the model type, number of primitives and the temporal smoothness prior. Our approach is based on a Laplace approximation to the posterior distribution of the parameters of a given blind source separation model, re-formulated as a Bayesian generative model. We first validate our criterion on ground truth data, showing that it performs at least as good as traditional model selection criteria [Bayesian information criterion, BIC (Schwarz, 1978) and the Akaike Information Criterion (AIC) (Akaike, 1974)]. Then, we analyze human gait data, finding that an anechoic mixture model with a temporal smoothness constraint on the sources can best account for the data.

Keywords: motor primitives, blind source separation, temporal smoothing, model selection, laplace approximation, bayesian methods, movement primitives

1. INTRODUCTION

In recent years substantial experimental evidence has been provided that supports the hypothesis that complex motor behavior is organized in modules or simple units called movement primitives (Flash and Hochner, 2005; Bizzi et al., 2008). In this framework each module, or motor primitive, consists of a set of movement variables, such as joint trajectories (Santello et al., 1998; Kaminski, 2007) or muscle activations (d'Avella et al., 2006; Chiovetto et al., 2010) acting synergistically over time. By combination of small numbers of these primitives complex motor behaviors can be generated. Several methods have been used so far in the literature for the identification of motor primitives starting from experimental data sets, which include both well-known classical unsupervised learning techniques based on instantaneous mixture models, such as principal component analysis (PCA) and independent component analysis (ICA) (Chiovetto et al., 2010; Dominici et al., 2011), or even more advanced techniques that include the estimation of temporal delays of the relevant mixture components (d'Avella et al., 2006; Omlor and Giese, 2011). On the one hand, all these approaches differ from each other in multiple aspects, such as their underlying generative models or the specific priors imposed on the parameters. On the other hand, however, for all of them the number of primitives to be extracted and subsequently used to approximate the original data has to be set a priori. To our knowledge only very few motor control studies have so far addressed the problem of model selection in a principled way, see e.g., Delis et al. (2013); Hart and Giszter (2013) for notable exceptions. The existing generative models for the extraction of motor primitives have indeed been demonstrated to provide a low-dimensional decomposition of the experimental data, but no clear criterion has been developed to objectively determine which model is best suited for describing the statistical features of the data under investigation. We are concerned with two types of statistical features:

- "hard" constraints, such as the number of primitives. Determining this number is also known as "model order estimation."
- "Soft" constraints, e.g., regularity measures. In other words, a constraint on a parameter is "soft," if it expresses a preference or expectation for the parameter's value, but does allow for deviation from this preference given sufficient evidence. For example, when modeling human walking, we expect a periodic movement with predominantly low frequency components. However, higher frequency components might be critical to capture specific, more complex movement primitives. We therefore would like to allow for the possibility of overriding our initial expectations if the data indicate that this is appropriate. One such regularity measure, *temporal smoothness* quantified by a kernel function, is a novelty of our approach in the context of model selection for blind source separation in motor control.

Concerning the model order selection, several criteria have been developed. Most of them require the computation of the likelihood function (Schwarz, 1978; Akaike, 1987; Basilevsky, 1994; Minka, 2000; Zucchini, 2000) and attempt to determine the right model order as the one that offers the best trade-off between accuracy of data fitting and complexity of the model. Our approach uses this trade-off in a more general setting. Such information criteria were proven to identify with almost no error the model

order of noisy data sets when these were corrupted with Gaussian noise, but performances were shown to be noticeably worse when data were corrupted with signal-dependent noise (Tresch et al., 2006), which is actually thought to affect strongly the neural control signals (Harris and Wolpert, 1998). In this article we present a new objective criterion for model-order selection that extends the other classical ones based on information-theoretic and statistical approaches. The criterion is based on a Laplace approximation of the posterior distribution of the parameters of a given blind source separation method, re-formulated as a Bayesian generative model. We derive this criterion for a range of blind source separation approaches, including for the first time the anechoic mixture model (AMM) described in Omlor and Giese (2011).

We provide a validation of our criterion based on an artificial ground truth data set generated in such a way to present well-known statistical properties of real kinematic data. We show in particular that our method performs at least as well as other traditional model order selection criteria [Akaike's Information Criterion, AIC (Akaike, 1974) and the Bayesian Information Criterion, BIC (Schwarz, 1978)], that it works for both instantaneous and delayed mixtures and allows to distinguish between these given moderately sized datasets, and that it can provide information regarding the level of temporal smoothness of the generating sources.

We finally apply the criterion to actual human locomotion data, to find that, differently from other standard synchronous linear models, a linear mixture of time shiftable components characterized by a specific degree of temporal smoothness is a better account of the data-generating process.

1.1. RELATED APPROACHES

The well-known plug-in estimators, BIC and AIC, have the advantage of being easy to use when a likelihood function for a given model is available. Hence, they are often the first choice for model order estimation, but not necessarily the best one. In Tu and Xu (2011) several criteria for probabilistic PCA (or factor analysis) models were evaluated, including AIC, BIC, MIBS (Minka's Bayesian model selection) (Minka, 2000) and Bayesian Ying-Yang (Xu, 2007). The authors found that MIBS and Bayesian Ying-Yang work best. The approach presented in Kazianka and Pilz (2009) corrected the approximations made in MIBS, which yielded improved performance on small sample sizes. This corrected MIBS performed better than all other approaches tested in that paper, including AIC and BIC.

The authors of Li et al. (2007) estimated the number of independent components in fMRI data with AIC and minimum description length [MDL, (Rissanen, 1978)], which boils down to BIC. They showed that temporal correlations adversely affect the accuracy of standard complexity estimators, and proposed a subsampling procedure to remove these correlations. In contrast, we demonstrate below how to deal with temporal dependence as a part of our model. Another MDL-inspired approach, code length relative to a Gaussian prior (CLRG) was introduced in Plant et al. (2010) to compare different ICA approaches and model orders. It was demonstrated to work well on simulated data without the need of choosing additional parameters, such as thresholds, and it was shown that it is able to recover task-related fMRI components better than heuristic approaches.

Such heuristic approaches typically utilize some features of the reconstruction error (or conversely, of the variance-accounted-for (VAF)) as a function of the model order, e.g., finding a "knee" (inflection point) in that function, a procedure which is inspired by the scree test for factor analysis (Cattell, 1966). For example, the authors of Cheung and Xu (1999) experimented with an empirical criterion for ICA component selection. The independent components were ordered according to their contribution to the reduction of reconstruction error. Only those independent components were retained that had a large effect on this error. Similarly, the approach of Sawada et al. (2005) used "unrecovered power," which is basically reconstruction error, to determine which components of a (reverberant) mixture are important. The work in Valle et al. (1999) compared various criteria for PCA component selection on real and simulated chemical reactor data, finding that some of the heuristic reconstruction-error based methods still perform well when PCA model assumptions are violated by the data-generating process.

To distinguish convolutive (but undelayed) mixtures from instantaneous ones, the work in Dyrholm et al. (2007) employed the framework of Bayesian model selection for the analysis of EEG data. Related to our approach, the authors of Penny and Roberts (2001) derived Laplace approximations to the marginal likelihood of several ICA model classes for model selection and model order determination. Their work is conceptually similar to our approach, but we also consider delayed mixtures.

All approaches reviewed so far are deterministic in nature. There are also sampling methods available for model selection purposes, see Bishop (2007) for details. One example is e.g., the work of Ichir and Mohammad-Djafari (2005) which used importance sampling and simulated annealing for model-order selection of L1-sparse mixtures.

2. MATERIALS AND METHODS

We develop our model (order) criterion in the framework of Bayesian generative model comparison Bishop (2007). Let D be observable data, Θ_M a tuple of model parameters for a model indexed by M (the "model index") and Φ a tuple of hyperparameters. Using standard terminology, we denote

$$\text{likelihood} : p\left(D|\Theta_M, \Phi, M\right) \tag{1}$$

$$\text{prior} : p\left(\Theta_M|\Phi, M\right). \tag{2}$$

The likelihood is the probability density of the data given the model parameters, model index and hyperparameters. The parameter prior is the probability density of the model parameters. Then the marginal likelihood of M, or model evidence for M is given by

$$\begin{aligned} p(D|\Phi, M) &= \int d\Theta_M p\left(D, \Theta_M|\Phi, M\right) \\ &= \int d\Theta_M p(D|\Theta_M, \Phi, M) p\left(\Theta_M|\Phi, M\right) \end{aligned} \tag{3}$$

where the second equality follows from the product rule for probability distributions. Strictly speaking, the Φ would have to be integrated out as well after choosing a suitable prior for them. However, to keep the problem tractable we determine their value by maximizing the model evidence with respect to them, finding that this yields sufficiently good approximations for our purposes. Once we have evaluated Equation 3 for all M, we can select that M which maximizes the model evidence, since we have no *a-priori* preference for any M.

To apply this model selection framework, we reformulate three popular blind source separation (BSS) methods, namely probabilistic PCA (pPCA), ICA and anechoic demixing as generative models in section 2.1. This reformulation allows us to evaluate their likelihoods and parameter priors. We then use a Laplace approximation (Laplace, 1774) to compute an approximation to the marginal likelihood of each model. This approximation is derived in section 2.2.

2.1. GENERATIVE MODELS OF BLIND SOURCE SEPARATION METHODS

The BSS methods we consider all assume a linear generative model in discrete time, where observable data $\mathbf{X}$ can be written as a linear superposition of sources $\mathbf{S}$ multiplied by weights $\mathbf{W}$. Let $t = 1, \ldots, t$ be the T (equally spaced) time points, $i = 1, \ldots, I$ the source index, and $j = 1, \ldots, J$ the signal index. Note that J could also be interpreted as a trial index, i.e., one signal repeated J times, or any combination of trials and signals. For the models we consider, there is no formal difference between "trial" and "signal," as opposed to e.g., the time varying synergy model (d'Avella et al., 2006). Then $\mathbf{X}$ is a $(J \times T)$ matrix, $\mathbf{S}$ is $(I \times T)$ and consequently $\mathbf{W}$ must be $(J \times I)$ so that

$$\mathbf{X} = \mathbf{WS} + \mathbf{\Sigma} \tag{4}$$

$$\Sigma_{jt} \sim \mathcal{N}\left(0, \sigma_n^2\right) \tag{5}$$

where the entries of the noise matrix $\mathbf{\Sigma}$ are drawn independently from a Gaussian distribution with zero mean and variance σ_n^2. In an anechoic (delayed) mixture, the sources additionally depend on the signal index j (see section 2.1.3 for details).

The differences between the BSS approaches can be expressed as priors on $\mathbf{S}$ and $\mathbf{W}$, which we describe in the following.

2.1.1. Probabilistic PCA (pPCA)

PCA is one of the most widely used BSS approaches. In Tipping and Bishop (1999), it was demonstrated how PCA results from a probabilistic generative model: assuming the data have mean zero (i.e., $\forall j : \sum_t \mathbf{X}_{jt} = 0$), and using an independent zero-mean Gaussian prior on the sources, i.e.,

$$\mathbf{S}_{it} \sim \mathcal{N}\left(\mu = 0, \sigma^2\right) \tag{6}$$

the weights $\mathbf{W}$ which maximize the marginal likelihood of $\mathbf{X}$ after integrating out $\mathbf{S}$, are given by the scaled (and possibly rotated) principal I eigenvectors of the $(J \times J)$ data covariance matrix, $\frac{1}{T}\mathbf{X}\mathbf{X}^T$. This model differs from PCA insofar as the sources will only be equal to the PCA factors in the noise-free limit $\sigma_n \to 0$, and is hence referred to as *probabilistic* PCA (Tipping and Bishop, 1999). Similarly, when we put a prior on the weights

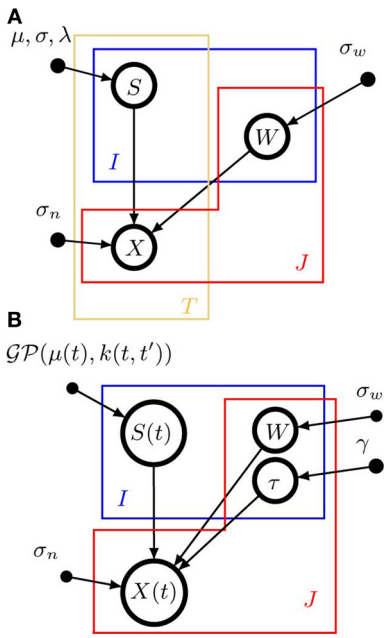

FIGURE 1 | Graphical model representations of the blind source separation algorithms for which we compute a model evidence approximation. We follow standard graphical modeling terminology (see e.g., Bishop, 2007). Open circles represent random variables, which may also be random functions. Filled circles are parameters. Arrows denote conditional dependencies. The *plates* (colored frames) indicate that the enclosed structure is repeated as often as the corresponding letter indicates. Enclosure in multiple plates indicates a product of repetitions. For example, in panel **(A)** there are $I \times T$ random variables S which comprise the source matrix. **(A)** Instantaneous, undelayed mixtures such as pPCA (where $\lambda = 0$) and ICA. $J \times T$ signals X are computed by mixing $I \times T$ sources S with $J \times I$ weights W. σ_w is the standard deviation of the zero-mean Gaussian prior on the weights. σ_n is the noise standard deviation. μ and σ are the parameters of the Gaussian part of the prior on the sources, λ measures the deviation from Gaussianity. **(B)**. Convolutive, delayed mixtures, like the anechoic mixture of Omlor and Giese (2011) with additional temporal smoothness constraints. I source functions $S(t)$ are drawn from a Gaussian process $\mathcal{GP}(\mu(t), k(t,t'))$ with mean function $\mu(t)$ and kernel $k(t,t')$. These sources are shifted in time by $J \times I$ many delays (one per trial and source) drawn from an exponential distribution with parameter γ and mixed with $J \times I$ weights W which are drawn from a zero-mean Gaussian distribution with standard deviation σ_w, to yield J signals $X(t)$. For details, see text.

$$\mathbf{W}_{ji} \sim \mathcal{N}\left(0, \sigma_w^2\right) \tag{7}$$

and integrate them out, we find that the best I sources $\mathbf{S}$ are the principal eigenvectors of the $(T \times T)$ data covariance matrix $\frac{1}{J}\mathbf{X}^T\mathbf{X}$ (assuming zero mean signals at every time step, i.e., $\forall t : \sum_j \mathbf{X}_{jt} = 0$). We will therefore use both priors for a completely probabilistic pPCA model[1].

A graphical model representation of pPCA is shown in **Figure 1A**. Open circles represent random variables, which may

[1]We will refer to this model interchangeably by pPCA or just PCA in the following.

also be random functions. Filled circles are parameters. Arrows denote conditional dependencies. The *plates* (colored frames) indicate that the enclosed structure is repeated as often as the corresponding letter indicates. Enclosure in multiple plates indicates a product of repetitions. Thus, in a pPCA model, $I \times T$ sources are *a-priori* drawn independently of each other (μ and σ are parameters, not random variables), and source values have no dependencies across time. Likewise, weights have no dependencies across sources or signals. In contrast, data points depend on both weights and sources, as indicated by the arrows converging on **X** from **S** and **W**.

Given the generative model (Equation 4) and the prior specification (Equation 6 and Equation 7), we can now write down the likelihood and prior terms which we need for the evaluation of the model evidence (Equation 3). To this end, we identify the number of sources I with the model index M, and (cf. Equation 3)

$$D = \mathbf{X} \tag{8}$$

$$\Theta_M = (\mathbf{W}, \mathbf{S}) \tag{9}$$

$$\Phi = (\mu, \sigma, \sigma_w, \sigma_n) \tag{10}$$

$$p\left(D|\Theta_M, \Phi, M\right) = \frac{\exp\left(-\frac{1}{2\sigma_n^2}\left\|\mathbf{X} - \mathbf{WS}\right\|_F\right)}{\sqrt{2\pi\sigma_n^2}^{JT}} \tag{11}$$

$$p(\Theta_M|\Phi, M) = \frac{\exp\left(-\frac{1}{2\sigma^2}\left\|\mathbf{S}_{it} - \mu \cdot \mathbf{1_{IT}}\right\|_F\right)}{\sqrt{2\pi\sigma^2}^{IT}} \times \frac{\exp\left(-\frac{1}{2\sigma_w^2}\left\|\mathbf{W}\right\|_F\right)}{\sqrt{2\pi\sigma_w^2}^{JI}} \tag{12}$$

where $\mathbf{1}_{IT}$ is an $(I \times T)$ matrix with every element being 1, and $\|\mathbf{A}\|_F$ is the Frobenius norm of matrix **A**.

2.1.2. Independent Component Analysis (ICA)

The term ICA refers to a variety of BSS methods which try decompose signals into sources with two main goals:

1. The sources are as statistically independent as possible according to some suitably chosen measure, and
2. the sources allow for a good reconstruction of the signals.

Infomax ICA (Bell and Sejnowski, 1995) tries to achieve these goals by maximizing the mutual information (Cover and Thomas, 1991) between sources and signals, which clearly promotes the second goal. The first one is promoted if the BSS system contains an information bottleneck, e.g., fewer sources than signals. In that case, maximizing mutual information amounts to maximizing the total source entropy, which is achieved if the sources are independent.

The FastICA algorithm (Hyvarinen, 1999) aims directly at minimizing the mutual information between the sources, thereby promoting goal one. Goal 2 is achieved by constraining the (linear) transformation from signals to the sources to be invertible, or at least almost invertible in the noisy or lossy case, such that the signals can be reconstructed using the generative model above (Equation 4). Mutual information is measured via *negentropy*, which is the negative difference between the entropy of a source and the entropy of a variance-matched Gaussian variable, i.e., it is a measure of non-Gaussianity. Maximizing negentropy then minimizes mutual information. To measure negentropy, the authors of Hyvarinen (1999) used the "contrast function" approach developed in Hyvärinen (1998). Contrast functions provide constraints on expectations of probability distributions, in addition to the mean and variance constraints of Gaussians. Consequently, the maximum entropy distributions obeying these constraints have the contrast function(s) as sufficient statistics, with an associated natural parameter, which controls the deviation of the resulting distribution from a Gaussian. For a detailed derivation see Hyvärinen (1998). This motivates the following source prior for probabilistic ICA models: let $G(.)$ be the contrast function, then

$$p\left(\mathbf{S}_{it}\right) = \frac{1}{Z(\mu, \sigma, \lambda)} \exp\left(-\frac{1}{2\sigma^2}(\mathbf{S}_{it} - \mu)^2 + \lambda G(\mathbf{S}_{it} - \mu)\right) \tag{13}$$

where λ is the natural parameter associated with $G(.)$. The normalization constant $Z(\mu, \sigma, \lambda)$ can be evaluated by numerical integration, since the prior is a density over a one-dimensional random variable. Similar to pPCA, we use a Gaussian prior on the weights. The graphical model representation of ICA is the same as for pPCA (see **Figure 1A**), since there is no a-priori dependency between sources or weights across time.

We can now identify the number of sources I with the model index M, and furthermore (cf. Equation 3)

$$D = \mathbf{X} \tag{14}$$

$$\Theta_M = (\mathbf{W}, \mathbf{S}) \tag{15}$$

$$\Phi = (\mu, \sigma, \sigma_w, \sigma_n, \lambda) \tag{16}$$

$$p(D|\Theta_M, \Phi, M) = \frac{\exp\left(-\frac{1}{2\sigma_n^2}\left\|\mathbf{X} - \mathbf{WS}\right\|_F\right)}{\sqrt{2\pi\sigma_n^2}^{JT}} \tag{17}$$

$$p(\Theta_M|\Phi, M) = \prod_{i,t} p(\mathbf{S}_{it}) \times \frac{\exp\left(-\frac{1}{2\sigma_w^2}\left\|\mathbf{W}\right\|_F\right)}{\sqrt{2\pi\sigma_w^2}^{JI}} \tag{18}$$

2.1.3. Anechoic mixture models (AMM) and smooth instantaneous mixtures (SIM)

AMMs may be seen as an extension of the above BSS approaches to deal with time-shifted sources (Omlor and Giese, 2007a). Such time shifts are obviously useful in motor control, where coordinated movement patterns, such as gaits, might be characterized by opposite joints moving in a similar manner but time-shifted against each other (e.g., the legs during walking); the well-known time-varying synergy model (d'Avella et al., 2006) is a kind of AMM. The generative models of AMMs are linear with additive Gaussian noise (similar to Equation 4), but the sources $S_i(t)$ are shifted by delays τ_{ji}, which are the elements of a $(J \times I)$ matrix τ. We draw these delays from an exponential prior with mean γ,

which promotes delays that differ sparsely from zero.

$$\mathbf{X}_{jt} = \sum_i \mathbf{W}_{ji} S_i(t - \tau_{ji}) + \eta_{jt}$$

$$= \sum_i \hat{\mathbf{X}} + \eta_{jt} \tag{19}$$

$$\eta_{jt} \sim \mathcal{N}(0, \sigma_n) \tag{20}$$

$$p(\tau_{ji}) = \gamma \exp\left(-\frac{\tau_{ij}}{\gamma}\right) \tag{21}$$

where we define the matrix of the reconstructed signals $\hat{\mathbf{X}}$ as $\hat{\mathbf{X}}_{ji} = \sum_i \mathbf{W}_{ji} S_i(t - \tau_{ji})$. Moreover, we impose soft temporal regularity constraints on the sources. To this end, we draw the sources from a Gaussian process (GP) (Rasmussen and Williams, 2006) with mean function $\mu(t)$ and covariance (or kernel) function $k(t, t')$. A GP is a prior over functions $S(t)$ where the joint distribution of any finite number of function values at times $t_1, \ldots, t_N$ follows a multivariate Gaussian distribution i.e.,

$$\vec{S} = (S(t_1), \ldots, S(t_N)) \tag{22}$$

$$\vec{\mu} = (\mu(t_1), \ldots, \mu(t_N)) \tag{23}$$

$$\mathbf{K}_{mn} = k(t_m, t_n) \tag{24}$$

$$\vec{S} \sim \mathcal{N}(\vec{\mu}, \mathbf{K}) \tag{25}$$

Thus, the choice of kernel function determines how much the function values at different points tend to co-vary a priori. Throughout this paper, we will use kernel functions of the form

$$k(t, t') \propto \mathrm{sinc}(2f_0|t - t'|) = \frac{\sin(2\pi f_0|t - t'|)}{2\pi f_0|t - t'|} \tag{26}$$

which is also called *wave kernel* (Genton, 2001) in the machine learning literature. This choice is motivated by the observation that the inverse Fourier transform of an ideal low-pass filter with cutoff-frequency f_0 is proportional to this kernel. Thus, functions drawn from a GP with this kernel will vary on timescales comparable to f_0, see **Figure 2** for examples. Note, however, that the regularization provided by the kernel is "soft": when learning sources from small datasets, they will have the smoothness properties given by the kernel. For large datasets, the kernel regularization may be overridden by the data.

With this prior, the matrix of reconstructed signals $\hat{\mathbf{X}}$ and using as model index the tuples $M = (I, f_0)$ we find

$$D = \mathbf{X} \tag{27}$$

$$\Theta_M = (\mathbf{W}, \tau, S_1(t), \ldots, S_I(t)) \tag{28}$$

$$\Phi = \left(\mu(t), k_{f_0}(t, t'), \sigma_n, \sigma_w\right) \tag{29}$$

$$p(D|\Theta_M, \Phi, M) = \frac{\exp\left(-\frac{1}{2\sigma_n^2}\|\mathbf{X} - \hat{\mathbf{X}}\|_F\right)}{\sqrt{2\pi\sigma_n^2}^{JT}} \tag{30}$$

$$p(\Theta_M|\Phi, M) = \frac{\exp(-\frac{1}{2}\mathbf{S}_i\mathbf{K}^{-1}\mathbf{S}_i^T)}{\sqrt{2\pi}^T\sqrt{|\mathbf{K}|}} \prod_{j,i} \gamma \exp\left(-\frac{\tau_{ji}}{\gamma}\right)$$

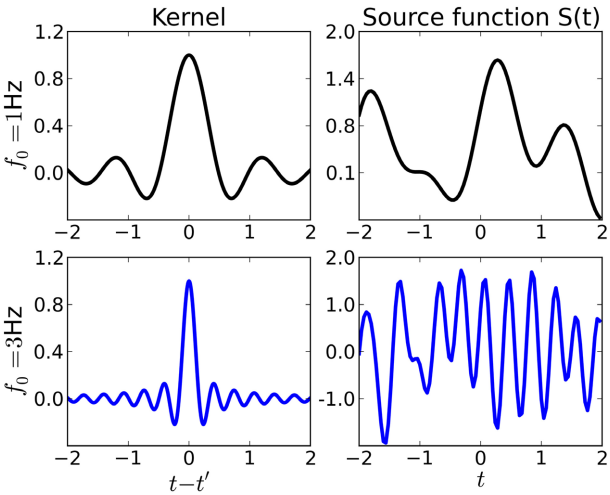

FIGURE 2 | Examples of kernel functions (left) and sources (right) drawn from a Gaussian process prior with the corresponding kernel. Throughout this paper, we use shift-invariant kernels of the form $k(t, t') \propto \mathrm{sinc}(2f_0|t - t'|)$. **Top row:** Kernel function for $f_0 = 1$Hz (left) and source function drawn from a Gaussian process with that kernel. The source varies rather smoothly on a timescale comparable to f_0. **Bottom row:** Kernel function and source for $f_0 = 3$Hz.

$$\times \frac{\exp\left(-\frac{1}{2\sigma_w^2}\|\mathbf{W}\|_F\right)}{\sqrt{2\pi\sigma_w^2}^{JI}} \tag{31}$$

where $\mathbf{S}_i$ is the i-th row of the *undelayed* source matrix, i.e., the matrix of the source functions sampled at times $t = 1, \ldots, T$. A graphical model representation of AMM is shown in **Figure 1B**.

As a special case of the AMM model above, we consider the case $\forall i, j : \tau_{ji} = 0$, i.e., a mixture without delays, but GP-induced temporal regularization. In the following, we refer to this as the *smooth instantaneous mixture*, or SIM.

2.2. LAPLACE APPROXIMATION

We now turn to the evaluation of the model evidence, Equation 3. The difficult part, as usual in Bayesian approaches, is the integral over the model parameters Θ (we drop the index M in the following for notational simplicity, since we evaluate the model evidence for each M separately). Instead of an exact solution, we therefore resort to a *Laplace approximation* (Laplace, 1774; Bishop, 2007). To use this approach, concatenate the Θ into a vector and then construct a saddle-point approximation (Reif, 1995) of intractable integrals of the form

$$\int d\Theta \exp\left(-f(\Theta)\right) \tag{32}$$

assuming that $f(\Theta)$ has a single, sharply peaked minimum at some $\Theta^* = \mathrm{argmin}_\Theta f(\Theta)$ and is twice continuously differentiable. In this case, only exponents close to the minimal exponent $f(\Theta^*)$ will make noticeable contributions to the integral. Hence,

we can approximate $f(\Theta)$ *locally* around Θ^* by a Taylor expansion

$$f(\Theta) \approx f(\Theta^*) + \nabla_{\Theta^*} f(\Theta)^T (\Theta - \Theta^*) + \frac{1}{2}(\Theta - \Theta^*)^T \mathbf{H} (\Theta - \Theta^*) \tag{33}$$

where

$$\mathbf{H}_{uv} = \left. \frac{\partial^2 f(\Theta)}{\partial \theta_u \partial \theta_v} \right|_{\Theta^*}$$

is the Hessian matrix of the 2nd derivatives evaluated at Θ^*. Since Θ^* is the location of the minimum of $f(\Theta)$, it follows that $\nabla_{\Theta^*} f(\Theta)^T = 0$ and $\mathbf{H}$ is positive (semi-)definite. Thus

$$f(\Theta) \approx f(\Theta^*) + \frac{1}{2}(\Theta - \Theta^*)^T \mathbf{H} (\Theta - \Theta^*) \tag{34}$$

and we can approximate the integral as

$$\begin{aligned}
&\int d\Theta \exp\left(-f(\Theta)\right) \\
&\approx \int d\Theta \exp\left(-f(\Theta^*) - \frac{1}{2}(\Theta - \Theta^*)^T \mathbf{H} (\Theta - \Theta^*)\right) \\
&= \exp\left(-f(\Theta^*)\right) \int d\Theta \exp\left(-\frac{1}{2}(\Theta - \Theta^*)^T \mathbf{H} (\Theta - \Theta^*)\right) \\
&= \exp\left(-f(\Theta^*)\right) \frac{(2\pi)^{\frac{F}{2}}}{\sqrt{|\mathbf{H}|}}
\end{aligned}$$

where $F = \dim(\Theta)$ is the dimensionality of Θ. For the derivation of our model comparison criterion, we will need the logarithm of this integral:

$$\log\left(\int d\Theta \exp\left(-f(\Theta)\right)\right) \approx -f(\Theta^*) + \frac{F}{2}\log(2\pi) - \frac{1}{2}\log\left(|\mathbf{H}|\right). \tag{35}$$

In summary, the Laplace approximation replaces the intractable integral with differentiation, which is always possible for the models we consider.

To approximate the model evidence (Equation 3) in this way, let

$$\Theta^* = \text{argmin}_\Theta \left[-\log(p(D|\Theta, \Phi, M)) - \log(p(\Theta|\Phi, M))\right] \tag{36}$$

in other words, Θ^* are the parameters which maximize the likelihood subject to the regularization provided by the parameter prior. Furthermore, denote

$$\begin{aligned}
\mathbf{H}_{uv} = &- \left. \frac{\partial^2 \log(p(D|\Theta, \Phi, M))}{\partial \Theta_u \Theta_v} \right|_{\Theta^*} \\
&- \left. \frac{\partial^2 \log(p(\Theta|\Phi, M))}{\partial \Theta_u \Theta_v} \right|_{\Theta^*}
\end{aligned} \tag{37}$$

and thus

$$p(D|\Phi, M) \approx \underbrace{\log(p(D|\Theta^*, \Phi, M))}_{\text{log-likelihood}} + \underbrace{\log(p(\Theta^*|\Phi, M))}_{\text{log-prior}} + \underbrace{\frac{\dim(\Theta)}{2}\log(2\pi) - \frac{1}{2}\log(|\mathbf{H}|)}_{\text{log-posterior-volume}} \tag{38}$$

which we will refer to as the *LAP* criterion for model comparison: the larger LAP, the better the model. It comprises three parts, which can be interpreted: the log-likelihood measures the goodness of fit, similar to explained variance or VAF. The second term is the logarithm of the prior, which corresponds to a regularization term for dealing with under-constrained solutions for Θ when the datset is small. Finally, the third part measures the volume of the parameter posterior, since $\mathbf{H}$ is the posterior precision matrix (inverse covariance) of the parameters in the vicinity of Θ^*, i.e., it indicates how well the data constrain the parameters (large $|\mathbf{H}|$ means small posterior volume, which means Θ is well-constrained).

We will compare the LAP criterion to two standard model complexity estimators below (see section 3): BIC and AIC. BIC is given by

$$\text{BIC} = -2\left(\log(p(D|\Theta^*, \Phi, M)) - \frac{1}{2}\dim(\Theta)\log(N)\right) \tag{39}$$

where N is the number of data-points. The best model is found by minimizing BIC w.r.t. M. BIC can be obtained from LAP in the limit $N \to \infty$, by dropping all terms from LAP which do not grow with N and multiplying by -2. Assuming that the model has no latent variables (whose number typically grows with N), the terms to be dropped from Equation 38 are the log-prior, the first term of the posterior volume, and the second term of the Hessian (Equation 37). For i.i.d. observations, the determinant of the first term of the Hesssian will typically grow like $Nc^{\dim(\Theta)}$ where c is some constant independent of N. Hence, the BIC follows. While this reasoning is somewhat approximate (a rigorous derivation can be found in Schwarz (1978)), it highlights that we might expect LAP to become more similar to BIC as the dataset increases.

AIC is originally derived from information-theoretic arguments (Akaike, 1987): a good model loses only a small amount of information when approximating (unknown) reality. When information is measured by Kullback-Leibler divergence (Cover and Thomas, 1991), AIC follows. Alternatively, it also obtained by choosing a model complexity prior which depends on N and $\dim(\Theta)$ (Burnham and Anderson, 2004) and is given by

$$\text{AIC} = -2\left(\log(p(D|\Theta^*, \Phi, M)) - \dim(\Theta)\right). \tag{40}$$

Like BIC, a good model has a low AIC score.

2.3. ASSESSMENT OF CRITERION PERFORMANCE

To validate our criterion we assessed its performance on synthesized data sets with well-known statistical properties and on actual kinematic data collected from human participants during a free walking task. We also compared the results with those provided by AIC and BIC. Before applying the model selection criteria we factorized each available data set according to the mixture models Equation 4 and Equation 19. The identification of

the parameters Θ was carried out in two phases: first, we applied singular value decomposition to identify the principal components (for PCA), or fastICA (Hyvarinen, 1999) or the anechoic demixing algorithm mentioned above (Omlor and Giese, 2011) to yield weights and sources. Second, we used these solutions to initialize an optimization of the corresponding likelihood function, to determine the optimal parameters Θ^* and hyperparameters Φ needed for the Laplace approximation. The optimization in the second step was carried out using the L-BFGS-B routine in the SciPy package (Jones et al., 2001) for Θ^*, Φ was then re-estimated for fixed Θ^*. This second optimization was necessary for two reasons: the statistical reformulations of pPCA and ICA will yield solutions which are very similar, but not identical to the original algorithms, and the AMM method from Omlor and Giese (2011) can not handle temporal smoothness priors. The number of components I identified ranged, for all algorithms, from 1 to 8.

2.3.1. Ground-truth data generation

We simulated kinematic-like data (mimicking, for instance, joint-angle trajectories) based on the generative models Equation 4 and Equation 19 that is linear combinations of I primitives that could be synchronous (SIM) or shifted in time (AMM). For the generation of each primitive $S_i(t)$ we drew 100 random samples from a normal distribution (MATLAB (2010) function "randn") and then we low-pass filtered them with a 6th-order Butterworth filter [MATLAB (2010) functions "butter" and "filtfilt"]. Two cut-off frequencies were used for filtering, respectively, 5 and 10 Hz, to simulate data with two different frequency spectra. Sampling frequency of the data was assumed to be 100 Hz. This procedure allowed to generate band-limited sources mimicking actual kinematic or kinetic trajectories of time duration $T = 1$ s. We generated artificial mixture data by combining a number of sources ranging from 1 to 4. Combination coefficients of the mixing matrix $\mathbf{W}$ were generated from a uniform continuous distribution in the interval $[-10,10]$. Temporal delays τ_{ji} were drawn, when needed, from an exponential distribution of mean 20. Sets of noisy data were generated by corrupting noiseless data generated as described above with signal dependent noise. Noise was drawn from a Gaussian distribution of variance $\sigma = \alpha\,|x_i(t)|$, where α is the slope of the relationship between the standard deviation and the noiseless data values $x_i(t)$ (Sutton and Sykes, 1967; Schmidt et al., 1979; van Beers et al., 2004). The slope α was computed though an iterative procedure. Starting from $\alpha = 0$, its value was iteratively increased by a predefined increment until a desired noise-level $1 - R^2$ was reached and stayed constant for at least 10 consecutive computations of $1 - R^2$ given the same value of α. We define R^2 as follows: as the artificial noiseless data sets and their corresponding noisy versions are multivariate time-series, a measure of similarity (typically a ratio of two variances) must be defined using a multivariate measure of data variability. We used the "total variation" (Mardia et al., 1979), defined as the trace of the covariance of the signals, to define a multivariate measure as follows:

$$R^2 = 1 - \frac{\left\|\mathbf{X}_{noiseless} - \mathbf{X}_{noisy}\right\|^2}{\left\|\mathbf{X}_{noiseless} - \overline{\mathbf{X}}_{noiseless}\right\|^2} \tag{41}$$

where $\mathbf{X}_{\text{noiseless}}$ is the matrix of the noiseless data set, $\mathbf{X}_{\text{noisy}}$ the noisy data, and where $\overline{\mathbf{X}}_{\text{noiseless}}$ is a matrix with the mean values of the noiseless data over trials. For each noiseless data set, two datasets were generated with $1 - R^2$ levels equal to 0.15 and 0.3, corresponding to approximate signal-to-noise ratios of 22 dB and 15 dB, respectively. We thus generated 2 models (AMM/SIM) x 2 cut-off frequencies (5 Hz/10 Hz) $\times$ 4 number of sources x 3 levels of noise $=$ 48 different data sets. Each of those datasets contained $J \in \{5; 10; 25\}$ (data) trials. A "trial" (one row of the matrix $\mathbf{X}$ in Equation 4) is a one-dimensional time-series sampled at T points in time. For reliable averages, we drew 20 data sets for each number of trials.

2.3.2. Actual kinematic data

We applied the model selection criteria to select also the model of a second data set consisting of movement trajectories of human actors walking neutrally, or with different emotional styles (happy and sad). This data was originally recorded for the study presented in Roether et al. (2008). The movements were recorded using a Vicon (Oxford, UK) optoelectronic movement recording system with 10 infrared cameras, which recorded the three-dimensional positions of spherical reflective markers (2.5 cm diameter) with spatial error below 1.5 mm. The 41 markers were attached with double-sided adhesive tape to tight clothing, worn by the participants. Marker placement was defined by the Vicon's PlugInGait marker set. Commercial Vicon software was used to reconstruct and label the markers, and to interpolate short missing parts of the trajectories. Sampling rate was set at 120 Hz. We recorded trajectories from six actors, repeating each walking style three times per actor. A hierarchical kinematic body model (skeleton) with 17 joints was fitted to the marker positions, and joint angles were computed. Rotations between adjacent body segments were described as Euler angles, defining flexion, abduction and rotation about the connecting joints. The data for the BSS methods included only the flexion angles of the lower body joints, specifically right and left pelvis, hips, knees and ankles, since the other angles had relatively high noise levels. From each trajectory only one gait cycle was extracted, which was time normalized. This resulted in a data set with 432 samples with a length of 100 time points each. It was already shown previously (Omlor and Giese, 2007a,b) that an anechoic mixture model is more efficient than synchronous models for the representation of such kinematic data. To test the capability of the new LAP criterion to confirm such an observation we applied temporal shift to each trajectory of the data set. Each delay corresponding to a specific trajectory was drawn from a continuous uniform statistical distribution in the interval $[-20,20]$, the sign of the delay determining the shift direction (forwards or backwards), signals were wrapped around at the boundaries of the 100 time-point interval.

3. RESULTS

We first present the evaluation of the three model selection criteria, LAP, BIC and AIC on the ground truth data described above in section 2.3.1. The evaluation is done with respect to three questions: how well can the generator type be detected (AMM or SIM), how accurate is the number of sources I estimation, and

whether the amount of temporal smoothness [i.e., f_0 in Equation 26] can be determined. Second, we analyze the human gait data.

3.1. GROUND TRUTH EVALUATION

3.1.1. Model type detection

We measure the accuracy with which the generating model can be detected by the classification rate, averaged across generating and estimated number of sources, the estimated f_0 and the 20 data sets per condition. It is given by

$$\text{classification rate} = \frac{\text{number of correct detections}}{\text{total number of trials}} \tag{42}$$

The results are summarized in **Table 1** for each number of trials J. LAP clearly outperforms BIC and AIC, particularly for small J. To understand where this difference comes from, **Figure 3** shows a detailed analysis of the results for $J = 10$ trials. The anechoic generator is correctly detected by both LAP and BIC in most cases, whereas AIC often mistakes it for a pPCA model. The SIM generator, on the other hand, is only detected by LAP, both BIC and AIC mistake it for a pPCA model. Hence, LAP achieves very high classification rates, BIC is wrong about half the time, and AIC is even worse. This is due to the terms in BIC and AIC which punish complex models (second terms in Equation 39 and Equation 40, respectively): they only depend on the *number* of degrees of freedom and the number of data-points, but do not measure the effects of any "soft" constraints. Since such soft constraints will have a reducing effect on the likelihood, BIC and AIC will prefer models without such soft constraints over those with constraints. Consequently, BIC and AIC select pPCA over SIM. Note that in the limit of $f_0 \to \infty$, the kernel of the SIM model will give rise to a diagonal covariance matrix $\mathbf{K}$, and thus uncorrelated sources, whereas the $\mathbf{K}$ for finite f_0 will impose a correlational constraint. Thus, the SIM model will turn into a pPCA model in this limit.

In contrast, the LAP criterion measures the effect of the source correlations via the log-prior and log-posterior-volume terms. If the posterior is concentrated in a region of parameter space where the prior is high, the effects of the reduced likelihood can be counterbalanced. Since we evaluated the LAP criterion for $f_0 \in \{5\,\text{Hz}, 10\,\text{Hz}\}$, one of the tested SIM models will match the generator and have a correspondingly high LAP score.

3.1.2. Estimating the number of sources

Next, we looked at how well the criteria are suited for estimating the number of sources. **Table 2** shows the average difference between estimated and generating number of sources, averaged across noise levels, number of generating sources and f_0s. An empty cell indicates that this model would have been picked by the above model type detection only very infrequently.

Particularly for a small number of trials J, LAP is closer to the correct number of sources than BIC or AIC. For larger number of trials, the results between BIC and LAP become more similar, which is to be expected, even though BIC does not detect the correct model type. Moreover, the average number of sources estimated by LAP is always within one standard deviation of 0, and these standard deviations are mostly smaller than those of BIC and AIC.

Table 1 | Model type classification rates of the three tested criteria, for number of trials between 5 (top) and 25 (bottom).

$1 - R^2$	LAP	BIC	AIC
NUMBER OF TRIALS J: 5

0.15	▶0.978 ± 0.008	0.484 ± 0.028	0.388 ± 0.027
0.30	▶0.947 ± 0.012	0.469 ± 0.028	0.314 ± 0.026

$1 - R^2$ is the noise level from Equation 41.

*▶ indicates the best criterion for each row. LAP consistently outperforms BIC and AIC, mostly because the latter two are unable to distinguish between a smooth instantaneous mixture and a pPCA model (see also **Figure 3**). Furthermore, for 5 trials BIC and AIC tend mistake an anechoic mixture for an ICA model, leading to model type classification rates which are virtually zero.*

The dependency of the estimated number of sources on the noise level is depicted in **Figure 4** for $J = 10$. Also unsurprisingly, the estimated number of sources decreases with increasing noise level, since noisy data contain less information about the generating process.

3.1.3. Temporal smoothness constraints

In section 3.1.1, we showed that LAP is the only criterion which can detect the presence of temporal smoothness constraints. Now we investigate whether it can also identify the amount of smoothness, i.e., f_0 in Equation 26. To this end, we computed the LAP score for 16 smoothness settings: {1Hz, 2Hz, . . . , 15Hz}, and also without smoothness constraint (i.e., effectively a pPCA model). We select the optimal smoothness setting for each dataset, and compute the average deviation to the generator smoothness (either 5 or 10 Hz) across all numbers of generating and estimated sources. The results are summarized in **Table 3** for all noise levels, **Figure 5** shows the detailed distributions for $J = 10$ trials. Except for the noiseless anechoic case, the correct temporal smoothness is found with average deviations near zero and standard deviations < 1.5Hz. We have as of yet no explanation for the overestimation in the noiseless anechoic case, but speculate that it is due to some jitter in the estimated delays of the anechoic model, which can be "explained away" by allowing for high-frequency components in the sources. As soon as noise is present in the data, this effect disappears.

3.2. HUMAN GAIT ANALYSIS

Having confirmed the validity of the LAP criterion on the synthetic ground truth, we now turn to real data. Since we are interested in smoothness properties as well as model types, we carried out a comparison between PCA and ICA; and SIM and AMM models with different $f_0 \in \{1\text{Hz}; \ldots; 12\text{Hz}\}$. The results

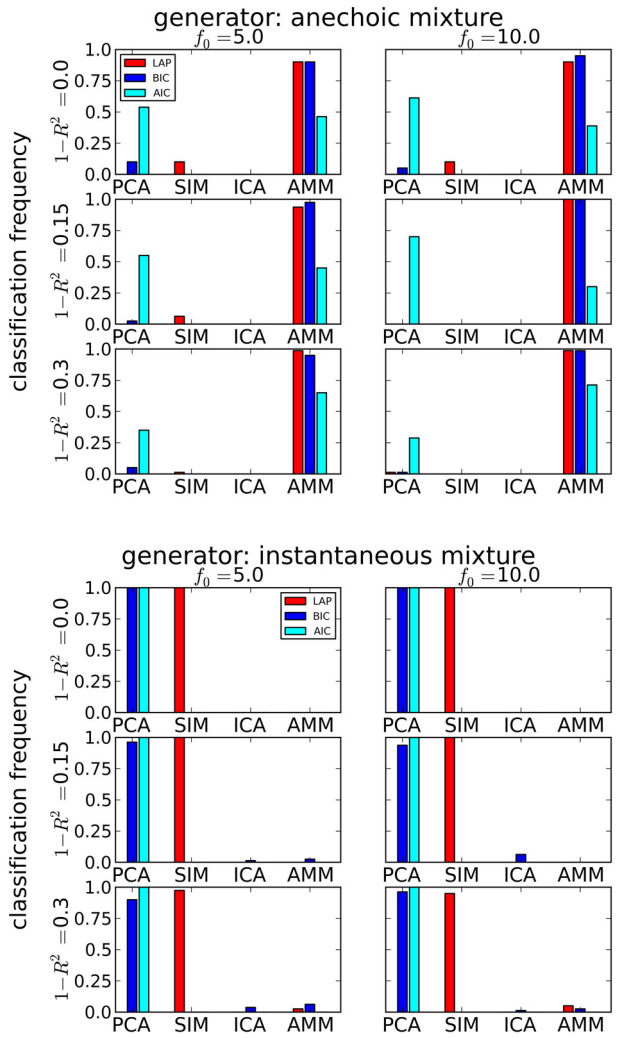

FIGURE 3 | Determining if the model type is a smooth instantaneous mixture (SIM) or an anechoic delayed mixture (AMM) from 10 trials, after marginalizing the estimated number of sources. Top: Anechoic ground truth. BIC and LAP perform comparably well, AIC often mistakes an AMM for a pPCA model. **Bottom**: Ground truth from smooth instantaneous mixture. Only the Laplace approximation criterion (LAP) correctly detects the SIM model in the majority of cases, BIC and AIC confuse SIM with pPCA due to their inability of handling soft constraints. For details, see text.

are summarized in **Figure 6**, top, where the simple "Anechoic" model (dark blue) is an AMM without smoothness constraints. As might be expected, AMMs are the best models (within our tested models) for this kind of data. Furthermore, a correctly chosen f_0 increases the LAP score significantly, i.e., the soft constraint provided by the smoothing kernel is an important feature of these kinematic data, see **Figure 6**, bottom. The best AMM has 3 sources, whereas the best SIM model needs 5, and has a lower score (see **Figure 6**, bottom).

LAP is an approximation of the marginal log-probability of the data [cf. Equation 3]. The best SIM model and the best AMM differ by a LAP score of ≈ 46, which translates into a probability ratio of $\frac{P(\text{AMM})}{P(\text{SIM})} > 10^{19}$. The best PCA model (5 sources) has a LAP score which is lower than the 7 Hz AMM score by ≈ 600.

Table 2 | Estimating the number of sources, marginalized across all noise levels and cutoff frequencies f_0.

*Shown is the difference between the best number of sources determined with a given criterion (LAP, BIC, or AIC) and the number of sources in the generator. Gen. is the generating model, either anechoic (AMM) or smooth instantaneous (SIM) mixture. Anal. is the analysis algorithm. An empty cell indicates that a model comparison criterion (LAP, BIC, AIC) would have picked the corresponding analysis algorithm with a chance of less than 10% (cf. **Figure 3** and **Table 1**). For rows with more than one entry, ▶ indicates best criterion.*

Note that individual datasets consisted of $J = 8$ trials (one per joint angle), therefore models with more than 8 sources are a priori too complex. This fact is also detected correctly by LAP, which assigns a roughly linearly decreasing score (exponentially decreasing in marginal probability) to models with ≥ 8 sources.

4. DISCUSSION

In this study, we attempted to develop a more objective probabilistic criterion for motor primitive model selection. Our criterion turned out to be more reliable than other already existing classical criteria (cf. sections 1.1 and 3) in selecting the generative model underlying a given data set, as well as in determining the corresponding dimensionality. The criterion can moreover provide accurate information about soft constraints, here the smoothness of the temporal evolution of the signals.

We tested LAP performance on synthesized, kinematic-like data and on actual motion capture trajectories. However, motor primitives have also been identified at the muscle level (Bizzi et al., 2008), where usually the signals are rectified after collection. As we tested LAP only on data with unconstrained signs, its applicability to positive-only data, such as EMG recordings, is a subject for further investigations.

The application of the criterion to emotional gait trajectories suggested the anechoic model as the most suitable description of the data. This result is in agreement with previous findings from our lab (Omlor and Giese, 2007b), where it was demonstrated that the anechoic model can represent emotional gait data more

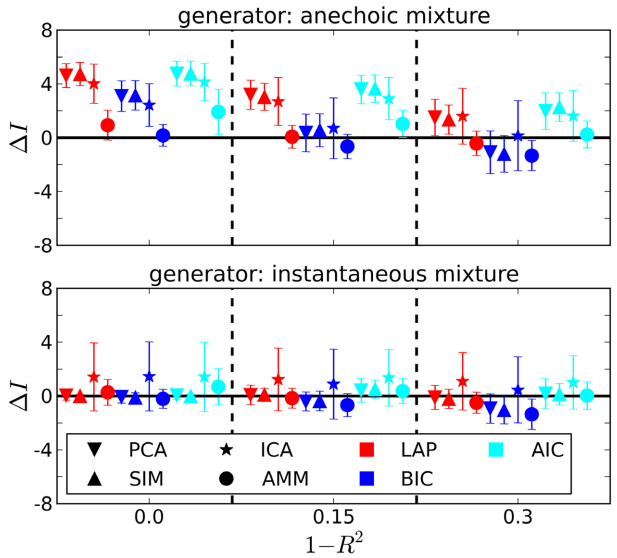

FIGURE 4 | Estimating the number of sources in the ground truth from $J = 10$ trials. ΔI =estimated-generating number of sources. $1 - R^2$: noise level from Equation 41. Error bars are ± one standard deviation. Symbol shapes stand for analysis algorithms, colors indicate the selection criterion. **Top panel**: Anechoic generator. If an AMM is used for analysis, BIC and LAP perform comparably well within the error bars, AIC tends to overestimate. For incorrect analysis models (SIM/ICA/PCA), all criteria overestimate the number of sources, since the extra variability provided by the time shifts needs to be explained via additional sources in instantaneous mixture models. Note, however, that a model type determination step based on BIC or LAP would have ruled out an instantaneous mixture with high probability (cf. **Figure 3** and **Table 2**). **Bottom panel:** For the instantaneous mixture (bottom panel) all three criteria give good results when using PCA or SIM models.

Estimation accuracy is given by best estimated f_0 (see Equation 26) as determined by LAP minus actual cutoff frequency (either 5 or 10 Hz). Gen. is the generative model: anechoic (AMM) or smooth instantaneous mixture (SIM). $1 - R^2$ is the noise level (Equation 41). Except for the zero-noise anechoic generator, f_0 can be determined to within 1 Hz of its true value. For details, see text.

efficiently (in terms of data compression) than other classical synchronous models. Also the best number of primitives determined by LAP is in line with Omlor and Giese (2007b), where three components were found capable to explain about 97% of the total data variation. Interestingly, the criterion suggested a temporal smoothness regularization with $f_0 = 7$ Hz. Such a value may at first seem to be in contradiction with the step frequency of normal walking behavior that tends to be around 2 Hz (Pachi and Ji, 2005). The higher frequency value found by LAP can however be justified by multiple reasons. First, our data comprised also happy walks, which are known to be characterized by higher movement energy (Omlor and Giese, 2007b; Roether et al., 2009) and higher average movement velocity when compared to neutral or sad walks (Omlor and Giese, 2007a; Roether et al., 2009). Therefore, the average frequency power spectrum of the walking trajectories shows indeed considerable power within the band ranging from 0 to 10 Hz, with a peak at 5 Hz. In addition, in **Figure 6** the maximum LAP score occurs at $f_0 = 7$ Hz. However, taking the error bars into account, the LAP score associated with the optimal frequency is not statistically different from that associated with any score in the range [3 Hz, 10 Hz], in agreement with the power spectrum. Another factor contributing to $f_0 = 7$ Hz might be the tendency of LAP to overestimate the cutoff frequency slightly for nearly noise-free datasets, see **Figure 5**.

Additional and more advanced models of motor primitives, corresponding to a multivariate version of the anechoic mixture model considered in this study, have been developed (d'Avella et al., 2003, 2006) to describe the modular organization associated with EMG data sets. As we have not computed the LAP for these models, they are not among the possible model selection options yet. Future work will therefore aim to formulate the priors and generative models which would allow for the application of LAP to EMG data.

An interesting feature of LAP is its capability to discriminate between instantaneous vs. anechoic mixtures. The importance of introducing temporal delays in the model of a motor behavior has revealed to be crucial in some cases such as, for instance, in the modeling of emotional movements or facial expressions (Roether et al., 2008; Giese et al., 2012). LAP is to our knowledge the first model selection criterion explicitly designed for this.

Another remarkable feature of LAP is its capability, thanks to the addition a smoothness prior, to identify the amount of smoothness in the data, in other words to select the frequency f_0 in Equation 26 based on the available data. While a Fourier analysis would also reveal where the power spectrum drops off, LAP has the advantage of providing a principled, quantitative trade-off between smoothness and goodness-of-fit, which allows for a more objective selection of f_0. However, computing the power spectrum could be a first step to determine the range of f_0s across which to search for the optimum.

Moreover, incorporating smoothness priors in time and/or space might be a viable extension of LAP to make it suitable to distinguish between a low-dimensional generative model based on time-invariant primitives vs. a model based on space-invariant primitives. Muscle synergies, for instance, have indeed been presented in the literature in those terms. Among

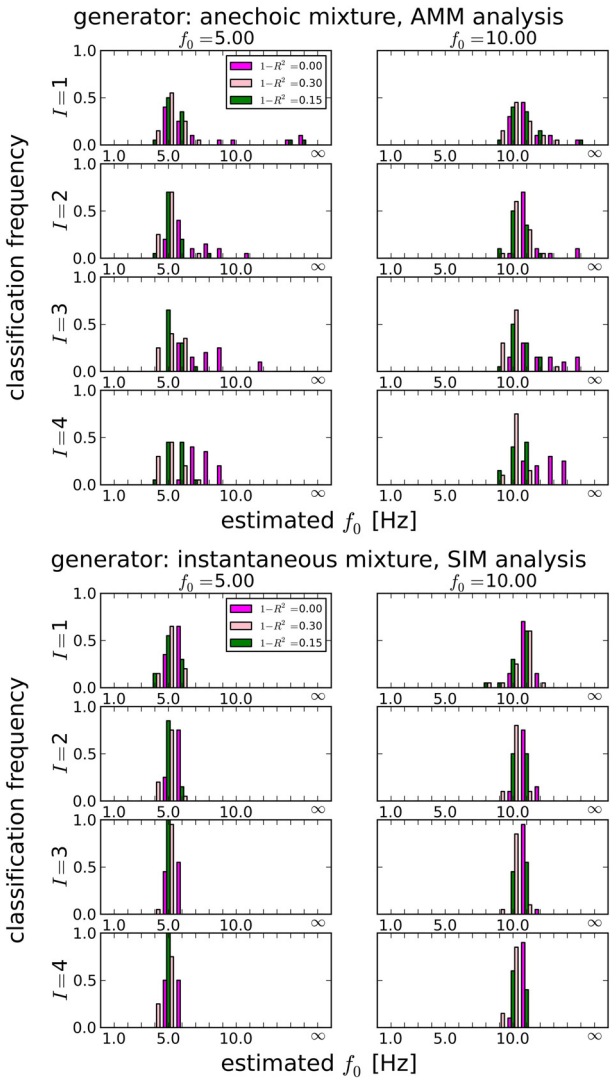

FIGURE 5 | Estimating the best temporal smoothness regularization cutoff frequency f_0 (Equation 26) for $J = 10$ trials. Results obtained with LAP criterion. This estimation can not be done with AIC or BIC: temporal smoothness, while it reduces the effective degrees of freedom (DF), cannot be expressed in BIC or AIC, because these criteria need an integer number for the DF, which would not change with a continuous regularization like smoothness. We tested 16 smoothness settings: {1Hz, 2Hz, . . . , 15Hz} and no smoothness constraint, indicated by "∞" in the plots (this is equivalent to a pPCA model). Left column: 5 Hz ground truth, right column: 10 Hz ground truth. Estimating the smoothness works well for both anechoic **(Top)** and instantaneous **(Bottom)** mixtures, except for the zero-noise anechoic case, where f_0 is overestimated by ≈ 2 Hz on average.

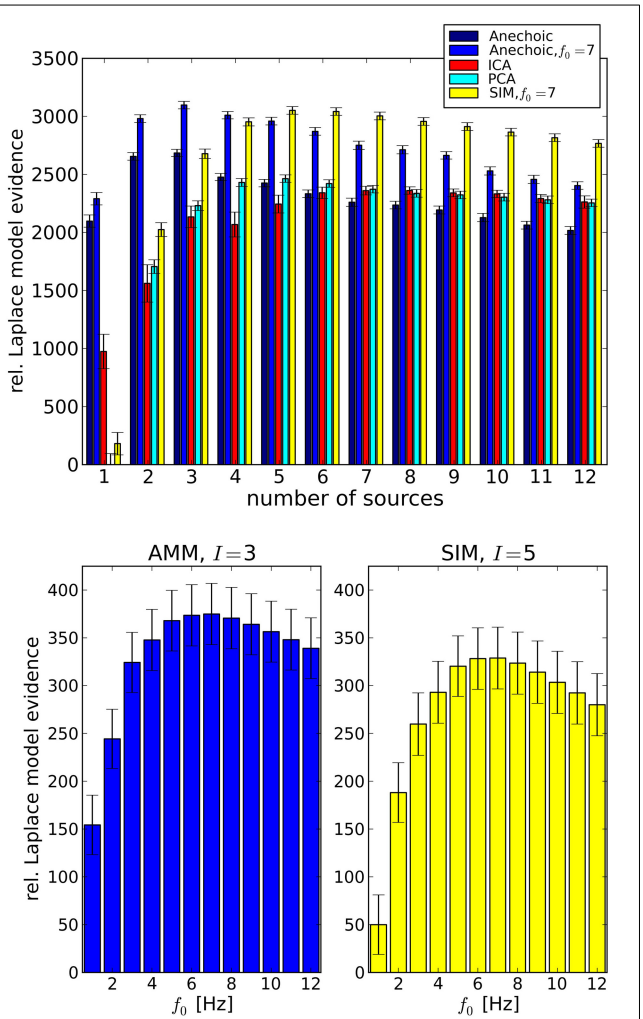

FIGURE 6 | Top: Analysis of emotional gait data from Roether et al. (2008) with PCA, ICA and Anechoic demixing for different numbers of sources. The bars represent model evidences computed with Laplace approximation, relative to the lowest observed model evidence (PCA, 1 source). The anechoic analyses were carried out either without smoothing (black, $f_0 \to \infty$) or with the optimal $f_0 = 7$ Hz (blue) for the wave kernel (see Equation 26). Error bars are standard errors, computed across trials. The best model (highest evidence) is the anechoic mixture with three sources and $f_0 = 7$ Hz, followed by the SIM model with $f_0 = 7$ Hz. PCA and ICA are significantly worse for any number of sources. **Bottom**: Detailed cutoff frequency analysis of the AMM model (left) and the SIM model (right), at their respective best number of sources I. The LAP score (relative to the SIM model with $I = 1$ set to 50) for both models peaks at $f_0 = 7$Hz. However, the best AMM model's approximate posterior probability is larger than the best SIM posterior by a factor of $\approx 10^{19}$. For details, see text.

them, "synchronous" synergies (Cheung et al., 2005; Ting and Macpherson, 2005; Torres-Oviedo et al., 2006) have been described as stereotyped co-varying groups of muscles activations, with the EMG output specified by a temporal profile determining the timing of each synergy during task accomplishment. This definition of synergies reflects the idea of invariance across space (namely the space spanned by the muscles) mentioned above. "Temporal" synergies (Ivanenko et al., 2004, 2005; Chiovetto et al., 2010, 2012), are instead defined as temporal activation profiles that can be simply linearly combined together to reconstruct the actual activity of each muscle. Such a definition of synergies is therefore incorporating a notion of invariance across time. Also more "hybrid" definition of primitives have been given. "Time-varying" synergies (d'Avella et al., 2003, 2006), for instance, are defined as spatio-temporal pattern of muscle activations, with corresponding EMG output determined by the

scaling coefficients and time delays associated with each synergy. Chiovetto et al. (2013) already showed heuristically what movement features these definitions of synergies are describing. Although this knowledge can surely help to decide, dependent on the kind of analysis that one needs to carry out, which kind of synergies to extract from a given EMG data set, it however, does not provide a systematic criterion for such a decision. An extension of LAP might help here, too.

To apply LAP to a given source extraction method, it is necessary to (re)formulate this method in the language of generative probabilistic models. Only when the joint probability of the data and all latent variables (such as **W** or **S**) is available can Equation 38 be evaluated. Furthermore, since LAP results from a second-order approximation to the exponent of that joint probability, LAP will only yield (approximately) correct answers if such an approximation is valid. While the possibility of reformulating a given method can usually be decided *a-priori*, the validity of the second-order approximation typically needs testing on ground-truth data.

In conclusion, we presented an innovative and objective criterion that can be used to reliably select an adequate factorization model to explain the variance associated with kinematic/dynamic data and its corresponding dimensionality. We showed LAP to perform better than two plug-in estimators, BIC and AIC. It needs, however, to be extended to be used in the future for additional types of data, such as EMG data.

The muscle synergy hypothesis is an archetype of the notion of Dimensionality Reduction (DR) occurring in the central nervous system due to modular organization. Toward validating this hypothesis, it is important to understand if muscle synergies can reduce the state-space dimensionality while maintaining task control. In this paper we present a scheme for investigating this reduction utilizing the temporal muscle synergy formulation. Our approach is based on the observation that constraining the control input to a weighted combination of temporal muscle synergies also constrains the dynamic behavior of a system in a trajectory-specific manner. We compute this constrained reformulation of system dynamics and then use the method of system balancing for quantifying the DR; we term this approach as Trajectory Specific Dimensionality Analysis (TSDA). We then investigate the consequence of minimization of the dimensionality for a given task. These methods are tested in simulations on a linear (tethered mass) and a non-linear (compliant kinematic chain) system. Dimensionality of various reaching trajectories is compared when using idealized temporal synergies. We show that as a consequence of this Minimum Dimensional Control (MDC) model, smooth straight-line Cartesian trajectories with bell-shaped velocity profiles emerged as the optima for the reaching task. We also investigated the effect on dimensionality due to adding via-points to a trajectory. The results indicate that a trajectory and synergy basis specific DR of behavior results from muscle synergy control. The implications of these results for the synergy hypothesis, optimal motor control, motor development, and robotics are discussed.

Keywords: modular motor control, muscle synergies, dimensionality reduction, system balancing, Hankel singular values, optimal motor control

1. INTRODUCTION

There is increasingly a consensus that the solution to the *Degree of Freedom (DoF) Problem* of Bernstein (1967) involves some form of Dimensionality Reduction (DR) resulting from modularization, although it is unclear how exactly this occurs. Of the many kinds of modules that have been proposed (Flash and Hochner, 2005), the muscle synergy hypothesis, typified by coordinated activation of groups of muscles, has in recent times emerged as one of the front runners (Alessandro et al., 2013). Spatio-temporal regularities in activation patterns across many muscles that seemingly are task and subject independent is usually cited as evidence for DR in the muscle synergy hypothesis (d'Avella et al., 2003; Hart and Giszter, 2004; Ivanenko et al., 2004; Ting and Macpherson, 2005; Tresch et al., 2006). Nevertheless, a recurring criticism of the hypothesis is its phenomenological nature and difficulty of falsification (Tresch and Jarc, 2009; Kutch and Valero-Cuevas, 2012). One approach toward validating the hypothesis, is to develop a well grounded theoretical understanding of the functionality offered by muscle synergies for neural control.

Although various formulations have been proposed for muscle synergies in literature (Chiovetto et al., 2013), there are some common characteristics to the various models: (1) there is a task-specific recruitment of task-independent modules; (2) the synergies themselves are considered as input-space generators (d'Avella et al., 2003); (3) suggested in some formulations that the number of modules available for recruitment represents a DR of the control input (Ting, 2007; Chiovetto et al., 2013); (4) there is a linearization of the highly non-linear control problem (Alessandro et al., 2012). From a computational viewpoint, each of these features facilitate real-time control and speed up motor learning. However, from a control perspective, modularization could also potentially constrict the functionality of the system. Consequently, investigators have begin to examine the theoretical basis (Berniker et al., 2009; Alessandro et al., 2012) and the feasibility of experimentally extracted synergies for task control (Ting and Macpherson, 2005; Neptune et al., 2009; McKay and Ting, 2012; de Rugy et al., 2013). We propose that this task-space perspective (Alessandro et al., 2013) must be extended to also incorporate the ability of a given set of muscle synergies to reduce behavior dimensionality. Muscle synergies must be evaluated both for task performance and effectiveness as a reduced dimensional controller. In the context of this paper, we denote behavior dimensionality as simply the

(apparent) state-space dimensionality of the dynamics of the motor behavior.

The necessity for reducing behavior dimensionality is best seen from the viewpoint of optimal control theory. Observations of a number of regularities in biological movements that are seemingly task-independent have lead to the claim of optimality principles underlying motor control. One the one hand, several investigators have attempted to uncover empirical rules governing motor behaviors such as the *Fitt's* law, 2/3rd power law (Viviani and Flash, 1995), or the bell-shaped velocity profiles of reaching behaviors (Morasso, 1981). Alternately, the so-called complete models (Todorov and Jordan, 1998) have instead suggested that these features are a consequence of minimizing some performance index; several such candidate indices have been proposed, such as energy, force, accuracy, time, peak acceleration, torque changes etc. (Flash and Hogan, 1985; Harris, 1998b; Todorov, 2004). Nevertheless, it is unclear how organisms might autonomously acquire the optimal behavior; i.e., how the neural instantiation of optimality occurs. Developmental motor hypotheses instead suggest that this optimal control is acquired through an ontogenetic learning strategy (Vereijken et al., 1992; Sporns and Edelman, 1993; Ivanchenko and Jacobs, 2003); typically involving some form of progressive exploration of state-space by an organism. There is also evidence for some form of adaptive optimization mechanism underlying motor control learning (Izawa et al., 2008; Wolpert et al., 2011). However, regardless of the actual mechanism underlying motor learning, large state-space dimensionality has a critical impact on the tractability of iteratively acquired optimal behavior, i.e., the *learnability* of the control (Kuppuswamy and Harris, 2013). DR in this case might have a vital role to play in guaranteeing a tractable developmental acquisition of control. We contend that a control strategy composed of synergies, in addition to input dimensionality reduction, must also facilitate a reduction in the dimensionality of the state-space relevant to the optimal motor control problem. This entails an analysis of the DR resulting from the constraints placed on the dynamics due to muscle synergy control.

The reduced dimensional control perspective on muscle synergies was investigated by Berniker et al. (2009), who proposed a time-invariant synergy synthesis technique that utilized the method of system balancing (Lall and Marsden, 2002) for DR of the dynamics. A task variable relevant reduced dimensional dynamic model was generated from an accurate musculo-skeletal model of a frog's leg. This reduced dimensional model was used for synergy synthesis and control planning. Although the method yields synergies that closely correspond with those extracted experimentally, it must be noted that the time-invariant synergy formulation does not conveniently encode the temporal complexity of natural behaviors. For instance, in the analysis of locomotor movements it has been shown that temporal synergies (Ivanenko et al., 2003, 2004, 2005) are more effective in capturing the temporal aspects of the muscle activation patterns at various instances within a gait cycle. Temporal synergies are characterized by a dominant timing sequence that are seemingly independent of sensory feedback (Ivanenko et al., 2005). The synergies can then be interpreted as a pool of task-independent fixed temporal patterns that are selectively recruited in a task-dependent manner for generating the necessary muscle activation (Chiovetto et al., 2013). This formulation has also been used to model motor skill development; an increasing pool of synergies is seemingly employed by adults when compared with infants (Dominici et al., 2011), or in allowing increased behavioral complexity (Ivanenko et al., 2005). Therefore, we use the temporal synergy formulation for exploring the DR in motor behaviors of a system. The control input is composed of a weighted combination of task-independent orthonormal basis patterns as synergies—the weight matrix uniquely specifies the behavior (trajectory) of the system. This enables us to extend the procedure of Berniker et al. (2009) to generate both a task variable, as well as synergy basis relevant analysis of the DR of motor behavior.

In this paper, we first develop a method for the analysis of the constraints placed on the dynamics due to temporal muscle synergy control. For a given dynamical system, where the set of synergies, and the weight matrix corresponding to a given trajectory are pre-specified, a "*constrained reformulation*" of the dynamics is computed. This is a trajectory, and synergy basis specific constrained reformulation of the dynamics where the temporal synergies are treated as control inputs triggered for the duration of the movement. We then quantify the DR by using the approach of system balancing (Moore, 1981; Hahn and Edgar, 2002; Lall and Marsden, 2002). This approach preserves the features of the dynamics that are most relevant to control; the subspace of the state that is most affected by the input (control variables) and in turn has the greatest effect on the output (task variables) is identified.

Our proposed Trajectory Specific Dimensionality Analysis (TSDA) obtains both the dimensionality of this subspace and the corresponding reduced-dimensional dynamics of the system following a given trajectory. We then demonstrate that synergies can contribute to a DR in behaviors, however, the resulting reduction is specific to the synergy basis utilized and the trajectory that is followed in order to realize the task. We test our methods in simulations on two kinds of systems: (1) a linear system composed of a tethered mass, and (2) a non-linear compliant kinematic chain, and contrast the DR in performing reaching tasks in various trajectories. Idealized temporal synergies composed of Legendre polynomial and the Fourier bases are used for the experiments.

We then examine the consequences of reducing the dimensionality of a given task to the greatest extent possible. A cost function for quantifying the dimensionality is developed using the system balancing measure of Hankel Singular Values (HSV). Numerical minimization of this cost function obtains the weight matrix, and the corresponding trajectory, that best minimizes the dimensionality while satisfying the task constraints. This control model of Minimum Dimensional Control (MDC) is tested in the simulated linear and non-linear systems for two kinds of tasks: (1) reaching tasks, (2) via-point tasks. From the results it can be seen that smooth trajectories with bell-shaped velocity profiles emerges as the optima. Furthermore, we show that the velocity profiles of the trajectories are dependent on the temporal synergy basis that

is employed. The similarity of the resulting trajectories to experimentally observed human behaviors lead us to hypothesize that a dimensionality reduction principle might underlie motor control.

We introduce our approaches in the following way: In section 2 we first outline the temporal synergy control problem and review dimensionality reduction and system balancing. Subsequently we derive the TSDA and our proposed minimization model of MDC. This is followed by a description of the simulation setup and experiments in section 2.5 and the results in section 3. We then discuss the implications in section 4.

2. MATERIALS AND METHODS

We first introduce some basic formalism to the optimal control problem. Consider the following representation of the neuro-mechanical dynamics,

$$\mathbf{y}(t) = h(\mathbf{x}, t), \quad \dot{\mathbf{x}} = f(\mathbf{x}, t) + g(\mathbf{x}, \mathbf{u}, t), \tag{1}$$

where the variables $\mathbf{x}(t)$ denotes the state, $\mathbf{u}(t)$ the input, and $\mathbf{y}(t)$ the output. For this system the state-space dimensionality can be described by $\mathbf{x}(t) \in \mathbb{R}^N$, the input by $\mathbf{u}(t) \in \mathbb{R}^{N_i}$, the output by $\mathbf{y}(t) \in \mathbb{R}^{N_o}$ and N_i and N_o need not be equal to N. We utilize a continuous-time deterministic control system description, so $\mathbf{u}$ can be considered to lie in the infinite dimensional space of continuous functions. Let us define this system by $\mathcal{F}(f(\cdot), g(\cdot), h(\cdot))$, where, $\mathcal{F} \in \Omega$, a space of sufficiently regular (continuously differentiable) functions.

Although in this paper, we consider $\mathbf{u}(t)$ to be input joint torques or actuator forces, the approach is unaffected if muscle activation dynamics are instead incorporated. The aim of control in the system $\mathcal{F}$ is to influence the behavior in order to satisfy task requirements. For the scope of this paper, we simply define behavior as the trajectory followed by the system in accomplishing a task. A task $\mathcal{T}$ is then denoted by a set of Cartesian constraints that must be obeyed, i.e., by the tuple $C_\mathcal{T} = \{\mathbf{y}_\mathcal{T}(t_d) = \mathbf{y}_{\mathcal{T}t_d}, \dot{\mathbf{x}}_\mathcal{T}(t_d) = \dot{\mathbf{x}}_{\mathcal{T}t_d}\}$. The constraints are specified by a set of boundary conditions on the behavior such as zero end-point velocity for reaching, or as a discrete set of via-points to be followed.

A trajectory is then denoted by T, one of the many possible unique paths in the task space satisfying all of the task constraints C_T. For this system, from an engineering perspective, the feed-forward control problem is to compute the function (or policy) $\mathbf{u}(t) = f_f(, \mathbf{x}(t_0))$. Let us denote then $\mathbf{u}(t) \in \mathcal{U}$ as the set of admissible control inputs that satisfy the desired objectives $C_\mathcal{T}$. There may exist multiple solutions for the task, i.e., multiple trajectories, and therefore the cardinality of $\mathcal{U}$ could be considered to be greater than 1. This relation is the well-known *redundancy problem* of motor control, i.e., there is a non-univocal relationship between observed movements and input actuation (Bernstein, 1967).

Many investigators have suggested that the solution to the redundancy problem arises from minimizing some form of cost function $J(\mathbf{x}(t), \mathbf{u}(t), t)$—i.e., an underlying optimization principle to motor control. Typically such cost functions have been justified by citing various biologically relevant factors that impact survival such as energy requirements, accuracy, stability of control etc. (Hogan, 1984; Harris and Wolpert, 1998; Todorov and Jordan, 2002).

The optimal control approach to solve this problem typically is based on methods such as solutions to Hamilton-Jacobi-Bellman (HJB) equation or the Pontryagin Minimum Principle (PMP) (Bertsekas, 1995). However, it may not always be possible to obtain analytical solutions to problems—complexity of plant dynamics and the requirement for accurate dynamic models have been major issues. Also, proponents of optimality in biological motor control do not really address how an organism might autonomously acquire optimal solutions. It is instead implied that some form of motor learning or adaptation at different time scales allows the acquisition of optimal behavior (Wolpert et al., 2011). Several developmental theories, such as the Bernstein's three-stage learning model (Bernstein, 1967) have been put forward to how this might be autonomously acquired through a process of state-space exploration. In this context, state-of-art methods in artificial systems such as iterative optimal control and the algorithms of reinforcement learning (Sutton and Barto, 1998) have proved to be a popular alternative to analytical optimal control techniques and have found many applications in areas such as robotics (Kober et al., 2013).

Regardless of the actual mechanism of neural learning, for the system in Equation (1), the complexity of control learning is dictated by a number factors such as the dimensionality of the input N_i, the dimensionality of the goal N_o, the temporal complexity of the goal trajectory $\mathbf{y}_\mathcal{T}(t_d)$, the complexity of the cost function $J(\mathbf{x}(t), \mathbf{u}(t), t)$ and finally the dimensionality of the state, N. For even moderate dimensional systems, this represents a serious limitation on the tractability of computing an appropriate control policy. Also non-linearities in the functions $f(\cdot)$, $g(\cdot)$, and $h(\cdot)$ can further complicate the problem.

Even from a neuroscientific perspective, most investigations in optimal motor control have focussed on relatively simpler models approximating real musculo-skeletal structures (Harris, 1998b). However, optimal control models such as the minimum energy, minimum torque change, minimum jerk, and the minimum variance may instead be intractable for an organism when confronted with anything more than a moderate number of dimensions. Clearly the redundancy and dimensionality problem is not just a motor neuroscience question but represents a constraint on learning for an organism (Kuppuswamy and Harris, 2013). The famous phrase "*curse of dimensionality*" coined by Bellman (1961) to describe the exponential increase in search space of discrete optimization problems due to dimensionality increase seems appropriate in describing this predicament. DR in this case offers an obvious coping strategy wherein the tractability of control learning can be ensured. It has therefore been suggested that neural architectures must intrinsically incorporate some form of DR such as the muscle synergies. The temporal muscle synergy formulation is introduced next within this framework.

2.1. TEMPORAL MUSCLE SYNERGY FORMULATION

Most models of the muscle synergy hypothesis tackle the DoF problem by constraining the space of control inputs into

combinations of predefined primitives. The temporal synergy formulation has the advantage of conveniently delineating the spatial task-dependent and temporal task-independent components of a synergistic control (Alessandro et al., 2013). Temporal synergies are primarily relevant to locomotor tasks and are a direct example of dimensionality reduction in the control input (Ivanenko et al., 2003, 2004, 2006; Cappellini et al., 2006) with relevance to development and evolutionary theories (Ivanenko et al., 2005; Dominici et al., 2011). Chiovetto et al. (2013) tested the equivalence of temporal muscle synergies with the other main formulations of time-invariant and time-varying synergies on reaching task. The temporal synergy model also has the added advantage of allowing interpretation of the temporal components of the muscle activation occurring at different segments of the movement.

In this formulation, the input $\mathbf{u}(t)$ is constrained in the form of a weighted linear combination of S synergies $\psi_i(t)$ represented by,

$$\mathbf{u}(t) = \sum_{i=1}^{S} w_i \psi_i(t), \tag{2}$$

which can be rewritten in matrix notation by $\hat{W}\Psi(t)$ such that $\Psi(t) = [\psi_1(t) \dots \psi_S(t)]^T$ defines the temporal synergies and the weight matrix $\hat{W} = [w_1 \dots w_S]$ contains the linear combinators approximating a particular input signal $\mathbf{u}(t)$. In the reported models, arbitrary phase shifts are also included in the synergies, however, we do not incorporate them into the analysis presented in this paper.

There is a unique $\hat{W}$ for a given $\mathbf{u}(t)$ if the functions $\psi_1(t), \dots \psi_s(t)$ are linearly independent and $\hat{W} \in \mathbb{R}^{I \times S}$, i.e., the synergies are an orthonormal basis set of the space of inputs. The synergies are specified as a task-independent basis spanning the space of inputs, while the appropriate weight matrix is then computed in a task-dependent manner.

The control learning problem is to obtain the appropriate weight matrix $\hat{W}_d$ corresponding to a desired task $\mathbf{y}_d(t)$. Due to the reduction in dimensionality, the desired solution is within a space of size $N_i \times S$. This is a linear space of inputs and therefore learning can be accomplished by a number of tools and superposition can be utilized to generalize to novel problems. The direct approach for trajectory learning in temporal synergies using an inverse dynamic model can be seen in the top part of the schematic in **Figure 1**.

Despite the reduction in dimensionality of inputs, we contend that the complexity of the optimal motor control problem may not necessarily be reduced simply through reduction of input space dimensionality. For instance, if the desired cost function is a function of the state $\mathbf{x}$, the state dimensionality is a bottleneck affecting learnability. Also, the specification of the task might have an important role to play in existing methods of quantifying the dimensionality of synergies (de Rugy et al., 2013); i.e., the number of synergies may be insufficient to ensure optimal control or learning convergence.

In the case of synthetic systems, parameterized control policies in this form (sometimes also called as motor primitives Ijspeert et al., 2013) have been successfully applied in planning and control for robotics. Reinforcement learning approaches such as policy gradients (Peters and Schaal, 2008) offer several methods for iteratively updating policy parameters depending on some predefined behavior objective. However, in the synthetic context, several *a priori* design choices must be carefully made in order to ensure convergence of the learning within reasonable time-scales in high-dimensional control problems (Kober et al., 2013); DR is one such approach toward rendering optimal control learning tractable. Clearly, if the policy design itself could facilitate DR of a system for a given task, the learning would in turn be naturally facilitated.

The primary question investigated in this paper is therefore: do temporal muscle synergies reduce the state-space dimensionality of the system in performing motor behaviors? Next, dimensionality reduction and system balancing are briefly introduced.

2.2. DIMENSIONALITY REDUCTION AND HANKEL SINGULAR VALUES

From the control engineering viewpoint, the aim of dimensionality reduction is to simplify the input–output dynamics of a system in order to reduce the complexity of simulation and control optimization. Many algorithms have been proposed for model and controller order reduction (Antoulas et al., 2001) including both analytic and computational methods. Consider the state-space model of a system in Equation (1). The DR problem is the synthesis of an equivalent system given by,

$$\tilde{\mathbf{y}}(t) = h'(\mathbf{z}, t), \quad \dot{\mathbf{z}} = f'(\mathbf{z}, t) + g'(\mathbf{z}, \mathbf{u}, t), \tag{3}$$

where $\mathbf{z}(t) \in \mathbb{R}^{\mathcal{K}}$, and typically the dimensionality of the new state variable $\mathcal{K} < N$. Note that when driven by input signals $\mathbf{u}(t)$ the output of the reduced system is $\tilde{\mathbf{y}}(t)$ is close to $\mathbf{y}(t)$ for some measure of similarity. The dimensionality of the inputs and outputs remain unaffected by the reduction.

We seek a quantification of DR in a system instead of simply reducing it to the form of Equation (3). Therefore, we define the reduced dimensionality of a system by the operator $\mathcal{D}$,

$$\mathcal{D}(\mathcal{F}) = D, \tag{4}$$

where $D \in \mathbb{Z}^+$, the space of positive integers. For the system defined in Equation (1), $1 \leq D \leq N$ for any given measure of dimensionality, or reduction algorithm. Obviously, $D = \mathcal{K}$ for the reduction leading to the system in Equation (3).

In order to achieve this kind of a reduction, the commonly used approach is to compute a projection of the full dimensional state into a lower dimensional subspace. This is defined as a mapping W, such that, $\mathbf{z} = W\mathbf{x}$. Various methods exist for computation of an appropriate W, such that certain conditions are met in the input, state and output relationship. We utilize the well known method of system balancing (Moore, 1981) due to its relevance for control and stable numerical properties. System balancing also offers bounds on the approximation errors (Gugercin and Antoulas, 2004) which is crucial for robust controller design.

Through system balancing, we seek to rotate the system coordinates (i.e., the state-space) in order to balance the controllability (difficulty of reaching a state) and observability (difficulty of

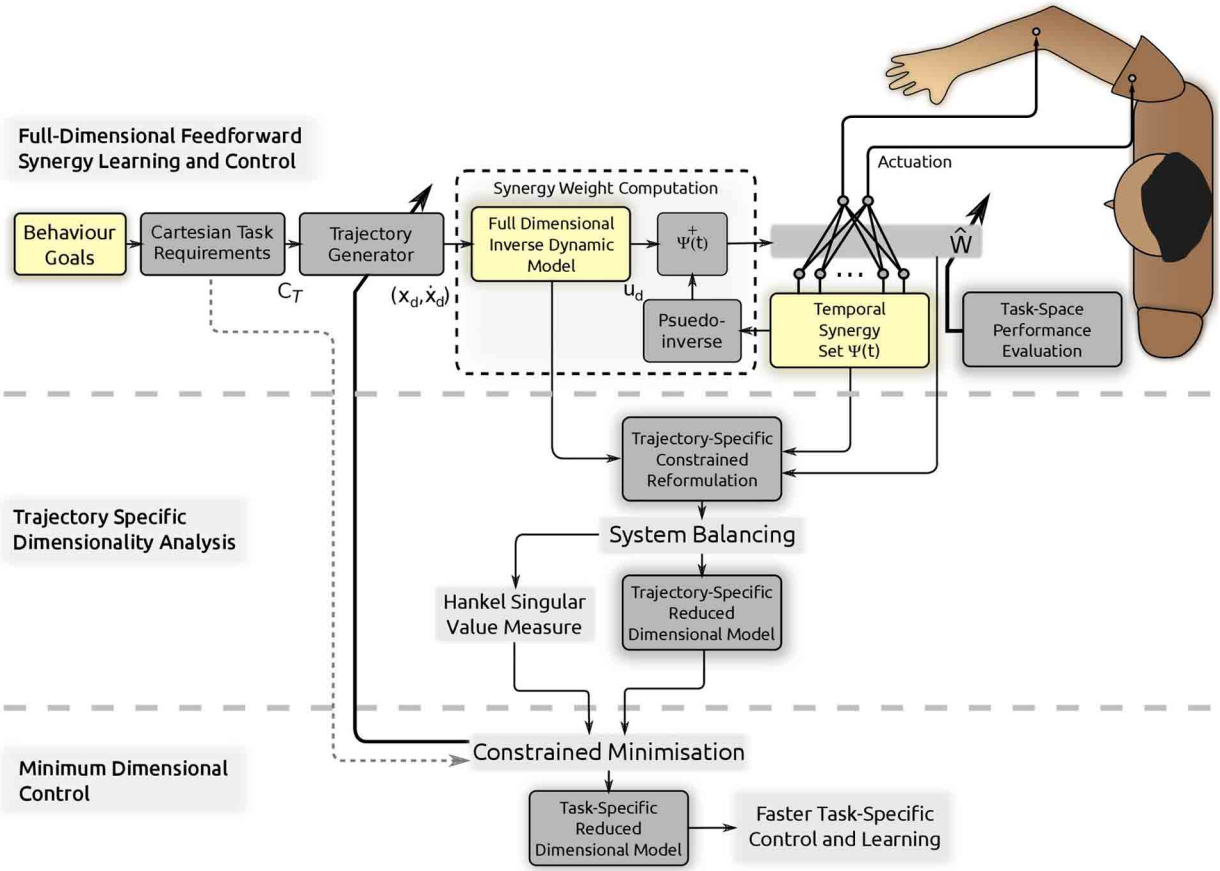

FIGURE 1 | Conceptual schematic of the proposed methods and control model. First a simple feedforward control and learning scheme using temporal muscle synergies $\Psi(t)$ and full-dimensional system dynamics is used to convert Cartesian task requirements $C_{\mathcal{T}}$ obtained from behavior goals into the necessary synergy weight matrix $\hat{W}$. A trajectory (and synergy basis) specific constrained reformulation is then obtained and the procedure of system balancing is used to reduce the dimensionality: the proposed Trajectory Specific Dimensionality Analysis (TSDA). The Hankel Singular Value measure computed through system balancing is developed into a performance index for minimization in the Minimum Dimensional Control (MDC) model. The resulting reduced dimensional model can instead be used within the synergy control learning in the control and learning scheme (on top) to speed up learning and adaptation in a task-specific manner.

observing a state) of the system (Skogestad and Postlethwaite, 1996). This process reorganizes the system by ranking the importance of each of the state variables using a Hankel Singular Value (HSV) measure. They are defined as the square root of the eigenvalues of the product of the controllability ($\mathcal{P}$) and observability Gramians ($\mathcal{Q}$); measures computed on the dynamics of the system. For a Linear Time Invariant (LTI) system in the form of Equation (1), defined by the matrices in $f(\mathbf{x}, t) = A\mathbf{x}(t)$, $g(\mathbf{x}, \mathbf{u}, t) = B\mathbf{u}(t)$, and $h(\mathbf{x}, t) = C\mathbf{x}(t)$, analytical formulations exist for the Gramians defined by,

$$\mathcal{P} = \int_0^\infty e^{At} B B^T e^{A^T t} \mathrm{dt}, \quad \mathcal{Q} = \int_0^\infty e^{A^T t} C^T C e^{At} \mathrm{dt}, \tag{5}$$

For non-linear systems, there is no analytical solution but instead *Empirical Gramians* may be computed using datasets of system behavior (Lall and Marsden, 2002).

First the system is perturbed in r different (input) directions (defined by the set $T^{n_i} = \{T_1, \ldots, T_r\}$, where ${T_i}^T T_i = I$, $T_i \in \mathcal{R}^{n_i \times n_i}$, $i = 1 \ldots r$) at s different sizes of perturbations in each direction (defined by the set $M = \{c_1, \ldots, c_s\}$ where $c_i \in \mathcal{R}$, $c_i > 0$, $i = 1 \ldots s$) across all the n_i inputs and across all n states (defined by the set of unit vectors $E^n = \{\mathbf{e}_i, \ldots, \mathbf{e}_n\}$) of the system. Then the empirical Gramians are obtained from the resulting state trajectories as,

$$\hat{\mathcal{P}} = \sum_{l=1}^{r} \sum_{m=1}^{s} \sum_{i=1}^{p} \frac{1}{rsc^2{}_m} \int_0^\infty \Phi^{ilm}(t) dt,$$

$$\hat{\mathcal{Q}} = \sum_{l=1}^{r} \sum_{m=1}^{s} \frac{1}{rsc^2{}_m} \int_0^\infty T_l \Upsilon^{lm}(t) {T_l}^T dt, \tag{6}$$

where for the controllability Gramian $\hat{\mathcal{P}}$, $\Phi^{ilm}(t) \in \mathcal{R}^{n \times n}$ is given by $\Phi^{ilm}(t) = (\mathbf{x}^{ilm}(t) - {\mathbf{x}_0}^{ilm})^T$, for $\mathbf{x}^{ilm}(t)$ being the state of the

non-linear system corresponding to the impulse input $\mathbf{u}(t) = c_m T_l \mathbf{e}_i \delta(t)$ and for the observability Gramian $\hat{\mathcal{Q}}$, ${\Upsilon^{ilm}}_{ij}(t) \in \mathcal{R}^{n\times n}$ is given by ${\Upsilon^{ilm}}_{ij}(t) = (\mathbf{y}^{ilm}(t) - {\mathbf{y}^{ilm}}_0)^T(\mathbf{y}^{ilm}(t) - {\mathbf{y}^{ilm}}_0)$, and $\mathbf{y}^{ilm}(t)$ is the output of the system for the initial condition $\mathbf{x}(0) = c_m T_l \mathbf{e}_i + \mathbf{x}_0$, and ${\mathbf{y}^{ilm}}_0$ is the steady state output. A detailed description of the non-linear balancing model reduction utilizing the empirical Gramian method can be found in Hahn and Edgar (2002).

These Gramians allow quantification of how controllable and how observable the state variables are; taken together they measure the "importance" of individual state variables and can thus be used for a dimensionality reduction algorithm. For both linear and non-linear systems, the Hankel Singular Values (HSV) of a system σ_{HSV} are then obtained as,

$$\sigma_{HSV} = \sqrt{\lambda(\mathcal{PQ})}, \tag{7}$$

where the λ operator yields the eigenvalues of the product matrix, and the resulting set $\sigma_{HSV} = [\sigma_1 \ldots \sigma_N]$ are the HSVs corresponding to each state variable.

The HSVs can be viewed as a score of the control 'energy' of the state variables. Thus to reduce dimensionality it is sufficient to eliminate the states with a low HSV magnitude. This process can be automated by first obtaining a rotation on the system T of the form $\hat{\mathbf{x}} = T\mathbf{x}$ which reorders the states in decreasing magnitude of HSV—i.e., system balancing. This results in a transformation of the system to a basis where the transformed states that are easiest to reach (control) are simultaneously easiest to measure (observe). Computational efficient methods exist for linear systems for computing the balancing transform T (Laub et al., 1987). Then its possible to truncate the resulting system to the first $\mathcal{K}$ states—hence the method is called balancing truncation (Moore, 1981). The choice of $\mathcal{K}$ is typically dependent on the requirements of the controller design and is usually fixed after examination of the HSV magnitudes (Hahn and Edgar, 2002).

If the HSVs are normalized by using the sum, the DR is directly given by,

$$\mathcal{D}_{\mathcal{HSV}}(\mathcal{F}) = \begin{cases} \mathcal{K} & \text{if there exists } \sigma_{\mathcal{K}} \leq t_r, \\ 1 & \text{otherwise} \end{cases} \tag{8}$$

where the threshold $t_r \in \mathbb{R}^+$, $t_r \leq 1$, and the resulting $\mathcal{K} \in \mathbb{Z}^+$, with $1 < \mathcal{K} \leq N$. Clearly, this form of DR is dependent on the choice of threshold. In the case of control engineering applications, the threshold is chosen on the basis of careful observation of the system (Antoulas et al., 2001). In our approach, presented next, we present a method to simplify choice of this threshold.

2.3. TRAJECTORY SPECIFIC DIMENSIONALITY ANALYSIS (TSDA)

Through system balancing we can quantify the DR of a system. This is a task-independent quantification and depends on the system properties, for e.g., the passive mechanical properties. However, if DR is to be utilized in order to facilitate learning and real-time control of various tasks, the task-dependent reduction of the state-space must instead be considered.

Figure 1 depicts the stages of TSDA computation. The first step is to evaluate the constraints on the system dynamics resulting from the constraints placed on the input due to usage of temporal muscle synergies. The system in Equation (1) can now be represented by,

$$\mathbf{y}(t) = h(\mathbf{x}, t), \quad \dot{\mathbf{x}} = f(\mathbf{x}, t) + \hat{g}(\mathbf{x}, \Psi, t), \tag{9}$$

We term this as a constrained reformulation of the system dynamics where the inputs are the temporal synergies $\Psi(t)$, and can be viewed as signals which control the onset and termination of the movements for a task. For the duration of the behavior, the dynamics is described by Equation (9) due to the constrained input function $\hat{g}(\cdot)$ where,

$$\hat{g}(\mathbf{x}, \Psi, t) = g(\mathbf{x}, \hat{W}\Psi, t). \tag{10}$$

It must be emphasized that the constrained reformulation only describes a *virtual* system dynamics for the duration of the movement when actuated by the synergistic input $\Psi(t)$. The state-space, however, has not changed; i.e., the state variable x for constrained-reformulated system is the same as the original system. Let us denote the system of Equation (9) by $\hat{\mathcal{F}}(f(\cdot), \hat{g}(\cdot), h(\cdot))$.

Clearly, $\hat{F}$ is unique to a given trajectory and given synergy basis set, since it incorporates the weight matrix $\hat{W}$ corresponding to a trajectory T and uses input signals in the form of temporal synergies. Therefore $\hat{\mathcal{F}}$ can be considered to be a trajectory specific constrained reformulation of the dynamics. Then the trajectory specific dimensionality is given by,

$$\mathcal{D}(\hat{\mathcal{F}}) = D_T, \tag{11}$$

If $\hat{W}$ is computed to solve a given task $\mathcal{T}$ uniquely, Equation (11) gives the DR of the equivalent trajectory that satisfies the task requirements. The TSDA measure can be contrasted against the intrinsic DR of the system of Equation (4), which is task independent.

In this formulation, although any kind of DR algorithm can be utilized for computing D_T, we use the system balancing and HSV based approach due to its relevance for the control problem. HSVs measure the importance of each of the state variables of the system $\hat{\mathcal{F}}$ for both the outputs (the task) and the inputs (synergy patterns). Thus they quantify the DR of the behaviors that is dependent on the kind of synergy used and the kind of task that is being performed.

In order to compute the DR, it is desirable that the importance of the careful choice of the threshold HSV measure of Equation (8) is reduced. Depending on the structure of the constrained-reformulated system, it can be expected that HSVs computed for different trajectories may be of completely different orders of magnitudes. Even if normalization using the sum of the HSVs is employed, this may complicate the choice of threshold to compare trajectories. Furthermore this could limit the applicability of

the method in comparing different kinds of temporal synergies in reducing the dimensionality.

In order to address this issue in our approach, we simply normalize the HSVs after utilizing a cumulative sum. First the individual HSVs are redefined by,

$$\tilde{\sigma_i} = \sum_{j=1}^{i} \sigma_j / \sum_{l=1}^{N} \sigma_l, \tag{12}$$

therefore, the vector $\tilde{\sigma}_{HSV}$ is the normalized cumulative sum of σ_{HSV}. This process renders the relationship $\tilde{\sigma}_{HSV_N} = 1$. Thus, independent of basis or the weight matrix magnitude, the threshold can be chosen to lie in the interval $0 < t_r < 1$. We later discuss the implications of the choice of threshold magnitude on motor skill development.

Using the threshold normalized HSVs, the trajectory specific dimensionality is therefore given by,

$$\mathcal{D}_T(\hat{\mathcal{F}}) = \begin{cases} \mathcal{K} & \text{if there exists } \tilde{\sigma}_{\mathcal{K}} \leq t_r, \\ 1 & \text{otherwise} \end{cases} \tag{13}$$

The TSDA can therefore be computed for both linear and non-linear systems. It must also be noted that through computation of the TSDA, an equivalent trajectory-specific reduced dimensional model of the behavior is also computed as described in **Figure 1**. We now extend these methods in order to examine the implications of dimensionality minimization, as described next.

2.4. MINIMUM DIMENSIONAL CONTROL (MDC)

The objective of this paper is to test the supposition that temporal muscle synergies lead to a DR of the state-space dimensionality. Through the method presented developed in the previous section, we can compare various trajectories that satisfy task requirements in terms of the reduction in dimensionality. Now we examine the consequence of minimization of this DR for a given task and a given synergy basis. We define the minimization problem as follows.

As described earlier, for an orthonormal basis set of temporal synergies $\Psi(t)$ each weight matrix $\hat{W}$ corresponds to a unique trajectory in state-space (for the same initial conditions of the dynamical system). Therefore the problem is posed as a constrained minimization for identifying the optimal weight matrix $\hat{W}^*_{\mathcal{T}}$ that minimizes a dimensionality performance index $J(\mathcal{D}_T)$ while satisfying task constraints $C_{\mathcal{T}}$ as,

$$\begin{aligned} \hat{W}^*_{\mathcal{T}} &= \underset{\hat{W}_T}{\text{argmin}} \quad J(\mathcal{D}_T), \\ \text{subject to} \quad \dot{\mathbf{x}} &= f(\mathbf{x}, t) + g(\mathbf{x}, \mathbf{u}, t), \\ \mathbf{y}_{\mathcal{T}}(t_d) &= \mathbf{y}_{\mathcal{T} t_d}, \dot{\mathbf{x}}_{\mathcal{T}}(t_d) = \dot{\mathbf{x}}_{\mathcal{T} t_d}, \end{aligned} \tag{14}$$

where the task is specified by a set of task-space and state-space constraints. We term the solution to this minimization problem as Minimum Dimensional Control (MDC) as depicted in **Figure 1**. The key to this approach is the specification of an appropriate performance index.

In order to generalize our approach to different kinds of physical systems, a computational (numerical) solution is ideally sought. Therefore, the desired properties of this performance index $J(\mathcal{D}_T)$ are that it needs to be continuous, and computationally simple for any kind of physical system $\hat{\mathcal{F}}$.

From the definition of the normalized HSVs in Equation (12), it can be seen that $\tilde{\sigma}$ is a positive, real, bounded, and ordered vector of magnitudes. Also, by definition, the difference between adjacent HSVs, given by $\delta = \tilde{\sigma}_{i+1} - \tilde{\sigma}_i$, always monotonically decreases toward 0. This implies that the crucial determining factor for minimum reduced dimensionality $\mathcal{K}$ is the magnitude of the second cumulative HSV $\tilde{\sigma}_2$. This is because the magnitude of subsequent HSVs will be greater, and the first HSV magnitude $\tilde{\sigma}_1$ is irrelevant for the reduction since $D_{\mathcal{T}} \geq 1$.

For any convenient choice of threshold t_r, a large magnitude of $\tilde{\sigma}_2$ ensures that $\mathcal{K}$ is minimized since all subsequent HSV values $(\tilde{\sigma_2}, \ldots \tilde{\sigma_N})$ are in the interval $[\tilde{\sigma}_2, 1]$. Effectively, increasing $\tilde{\sigma}_2$ is equivalent to increasing the range of values of t_r that result in a reduction to a system of subspace dimensionality 1. Clearly, $\tilde{\sigma}_2$ is the critical magnitude determining reduction in dimensionality.

Based on this rationale the performance index we propose for the MDC is,

$$J(\mathcal{D}_T) = S_F(1 - \tilde{\sigma}_2), \tag{15}$$

where S_F is a positive rational scale factor. Computationally, the minimization can be carried out using any convenient numerical optimization algorithm. Since the obtained weight matrix $\hat{W}^*_{\mathcal{T}}$ is specific to a given task, a given synergy basis set and a given dynamical system, the obtained optimal trajectories are similarly system, task and synergy specific. Despite these conditions, as seen later in the results, invariant characteristics similar to human movements emerge as the optima on the tested linear and non-linear systems. An important consequence of deriving the MDC using the system balancing method is that the approach automatically yields a reduced dimensional dynamic model corresponding to the minimum dimensional trajectory. This is therefore a task-specific reduced dimensional model as depicted in the lower portion of **Figure 1**.

We hypothesize that the MDC trajectories will lower the difficulty of task learning and optimization. This is particularly relevant for the case of adaptive control, when the dynamics of the system changes with time and optimizing schemes need to keep track of changes, i.e., necessitating a cost on the number of dimensions. The MDC essentially allows task-specific adaptation which can gradually change in a manner mirroring development (Berthier et al., 1999).

It must be noted that MDC itself might be susceptible to the curse of dimensionality and is not meant to explain the neural instantiation of control signals for real-time task planning and control. Instead we propose that it is a model for an optimal mechanism underlying trajectory planning in order to overcome the limitations imposed on the learnability. MDC thus represents a bridge between the muscle synergy hypothesis and the optimal motor control models of redundancy resolution.

2.5. SIMULATION SETUP

The experiments were performed on two kinds of simulated systems, (1) the linear tethered mass, and (2) a non-linear compliant kinematic chain.

2.5.1. Tethered mass system

This system consists of a point mass constrained to move in a 2*D* plane as seen in **Figure 2A**. It is "tethered" to an origin by weak passive forces using linear springs and is subject to visco-elastic damping. The system can be actuated by independent forces in two orthogonal directions, and the output describes the position in the 2*D* space relative to the origin. The dynamics of this system are described by,

$$\ddot{\phi} = -K\phi - C\dot{\phi} + \mathbf{F}_u, \tag{16}$$

where $\phi(t) = [\phi_x(t), \phi_y(t)]^T$ is the position of the mass in space, K is a stiffness matrix, C is a damping matrix and $\mathbf{F}_u(t) = [\mathbf{F}_{u_x}, \mathbf{F}_{u_y}]^T$ are orthogonal input forces actuating the system. The simulation parameters were chosen as $C = 2\mathbb{I}$ N/m/s and $K = 6\mathbb{I}$ N/m.

The system can be considered to be a simplified analog of the oculomotor system. It describes the eye orb dynamics without taking torsional forces into consideration and approximates the passive effects of the orbital tissue. The output can be considered as the displacement angles in horizontal and vertical directions (in radians) since linear approximation of orb movements have been shown to be valid in the range of $\pm\pi/6$ radians (Bahill et al., 1980).

2.5.2. Compliant kinematic chain

This system is a two-link planar kinematic chain with passive joint compliance as seen in **Figure 2B**. Actuation is applied through the joint torques. The dynamics are described by Spong and Vidyasagar (2008),

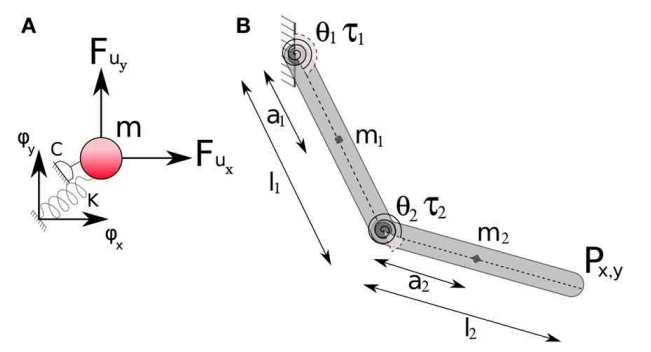

FIGURE 2 | Physical systems employed for demonstrating the TSDA. **(A)** Tethered mass (linear): motion of the mass is constrained to a 2D plane. The mass is anchored to the origin by weak passive forces and actuator forces are applied in two orthogonal directions. **(B)** Two-link planar compliant kinematic chain (non-linear): end-point motion is constrained to a 2*D* surface. Passive joint stiffness and damping effects are present and joint torques are used to actuate the system. The state-space descriptions of these systems have identical input (2), state (4), and output (2) dimensionality.

$$\ddot{\theta} = M(\theta)^{-1}[N(\theta, \dot{\theta})\dot{\theta} + K(\theta - \theta_0) + \tau], \tag{17}$$

where the state is described by $\theta(t) = [\theta_1(t), \theta_2(t)]^T$, $M(\theta)$ is denoted the mass-inertia matrix of the system, $N(\theta, \dot{\theta})$ is the Coriolis matrix and K is the joint stiffness matrix and the joint rest positions are given by θ_0. The system is actuated by the torques $\tau(t) = [\tau_1(t), \tau_2(t)]^T$ at the two joints. The parameters of the simulation are chosen as, $m_1 = 0.75$ kg, $m_2 = 0.5$ kg, $l_1 = 0.4$ m, $l_2 = 0.4$ m. The applied torques are scaled by a factor of 1.88 at joint 1 and 0.45 at joint 2. A joint stiffness of 0.6 Nm/rad and viscous joint friction of 0.15 Nm/rad is used at both the joints with rest angles fixed at $\theta(t_0) = [-\pi/16, \pi/8]^T$. The output of the system is the position $\mathbf{P} = [P_x(t), P_y(t)]^T$ in the 2*D* Cartesian space which are related to the joint angles through the forward kinematics.

This system describes the behavior of vertebrate limbs. The passive joint compliance not only adds to the biological realism, but also renders the system stable—this is a necessary condition for empirical balancing.

2.5.3. Synergy bases

Two kinds of idealized temporal synergies composed of orthonormal basis functions are tested: (a) Legendre polynomial basis ($\Psi_l(t)$), and (b) Fourier basis ($\Psi_f(t)$) in order to simplify the weight learning for the analysis; they are well known approximators used for curve fitting. They are represented by,

$$\Psi_l(t) = \sum_{i=0}^{n} a_i P_i((2t - t_d)/t_d),$$

$$\Psi_f(t) = a_0 + \sum_{i=1}^{n} a_i \sin(i\omega t) + b_i \cos(i\omega t), \tag{18}$$

respectively, where t_d is the duration of the movement and the weights are given by $\hat{W}_l = [a_0, \ldots a_n]$, and $\hat{W}_f = [a_0, a_1, \ldots a_n, b_1, \ldots b_n]$. The Legendre polynomials were computed using the standard Rodriguez formula. Since the polynomials are defined in $[-1, +1]$, they are time-scaled to accommodate the entire duration of the intended movement.

These synergies have another convenient property that their magnitudes are bounded, i.e., $\text{abs}(\Psi(t)) \leq 1$. This property is essential for non-linear TSDA using empirical balancing since the method involves perturbing the inputs using unit impulse signals (Lall and Marsden, 2002). Since the TSDA treats the synergies as input signals, this insures that a unity input perturbation can be applied.

2.5.4. Simulation framework

The simulation was performed on MATLAB (2012). The equations were integrated using the *ode15s* solver in the ODE package with the settings of absolute tolerance $= 5e^{-2}$ and relative tolerance $1e^{-3}$. Model reduction routines developed in Hahn and Edgar (2002), and Sun and Hahn (2005) were used for the non-linear system balancing. The weights $\hat{W}$ for the TSDA benchmark tasks and the MDC initialization were acquired by using a least-squares method. The numerical optimization

of MDC was carried out using the *fmincon* routine, with the *interior point* algorithm (Waltz et al., 2006) for the linear MDC and *active set* (Gill et al., 1981) for the non-linear MDC.

3. RESULTS

The results of the experiments on the test systems using TSDA and MDC are presented in this section.

3.1. TSDA ON THE TETHERED MASS

A set of four benchmark trajectories, denoted by $T_i = \phi_i(t)$, were compared using TSDA for the tethered mass system. Each trajectory described a motion from the origin to a target output position of $[0.5, 0.5]$, each thus representing a solution to the reaching task. The trajectories, seen in **Figure 3A**, were specified by via-points in Cartesian space and cubic-spline fit was computed with smoothness conditions enforced at the boundaries (2^{nd} order boundary conditions set to 0). The weight matrix $\hat{W}_i$ for the control of each of the trajectories were computed using a least-squares fit of the corresponding inverse dynamic control signals $u_{d_i}(t)$. Two kinds of synergies were compared: Fourier and Legendre polynomial bases of order 4 each as seen in **Figures 3B,C**. In the case of the Fourier basis temporal synergy 9 components are necessary corresponding to the sinusoidal and co-sinusoidal parts of the Fourier basis as seen in **Figure 3B**.

The result of the weight training can be seen in the Hinton diagrams of the weight matrices in **Figures 4A,B**. The weights, represented by the size of the shaded ellipses, clearly capture the temporal components of each of the trajectories. However, some trajectories are easier to interpret and understand for one kind of synergy alone. For instance, while the weights corresponding to trajectory T_1 are identical in both rows, in the case of T_3, mirroring of weights across the inputs is seen only for the Fourier basis synergy.

For each trajectory, the constrained-reformulated system was constructed and the corresponding reduction, denoted by the vector $\mathcal{K}_T$, was computed using the linear system balancing procedure. The cumulative normalized HSVs of the constrained-reformulated system can be seen in **Figures 4C,D**. As noted earlier, the final HSV ($\tilde{\sigma}_4 = 1$) for all trajectories, i.e., the last bar in each plot is always unity in magnitude. The magnitude of the other HSVs reflect the task, trajectory and the synergy choice.

For this experiment, a threshold value of $t_r = 0.975$ was utilized to compute the DR (black solid lines in **Figures 4C,D**). It can be seen that the straight line Cartesian trajectory seemingly has the minimum dimensionality of $\mathcal{K} = 1$ independent of the choice of threshold magnitude. For the chosen threshold, the DR for each of the trajectories was then obtained as $\mathcal{K}_{fourier} = [1, 3, 2, 3]$, and $\mathcal{K}_{legendre} = [1, 3, 3, 3]$. In the case of TSDA on the Legendre polynomial basis, it can be seen that tasks T_2, T_3, and T_4 are nearly identical in the HSV magnitudes barring minor differences in the 3rd HSV.

The obtained dimensionality on the straight line trajectories imply that it could be a possible candidate for the minimum

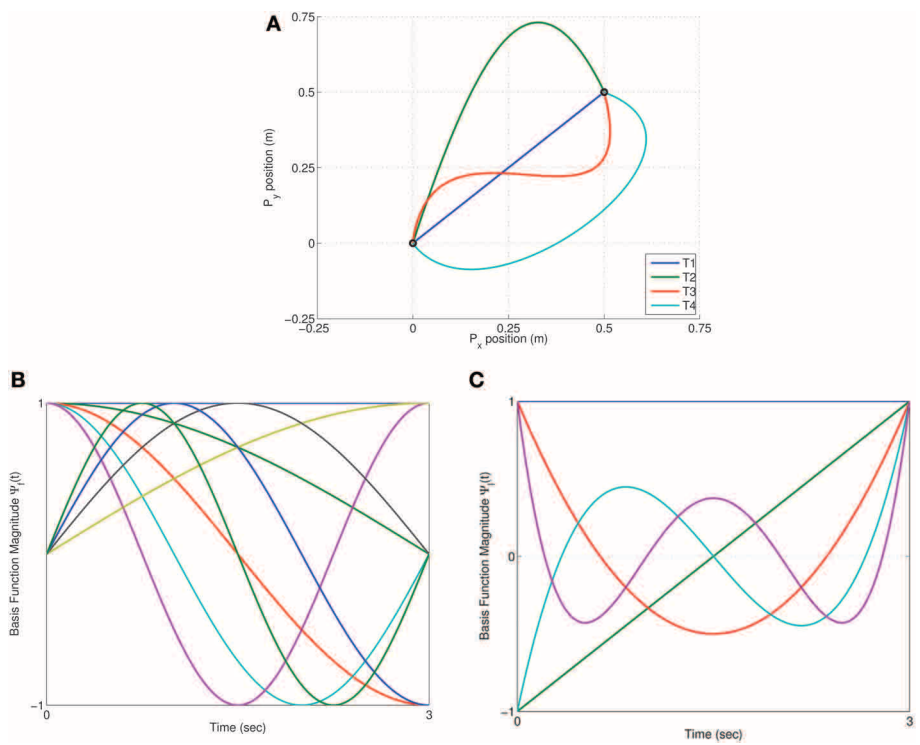

FIGURE 3 | Trajectory Specific Dimensionality Analysis (TSDA) used to compare four benchmark trajectories. (A) The task is to reach position (0.5, 0.5) in 3 s tracing each of the four trajectories $[T_1, \ldots T_4]$. Two kinds of temporal synergies are tested: **(B)** Fourier basis (order 4), and **(C)** Legendre polynomial basis (order 4) actuating the tethered mass system.

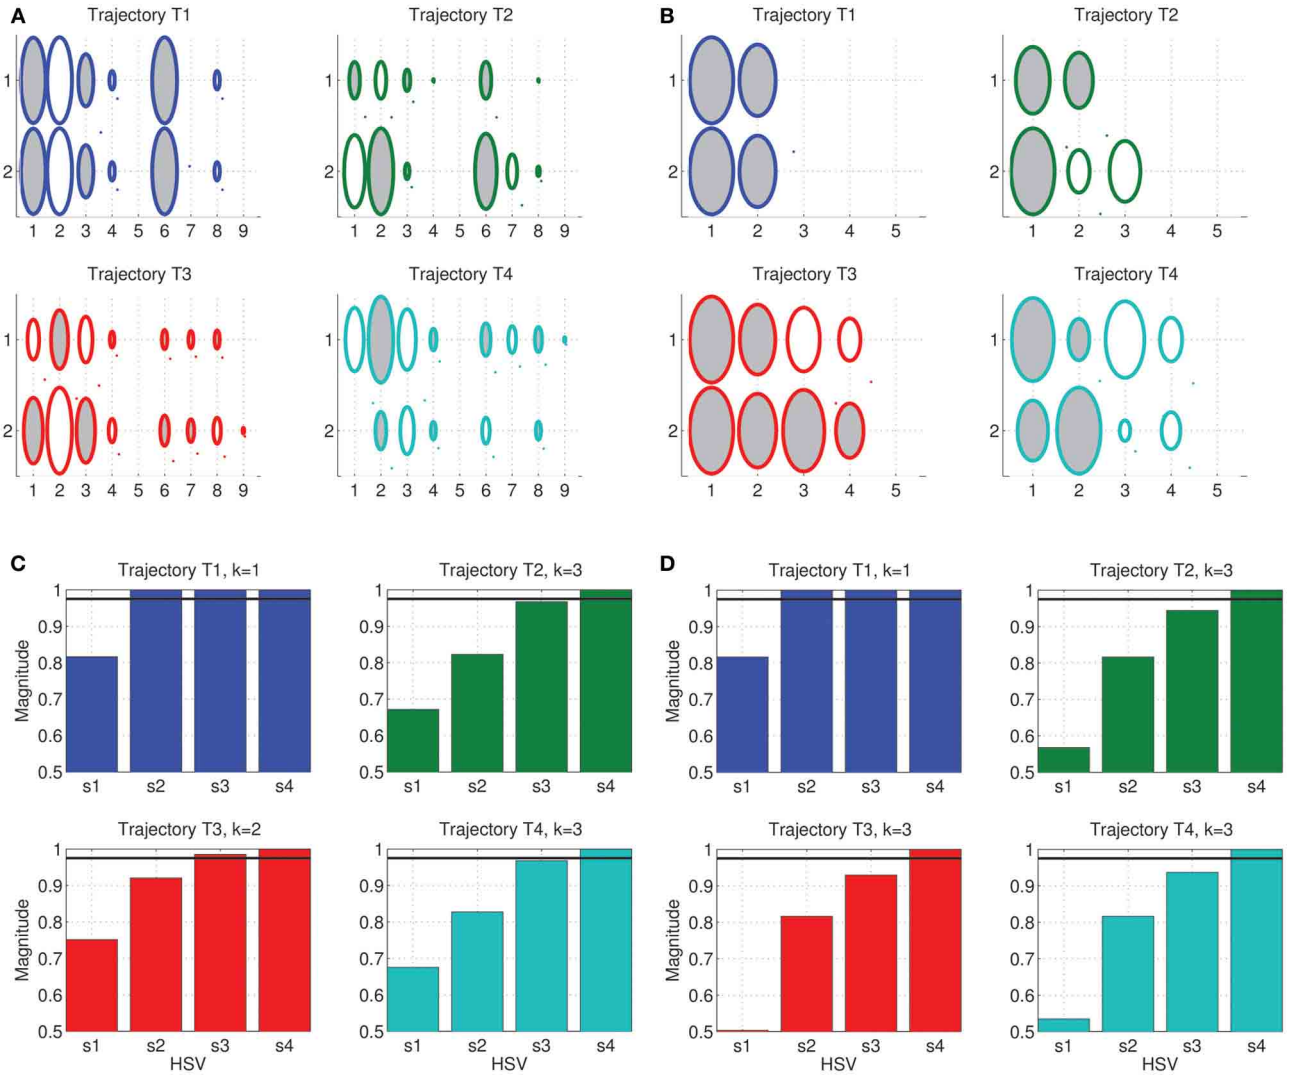

FIGURE 4 | Trajectory Specific Dimensionality Analysis (TSDA) for comparing the Fourier and Legendre polynomial basis temporal synergies actuating the tethered mass system, tracing the benchmark trajectories [$T_1, \ldots T_4$]. The synergy training is carried out using least-squares and full-dimensional inverse dynamics—The obtained weight matrices for the four trajectories are represented as Hinton diagrams (ellipse size is the magnitude, a dark region denotes positive weight and white region denotes a negative weight) for the **(A)** Fourier basis of size 2×9, and **(B)** Legendre polynomials of size 2×5. The corresponding cumulative normalized HSV magnitudes for **(C)** Fourier, and **(D)** Legendre polynomial basis synergies with the threshold $t_r = 0.975$ represented in both cases by the solid black line. The DR was computed as $\mathcal{K}_{fourier} = [1, 3, 2, 3]$, and $\mathcal{K}_{legendre} = [1, 3, 3, 3]$. The straight line trajectory has the minimum dimensionality for both of these synergy bases.

dimensional solution to the reaching tasks. This is investigated using the MDC framework as described next.

3.2. MDC ON THE TETHERED MASS

In this experiment, the MDC was synthesized for the tethered mass system for a point-to-point reaching task, i.e., with zero velocity at the boundaries. The constrained numerical optimization computed the weight matrix for the synergies which minimize the cost in Equation (15).

For the optimization the initial weights were set using a cubic-spline interpolate of a trajectory fitting the boundary constraints $(\phi(t_d) = [0.5, 0.5]^T, \dot{\phi}(t_d) = [0, 0]^T)$. A constraint tolerance of $\epsilon = 10^{-2}$ was used as a terminal criterion for the minimization. In each of the cases, a local minimum was achieved when using the interior-point algorithm for minimization.

The trajectories resulting from MDC can be seen in **Figure 5** for the Legendre, and Fourier basis synergies. Smooth sigmoidal trajectories were obtained as the optimal reaching solution in both cases for multiple movement durations. The terminal cost of optimization was obtained as 2^{nd} HSV $\tilde{\sigma}_2 \approx 0$ for all cases. The time normalized velocity profiles, as seen in **Figure 5B**, are bell-shaped.

Interestingly, from the peak velocities in **Figure 5B**, it can be seen that while the Legendre polynomial synergies correspond closely to the minimum jerk criterion (Hogan, 1984), the Fourier basis synergy result was a close match with the

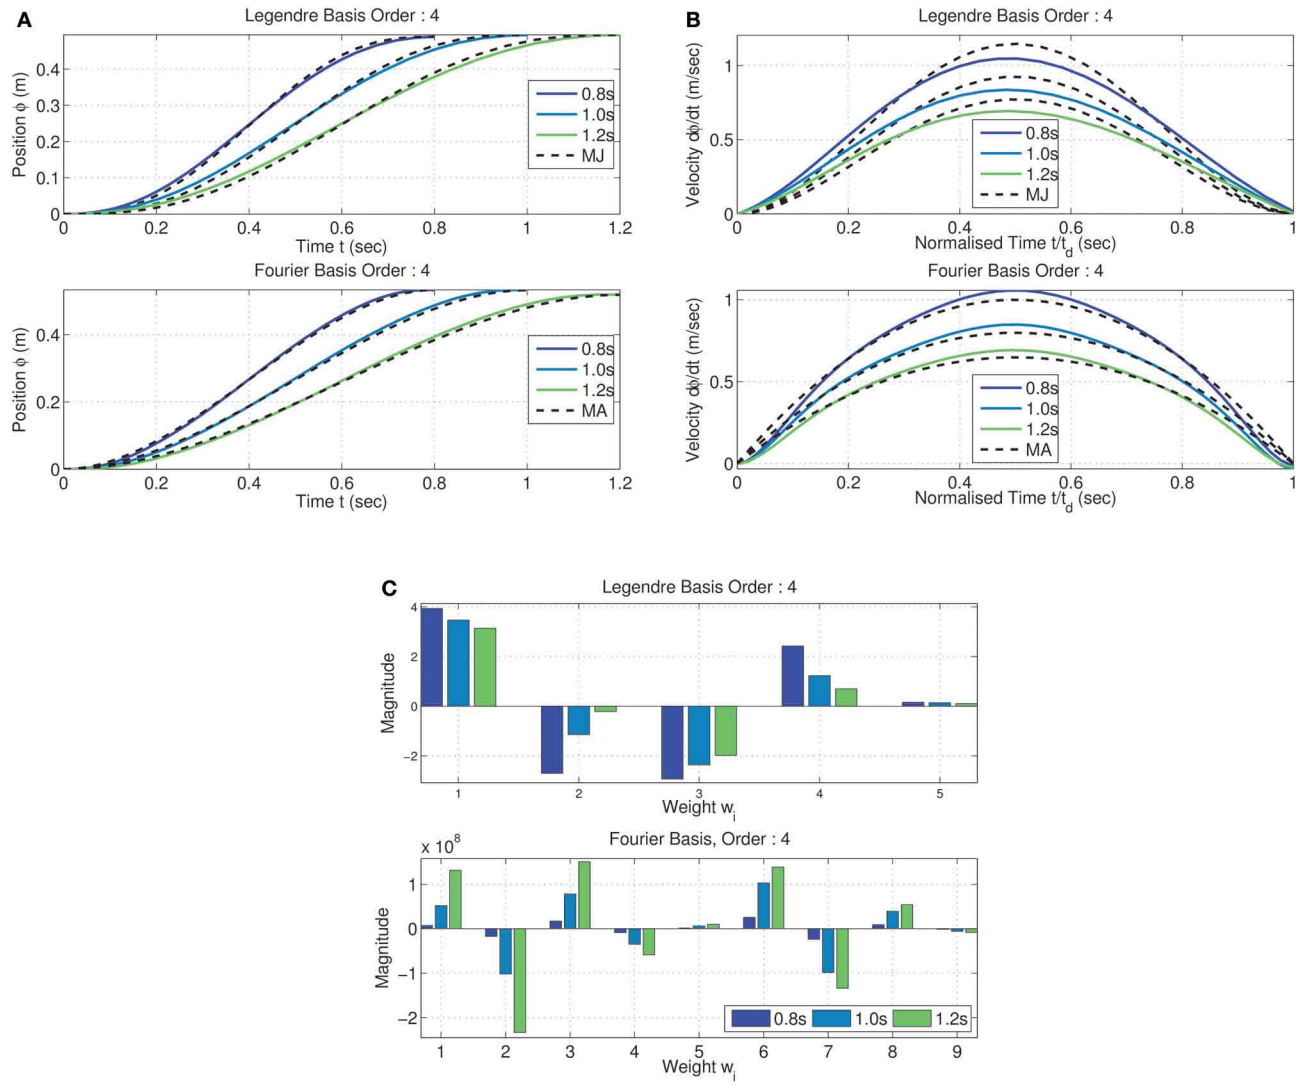

FIGURE 5 | Minimum dimensional control computed on the tethered mass for reaching position (0.5, 0.5) from the origin—two kinds of synergies (Legendre basis of order 6 and Fourier basis of order 4) and three desired time spans (t_d = [0.8, 1.0, 1.2]) analyzed. Trajectory of mass traces a sigmoid for all time spans and for both kinds of synergies. Trajectories **(A)** are similar to the minimum jerk (MJ) criterion for the Legendre polynomial basis and minimum acceleration (MA) for the Fourier basis case; **(B)** The corresponding bell-shaped velocity profiles. Weights corresponding to minimum dimension **(C)** for both Legendre polynomial and Fourier basis synergies linearly increase with movement duration across both inputs.

minimum acceleration criterion (Ben-Itzhak and Karniel, 2008) (represented by the dashed black lines in both cases). There were other minor differences between the trajectories for each kind of synergy. Nevertheless, in both cases the peak velocity of the trajectory scales linearly with the movement duration. The results show that the MDC model computes a synergy specific minimum dimensional trajectory for a given task. It must, however, be noted that MDC does not guarantee symmetric bell-shaped velocity profiles, this is a consequence of the boundary conditions specified and the initialization of the weights for the constrained minimization. Nevertheless, it can be seen that the minimum dimensional solution for the reaching task corresponds to a reduction to a 1 dimensional system independent of the synergy basis chosen.

Due to the linearity of the system, the weight matrix computed by MDC linearly scales with the movement duration as seen in **Figure 5C** (represented only for one of the inputs). The magnitude of the changes are synergy dependent. This implies that for linear systems the peak velocity and movement duration are a linear function of the synergy weights; the relationship depending on the synergy type.

The tethered mass system can be seen as an analog of the human eye mechanism. The passive forces acting on the mass are similar to the weak passive forces due to the orbital tissue. Although the notion of synergies does not seem to extend to the oculomotor system, the Fourier basis synergy can be viewed as a useful modeling tool for analysis of the frequency response characteristics (Harris, 1998a).

We then used the MDC framework to analyze the reduction in dimensionality in via-point tasks. Via-points were chosen to lie on a circle about the target position (as seen in **Figure 6**). The via-points were specified to be reached at exactly half the movement duration. In each case, the appropriate synergy weight matrix was computed for both the tested synergy types using an inverse dynamic model and the linear least-squares procedure. In this experiment, instead of just minimizing the performance index, the variation with via-point orientation was obtained, as seen in the polar plot in **Figure 6B**.

As expected from the earlier reaching experiments, the minimum dimensional via-point is seen to lie exactly along the diagonal, i.e., along the straight line connecting the origin to the target of the movement. Interestingly, for the linear system a minimum dimensional solution was also obtained for the via-points corresponding to the reversal task, i.e., the via-points that lie beyond the target position but along the same line connecting origin and target. Reversal tasks and straight-line reaching are therefore seemingly identical in dimensionality for the linear system. This result also implies that the symmetry of velocity profiles is not guaranteed through MDC, rather it is a consequence of the boundary conditions utilized.

In general, however, the results indicate that for the tested linear system, the choice of via-point can strongly impact the dimensionality of the dynamics. Furthermore the synergy basis specific nature of the dimensionality in following via-points can be seen in the difference between the blue (Legendre polynomials) and red (Fourier basis) lines in **Figure 6B**. Clearly, the differences in performance index with orientation between the two synergies indicate that certain via-points are 'easier' to reach with one kind of synergy basis. This observation is an ideal test-scenario for experimental investigation with subjects and could potentially be used to identify the most appropriate experimentally extracted synergy basis.

The generalization of the MDC is demonstrated in **Figure 7**. The numerical optimization was initialized with a trajectory passing through a via-point located at (0.4, 0.3). The MDC optimization converged toward the straight line trajectory with a bell-shaped velocity profile as seen in **Figure 7B**. The change in cost with each iteration of optimization shows that the algorithm rapidly converges towards the optimal solution of cost $J(\mathcal{D}_T)$. The synergy weight matrix in the optimal case consists of identical values in each row indicating that the MDC solution yields identical force inputs to the system for the reaching task.

3.3. TSDA ON THE KINEMATIC CHAIN

In case of the non-linear compliant kinematic chain system, the empirical balancing procedure was used to compute TSDA. Again a set of four benchmark trajectories $T_{1...4}$ were utilized. In each case, the arm was initialized with the angles $\theta(t_0) = [-\pi/16, \pi/8]^T$, i.e., the rest position. Similar to the linear system experiments, each trajectory described a motion from the initial position to an end position $[0.5, 0.2]$ in the Cartesian space. Again, the trajectories were obtained by fitting cubic splines to Cartesian via-points with smoothness conditions enforced at the boundaries (2nd order boundary conditions set to 0), each representing a variation on the reaching task. Inverse kinematics was then used to compute the joint angle trajectories for each trajectory; the "*down*" configuration was utilized mimicking the reaching behaviors in humans. The required torque $\tau_i(t) = [\tau_{i_1}(t), \tau_{i_1}(t)]^T$ corresponding to each task T_i was then computed by using the inverse dynamics of the system. The weight matrix was then computed for each trajectory using a least-squares procedure. For the experiments carried out, analysis was restricted to the Legendre polynomial synergies since it offered a better fit of the desired torques with a relatively low order in comparison with the Fourier basis synergies.

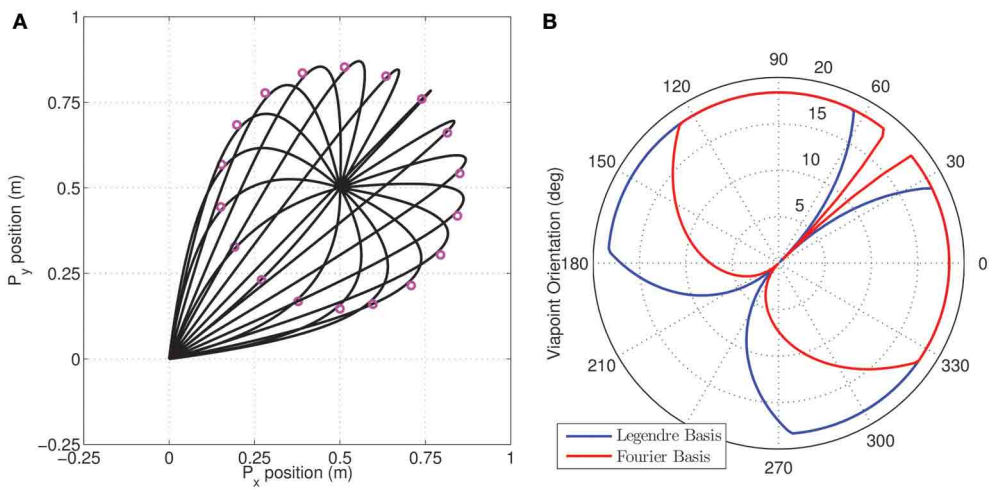

FIGURE 6 | Dimensionality analysis of via-point tasks. (A) A set of via-points were specified on a circle of radius 0.353 m centered on the target (0.5, 0.5) for a reaching movement from the initial position (origin); **(B)** Polar plot of the variation in the dimensionality performance index against orientation of via-point with respect to origin for the two kinds of tested synergies composed of Legendre polynomial (blue) and Fourier bases (red). The minimum value of 0 is located exactly along the straight line linking origin and target for both kinds of synergies.

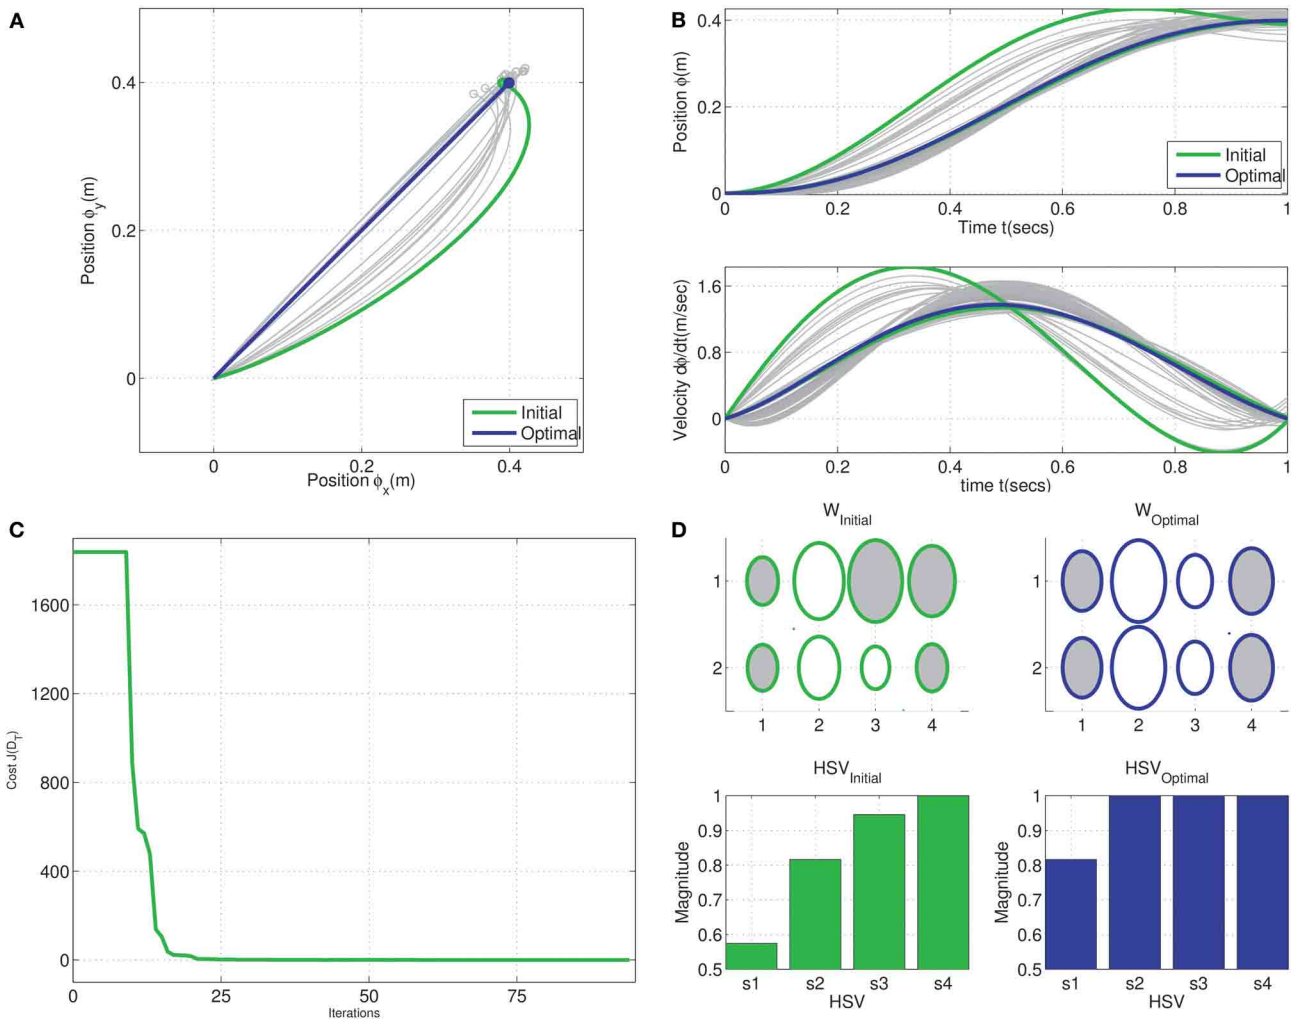

FIGURE 7 | Generalization of the minimum dimensional control for reaching tasks in the tethered mass system. Optimization was initialized with a trajectory passing through a via-point offset by 0.075 m from the straight line connecting origin and target $\phi_d = (0.4, 0.4)$; Gradual convergence to Cartesian straight-lines with bell-shaped time-normalized velocity profiles seen during intermediate stages of the optimization (shades of gray) in the, **(A)** Cartesian endpoint trajectories, and **(B)** position and velocity traces of endpoints. **(C)** Change in $J(\mathcal{D}_T)$ cost with each iteration of optimization, and **(D)** Hinton diagram of the initial and optimal weights and the corresponding normalized Hankel singular values.

The endpoint trajectories for the four cases using Legendre basis synergy control is seen in **Figure 8A**. The weight matrix is represented by the Hinton diagram in **Figure 8B**. From the size of the shaded ellipse, it can be seen that in all four cases, the contribution of the proximal joint inputs is much higher. The temporal aspects of the trajectories can been seen in the relative contributions of the negative weights (ellipses with white shading). Again, the corresponding constrained reformulation was obtained and the empirical balancing procedure was utilized to compute the approximate HSVs. Since the Legendre polynomial synergy magnitudes are bounded, the empirical Gramians were computed from the state trajectories resulting from applying unit impulses across the inputs of the constrained reformulated system.

The application of empirical balancing in this framework is equivalent to activating combinations of the synergies with bounded impulses; the magnitudes were chosen from a uniform distribution about an input ball of same dimension as the number of synergies, i.e., of dimension S. The HSVs corresponding to each task T_i computed by this method can be seen in **Figure 8C**. The DR using a threshold choice of $tr = 0.935$ was obtained as $\mathcal{K} = [1, 2, 2, 2]$. Similar to the earlier linear example, it can be observed that the straight line trajectory with a sigmoidal profile seemingly has the minimum dimensionality of 1. This observation was examined in detail in the MDC experiments, presented next.

3.4. MINIMUM DIMENSIONAL CONTROL IN KINEMATIC CHAIN

The MDC experiment was repeated on the kinematic chain system for a set of reaching targets within the workspace of the arm. Similar to the linear case, the minimization process was initiated with the constraints of zero velocity enforced at the boundaries. A constraint tolerance of $\epsilon = 10^{-2}$ was used as a terminal criterion for the minimization.

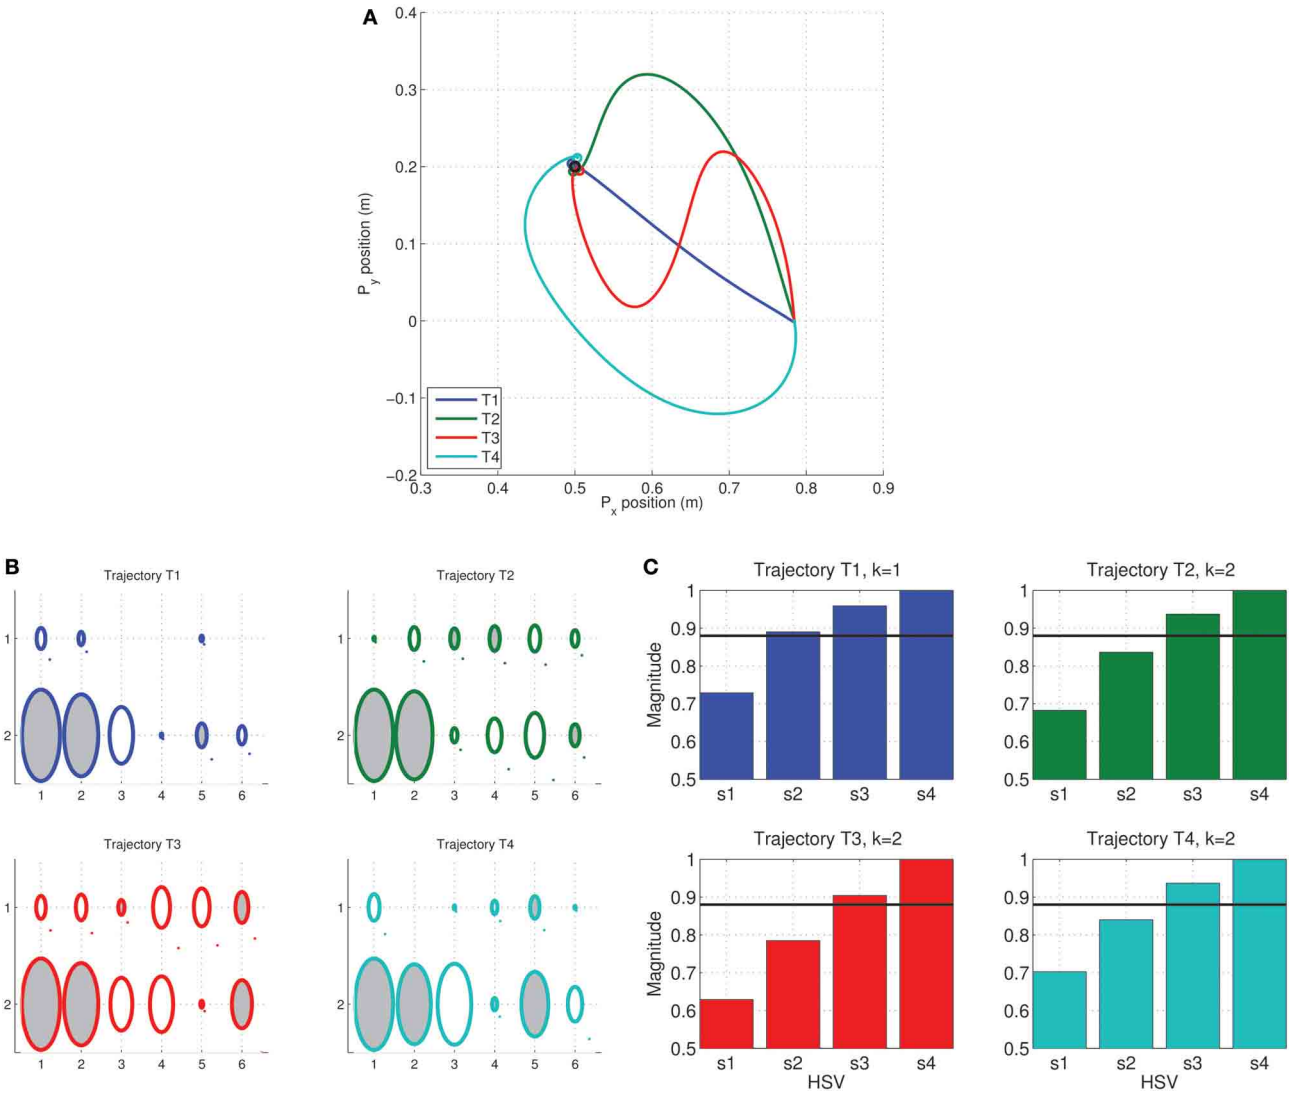

FIGURE 8 | Trajectory Specific Dimensionality Analysis (TSDA) computed on Legendre basis synergies (order 7) actuating the compliant kinematic chain system, the task was to reach position $P_d = (0.5, 0.2)$ in a time span of 2.5 s, the initial condition was a nearly fully extended kinematic chain. (A) Four benchmark trajectories $[T_1, \ldots T_4]$ traced by the mass under synergy control—synergy weights were computed from via-points using a least-squares approach; **(B)** Hinton diagram of the weight matrix (ellipse size is the magnitude, a dark region denotes positive weight and white region denotes a negative weight). **(C)** The normalized empirical HSV magnitudes for the non-linear reformulated composite systems for each trajectory. For a threshold magnitude choice of $t_r = 0.935$, represented by the solid black line, the DR was computed as $\mathcal{K} = [1, 2, 2, 2]$. The straight line trajectory T_1 has minimum dimensionality as measured by the HSV magnitudes.

The (locally) optimal trajectories resulting from MDC can be seen in **Figure 9** for the Legendre basis synergies. Smooth sigmoidal near-straight line trajectories emerge for some movement durations; the results were obtained for different movement durations of $t_d = 2.5$, 3.5, and 4 s. In contrast with the linear MDC case minor skewing effects can be seen in the velocity profiles. These effects are a consequence of the approximate fitting offered by a fixed set of synergies in order to meet the terminal boundary conditions.

Similar to the linear system experiments, the peak velocity obtained for the reaching movements is dependent on the movement amplitude. It can also be seen in this case that the correspondence of the obtained trajectories to the Minimum Acceleration (MA) model (Ben-Itzhak and Karniel, 2008) is greater (black dashed lines in **Figures 9A,B**).

Clearly, a close correspondence is seen between the obtained reaching trajectories and human reaching behavior as reported by Morasso (1981) and by several others.

As in the earlier linear system experiments, we use the MDC framework to analyze the reduction in dimensionality in via-point tasks. Via-points are chosen to lie on a circle about the target position (as seen in **Figure 10**). Again, the via-points are specified to be reached at exactly at half of the movement duration. For each trajectory, the appropriate synergy weight matrix

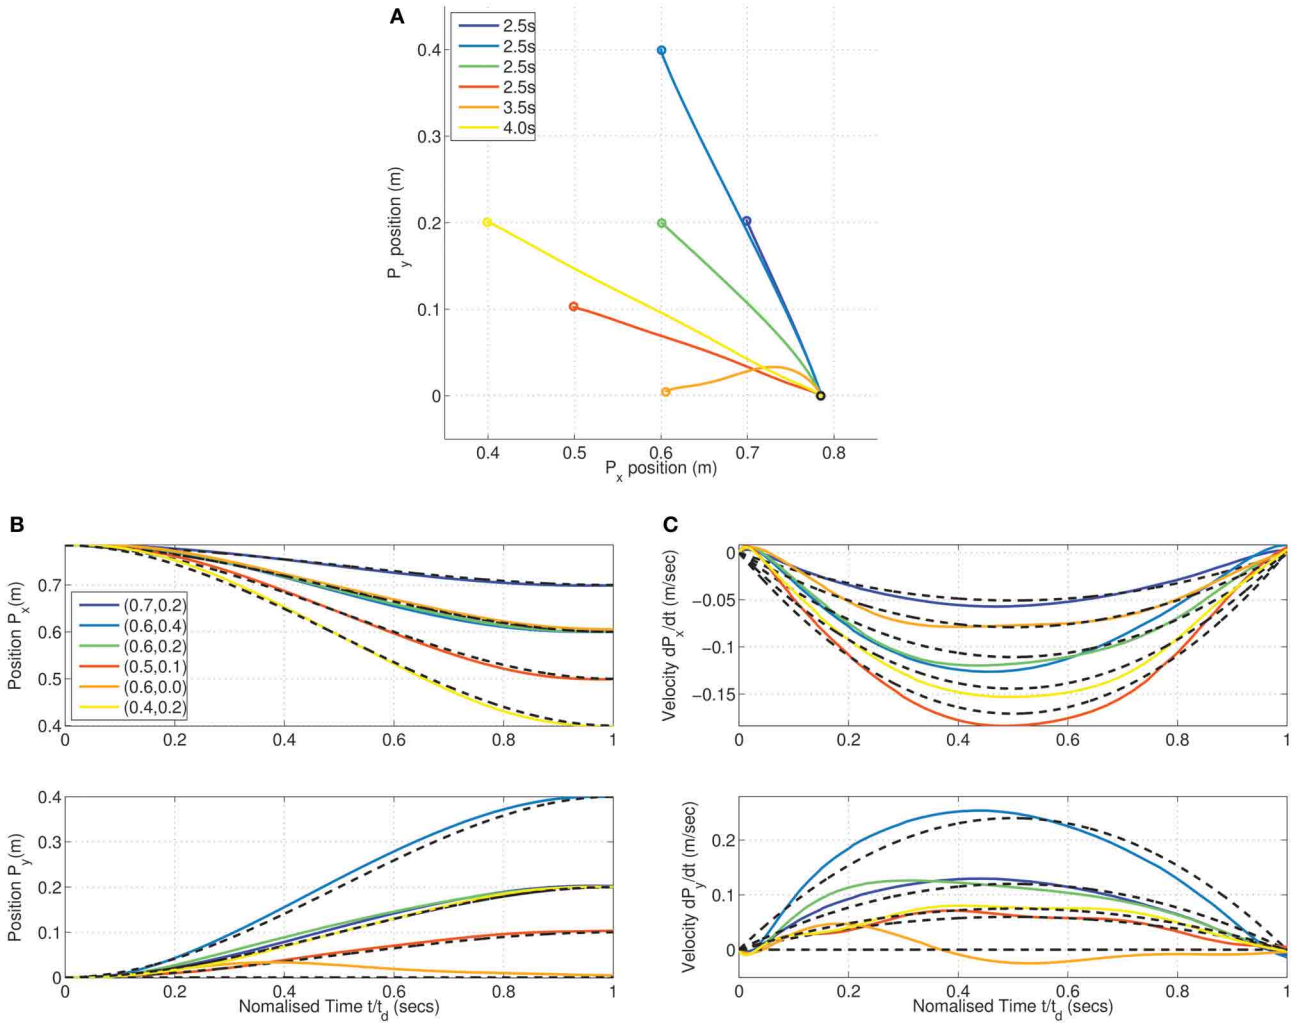

FIGURE 9 | Minimum dimensional control on the kinematic chain for reaching various positions using Legendre basis synergy (order 7). Minimum dimensional trajectories were obtained for targets (0.7, 0.2), (0.6, 0.4), (0.6, 0.2), and (0.5, 0.1) in a duration of 2.5, (0.6, 0.0) in 3.5 s and (0.4, 0.2) in 4 s, respectively. **(A)** Near straight lines seen in the Cartesian endpoint trajectories. **(B)** Trajectory of endpoint is sigmoidal, and **(C)** time-normalized velocity profiles show slightly skewed bell shapes. The peaks of the velocity profiles, however, are close match to the minimum acceleration (MA) criterion result.

was computed. The variation of the dimensionality performance index with respect to via-point orientation is obtained, as seen in the polar plot in **Figure 10B**.

In contrast with the linear example, it can be seen that there exists a non-zero minimum value of the performance index. The reaching target of (0.4, 0.2) was chosen from the set of points investigated in the earlier MDC reaching experiments. For this target position, it can be seen that the via-point resulting in the best DR lies on the straight line connecting origin and the target position. However, reversal tasks are greater in dimensionality implying that they are more complex to achieve in the kinematic chain system.

The generalization of the MDC in the non-linear case can be seen in **Figure 11**. The numerical optimization is initialized with a trajectory passing through a via-point located at (0.6, 0.1). The MDC converges toward a trajectory close to the straight line with bell-shaped velocity profile as seen in **Figure 11B**. The change in cost with each iteration of optimization shows that the algorithm rapidly converges towards the optimal solution of cost $J(\mathcal{D}_T)$. In contrast with the linear result earlier, at some stages of the optimization, the intermediate cost is below the terminal cost as seen in **Figure 11C**. This is a consequence of the *active-set* algorithm which results intermediate solutions which do not obey the constraints. The convergent (locally) optimal solution obeys the terminal position and velocity constraints as seen in **Figure 11B**.

4. DISCUSSION

In this paper, we develop a quantification for the reduction in the behavioral dimensionality in a system due to control in the form of muscle synergies. When using the temporal synergy formulation, the behavior dynamics are dependent on the synergy basis and the weight matrix. We model this as a trajectory-specific constrained reformulation of the dynamics of the system. Using the approach of system balancing, we quantified the reduction

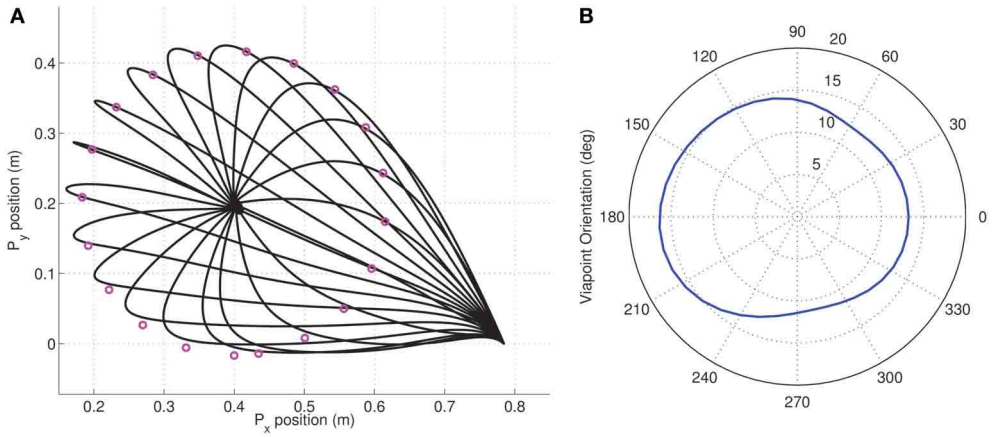

FIGURE 10 | Dimensionality analysis for via-point tasks. (A) A set of cartesian via-points were specified on a circle of radius 0.216 m centered on the target (0.4, 0.2) for a reaching movement from the initial position; **(B)** Polar plot of the variation in the dimensionality performance index against orientation of via-point with respect to origin. The minimum index of 11.21 is located at the orientation of 286.15° corresponding to the via-point at (0.61, 0.14) which is very close to the straight line linking origin and target.

in dimensionality using a threshold-normalized Hankel Singular Value (HSV) measure this process computes the dimensionality of the subspace of the dynamics of the balanced system. Using our method of Trajectory Specific Dimensionality Analysis (TSDA) we show that various trajectories that satisfy task constraints can be compared in terms of reduction in dimensionality in a system and synergy basis specific manner. We then develop a method for minimization of this dimensionality in our model of Minimum Dimensional Control (MDC). The method yields the weight matrix corresponding to the minimum dimensional trajectory that satisfies task constraints using a constrained minimization of the HSV measure. The proposed methods were simulated on biologically-relevant linear (tethered mass) and non-linear (compliant kinematic chain) systems. Using idealized temporal synergies, a task, synergy, and system specific reduction of dimensionality of behavior due to control using muscle synergies was demonstrated. The trajectories obtained as a consequence of this minimization, closely correspond with observations of some of the kinematically invariant features in human movements. We therefore propose that a dimensionality reduction principle might underlie motor control as a direct consequence of developmental necessities.

Bernstein's "*degrees of freedom problem*" remains a seminal observation of natural motor coordination, and continues to challenge our biological understanding as well presenting a fundamental obstacle to biomimetic engineering. Some kind of DR surely occurs, but whether it is an implicit/ emergent phenomenon (e.g., Lagrangian optimization), or an explicit 'simplifying' evolutionary and/or developmental strategy remains a conundrum. The muscle synergy hypothesis suggests that the DR is a fundamental advantage resulting from the partitioning of the space of inputs (Alessandro et al., 2013). However, it has faced criticism. Although statistical regularities seem to be present in the measurements of EMG, and kinematic data from subjects performing behavioral tasks, the extracted synergies are strongly dependent on the nature of observations that can be made (Steele et al., 2013). Despite recent approaches for careful experiment design have aimed at addressing this criticism, the perception that this hypothesis represents only a phenomenological view of motor control seems hard to shake off (Tresch and Jarc, 2009). Falsification of this theory requires careful identification of the actual functionality offered by muscle synergies toward learning and control of optimal motor behavior.

Our view is that for DR to exist in biological organisms, it would need to impact on the organism's behavior, as this is a major determinant of fitness. Muscle synergies would probably only evolve if they had a positive influence on an organisms ability to solve tasks, learn motor skills, and adapt to changes. To this end, TSDA quantifies the DR in dynamic behavior. The dimensionality of behavior is taken to denote the dimensionality of the state-space of the system under synergy control. It is specific to a task and to a defined set of synergies. The dynamic models obtained through the task-specific reduction of this state-space are reminiscent of the internal model hypothesis (Wolpert et al., 1998; Kawato, 1999). Although we do not investigate this relationship further in this work, the task-specific reduced internal representations associated with our MDC trajectories could be very relevant for motor planning for tasks (Braun et al., 2009). Through following these minimum dimensional trajectories, an organism could minimize the neural complexity required for learning internal models.

Attempts have been made to fit synergy data extracted from behavior onto musculoskeletal models (Neptune et al., 2009; McKay and Ting, 2012; Steele et al., 2013). Our approach could potentially complement this analysis and allow the quantification of the differences between synergies extracted by various methods on a given dataset. This would then be a synthetic approach for testing the validity of any set of synergies toward simplifying the control and learning problem. Although we only employed fictitious synergies composed of idealized bases of Legendre and Fourier components, our methods can be applied to any synergy set specified by a time series. TSDA can also potentially

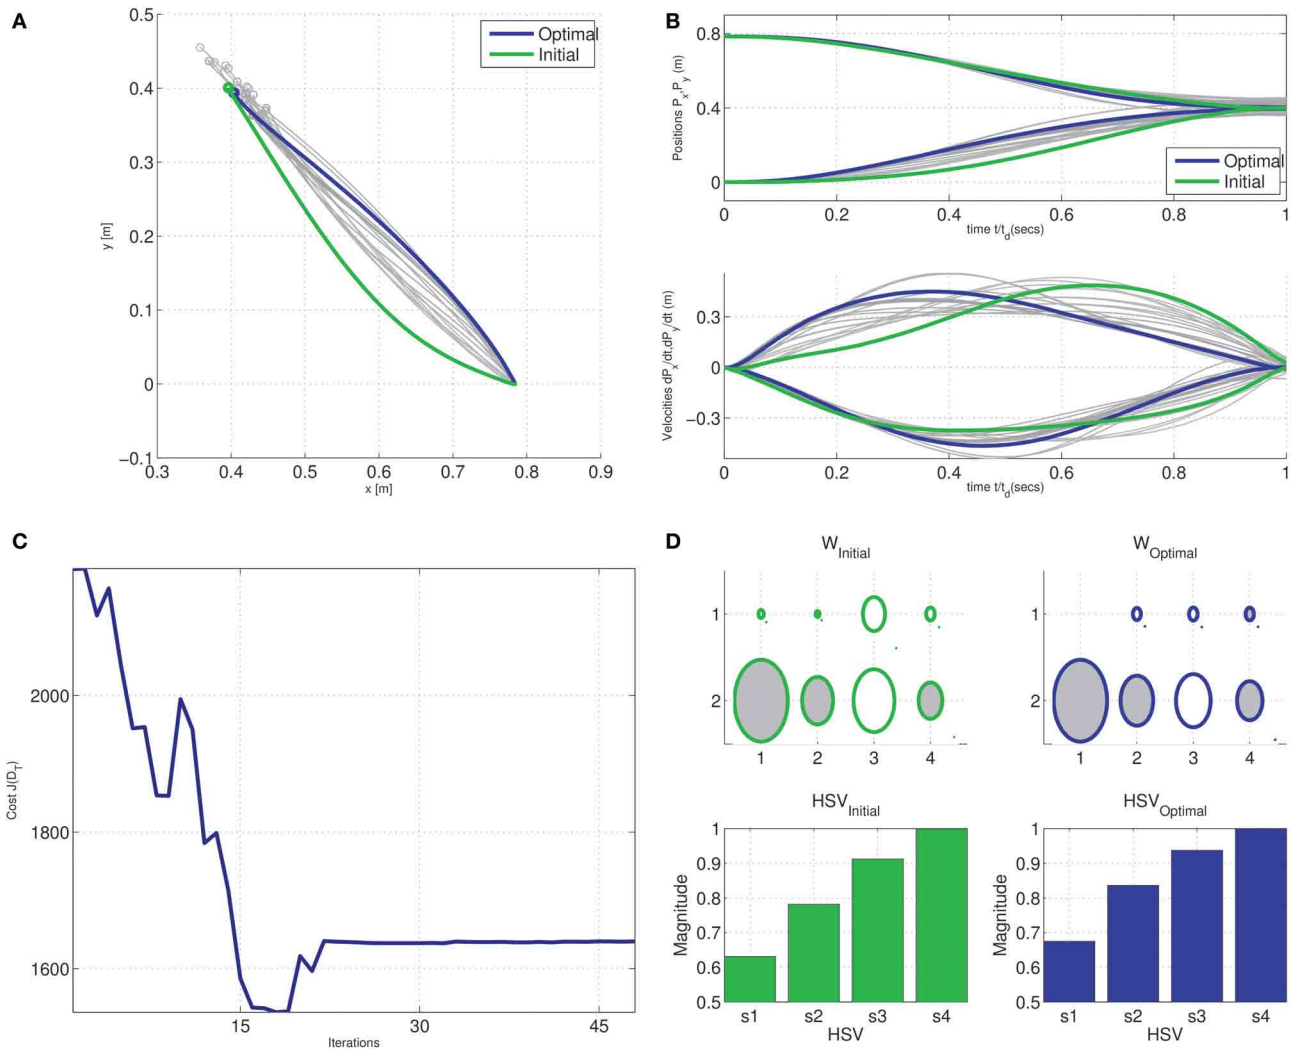

FIGURE 11 | Generalization of the minimum dimensional control in reaching in the compliant kinematic chain system. Optimization was initialized with a trajectory passing through a via-point offset by 0.04 m from the straight line connecting origin and target (0.4, 0.4); Gradual convergence to Cartesian straight-lines with bell-shaped time-normalized velocity profiles seen during intermediate stages of the optimization (shades of gray) in the, **(A)** cartesian endpoint trajectories, and **(B)** position and velocity traces of endpoints. **(C)** Change in $J(\mathcal{D}_T)$ cost with each iteration of optimization, and **(D)** Hinton diagram of the initial and optimal weights and the corresponding normalized Hankel singular values.

be used to test the validity of a task definition, in terms of constraints presented to subjects, as well as the nature and quality of the number of EMG measurements that are employed for synergy extraction. Although our demonstration focussed on the temporal synergy model, in principle the methods can be used for quantification of other models of synergies such as the time-varying synergies (d'Avella and Bizzi, 2005).

The methods we developed in this paper represent a control-theoretic perspective on the muscle synergy hypothesis. This entails a synthetic examination of the role of muscle synergies in acting as facilitators of optimization through control dimensionality reduction. In this view, it is not only important to extract spatio-temporal regularities from biological behavior datasets, but also to carefully examine if task control and learning is indeed facilitated (Alessandro et al., 2013; de Rugy et al., 2013). In particular, Berniker et al. (2009) suggested that synergies represent a task-variable specific reduction in controller dimensionality. We essentially extend this view by quantifying a task-variable and synergy basis specific reduction—thereby allowing us to understand the temporal aspects of motor behaviors. Our approach is also closely related to a recent analysis of the synergy hypothesis from an intermittent hierarchical control perspective (Karniel, 2013). In principle, the notion of minimal intermittancy and our concept of minimum dimensionality both have an underlying objective of minimizing control effort, and further investigation of this relationship is definitely warranted.

The methods presented in this paper also have potential applications in the control of artificial systems such as robots. Current state-of-art methods such as policy gradients (Peters and Schaal, 2008), and the PI^2 algorithm (Policy Improvement

through Path Integrals) (Theodorou et al., 2010) have been used for demonstrations of reinforcement learning being applied to high-dimensional robot systems. In comparison with model-free reinforcement learning, model-based methods offer several advantages such as the ability to update policies offline and then performing sporadic updates from real-world data. Also model-based methods allow safe exploration without risking damage of robots. Our approach naturally facilitates tractable model based learning and could serve as a planning tool acting in concurrence with existing reinforcement algorithms in order to speed-up learning.

In several reinforcement learning proposals, the trade-off between exploration and exploitation is often discussed. It is important to note that a method based on reduced dimensional internal models, although offering potential speed-up of learning, could also limit the scope of the obtained solutions—i.e., the learning could converge to suboptimal behavior. Within the context of our framework, we believe that this problem could instead be tackled by a developmental scheme of progressively increasing internal model dimensionality along with the acquisition of control of newer skills. This notion is similar to the developmental hypothesis of degree-of-freedom freeing and unfreezing (Bernstein, 1967). Consequently, the developmental increase in the number of synergies to cope with increased task requirements (Dominici et al., 2011) would than be equally supplemented by a progressive increase in internal model dimensionality. Thus task-specific models of internal models of increasing complexity would progressively be evaluated as the organism matures.

Although the scope of this paper was limited to the analysis of deterministic continuous-time systems, the methods can in principle be adapted to deal with stochastic effects and discretization. The resulting approach could then be used to supplement existing state-of-art methods in iterative stochastic optimal control (Theodorou et al., 2010). Furthermore, although the investigations focussed on a feedforward control scenario, the methods can easily incorporate a feedback control formulation of plant dynamics; the models we tested already include a weak mechanical feedback in the form of passive joint compliance. Nevertheless, it must be noted that several existing models in the synergy hypothesis suggest that muscle synergies are a high-level feedforward control scheme that incorporates low-level feedback (d'Avella et al., 2003; Hart and Giszter, 2004; Ivanenko et al., 2004; Ting and Macpherson, 2005; Tresch et al., 2006). In an artificial context, this notion has also been explored in the design of dynamical movement primitives (Ijspeert et al., 2013) wherein the policies encode trajectory features while the primitives themselves can then be modified online in a smooth manner taking into account disturbances etc. due to their dynamic nature.

The Optimal Control Theory (OCT) models of human motor behavior originate from a evolutionary perspective; there is a fitness-driven necessity for behaviors to be optimal. Various Lagrangians have been proposed to quantify task optimality depending on the different perspectives of the system such as the output (kinematic) (Flash and Hogan, 1985), control input (minimum variance Harris and Wolpert, 1998, minimum norm Dean et al., 1999), or intermediate variables (minimum torque Nakano et al., 1999). However, it must be noted that OCT hypotheses employ relatively complex mathematical techniques; current theoretical limitations mean that OCT methods can only be applied analytically on relatively simpler models such as linearized models of the oculomotor system or limb movements (Harris and Wolpert, 1998). Also, there is no testable suggestion so far as to how and where the optimization might actually be happening in terms of actual neural mechanisms. The method proposed in this paper is possibly a step toward this goal, since we relate optimization to the actual recruitment of synergies to accomplish tasks.

From a developmental perspective, the process of acquisition of motor coordination is gradual and seemingly composed of intermediate stages of learning (Sporns and Edelman, 1993). If we consider that optimal solutions exist in a high dimensional space (system dynamics, neural control input) unique to an individual organism, then fitness must also depend on the ability to find good solutions in the developmental time frame (Harris, 2011). Searching for an optimal trajectory has a little value if it takes a long time to find. We propose that the time taken to learn an optimal control, which we call "learnability" is itself an important parameter in a self-organizing system (Kuppuswamy et al., 2012). DR is one possibility which may speed up learning, but there might be a trade-off with precision and learning rate to the extent that non-redundant degrees of freedom are eliminated. Our approach provides a mechanism to examine this hypothesis through the measurement of dimensionality of empirically measured trajectories relative to some assumed or computed basis set of synergies.

The most interesting results obtained through our methods are the smooth straight-line sigmoidal trajectories with bell-shaped velocity profiles as the minimum dimensional solution to reaching tasks. The similarity at the output for two basis sets (Legendre and Fourier) and for both linear and non-linear systems suggests the possibility of some kind of invariance at the output task variable level. We also observed that the symmetry of the velocity profiles is strongly affected by the specification of boundary conditions on the behaviors. Smoothness implies a potential relationship between DR and bandwidth reduction. Clearly, task demands place constraints on possible trajectories, and hence on their spectral content. In point-to-point reaching trajectories with zero velocity boundary conditions, the temporal truncation forces a strictly infinite bandwidth, with rapidly decaying spectral energy limiting envelope (Harris, 2004). The fastest movement that can be achieved without exceeding this spectral limit are the family of minimum square derivative functions, such as minimum acceleration for 2^{nd} order systems, or minimum jerk for 3^{rd} order systems. The DR trajectories had lower peak velocities than expected from the minim jerk profile, but were similar to minimum acceleration (dotted lines in **Figures 5**, **9**). The relationship between DR and low bandwidth is unclear at present, but has two important implications.

If this invariance is upheld, it implies that the choice of basis set is not critical (presumably provided the output trajectory can be spanned by the input basis set). Indeed, it may reflect the

possibility that DR occurs at the output directly. In our work we only examine the state-space dimensionality and the computation of minimum dimensional weight matrix. In principle, this approach may also be used for investigating the optimal temporal characteristics of the basis set themselves. For example, using the Legendre polynomial basis, we observe a reduction in dimensionality across tasks, both in the input as well as in the output. In this respect, it is interesting that low bandwidth signals also have low Shannon numbers (although the Shannon number is an imprecise measure of signal dimension when duration is finite).

Second, there is a coincidence between low dimensionality and optimal control. That is, if low dimensionality is maintained, optimal or near-optimal trajectories are automatically generated for a given set of boundary conditions, and the curse of dimensionality is largely circumvented. An alternative is that the optimality approach itself is a misconstrued attempt to explain low dimensionality via a Lagrangian. However, for the minimum variance model, it would be difficult to explain the known presence of signal-dependent noise unless the noise is somehow a product/compensation for DR.

This last point is also relevant to synthetic (robotic) systems. Minimization of biologically relevant Lagrangians in synthetic systems does not necessarily lead to biologically realistic behavior, but depends on the synthetic architecture. For example, minimizing reaching time in a natural system appears to be achieved by the smooth bell-shape velocity profiles, but in a linear robot the same Lagrangian (functional mimicry) would be optimized by bang-bang control leading to skewed velocity profiles. In any case, finding such solutions in real-time is non-trivial, and often natural behavior must be programmed explicitly into the artificial system (esthetic mimicry) (Harris, 2009). However, when we consider DR as the underlying principle for generating natural behavior, we envision that functional mimicry in a robot would produce similar or the same natural behavior. It is not entirely clear at present, how precisely the mimicry would need to be. It is plausible that only crude approximations are needed. Furthermore, although we investigated two relatively simple systems performing reaching and via-point type tasks, the methods are computationally applicable to any control-affine systems. Thus in principle, these methods could be used to compute "natural" behaviors in robots of a variety of morphologies. A related application would be to optimize behavior in artificial systems that are driven by pattern based mechanisms such as Central Pattern Generators (CPG) (Ijspeert, 2008). Our approach is thus a potential path toward robots with neurally inspired motor control of reduced complexity.

FUNDING

This research was supported by the European Community under the 7th Framework Programme by the projects RobotDoc (Grant Agreement No. 235065), a Marie Curie Action ITN, and AMARSi (Grant Agreement No. 248311).

ACKNOWLEDGMENTS

The Authors would like to thank Dr. Juan-Pablo Carbajal for the discussions that lead to this work and Dr. Cristiano Alessandro for offering helpful comments on early versions of the manuscript. We also would like to thank the reviewers for their helpful comments and suggestions in shaping this manuscript.

A human motor system can improve its behavior toward optimal movement. The skeletal system has more degrees of freedom than the task dimensions, which incurs an ill-posed problem. The multijoint system involves complex interaction torques between joints. To produce optimal motion in terms of energy consumption, the so-called cost function based optimization has been commonly used in previous works.Even if it is a fact that an optimal motor pattern is employed phenomenologically, there is no evidence that shows the existence of a physiological process that is similar to such a mathematical optimization in our central nervous system.In this study, we aim to find a more primitive computational mechanism with a modular configuration to realize adaptability and optimality without prior knowledge of system dynamics.We propose a novel motor control paradigm based on tacit learning with task space feedback. The motor command accumulation during repetitive environmental interactions, play a major role in the learning process. It is applied to a vertical cyclic reaching which involves complex interaction torques.We evaluated whether the proposed paradigm can learn how to optimize solutions with a 3-joint, planar biomechanical model. The results demonstrate that the proposed method was valid for acquiring motor synergy and resulted in energy efficient solutions for different load conditions. The case in feedback control is largely affected by the interaction torques. In contrast, the trajectory is corrected over time with tacit learning toward optimal solutions.Energy efficient solutions were obtained by the emergence of motor synergy. During learning, the contribution from feedforward controller is augmented and the one from the feedback controller is significantly minimized down to 12% for no load at hand, 16% for a 0.5 kg load condition.The proposed paradigm could provide an optimization process in redundant system with dynamic-model-free and cost-function-free approach.

Keywords: feedback error learning, motor synergy, optimality, interaction torques, redundancy, Bernstein problem, tacit learning

1. INTRODUCTION

A human motor system can continuously act to improve its behavioral performance toward optimal movement. Motor learning and control are executed seamlessly, adapting to environmental variations and newly-generated desired goals based on a person's intentions. In addition, when we move our limbs to execute a motor task, our body has more degrees of freedom (DOF) than the number of dimensions in its task space. Kinematic redundancy can contribute to better dexterity and versatility, but incurs an ill-posed problem of inverse kinematics from the task-description space to the human joint space. Such an ill-posed problem of DOF was originally formulated by Bernstein (1967) as the DOF problem. It is still an open problem on how motor controllers in the brain solve kinematic redundancy.

It is known that the cerebellum takes an important role in such motor learning by developing the internal model while comparing the actual outcome to the predicted outcome (Wolpert et al., 1998; Kawato, 1999). Ito (1972) first proposed that the cerebellum contains forward models of the limbs. This internal model theory has been well supported by behavioral studies in the field of motor control (Schweighofer et al., 1998) and by neurophysiological studies (Kawato, 1999). To establish such an internal model, feedback-error-learning (FEL) is well studied to provide computational adaptation paradigms, including prism adaptation, saccade adaptation and reaching (Kawato and Gomi, 1992a,b). There is extensive evidence that the learning system using feedback error relies on the cerebellum. FEL can provide an algorithm to establish the internal inverse dynamics model by minimizing the error against the desired joint angle trajectory. However, particularly for a redundant system, it does not provide a mechanism that can systematically improve performance toward optimal solutions such as minimizing total energy or torque changes (Uno et al., 1989). FEL has a computational adaptability, but for computational optimality in motor redundancy, FEL should be used together with the so-called cost function based optimization (Schweighofer et al., 1998; Todorov, 2004; Braun et al., 2009). In a typical approach to using FEL with a redundant system, the desired joint angle trajectory is prepared using optimization to solve the redundant problem, and FEL is then applied to

establish the inverse dynamics model to map the joint angles and torques.

Several types of optimality model have been proposed. Such models are often defined as "minimum X," where X can be jerk (Flash and Hogan, 1985), torque changes (Uno et al., 1989), motor command (Harris and Wolpert, 1998), and energy consumption (Alexander, 1997). In redundant manipulators, such cost function based optimal control was successfully applied in Todorov and Jordan (2002) and Guigon et al. (2007). In robotics, several methods were studied to deal with the redundancy (Nakamura, 1991; Nguyen-Tuong and Peters, 2011). They basically assume the use of a physical inverse dynamic model (Nakanishi et al., 2008) or approximation-based model (Peters and Schaal, 2008). The model-based cost function is commonly used for the optimization process. As for model-free approach, adaptive feedback control is already known in control society (Astrom, 1987; Marino and Tomei, 1993). Adaptive control is basically a mechanism of the parameter adjustment of the model or the gain adjustment of the controller using the trajectory error. However, adaptive control can not be applied to redundant systems without using cost function based optimization (Nakanishi and Schaal, 2004). In addition, dual task of the target task execution and the behavior optimization toward energy efficiency can not be performed in parallel.

The phenomenological optimal solutions appearing in human motion can be obtained using such a mathematical optimization approach. It is known that we employ muscle synergy (D'Avella et al., 2003; Alnajjar et al., 2013) for natural motion, which should have a relationship to optimal solutions in redundant space. Even if it is a known fact that an optimal motor pattern is employed phenomenologically, there is no evidence that shows the existence of a physiological process that may be similar to such a mathematical optimization in our brain or central nervous system (CNS). For instance, infants can modify their motion toward an optimal solution through repetitive interactions with the environment, but the appropriate cost function may initially not have been obtained. In addition, cost function based optimization is a process which involves a global image of the dynamic system over time rather than a simple feedback process of the states for an instant in time, which is a complex process to be embedded in the CNS as a modular configuration. Thus, we believe that there is an importance to find an alternative simpler computational paradigm which can induce equivalent optimization property. There are two types of redundancy in human motion. One is about muscle redundancy, and the other is about kinematic redundancy. In this study, we focus on the control solutions on kinematic redundancy, and we define a coordinated command pattern in the joint level as motor synergy.

In this study, we aim to find a more primitive computational mechanism to realize both adaptability and optimality in a redundant system with a dynamic-model-free and cost-function-free approach. A simple control architecture which can deal with optimality in a redundant system, can be a key organizational principle that CNS employs for achieving versatility and adaptability in motor control. FEL allows to establish the internal model, but does not provide an optimization process in a redundant system. Thus, the main contribution of this paper is to propose a new way of inducing optimization process without a prior knowledge of the system dynamics by using the task space error. Recently, a novel learning scheme named *Tacit Learning* was proposed (Shimoda and Kimura, 2010; Shimoda et al., 2013) as an unsupervised learning paradigm. Tacit learning is a biomimetic learning architecture where the primitive behaviors composed of reflex actions are tuned to the adaptive behavior. The experimental results demonstrated that the walking gait composed of primitive motions was well adapted to the environment in terms of walking efficiency (Shimoda et al., 2013). Here, we reformulated the paradigm as a supervised learning approach applied to simple cyclic reaching tasks using the feedback motor command error as a supervising signal.

This work is also oriented for reaching simulation of motor-impaired subjects and able-bodied subjects. The skeletal system has a complex series of linkages that produce coupled dynamics. For instance, when we quickly move our forearm by flexing the elbow joint, the flexion torques on the elbow joint accelerate our forearm. However, because of the forearm's inertia, this acceleration also produces torques on the shoulder. These interaction torques induce the undesired effect of accelerating the upper arm segment. The dynamics of multijoint limbs often cause such complex torques. However, an able-bodied subject can normally handle such interaction torques through motor learning and predict them without difficulty (Shadmehr and Wise, 2005; Braun et al., 2009). In contrast, the vertical reaching task was studied in patients with cerebellar lesions in Bastian et al. (1996). They concluded that cerebellar patients had specific deficits in their predictive compensation for the interaction torques. In control subjects, the elbow and shoulder joints rotated in a synergetic manner to compensate for the interaction torques (Gribble and Ostry, 1999). In a patient with cerebellar damage, it was difficult to control the endpoint of the arm in a synergetic way between multiple joints because of gravity and interaction torques. This implied that cerebellar damage affects the prediction of interaction torques that is normally based on the internal model established from motor learning. Thus, it is significant to enable the control simulation of motor performance for subjects who are successful in dealing with the interaction torques and those who can not manage. In this paper, the control simulation results with redundant actuators demonstrate that the proposed method can systematically produce motor synergies and energy efficiency while finding a way to compensate the interaction torques during multijoint reaching tasks.

2. MATERIALS AND METHODS

2.1. VERTICAL REACHING AND DYNAMICS SIMULATION

In this study, we propose an optimal control paradigm in motor learning which has adaptability similar to FEL and optimality without using cost-function based optimization. We verified the performance of tacit learning in vertical reaching that involves complex interaction torques and the gravitational effect, as shown in **Figure 1**. This configuration was used in Bastian et al. (1996). We evaluated whether the proposed computational learning paradigm can learn how to compensate the interaction torques during multijoint reaching.

For simulating joint dynamics, we used MatODE (Caarls, 2010) which is a Matlab interface to the Open Dynamics Engine (Russell Smith, 2000). In a sagittal plane, 3DOF composed of the shoulder, elbow and wrist joint were assumed. The upper arm, forearm and hand segments were connected through each joint in the dynamics simulation environment. All the dynamics simulations were managed by external ODE package, in which the control module has access only to the control of each joint torque, and none to the manipulator dynamics model itself, in the learning process. It should be noted that the configuration used in this study is in the so-called Bernstein's DOF problem where we have actuation redundancy because the task is performed in 2D with a 3DOF manipulator.

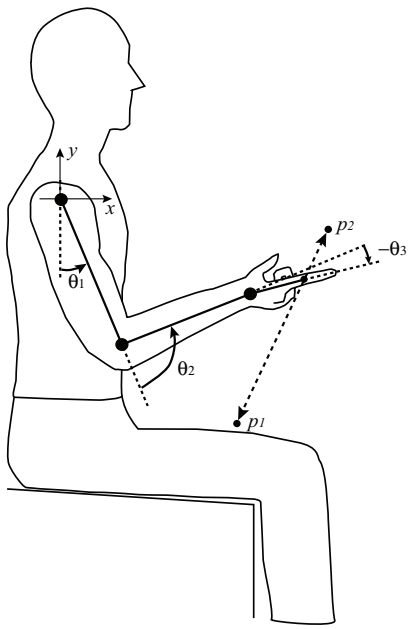

FIGURE 1 | Schematic representation of the vertical reaching task.

2.2. CONFIGURATION OF CONTROLLER WITH TACIT LEARNING

In tacit learning, the command signal accumulations during repetitive interactions with the environment, play a main role in creating appropriate behavior. In biological controllers, signal accumulations can be considered as the typical learning method to create the adaptive behaviors, such as long-term depression (LTD) and long-term potentiation (LTP) in the cerebellum (Coesmans et al., 2004).

Previously in tacit learning for biped walking, joints were divided into kinematically specified and unspecified groups (Shimoda et al., 2013). The unspecified joints were then controlled with tacit learning as an unsupervised learning paradigm. In this reaching task, only the desired position in task space was given as a target to follow, and all the joints were controlled with tacit learning as in **Figure 2**. The block diagram was formulated as a supervised learning paradigm using the feedback motor command error. Conceptually, it has an approach in common with FEL in how to use feedback errors as supervising signals. However, in FEL, optimization of some criteria is still necessary to achieve optimality. Thus, we aim to provide a primitive mechanism for realizing such optimality along with a FEL-like controller without using cost function. As in the mechanism of the cerebellum with regard to LTD and LTP, simple tacit learning with torque signal accumulation is employed to realize both adaptation and optimal control synchronously. This study is oriented for compensation of the interaction torques of unknown multijoint dynamics. We assume that only forward kinematics (FK) information is available. In contrast, in FEL, the given inverse kinematics computation is typically assumed to establish the internal inverse dynamics (ID) model.

Let us explain the details of the proposed learning paradigm shown in **Figure 2** by listing separated steps:

1. The intention of the subject to follow the target is expressed by a force vector in the task space, which represents the direction to the target, and the distance as its intensity, using the proportional (P) feedback error between the target and current endpoint.

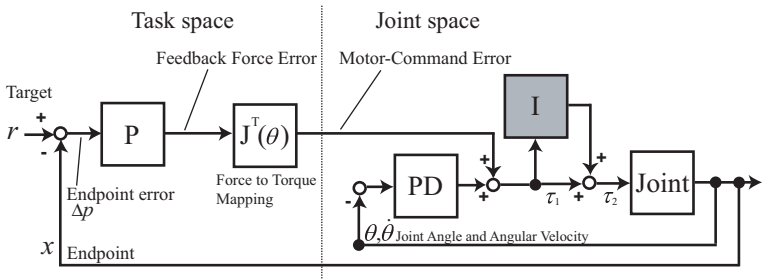

FIGURE 2 | A block diagram of motor learning for reaching motion using tacit learning. P represents Proportional, D Derivative, and I the Integral controller, respectively. The box named joint represents the physical joint of the arm. The intention of the subject is expressed by a force vector in the task space, which represents the direction to the target and the distance as its intensity, using the proportional feedback error between the target and current endpoint. The feedback torque command error at each joint space is computed through the Jacobian of the arm by mapping the feedback force into the joint torque space. Local PD control represents the local reflex loop as a function of a muscle spindle. The torque command accumulation part in gray color corresponds to tacit learning.

2. The feedback force error is mapped through the Jacobian of the arm into the joint torque space. It can be regarded as motor-command error that works as a supervising signal, as in FEL.
3. Local proportional derivative (PD) control mainly corresponds to a local reflex loop as a function of the muscle spindles. This part basically contributes to changing the joint angles smoothly.
4. Torque command accumulation part shown as gray box corresponds to tacit learning. This Integral (I) part serves as a unique learning process. This motor command accumulation part starts to learn how to compensate the interaction torques, and turns into a predictive torque patterns after the motor learning.

Specifically, the controllers for PD feedback and tacit learning can be expressed as follows.
PD feedback case:

$$\boldsymbol{\tau}_1 = -\boldsymbol{J}^T(\boldsymbol{\theta})k\Delta\boldsymbol{p} - \boldsymbol{A}\Delta\boldsymbol{\theta} - \boldsymbol{B}\dot{\boldsymbol{\theta}}. \quad (1)$$

Tacit Learning case:

$$\boldsymbol{\tau}_2 = -\boldsymbol{J}^T(\boldsymbol{\theta})k\Delta\boldsymbol{p} - \boldsymbol{A}\Delta\boldsymbol{\theta} - \boldsymbol{B}\dot{\boldsymbol{\theta}} + \boldsymbol{C}\int \boldsymbol{\tau}_1 dt. \quad (2)$$

$$\boldsymbol{\tau}_1, \boldsymbol{\tau}_2, \Delta\boldsymbol{\theta}, \dot{\boldsymbol{\theta}} \in R^m, \Delta\boldsymbol{p} \in R^n, \boldsymbol{J}^T(\boldsymbol{\theta}) \in R^{m\times n}, \boldsymbol{A}, \boldsymbol{B}, \boldsymbol{C} \in R^{m\times m}$$

where, m is the number of the joints, n is the dimensional number of the task space, $\boldsymbol{\tau}$ implies the control torque inputs of the joints, $\boldsymbol{\theta}$ implies the angles of the joints, $\dot{\boldsymbol{\theta}}$ implies the angular velocities of joints. $\boldsymbol{J}^T(\boldsymbol{\theta})$ is the transpose of the Jacobian of the arm, k is the gain of the task space propotional feedback, $\Delta\boldsymbol{p}$ is the endpoint error vector. This term corresponds to the neural substrate of force mapping functionality presumably due to corticospinal control (Bizzi et al., 1991).

$\boldsymbol{A}$ and $\boldsymbol{B}$ are diagonal matrices which consist of the proportional and derivative gains of the PD controllers. $\boldsymbol{C}$ is a diagonal matrix which consists of the gains of the torque command integration regarding motor-command error and local feedback torque. The term $\boldsymbol{A}\Delta\boldsymbol{\theta}$ is optional, and it can be set if you specify the neutral position of the joint. In this simulation, this neutral position is specified only for the wrist joint, because the wrist tries to return to the neutral position when we relax.

As for local PD feedback, this part corresponds to a local reflex loop as a function of the muscle spindles (Shadmehr and Mussa-Ivaldi, 1994). When a muscle is stretched, primary sensory fibers of the muscle spindle respond to changes in muscle length and velocity. The reflexivity evoked activity in the alpha motoneurons is then transmitted via their efferent axons to the muscle, which generates force and thereby resists the stretch. This work is still at joint level representation, but the resisting feature against muscle length change and velocity change can be captured by the resisting feature in the joint angle and angular velocity changes as in local PD control.

Note that all joints are controlled independently, then this configuration can be regarded as a modular structure presumably implemented within cerebellar pathways. All dynamical parameters, such as segment inertia and mass, and the model itself, are completely blind to the controller. Differently from typical optimal solutions that is based on model-based cost functions, our approach is to produce such optimization process without using cost function, purely with repetitive interactions with the environment. It purely works only with the controller presented, that tends to find optimal solutions by the given dynamic environment. The difference between the PD feedback case and the tacit learning case is only the last term of the command signal accumulation in Equation (2).

2.3. MECHANISM OF TACIT LEARNING FOR REACHING

As for the neurological explanation of the proposed control model, it has a common concept with FEL regarding the use of feedback error as a supervising signal. We can basically apply the same physiological roles as in FEL and the so-called internal model theory in the cerebellum (Kawato, 1999). The climbing fiber inputs to Purkinje cells carry error signals in the motor command coordinates, and their temporal waveforms can be well reproduced using the inverse dynamics model. The phase shift between feedback control and feedforward control during motor learning is well justified by obtaining the internal model in the cerebellum in previous papers (Kitazawa et al., 1998; Kawato, 1999). Feedforward movements are made without sensory feedback, which have predictive nature of the given dynamics. Feedback control, in contrast, involves modification of the current movement using information from sensory receptors and error detection. Optimal movement control likely reflects a combination of both feedback and feedforward processes (Desmurget and Grafton, 2000).

The difference in this work from a typical FEL configuration is first the point where the motor-command error is created by the mapping between the task space force and the joint space torque. In FEL, the optimized desired trajectory of position and velocity in joint space should be prepared in advance by optimizing some criteria specifically for the arm with redundant degrees of freedom (Schweighofer et al., 1998). Even if we use the Jacobian information, we do not perform inverse kinematic (IK) computation explicitly. The pseudo-inverse of Jacobian is not computed in this method differently from the typical methods in the robotics approach. Thus, the dimension reduction is not performed. The Jacobian itself can be obtained with the knowledge of the FK model. Thus, only FK information is assumed in this method, and the IK and ID models are unknown, then how to take the dynamics into account is being learned by the repetitive interactions with the environment. Thus, the controller design is different from a typical FEL configuration. In the proposed method, the optimality can also be addressed by tacit learning with command signal accumulations. Thus, along with the adaptivity originating from the FEL architecture, the optimal solution manageability can be a significant contribution of this study.

As for the explanation on how motor performance can be optimized over time, the motor command accumulation part serves as an energy feedback with task space directional information. Simply, in general error feedback control, when the error is feedback, the error can be minimized. Similarly, the integrated torque command contains an energy measure since it accumulates the

past torque generation history during cyclic reaching task. Then this term works as directional energy feedback, thus naturally the energy can be minimized as it is in a feedback loop. Thus, tacit learning can induce energy minimization through the repetitive actions with the environment while minimizing the endpoint error toward a given target point in the task space.

2.4. CONTROL SIMULATION STUDY OF VERTICAL REACHING

The task of vertical reaching is to move the endpoint of the arm following the target which is moving between two points at a frequency $f = 0.5$ Hz. These two points in the coordinate system of **Figure 1** and the moving target $\boldsymbol{r}(t)$ are given as follows:

$$\boldsymbol{p}_1 = \begin{bmatrix} 0.25 & -0.5 \end{bmatrix}^T, \quad \boldsymbol{p}_2 = \begin{bmatrix} 0.35 & -0.1 \end{bmatrix}^T.$$
$$\boldsymbol{r}(t) = (\boldsymbol{p}_1 - \boldsymbol{p}_2)\sin(2\pi ft)/2 + (\boldsymbol{p}_1 + \boldsymbol{p}_2)/2. \quad (3)$$

Initial joint angles are $\theta_1 = 0°, \theta_2 = 90°, \theta_3 = 0°$. As for the segment length, the inertia around the z axis and the mass of the upper arm, forearm and hand, they are obtained from the anthropometric table reported in De Leva (1996). They are set respectively as follows:

$$l_1 = 0.282[\text{m}]\ l_2 = 0.269[\text{m}]\ l_3 = 0.086[\text{m}],$$
$$I_1 = 0.01275[\text{kgm}^2]\ I_2 = 0.006516[\text{kgm}^2]\ I_3 = 0.001305[\text{kgm}^2],$$
$$m_1 = 1.978[\text{kg}]\ m_2 = 1.183[\text{kg}]\ m_3 = 0.445[\text{kg}].$$

The control gains are set respectively as follows:

$$k = 20.0, \quad \boldsymbol{A} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0.05 \end{bmatrix}, \quad \boldsymbol{B} = \begin{bmatrix} 0.01 & 0 & 0 \\ 0 & 0.01 & 0 \\ 0 & 0 & 0.01 \end{bmatrix},$$
$$\boldsymbol{C} = \begin{bmatrix} 0.15 & 0 & 0 \\ 0 & 0.15 & 0 \\ 0 & 0 & 0.15 \end{bmatrix} \quad (4)$$

We investigate the motor learning with different loads at the endpoint. Two conditions, with no load or a 0.5 kg load attached to the hand, were evaluated. The energy consumption during each reaching cycle is compared between only PD control case and tacit learning controller in different load conditions. In this study, the 30% value of the above mass parameters both for arm segments and load, was used to achieve faster convergence of the learning within 60 s, to allow plotting of the whole range of the learning process in the limited space. Even in this condition, the allocated mass and inertial parameters create the effect of gravity and interaction torques. As long as these dynamical parameters are blind as set in this simulation, it does not influence the verification of the tacit learning performance except for the learning speed. The control gains are set the same for the two controllers and for the different load conditions.

2.5. COMPARISON TO MODEL-BASED OPTIMIZATION

The above proposed method is purely based on control with sensory feedback information and FK model without using a knowledge of manipulator dynamics. The standard solution for redundant system control is to use mathmatical optimization with dynamics model as described in introduction. Thus, we have also tried the model-based optimization to compare to the result of tacit learning. We first define the equation of motion of the manipulator with m revolve joints. The equation of motion of such manipulator can be described as follows (Nakamura, 1991):

$$\boldsymbol{\tau} = \boldsymbol{R}(\boldsymbol{\theta})\ddot{\boldsymbol{\theta}} + \frac{1}{2}\dot{\boldsymbol{R}}(\boldsymbol{\theta})\dot{\boldsymbol{\theta}} + \boldsymbol{S}(\boldsymbol{\theta}, \dot{\boldsymbol{\theta}})\dot{\boldsymbol{\theta}} + \boldsymbol{g}(\boldsymbol{\theta}), \quad (5)$$

where $\boldsymbol{\theta}, \dot{\boldsymbol{\theta}}, \ddot{\boldsymbol{\theta}} \in R^m$ implies the vectors of joint angle, angular velocities and acceleration, respectively. We assume that $\boldsymbol{\theta}$ expresses the relative angles between neighboring links. $\boldsymbol{R}(\boldsymbol{\theta}) \in R^{m\times m}$ is the inertia matrix that is symmetric and positive definite. The eigenvalue of $\boldsymbol{R}(\boldsymbol{\theta})$ has the upper and lower bounds for any $\boldsymbol{\theta}$ because all elements in $\boldsymbol{R}(\boldsymbol{\theta})$ are the constant or the trigonometric function of $\boldsymbol{\theta}$. $\boldsymbol{S}(\boldsymbol{\theta}, \dot{\boldsymbol{\theta}}) \in R^m$ denotes centrifugal and Coriolis forces. $\boldsymbol{g}(\boldsymbol{\theta}) \in R^m$ is the gravitational component derived from the potential energy of the manipulator $U(\boldsymbol{\theta})$. All elements in $\boldsymbol{g}(\boldsymbol{\theta})$ are trigonometric functions of $\boldsymbol{\theta}$. The link length, link mass and inertia are set as indicated in the previous section.

The Matlab function fminunc was used to optimize the joint torque $\boldsymbol{\tau}$ with the constraints of the endpoint at the desired trajectory. The inverse dynamics is available with closed-form explicit equations as in Equation (5). This allows the joint angle to be calculated from the torques and vice versa. Optimal control solutions were obtained by finding deterministic controls $\boldsymbol{\tau}(t) = \{\tau_i(t)\}(i = 1...m)$ in $[t_0; t_f]$ such that the cost function

$$E = \sum_{i=1...m} \int_{[t_0;t_f]} \tau_i(t)dt \quad (6)$$

is minimum during the cyclic reaching task. Fifty discrete points per one reaching cycle of 2 s are used for the optimization process.

3. RESULTS

3.1. MOTOR CONTROL WITH TACIT LEARNING

To evaluate the performance of the proposed tacit learning, we compare the control results for vertical reaching between (**A**) a PD feedback controller and (**B**) tacit learning with feedback controller. The task of vertical reaching is to move the endpoint of the arm following the target.

Figure 3 shows a control result for vertical reaching. The first plot is the endpoint in the case with only PD feedback, and the second plot is with tacit learning in addition to feedback control. The time sequential transition is illustrated using a color map which changes depending on the progress of time. The color map correspondence to time can be seen in the color bar on the right side of figure. A cool color map is used for (**A**) PD feedback control, and a jet color map is used for (**B**) tacit learning. This colormap configuration is also used in other figures in this Result section.

Figure 3 shows that PD control is largely affected by gravity and the interaction torques. In contrast, we see that the trajectory is corrected in time in the case of tacit learning, minimizing the effect of gravity and interaction torques. **Figure 4** shows a phase portrait for the joint angle-angular velocity of the shoulder,

elbow and wrist joints. We notice that each joint phase portrait in tacit learning is gradually shifted from its original form that is similar to the form in the PD controller. It seems that the joint space around the neutral position, which is $\theta_1 = 0°, \theta_2 = 90°, \theta_3 = 0°$., is being sought regardless of the effect of gravity and interaction torques.

3.2. EMERGENCE OF MOTOR SYNERGY VIA TACIT LEARNING

Figure 5 indicates a phase portrait of the shoulder-elbow joint angle in no load and 0.5 kg load conditions. We can find that the phase in tacit learning converges into more aligned synergetic solutions compared with the case with only feedback control. The phase form in PD control changed with the addition of a 0.5 kg load. It represents that the controller is significantly influenced by gravity and the interaction torques.

As a result, it shows more unrelated and non-synergetic solutions between the shoulder and the elbow for PD control. In contrast, the phase form is similar for different load conditions in tacit learning. The shoulder and elbow joints are used in a synergetic way even with the load. As the metrics of the joint synergy, the coefficient of correlation between joint angles is calculated as in **Figure 5**. It showed low value in both PD control cases, in contrast, it showed high value after the learning process in tacit learning case. This implies that tacit learning allowed it to learn how to manage the interaction torques and to find synergetic combinations between neighboring joints to achieve efficiency in multijoint coordination. It is interesting to see such a synergetic solution is gradually found with the dynamics-model-free and cost-function-free approach. "synergistic solutions" can be considered as equivalent to "reduced space coordination." The aligned solutions toward reduced dimension was appeared in different load conditions with tacit learning. It implies that the aligned solutions is also robust to the dynamic condition changes, since the phase form is not necessary to be largely modified.

The integrated torque term of the wrist joint is depicted in **Figure 6**. The plot in the cool color map represents the case with PD feedback. In this mode, there is no integrated torque term in the controller, but this term was computed for comparison. The plot in the jet color map is the integrated torque term in tacit learning. We can find that the torque pattern of this term is converging into a certain form as in **Figure 6**. This torque pattern can be regarded as the part that compensates for gravity and the interaction torques of the dynamic system. In this sense, this torque integration term can be considered a feedforward (FF) controller which anticipates the environmental interactions during the reaching task. Motor learning is a process that develops a feedforward controller and minimizes the contributions from

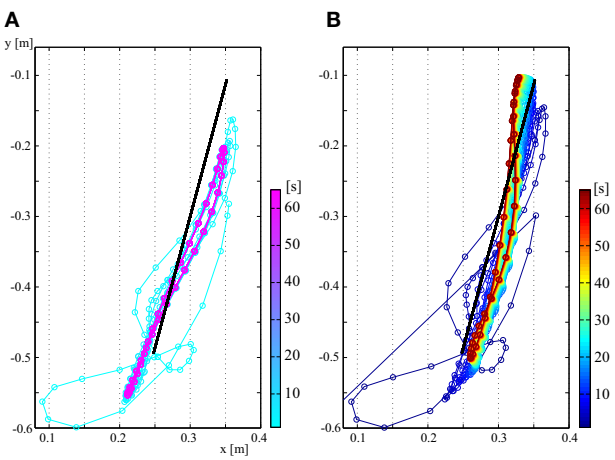

FIGURE 3 | Endpoint transition (no load at hand). (A) Only with feedback control and **(B)** with tacit learning in addition to feedback control.

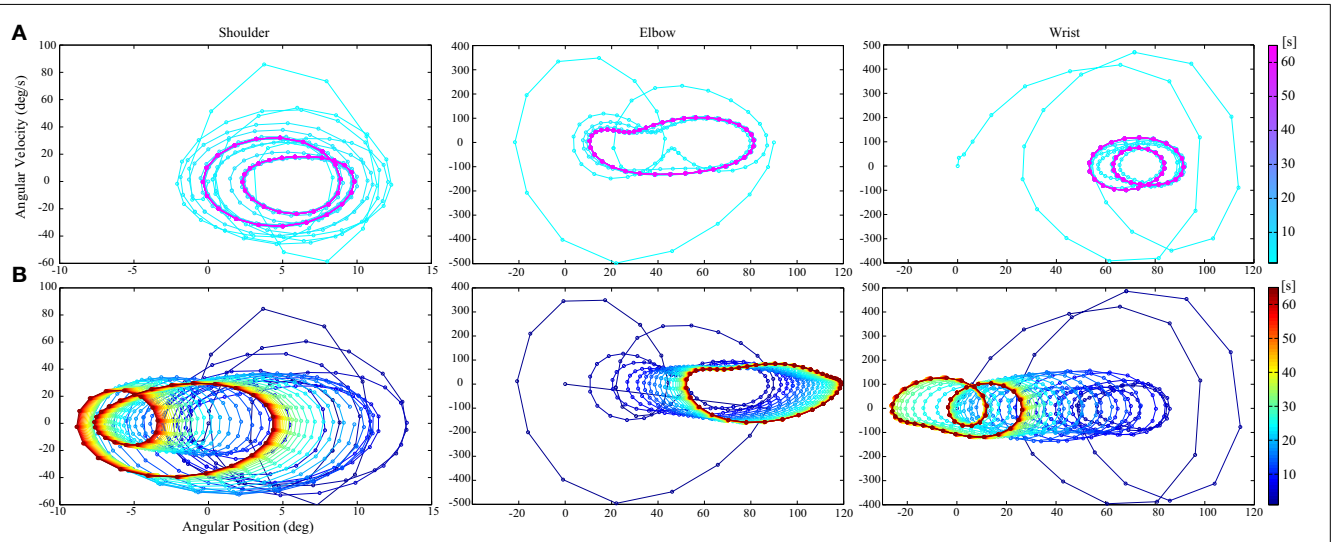

FIGURE 4 | Phase portrait of joint angle-angular velocity for the shoulder, elbow and wrist joints. (A) With only feedback control and **(B)** with tacit learning in addition to feedback control. We see that each joint phase portrait in tacit learning is gradually shifted through the interactions with the environment from its original form that corresponds to the solution of only feedback case.

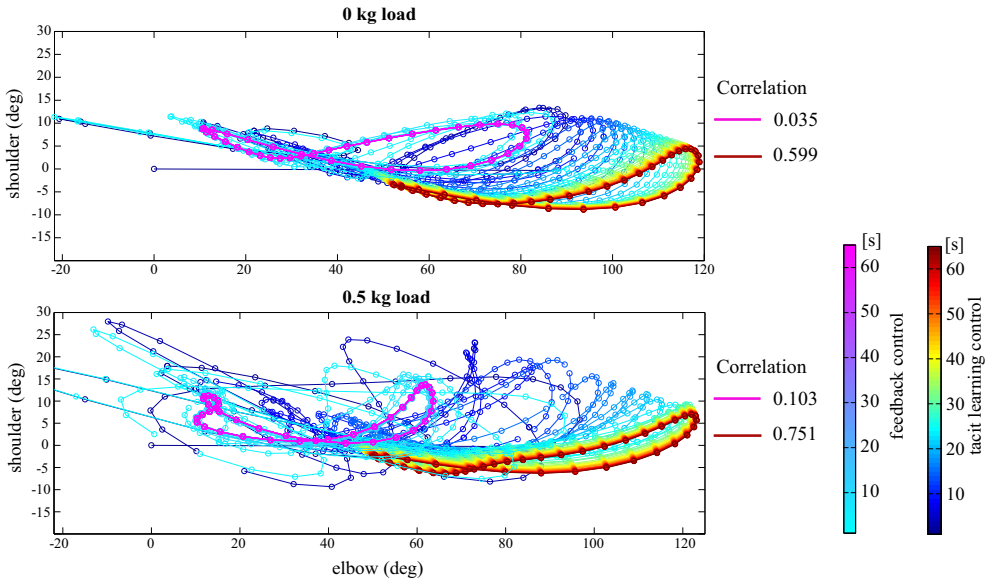

FIGURE 5 | Phase portrait between the shoulder and elbow joint angle in no load and 0.5 kg load conditions. The line in the cool color map indicates the result with only feedback control, and the line in the jet color map is that for tacit learning. We see the phase in tacit learning converges into more aligned synergetic solutions compared with the case in only feedback control. As the metrics of the joint synergy, the coefficient of correlation between joint angles represents the synergetic joint usage in the tacit learning case.

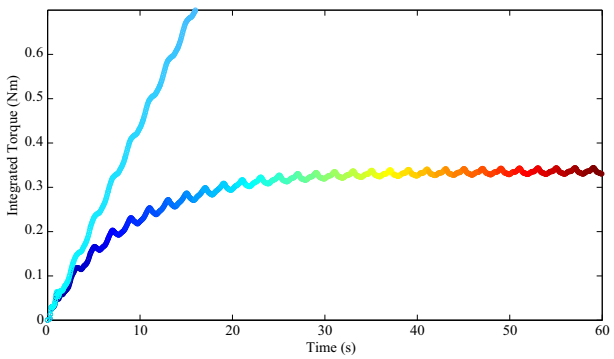

FIGURE 6 | The transition of integrated torque in the wrist joint (no load at hand). The line in the cool color map indicates the result with only feedback control. The integrated torque term was computed for comparison. The line in the jet color map is that for tacit learning. We see that the integrated torque pattern is converging into certain form that can be regarded as the predictive part which compensates gravity and interaction torques of the multijoint dynamics.

the feedback controller. During learning, the contribution from FF increased and the torque from FF converged into a certain pattern. Thus, tacit learning naturally matches this neurological learning process.

3.3. ENERGY EFFICIENCY AND TRACKING ERROR MINIMIZATION

Energy consumption in one cycle of reaching was measured and compared between PD control and tacit learning in different load conditions. The vertical reaching in this study was the motion between two vertically located points at a frequency of 0.5 Hz. Therefore, the energy consumption during every 2 s period was calculated by summing each joint energy consumption $2\pi\tau\dot{\theta}$. The transition of energy consumption in tacit learning with a 0.5 kg load is illustrated in **Figure 7** (middle). The corresponding endpoint error is also plotted with the calculation of the root-mean-square (RMS) error between the target point and current endpoint during one cycle as in **Figure 7** (top). The energy used in each joint is depicted by the red line for the shoulder, green for the elbow, and blue for the wrist joint as in **Figure 7** (bottom). In Equation (2), the torque component of PD feedback can be regarded as a feedback (FB) controller, and the integration term can be regarded as a FF controller. The energy consumption by each torque component was also computed, as shown in **Figure 7** (middle). For comparison, the transition of endpoint error and the energy consumption with a 0.5 kg load with feedback control case is shown in **Figure 8**. Initial transition phase is purely due to the stored energy in the mass-spring-damping property by PD control, since the arm starts to move from the stopped condition toward the moving target. Except this period, there is no adaptation process both in end point error as well as energy consumption. From the graph in **Figure 7**, the endpoint error is minimized asymptotically during motor learning. The energy consumption is also minimized globally, while the contribution from the FF controller is augmented in the course of motor learning and the contribution from the FB controller is minimized. In addition, we notice that the energy used in the elbow increased, while that in the shoulder decreased.

The endpoint error and energy consumption transition versus time is summarized in **Table 1** for all conditions. We can notice that the energy consumption in tacit learning is minimized during motor learning, while the energy transition remains

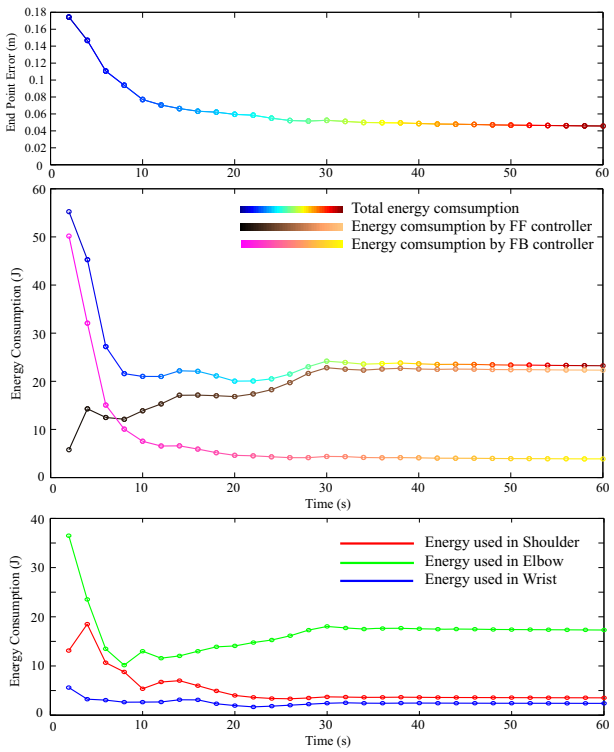

FIGURE 7 | The transition of endpoint error (top) and energy consumption in one cycle of reaching with a 0.5 kg load with tacit learning (middle). Not only improving the target tracking accuracy, but tacit learning solutions result in efficient total energy consumption. In addition, it was possible to observe the contribution ratio was switched between FB and FF controllers. Initially FB was mainly used, and with learning progress, the energy consumption with FB is significantly minimized. In addition, we notice that the energy used in the elbow increased while that in the shoulder decreased (**bottom**).

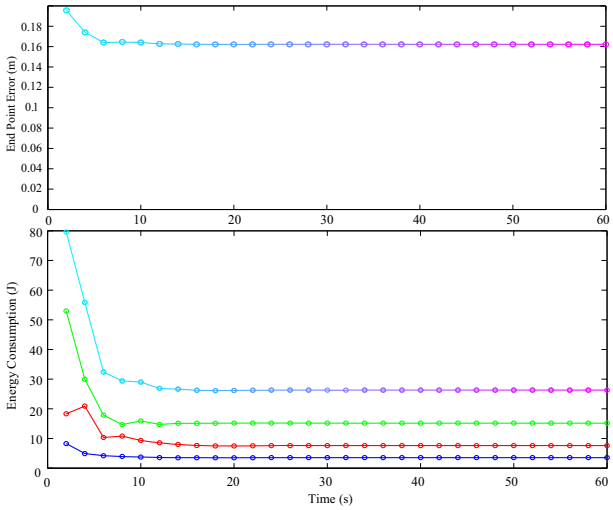

FIGURE 8 | The transition of endpoint error (top) and energy consumption in one cycle of reaching with a 0.5 kg load with feedback control case (bottom). Initial transition phase is purely due to the stored energy in the mass-spring-damping property by PD control, since the arm starts to move from the stopped condition toward the moving target.

constant in the case of feedback control because there is no adaptive functionality. As for endpoint error, it was also minimized to improve target tracking accuracy in tacit learning, while it remained constant in FB control. The energy consumption ratio by the FF controller was augmented, while that of the FB controller decreased. The figures in parentheses in **Table 1** indicate the cycle-to-cycle variability to evaluate the convergence of tacit learning. We can confirm that the error, the energy and the contributions of FF and FB are all converged in the course of the optimization process in tacit learning.

We should note that more energy was naturally necessary when we try to follow the moving target more precisely. The absolute energy consumption was not significantly different between the only feedback and the tacit learning cases. However, we should remember that the tracking error was largely different in both cases.

To realize accurate target tracking performance with only PD control, much greater energy will be required by increasing feedback gain because the dynamic effect should be canceled precisely, while having the conflicts between joints. With a load of 0.5 kg in tacit learning, both accuracy and total energy clearly improved with synergetic motor control of the shoulder and elbow joints, as a result of the optimality in tacit learning. In high-gain PD case, the four times larger gain k of the task space propotional feedback is used. Even though the end point error is similar scale to the one in tacit learning, the energy consumption becomes larger. Between PD and Tacit, the same gain k of the task space propotional feedback is used.

In addition, to show the performance for other tasks in different directions, a result for multidirectional reaching is shown as in **Figure 9**. The target moving line was tilted with every 60° for 3 directions. For each different target direction, the learning is started from center position with no prior knowledge. Here, the same control gains were employed for all the cases. Thus, we can find that the dynamics effect appears differently for different directions. For instance, the error and the energy consumption was different for each direction. Especially, direction 2 required larger energy than other directions. If we remind that the shoulder position is at origin of the coordinate, the inertial momentum around the shoulder and the swing-up momentum around the elbow can not be used effectively for direction 2, then we imagine that it was resulted in higher energy requirement.

3.4. RESULT WITH MODEL-BASED OPTIMIZATION

We analyzed the system also with model-based optimization by using a knowledge of the dynamics model. The endpoint error and energy consumption with the solution produced by model-based optimization are summarized in **Table 2**. We can notice that the energy consumption is similar to the one converged in tacit learning. It implies that the solution in tacit learning is close to the optimal solution by the so-called optimization approach. If we remind that in tacit learning, no dynamics knowledge is used differently from the case in so-called optimization, the result supports the advantage of the proposed method.

Table 1 | Endpoint RMS error (m) and energy consumption (J) in one cycle of reaching.

Time (s)	PD		Tacit				High-gain PD

kg	Error (m)	Energy (J)
0	0.019	16.51
0.5	0.019	22.65

4. CONCLUSIONS AND DISCUSSION

In this paper, we proposed a novel computational control paradigm in motor learning for a reaching task, especially vertical reaching which involves the management of interaction torques and gravitational effects. From the control results, we claim that the proposed method is valid for acquiring motor synergy in the system with actuation redundancy. We highlighted that tacit learning provides computational adaptability and optimality with dynamic-model-free and cost-function-free approach, in contrast to previous studies. Energy efficient solutions were obtained by the emergence of motor synergy in the redundant actuation space. Not only were the target tracking accuracy and energy efficiency improved, but the learning behavior was supported by a finding that the shift of contributions between the FB and FF controllers is observed, as shown in **Figure 7** (middle). Phenomenologically, this shift fits well with the findings reported in the internal model theory (Kawato, 1999).

Finally, the FF torque pattern converged to a specific temporal pattern in order to manage the given dynamics, as shown in **Figure 6**. Such effect of command signal accumulation may be regarded as phenomenological LTP and LTD, provided by the tacit learning. The above explanation is a qualitative interpretation. As for a theoretical explanation of the learning process, motor command accumulation part served as an energy feedback with task space directional information. As same as the case where the error can be minimized in error feedback loop, energy could be minimized when the integrated torque command was in the feedback loop through the repetitive actions with the environment.

In this work, FEL was taken as an example to be contrasted with the proposed method, but the result of this work actually doesn't conflict with FEL at all. On the one hand, the proposed method can be regarded as a special form of FEL. On the other, a neural network FEL architecture (Kawato et al., 1987) is still useful to memorize the optimal control solutions in the obtained

behavior together with sensory feedback signals for managing discrete movements. Thus, the proposed method could coexist alongside the conventional neural network FEL by adding a new optimality feature of the proposed method in a complementary role.

In addition, the simulation results showed good correspondence to the experimental results reported in Bastian et al. (1996). In their experiment, they found that the inability to produce accommodating joint torques for the dynamic interaction torques appeared to be an important cause of kinematic deficiencies shown by subjects with cerebellar abnormalities. Thus, the reaching by them showed lack of coordination of the shoulder and elbow joints, and a curved endpoint trajectory according to Bastian et al. (1996). The characteristics of reaching in subjects with cerebellar abnormality are equivalent to the results of **(A)** with only FB control in this study. In the case of PD feedback, we can confirm the failure to compensate for gravity and the interaction torques in **Figure 3**, and the curved non-synergistic joint use in **Figure 5**, which showed the conflicts between the joints. The level of the interference was higher in a 0.5 kg load condition because the interaction torque levels got higher.

In contrast, the experimental reaching of an able-bodied subject showed the correspondence to the result **(B)** with tacit learning. In Bastian et al. (1996), they suggest that a major role of the cerebellum is in generating joint torques with prediction of the interaction torques being generated by other moving joints and compensating for them. It implies that the proposed computational learning paradigm well represents the learning principles actually taking place in the cerebellum. The failure to manage interaction torques leads to the situation where one joint motion affects the motion of another. Thus, the solution to managing these environmental forces should be achieved by finding synergetic use of neighboring joints. When the conflicting torque could be minimized, it can naturally result in energy effective motion. It can be a reason why we employ motor synergy that can reduce the interaction conflicts in a multijoint system. In the results, the energy used in the elbow increased, while that in the shoulder decreased. This is one of the results from the strategy where an energy effective solution is being learned because the joint angle acceleration in the shoulder involves all the arm segments from the upper arm to the hand, while the joint angle acceleration in the elbow involves only the forearm and the hand, which are half the total mass in the arm dynamics system. Tacit learning found it only by repetitive interactions with the environment without using a dynamic model and cost function. This process is similar to human motor control principles, where even an infant can improve his motor control ability by repetitions without thinking about it. Increasing the contribution of the FF controller that corresponds to the so-called internal model development also matches well the nature of computational motor learning in a human being (Kawato, 1999). In **Table 1**, the contribution ratio was switched between FB and FF, initially FB was fully used, and with learning progress, the energy consumption with FB is significantly minimized down to 12% for no load, 16% for a 0.5 kg load condition. Instead, the contribution of FF is increased from initial 0% to 95% for no load, 96% for a 0.5 kg load condition. Since there is still remained conflicts between FB and FF solutions, the sum of both goes over 100%.

The results demonstrated in this paper also concern Bernstein's DOF problem. The Bernstein problem is how the CNS can find an optimal solution with actuation redundancy. The use of motor synergy was pointed out by Bernstein, but a fundamental motor control principal that can generate motor synergy has not yet been reported in neuroscience. In this study, it is a simple situation of actuation redundancy, but the proposed tacit learning first managed to generate motor synergy by a simple computational principle, which is more likely to be embedded as a modular configuration in the CNS, rather than the so-called cost function based mathematical optimization approach. The obtained solution in tacit learning also showed the similar energy consumption to the case with such model-based optimization.

In this study, we have not conducted the tuning of control gains, since we preferred to propose a new type of computational paradigm which can manage redundant system optimization process. However, in the given dynamic conditions and the given control gains, the tacit learning showed that the contribution of the FF controller is augmented in the course of motor learning and the contribution from the FB controller is minimized for all the directions and different loads. Further, more optimal solutions may be obtained in different control gain conditions. However, the detailed analysis on the dynamic stability of the system, would be required for the generalization of the control gain tuning for future work. Simple cyclic reaching task was used in this study to show the optimization process in redundant system. Toward complex task management, additional work would be necessary to establish the internal model from the optimized torque solutions obtained from the proposed method.

A recent study from the group of G. Courtine (Van Den Brand et al., 2012) reported that smart circuits embedded in the brain stem and spinal cord, may elaborate the detailed motor command toward optimum motor states, based on the supraspinal signal, current limb position, and constraints. As the proposed controller has a simple modular paradigm with a distributed structure that can be embedded into the individual controllers for multijoint coordination to achieve adaptivity and optimality for the total system, the proposed computational principle may also help to represent spinal adaptivity toward optimal solutions.

Moving in a cluttered environment with a six-legged walking machine that has additional body actuators, therefore controlling 22 DoFs, is not a trivial task. Already simple forward walking on a flat plane requires the system to select between different internal states. The orchestration of these states depends on walking velocity and on external disturbances. Such disturbances occur continuously, for example due to irregular up-and-down movements of the body or slipping of the legs, even on flat surfaces, in particular when negotiating tight curves. The number of possible states is further increased when the system is allowed to walk backward or when front legs are used as grippers and cannot contribute to walking. Further states are necessary for expansion that allow for navigation. Here we demonstrate a solution for the selection and sequencing of different (attractor) states required to control different behaviors as are forward walking at different speeds, backward walking, as well as negotiation of tight curves. This selection is made by a recurrent neural network (RNN) of motivation units, controlling a bank of decentralized memory elements in combination with the feedback through the environment. The underlying heterarchical architecture of the network allows to select various combinations of these elements. This modular approach representing an example of neural reuse of a limited number of procedures allows for adaptation to different internal and external conditions. A way is sketched as to how this approach may be expanded to form a cognitive system being able to plan ahead. This architecture is characterized by different types of modules being arranged in layers and columns, but the complete network can also be considered as a holistic system showing emergent properties which cannot be attributed to a specific module.

Keywords: insect locomotion, motor control, decentral architecture, action selection

INTRODUCTION

In this article, we propose a simple neural architecture that consists of basically independent, parallel sensori-motor procedures—or modules—that allows to orchestrate these modules. In addition this architecture shows the property for easy expansions of the system. This architecture is not based on a specific biological brain structure, but is inspired by behavioral experiments on insects (Cruse et al., 2009a) as are walking on unpredictable environment, performed with stick insects, and navigation, performed with desert ants and honey bees. Nonetheless, such a modular architecture may be of broader interest because many authors assume that a modular structure is a basic property of brains in general.

For example, Anderson (2010) has argued that evolution had to find specific solutions for quite different requirements posed by specific environmental conditions as are locomotion, mating, navigation or feeding, and problems occurring later during evolutionary development may be solved by combining existing (functional) modules in different ways, following the principle of "neural reuse" (Anderson, 2010). In this way, different procedures might be developed that finally serve the same or very much related purposes, thus leading to redundant structures. In insect navigation, for example, path integration and landmark navigation are used in parallel. In this case, different input modules are used to drive the same output elements. In turn, the same motor structure may be used for different purposes. This is obvious in the case of the Praying Mantis, where front legs can be used for walking, but can also be used for a completely different purpose, namely for catching prey, which requires specific neuronal structures for these different functions. Furthermore, Flash and Hochner (2005) have reviewed results on both vertebrates and invertebrates that lead these authors to the interpretation that "many different movements can be derived from a limited number of stored primitives." These movements can further be "combined through a well defined syntax of action to form more complex action."

Therefore, many results suggest the existence of such discrete primitives. The question as to how behavioral choice is performed, i.e., how the lower level elements are selected and orchestrated to control a specific behavior is still open (Briggman and Kristan, 2008). Activating such a subfset means to select a specific internal state that sets priorities. At a higher level, this

corresponds to the faculty of selective attention, i.e., the enactment of internal states that control which sensory input may be exploited. This top–down influence may be complemented by bottom–up attention: sufficiently strong, specific sensory inputs could influence and change the internal state of the system.

In this article, we propose a way how this problem could be addressed by exploiting an artificial neural network, Walknet, that has been developed to describe a huge amount of biological data concerning insect, i.e., hexapod (forward) walking (Dürr et al., 2004; Schilling et al., 2013). This network consists of a number of parallel modular elements able to control "microbehaviors" as for example swing movement of the left front leg or stance movement of the right middle leg. This decentralized architecture is able to control forward walking within a continuous range of velocities as observed in stick insects (Graham, 1972) or Drosophila (Wosnitza et al., 2013). Walknet can further describe a large number of behavioral experiments performed with stick insects, including difficult cases like climbing over a gap of about body size. In doing so, the controller shows its robustness with respect to disturbances resulting from unpredictable environment but also from the complex dynamics of the own body.

So, Walknet is able to deal with complex behavior, but still controls only one overarching specific context, namely forward walking as will be briefly reviewed in Section The Basic Version (for a recent review see Schilling et al., 2013). According to this structure, only local decisions are required, which concern the decision between swing and stance for a given leg. Walknet has been expanded by a body model, briefly reviewed in Section Body Model (for details see Schilling, 2011; Schilling et al., 2012), that represents the kinematics of the body, i.e., all 18 joints of the six legs plus two body joints, each with 2° of freedom, as can be found in stick insects and as they are used by the physical hexapod robot Hector (Schneider et al., 2011). However, to allow for controlling different behaviors, further decision structures are required. A simple case concerns the decision between forward and backward walking. In addition, the system may decide between 6-legged walking and 4-legged walking, where the front legs may be used for other purposes, for example as grippers, as is the case in the above mentioned Mantis. A more general problem concerns the ability to exhibit trial-and-error behavior, i.e., select a behavior that is not selectable in the current context. This faculty is a prerequisite for a further capability, namely being able to plan ahead (i.e., internal simulation of a selected behavior), a property which may not be found on the insect level. Another problem concerns the question how biological systems may be able to invent and deal with symbols, or new concepts. Hints exist that this property can already be found in insects (Giurfa et al., 2001), at least on a simple level.

Based on the already given Walknet, in this article we will introduce a neural architecture that provides a precondition for dealing with those problems. To this end, we will adopt a structure already successfully applied within a network, Navinet, that is able to control insect-like navigation (Cruse and Wehner, 2011; Hoinville et al., 2012). Navinet can then be used as an expansion of Walknet to allow for decisions at higher levels of integration. For example, a foraging ant may decide between selecting one of different food sources stored in memory, and, at a lower level, to select between inbound or outbound travels. After having selected the food source, the ant may decide to attend a visual landmark seen or not. In Navinet, this ability is given by a so-called motivation unit network, a structure that will now be applied to Walknet, too (Section Motivation Unit Network). This expansion allows the complete system to decide between different behaviors at different levels of integration. In the final version this will lead us to an architecture that will consist of many parallel "columns" which are organized in four layers. As the motivation unit network can be considered the "backbone" of the architecture proposed here, we call the latter Motivation Unit Based Columnar Architecture (MUBCA).

In this article we will show how Walknet can be expanded by motivation units and still does inherit its earlier properties. To this end the behavior of the expanded Walknet will be tested in different situations of forward walking including starting from uncomfortable leg configurations and the negotiation of very tight curves. These tests are critical for studying the stability of the system because due to the irregular stepping patterns, resulting from the dynamical properties of the body including possible leg slipping, the complete system is subject to continuous disturbances. We further will show that the network can select between states of forward walking and backward walking. To illustrate how the motivation unit network could be expanded for further procedures, as an example we will discuss the case of switching between 6-legged walking and 4-legged walking (Section Discussion) and will note how to connect Walknet with Navinet to equip the complete system with insect-like navigation procedures as are vector navigation and landmark navigation. In addition, to illustrate the capacity of this architecture we will briefly sketch how this structure could be exploited to equip the complete system with cognitive abilities in the sense to be able to plan ahead and how the use of symbols may be possible.

WALKNET

THE BASIC VERSION

Tightly based on the morphology of a stick insect (*Carausius morosus*), the walker has six legs, each of which is equipped with three joints. The abdomen and the head of the insect are not functionally relevant for walking. Therefore, the body of the walker consists of only three functional relevant body segments. The leg pairs are connected to those three body segments. The body segments are connected by joints, each allowing for 2° of freedom (up and down as well as side movements of the body segments). Therefore, the controller has to deal with 22° of freedom (DoF). As the position of one body segment in space is defined by only six DoFs (three for position in space, three for orientation) there are 16 DoFs free to be decided upon by the controller. However, "free" does not mean that the controller may leave the decision open, rather it has to make these 22 decisions in a sensible way at any moment of time and, as mentioned, in an unpredictable environment. Note that in many similar robots the number of free DoFs is artificially reduced by a central controller (e.g., an explicit tripod controller), which simplifies the control but, on the other hand, restricts the flexibility of the system.

As a first step—and to make it simple for our understanding, but not necessarily for the system itself—, the walker is not equipped with distance sensors like vision or acoustic sensors, but only with tactile sensors situated in the legs (and possibly the antennae) measuring contact with external objects, and with proprioceptors measuring position and velocities of joints.

The walking system to be described in the following and that has been tested to be able to control a six-legged robot (Dürr et al., 2004; Schmitz et al., 2008), is based on behavioral (and to some extent neurophysiological) studies on insects, in particular stick insects. For the purpose required here the reactive controller will also be equipped with elements forming plausible expansions. At first, we briefly describe the essentials of the earlier version, Walknet, and will then introduce the expansions in Sections Further Procedural Elements and Body Model.

Forward walking in stick insects, which has already been intensively studied (Cruse et al., 1998), consists, on the leg level, of the stance movement, during which the leg maintains ground contact and is retracted to propel the body forward while supporting the weight of the body, and the swing movement where the leg is lifted off the ground and moved in the direction of walking to touch down at the location where the next stance should begin. Experiments on the walking stick insect have shown that the neuronal system is organized in a decentralized way (Wendler, 1964; Bässler, 1983; Cruse, 1990). Derived from these results, a model has been proposed in which each leg is attributed to a separate controller (Dürr et al., 2004). These single leg controllers are assumed to be situated in the thoracic ganglia [for a review see (Bässler and Büschges, 1998)]. **Figure 1** sketches the approximate anatomical arrangement of the controllers and the numbering of the legs. Each controller is in charge of the behavior of the connected leg, as the controller decides which behavior is executed by this leg and in which way the joints are moved. **Figure 2** shows the details of the controllers as used in Walknet for two legs (leg1, leg2, e.g., the right front leg and the right middle leg). A single leg controller mainly consists of several procedures that are realized by artificial neurons forming a local, in general, recurrent neural network (RNN). In most cases these networks consist of perceptron-like feedforward networks. These modules might receive direct sensory input and provide output signals that can be used for driving motor elements. But other modules may also provide input to a module. All these networks may be considered to form elements of the procedural memory. The two most important procedural elements in our example are the Swing-net, responsible for controlling a swing movement, and the Stance-net controlling a stance movement [**Figure 2**, see (Dürr et al., 2004; Schumm and Cruse, 2006) for details concerning the Swing-net, and (Schmitz et al., 2008) for Stance-net]. In addition, each leg possesses a so-called Target_fw-net (**Figure 2**). This net influences the Swing-net to determine the endpoint of the swing movement during forward walking. During normal forward walking the swing end-position is situated in the anterior section of the leg's range of movement (anterior extreme position, AEP). During stance the leg is moved backward until it reaches the posterior extreme position (PEP), the latter being represented by another memory element (not depicted in **Figure 2**).

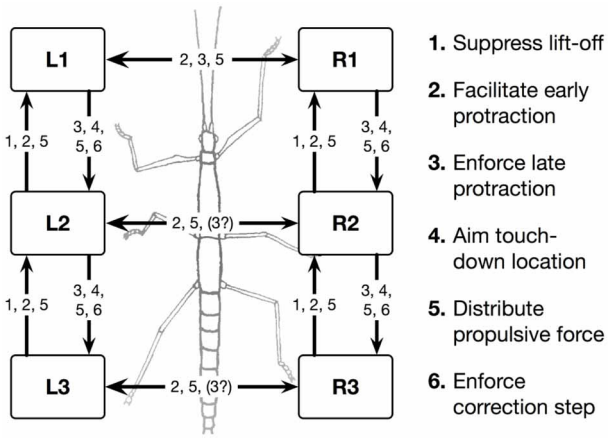

FIGURE 1 | Schema of the morphological arrangement of the leg controllers and the coordination influences (1–6) between legs. Legs are marked by L for left legs and R for right legs and numbered from 1 to 3 for front, middle, and hind legs, respectively. The question mark indicates that there are ambiguous data concerning this influence.

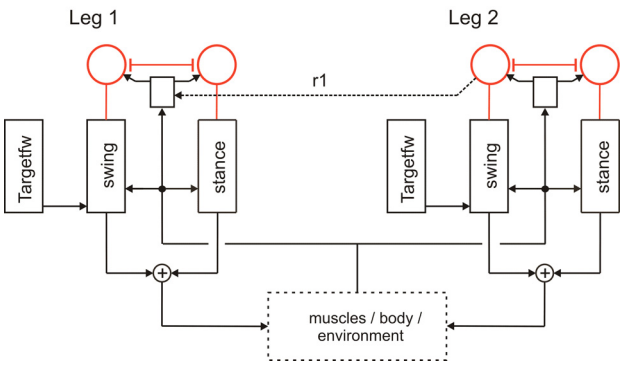

FIGURE 2 | A section of Walknet showing two leg controllers. Each consists of a Stance-net and a Swing-net, the latter being connected with a Target-net (Targetfw). The motor output acts on the legs (box muscles/body/environment). Sensory feedback is used by the motor procedures as well as to switch between the states (red units connected by mutual inhibition). r1 represents coordination rule 1 (see **Figure 1**).

Furthermore, a leg controller must also take into account the interaction with the other legs. Part of these interactions are mediated directly by the body and through the environment, making explicit computations superfluous [see, e.g., the local positive velocity feedback approach (Schmitz et al., 2008)]. While the physical coupling through the environment is important, it is not sufficient. In addition, the controllers of neighboring legs are coupled via a small number of channels transmitting information concerning the actual state of that leg (e.g., swing, stance) or its position (i.e., values of joint angles). These coordination rules were derived from behavioral experiments on walking sticks (Cruse, 1990; Dean, 1991a,b, 1992a,b). In **Figure 1** the channels are numbered 1–6. Coordination rules 1–3 influence the length of the stance movement by influencing the transition from stance to

swing movement, i.e., they change the PEP value. The Target-nets (rule 4) influence the AEP. As an example, in **Figure 2** (dashed line) only one connection is shown, rule 1 (r1), which suppresses the start of a swing movement of the anterior leg (in this case the front leg, leg1) during the swing movement of the posterior leg (here the middle leg, leg2).

The local sensory influences and the coordination influences are integrated in the so-called analog selector net (Schilling et al., 2007) that decides whether a swing movement or a stance movement is performed. Activation of the Stance-net is triggered by ground contact, activation of Swing-net is triggered when the current PEP value is reached. In **Figure 2** the selector net is represented by two units (marked red) which are connected by mutual inhibition, thus forming a winner-take-all network (WTA-net, for details see Section Motivation Unit Network). Activation of such a unit (between 0 and 1) controls the output of the corresponding procedure in a multiplicative way. The representation of the value for the default PEP is not depicted in **Figure 2** as well as the detailed influence of the coordination rules influencing the actual PEP value (for reviews see Dürr et al., 2004; Schilling et al., 2013).

Kinematic and dynamic simulations as well as tests on robots have shown that this network can control walking in different velocities, producing different insect gaits including the continuous transition between the so called tetrapod gait and the tripod gait, negotiate curves (Kindermann, 2002), climbing over obstacles (Dürr et al., 2004) and over very large gaps (Bläsing, 2006), and coping with leg loss (Schilling et al., 2007). Thus, Walknet exhibits a free gait controller where the gaits are not explicitly implemented but emerge from a strictly decentralized architecture. Including some more recent extensions, Walknet can describe further behaviors observed in stick insects walking on variously shaped substrates (e.g., Diederich et al., 2002; Schumm and Cruse, 2006).

In the following, we will expand Walknet as illustrated in **Figure 3**. These expansions concern (i) the introduction of further procedural elements (Section Further Procedural Elements), (ii) a body model (Section Body Model), and (iii) a motivation unit network (Section Motivation Unit Network). The properties of the robot simulator will briefly sketched in the Appendix.

FURTHER PROCEDURAL ELEMENTS

Further procedures are required when the controller should not only be able to perform one type of behavior, for example forward walking, but also others like backward walking. Specifically, further Target-nets are introduced which can influence the corresponding Swing-net to move the leg in posterior direction as during backward walking (bw) the swing end position is in the posterior (rear) section (**Figure 3**, Target_bw-net). Correspondingly, the default end position of the stance movement is represented by a "PEP-net," one for forward walking and another one for backward walking. For simplicity the latter are not depicted in **Figure 3**. The Target_fw-net mentioned above can be realized by a two-layer perceptron (Dean, 1990). Its function is to compute the anterior target position, the leg aims at during the swing movement. The anterior target is usually situated directly behind the current position of its anterior neighboring leg. The computation therefore represents the inverse kinematics. Alternatively, and this version is used in the simulation shown here, the Target-nets and the PEP memories are realized as a three-unit RNN with bias, representing a static memory element storing the corresponding target position. For backward walking in addition the corresponding coordination rules are required but not depicted in **Figure 3**.

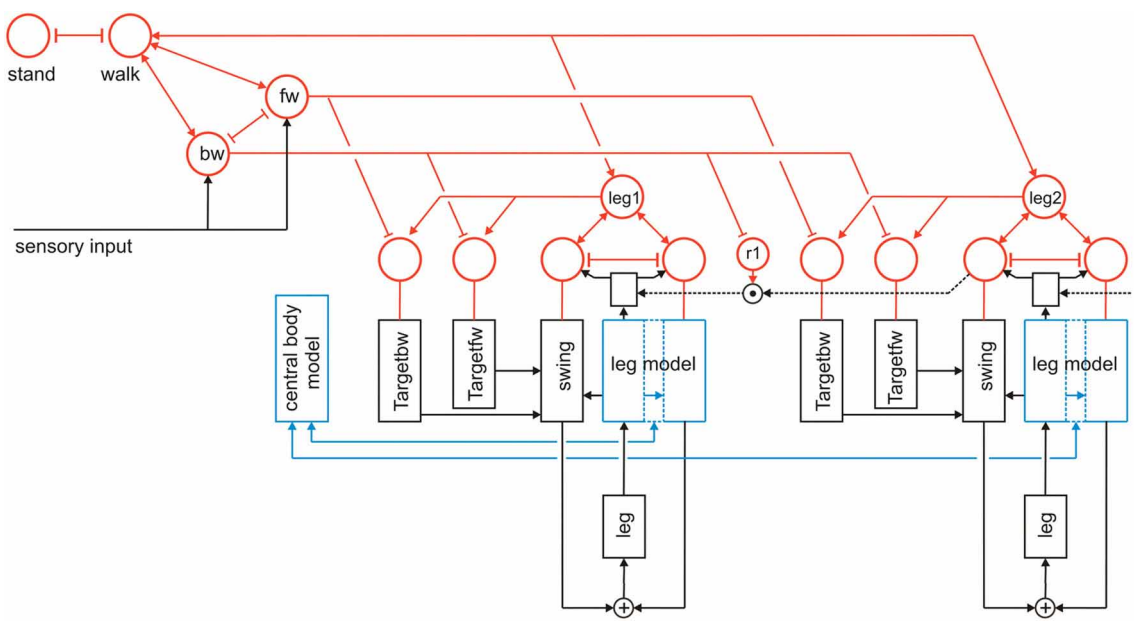

FIGURE 3 | Walknet as depicted in Figure 2, but now expanded by further procedures (Target_bw-net), a body model (blue) and a motivation unit network (red). The body is represented by the boxes "leg." Note that for clarity only the target nets are depicted, but not the PEP-nets.

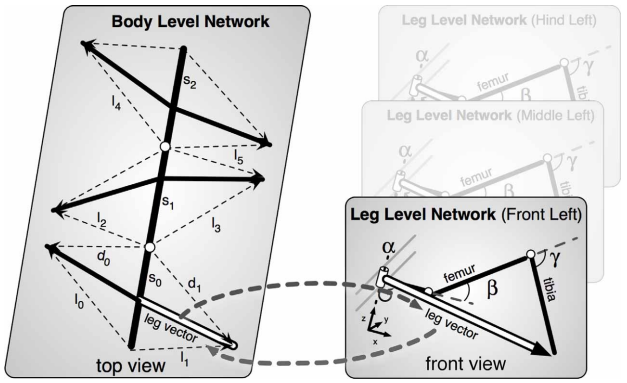

FIGURE 4 | The body model. Left, the upper, abstract level representing the body; **Right**, three of the six networks representing the legs.

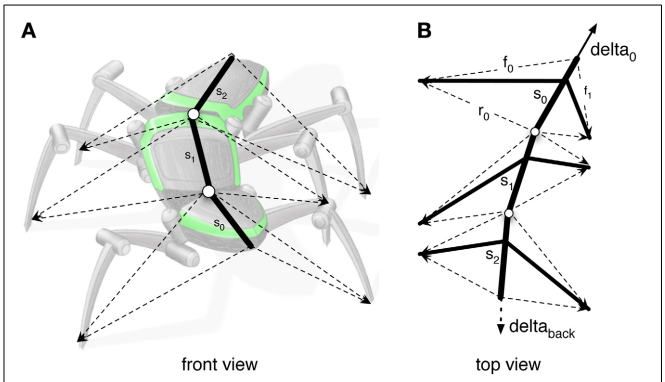

FIGURE 5 | (A) Illustrates how the body model is attached to the body of robot Hector. **(B)** shows the vectors delta_0 and delta_back pulling the model in forward or backward direction, respectively.

BODY MODEL

A second important expansion concerns the construction and implementation of a body model. This body model is represented by a specific RNN (Schilling, 2011) and has a modular structure (Schilling et al., 2012). It consists of six networks each representing one leg. These modules are connected on a higher level forming a seventh network representing the whole body. This network represents the central body and the legs in an only abstracted form. In **Figure 3** the elements of the body model are marked in blue. Thus, the body model is represented by a modular structure which, as it is constructed as a RNN, at the same time comprises a holistic system [**Figure 4**, for details concerning the body model see (Schilling, 2011; Schilling et al., 2012)].

In normal walking the body model is used for controlling stance movements. It is used in forward and backward walking as well as in negotiating curves and provides joint control signals to the system. Sensory data are fed into the body model. Due to its holistic structure the body model integrates redundant sensory information and is able to correct possible errors in the sensor data (Schilling and Cruse, 2012). As will be sketched in the Discussion, due to its ability of pattern completion, this model can also be used as a forward model (Schilling, 2009). Therefore, the model allows for prediction, too.

The function of the body model is to mediate the coupling between the single leg vectors (**Figure 4**). During a movement these vectors have to be moved in a coherent way. While the body moves to the front, the feet should stay on the same place on the ground, i.e., the relative position between the feet must not change. As the model mirrors the 22° of freedom of the insect body the task is underdetermined and therefore this is still a hard problem and a unique solution is not directly computable (Schilling and Cruse, 2012).

As a solution, we apply the idea of the passive motion paradigm to this problem (von Kleist, 1810; Mussa Ivaldi et al., 1988; Loeb, 2001). Like a simulated marionette puppet (**Figure 5B**), the internally simulated body is pulled by its head in the direction of desired body movement (**Figure 5B**, delta_0), provided, for example, by a vector based on sensory input from the antennae (Dürr and Schütz, 2011) or, if available, by visual or acoustic input (**Figure 3**, sensory input, **Figure 5B**, delta_0, delta_back). As a consequence, the stance legs of the puppet move in an appropriate way. The changes of the simulated joint angles as well as the body joints can be used as commands to control the actual joints. If such a body model is given that represents the kinematical constraints of the real body, we obtain in this way an easy solution of the inverse kinematic problem, i.e., for the question how the joints of legs standing on the ground have to be moved in concert to propel the body (for details and application for the control of curve walking see Schilling et al., 2012). In this case, the positive feedback input given to Stance-net, as was used in the earlier version (Schmitz et al., 2008) is not anymore necessary (although application of both influences may be sensible). The Stance-net can therefore be considered to only consist of Integral Controllers, one for each leg joint to which the body model provides the reference inputs.

MOTIVATION UNIT NETWORK

To allow the system to select autonomously between different behaviors as for instance standing and walking, or forward and backward walking, Walknet is expanded by introduction of a RNN consisting of so-called motivation units (**Figure 3**) as has been done for Navinet (Cruse and Wehner, 2011; Hoinville et al., 2012). The units used here are artificial linear summation neurons with a piece-wise linear activation function showing lower and upper limits of 0 and 1, respectively.

The function of a motivation unit as applied here is to control to what extent the corresponding procedural element contributes to the behavior. To this end, these units influence the strength of the output of this network (in a multiplicative way). In an earlier version (**Figure 2**, Schilling et al., 2007) such a network containing only two motivation units has been applied to control the output of Swing-net and Stance-net. In this network each motivation unit is reinforcing itself, whilst the two motivation units are mutually inhibiting each other forming a WTA-net. Due to this competition, only one of the two behaviors is active most of the time. This decision is influenced by sensory signals acting on the motivation units. When the leg touches the ground at the front during a swing movement, the ground contact causes

switching to the stance movement. When the leg reaches the PEP during stance, swing is initiated. Introduction of motivation units was inspired by Hassenstein (1983) and Maes (1991) and is based on the finding of Schumm and Cruse (2006) according to which there are indeed variable motivational states for individual procedures, in this case the swing controller.

Here we expand this network in two ways (**Figure 3**). First, each procedural element will be equipped with a motivation unit. This means that not only Swing-net and Stance-net, but also all Target-nets and all PEP memories as well as the leg coordination channels have an own motivation unit. Motivation units for Target-nets and PEP-nets are required to select between different target positions for forward walking and backward walking. The motivation units influencing the coordination rules are motivated by Dürr (2005), and Ebeling and Dürr (2006), who showed that coordination influences can be modulated (e.g., during curve walking).

Second, motivation units can also be used to influence other motivation units via excitatory or inhibitory connections. This is illustrated in **Figure 3**. Units which belong to the procedural nets controlling the six legs (only two legs are depicted in **Figure 3**) show mutual positive connections to a unit termed "walk" in **Figure 3**. This unit serves the function of arousing all units possibly required when the behavior walk is activated. Neurophysiological grounding of such an influence is given by Büschges (1998): when walking is started, the basic potential level in a number of relevant neurons is increased. In addition, following earlier authors (see Discussion) we introduce units "forward" and "backward" to activate procedures required for forward or backward walking (**Figure 3**, fw, bw), respectively, by selecting specific Target-nets and PEP-nets. It is only indicated in this figure that the unit "walk" may be coupled via mutual inhibition to other units that stand for different behaviors like, for example, standing still (unit "stand"). However, the corresponding procedures are not depicted (for a further expansion see **Figure 10**). Apart from the units fw and bw, it is also not shown that these "higher-level" motivation units, as is the case for the motivation units of Swing-net and Stance-net, may receive direct or indirect input from sensory units that influence the activation of a motivation unit.

As illustrated in **Figure 3**, this at first sight hierarchical structure is in general not forming a simple, tree-like arborization. As indicated by the bi-directional connections, motivation units form a RNN coupled by positive (arrowheads) and negative (T-shaped connections) influences (for details concerning the weights used see the Appendix). This structure may therefore be better described as "heterarchical." The combination of excitatory and inhibitory connections form a network that can adopt various stable attractor states. Some of these motivation units are coupled by local winner-take-all connections. This is true for the Swing-net and Stance-net of each leg, as well as for the motivation units for forward and backward walking. Thereby, a selection of one of the available Target-nets and of the PEP-nets is possible. Excitatory connections between motivation units allow for building coalitions. As depicted in **Figure 3**, there are different overlapping ensembles. For example, all "leg" units and the unit "walk" are activated during backward walking and during forward walking, but only one of the two units termed "fw" (forward) and "bw" (backward) and only some of the targeting modules are active in either case. This architecture can produce various stable attractor states or "internal states" (see Appendix for details). Such a state protects the system from responding to inappropriate sensory input. For instance, as a lower-level example, depending on whether a leg is in swing state or in stance state, a given sensory input can be treated differently: stimulation of a specific sense organ leads to a Levator reflex (when hitting an obstacle the leg is briefly retracted and then lifted) when in swing, but not during stance (see **Figure 5** from Dürr et al., 2004). Correspondingly, internal states can be distinguished on higher levels, as for example walking, standing still or forage (in the case of Navinet).

RESULTS

As this article is focused on demonstrating the structure and the functioning of the heterarchical network in cooperation with the decentralized procedural memory, we will not report on a detailed quantitative evaluation of the functional properties of the walking system as has been done by Kindermann (2002). Instead, we show six examples of walking situations for which various combinations of active motivation units are required (five cases for forward walking, one case for backward walking) as are different walking velocities, "uncomfortable" starting configurations, or curve walking. The behavior is illustrated by plotting the footfall pattern, i.e., for each leg the state swing (black) or stance (white) over time, to illustrate the temporal structure of the gaits. In addition, in the supplement we provide videos showing the behavior of the robot, the temporal development of the footfall patterns, as well as the temporal sequence of the internal states, represented by the activation of all motivation units.

During forward walking, continuously active units are walk, fw (forward), all six leg units and the units of the corresponding Target-nets and PEP-nets. More or less regularly alternating are the Swing and Stance units of the six legs.

STRAIGHT WALKING

In forward walking a vector (**Figure 5B**, delta_0), which might be provided by tactile input from the antennae or by visual input, is pulling the body model straight forward. Velocities are given as a dimensionless number (relative velocity v_rel = swing duration/stance duration). **Figure 6A** (**Movie S1**) shows high velocity walking (v_rel = 0.5) corresponding to what is usually called tripod gait (at least three legs are on the ground at any time). **Figure 6B** (**Movie S2**) shows a walk with lower velocity (v_rel = 0.4), usually called tetrapod (at least four legs are on the ground at any time). **Figure 6C** (**Movie S3**) shows very slow walking (v_rel = 0.15), sometimes termed wave gait. Note that, like in the insects, there is no clear separation between these "gaits." Rather, examples shown in **Figure 6** are taken from a continuum which depends on one control parameter, the velocity.

Figure 6D (**Movie S4**) shows a walk (v_rel = 0.3) starting from a difficult starting configuration (see legend). In this case, contralateral leg pairs started with exactly the same leg position. This leads to a gallop-kind stepping pattern (see the first three steps).

A symmetry-break occurs due to minor irregularities in the ODE simulation (e.g., short slipping of a leg). After another about three to four steps, a stable wave gait pattern can be observed (Videos for all example walking cases are provided as supplementary material.).

NEGOTIATING CURVES

Still in forward mode, the body model can also be used for walking in curves which leads to another kind of leg coordination. Only the pull vector acting on the body model has to be adjusted and has to point in the direction the agent should walk to. As mentioned, the pull vector may be provided by signals from the antennae or via visual input. The body model is pulled (at the front of the first segment, **Figure 5B**, delta_0) into this direction and all standing legs as well as the body segments are following (Schilling et al., 2012). **Figure 7** (**Movie S5**) shows a simulation run, where the body model is pulled to the front and the right by an angle of 12°. Velocity is set to v_rel = 0.4, i.e., no different velocities are required for right and left legs in contrast to the simulation of Kindermann (2002). We also did not change the nominal AEP and PEP values in contrast to the behavior observed in the insects (Jander, 1985; Dürr, 2005; Dürr and Ebeling, 2005; Rosano and Webb, 2007; Gruhn et al., 2009). As has been shown by these authors, during swing, the legs, in particular the front legs, target sideways, which may even allow these animals to turn on the spot (Cruse et al., 2009b). Nonetheless, the simulated agent can negotiate curves as tight as a radius of about one body length (distance between front leg coxa and hind leg coxa, 578 mm, see **Figure 8B**) compared to the approach of Kindermann (2002) whose tightest curves had a diameter of about three body lengths. During the sequence depicted in **Figure 7**, a curve of about 180° has been negotiated. In the simulation, inner legs show much smaller stance velocities and smaller step amplitude compared to the outer legs. As can be observed in **Figure 7**, the inner hind leg shows much smaller step frequencies and, depending on the radius of the curve, may even keep staying on the ground during the complete turn (not shown). Both results compare to those observed in insects (Dürr, 2005; Rosano and Webb, 2007; Gruhn et al., 2009).

Figure 8A Illustrates the movement of the leg tips during stance in a top–down view using as coordinate system that of the last body segment. Shown is at least one stance phase of each leg over the time of 2 s simulation time after the curve walking has been initiated for 6 s This means, that initialization of the curve has been completed and the behavior is now in a stable

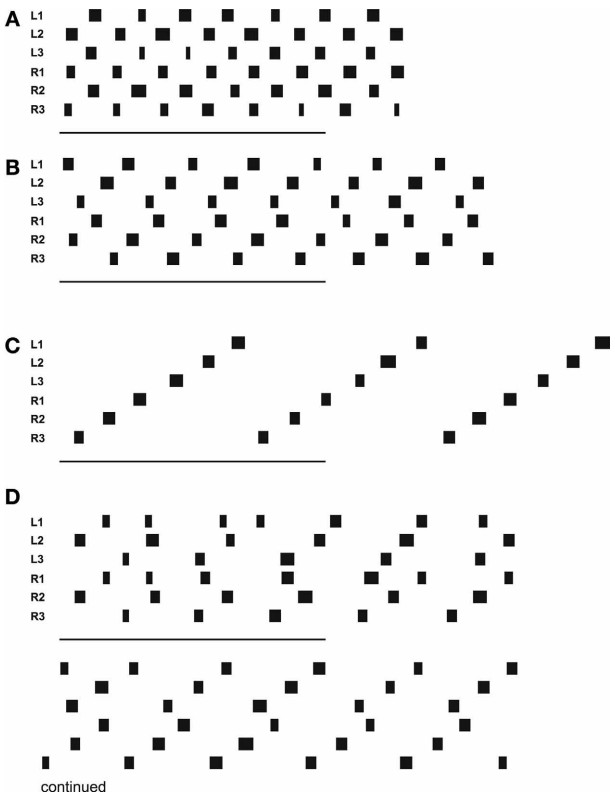

FIGURE 6 | Simulated Hector walking straight with high (A), middle (B), and low (C) speed, leading to tripod gait, tetrapod gait and wave gate, respectively. (D) shows a walk starting from uncomfortable starting configuration. Starting position (in m, origin is position of coxa) for **(D)**: L1: 0.15, R1: 0.15, L2: -0.1, R2: -0.1, L3: -0.02, R3: -0.02. Black bars indicate swing movement of the respective leg: left front, middle and hind leg, right front, middle and hind leg, from top to bottom. Abscissa is simulation time. The lower bars indicate 500 iterations corresponding to 5 s real time.

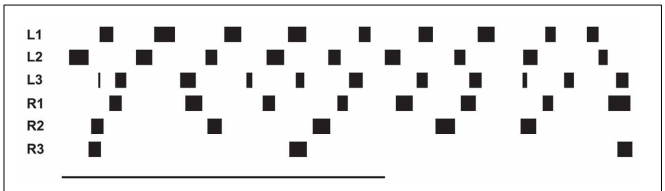

FIGURE 7 | Simulated Hector walking a turn to the right using the internal body model. The internal body model is constantly pulled to the front and the right. The complete run shown corresponds to a turn of about 180°. Starting positions (in m, origin is position of coxa): L1: 0.20, R1: 0.05, L2: -0.04, R2: -0.14, L3: -0.02, R3: -0.22; for further explanations see **Figure 6**.

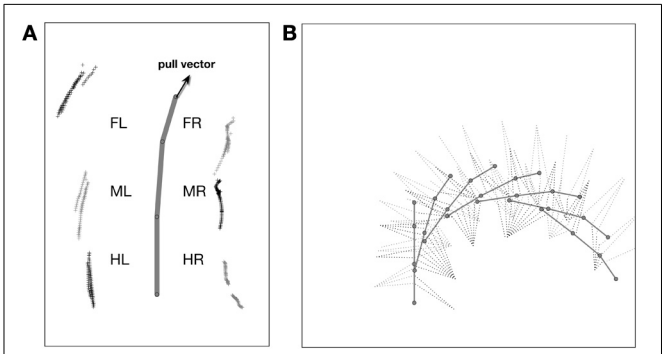

FIGURE 8 | Curve walking of the model. In **(A)** the movement of the leg tips during the stance movement is shown with respect to the last body segment. **(B)** shows snapshots of the movement over time. Every second of simulation time the body posture is shown, the postures of the legs in stance are shown four times each second.

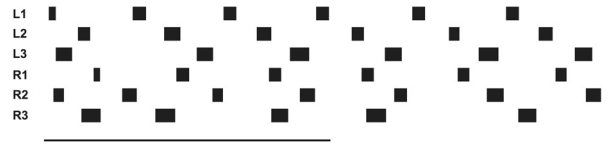

FIGURE 9 | Simulated Hector walking backwards. Starting positions (in m, origin is position of coxa): L1: 0.20, R1: 0.05, L2: -0.04, R2: -0.14, L3: -0.02, R3: -0.22; for further explanations see **Figure 6**.

execution state. This is also shown by the stable orientation of the body segment angles [first segment joint has a mean value of 15.0° (std. ± 1.27), second segment joint has a mean value of 4.8° (std. ± 0.35)]. The outer legs perform faster movements during stance than do inner legs (see different distances of symbols). The outer front leg is showing movements far away from the body, mostly because the body is pulled away from its footpoint. In **Figure 8B** the movement is shown as a sequence, emphasizing the tightness of the curve. Here, every second of simulation time the body posture is shown and the leg postures are given for standing legs in addition four times each second. **Figure 8B** includes the initiation of curve walking (see also the video provided as supplementary material).

BACKWARD WALKING

To trigger backward walking, the motivation unit for backward walking (**Figure 3**, bw) has to be activated. In animals, this behavior can be elicited by tactile stimulation of both antennae (Graham and Epstein, 1985). Motivation unit bw activates the corresponding Target-nets and PEP-nets. Activation of this motivation unit additionally sets the forward pull vector to zero, and activates a displacement vector being attached to the back of the last segment, thereby pulling the model backwards (**Figure 5B**, delta_back). Furthermore, the leg coordination rules required for backward walking are switched on (here we used a mirror image version of the rules used for forward walking). As in straight forward walking or curve walking, this vector is assumed to be provided by appropriate sensory input.

In the case of backward walking (**Figure 9**, v_rel $= -0.4$, **Movie S6**) the attractor states of the motivation unit network are characterized by the continuously active units walk, bw (backward), all six leg units as well as the units of the corresponding Target-nets and PEP-nets required for backward walking. As in forward walking, Swing-nets and Stance-nets of the six legs show variable activation patterns, which, in backward walking, also result from the different coordination rules applied. The corresponding video further outlines the details of the behavior.

DISCUSSION

We describe a novel architecture that can be used to control an autonomous robot and is based on earlier approaches, Walknet and Navinet. The neural controller Walknet, as described earlier (e.g., Dürr et al., 2004; Bläsing, 2006; Schmitz et al., 2008; Schilling et al., 2013), represents a typical case of an embodied controller: the network is able to control the movement of a hexapod walker in unpredictably varying environments without relying on other information than available using the given mechanosensors. This is possible because the body and properties of the environment are crucial elements of the computational system—the system is embodied not only in the sense that there is a body (i.e., that there are internal states being physically represented), but in the sense that the properties of the body (e.g., its geometry) are required for computational purposes. Exploiting the loop through the world (including the own body) allows for a dramatic simplification of the computation. In the version being expanded by an internal body model, too, control of DoFs does not result from explicit specification by the neuronal controller, but results from a combination/cooperation of the neuronal controller, the internal body model and the coupling via the environment.

The procedures forming the decentralized controller are basically arranged in parallel, i.e., obtain sensory input and provide motor output, but there are also procedures that receive input from other procedures and, as a consequence, procedures that provide output to other procedures. Application of such a decentralized architecture helps to solve the flexibility—automaticity dilemma. Modules have a fixed function, but can work together in a flexible way to solve difficult tasks. In the case described here this is realized by a system that, based on studies of insect behavior, has been designed to control hexapod walking but is also able to climb over very large gaps (Bläsing, 2006).

Flexibility of the system is improved by introduction of the motivation unit network (Section Motivation Unit Network), which allows to integrate additional behaviors in the process of behavioral selection. The organization of this network is especially designed to allow for competitions on different levels, in this way forming different clusters of units. For example, the competition on a leg level selects swing and stance movements, while, on a more global level, the walking direction or other behaviors different from walking can be selected. Activities of these motivation units not only allow for selection of behavioral elements, but also provide a context according to which specific sensory inputs are attended or not. In this sense, the motivation unit network can be considered to be a system allowing for controlling attention. This property is more obvious in another case, where the architecture proposed here has successfully been applied for controlling insect navigation ("Navinet," Cruse and Wehner, 2011; Hoinville et al., 2012). In this task the animals are able to select visiting one of a number of food sources learned, and to decide between traveling to the food source or back home. Of particular interest is here that a desert ant and also Navinet attend known visual landmarks only in the appropriate context, i.e., depending on the food source it is actually traveling to. In this way, the system controlled by the motivation network allows for selective attention. As Navinet provides walking direction as output, both Navinet and Walknet can directly be combined, whereby the output of Navinet controls the pull vector of the body model.

Introduction of motivation units does not impair the behavior of the basic Walknet structure, because during walking in one direction (forward or backward) all motivation units maintain their activation values except for the Swing and Stance motivation

units. Only the latter change their activation dynamically and do this in the same way as is the case in the earlier Walknet versions. Therefore, all properties of Walknet concerning forward walking are inherited in the version expanded by motivation units.

Although the procedures as such are essentially arranged in parallel, the motivation network provides connections between the modules that form a dynamical heterarchy. In contrast to Jenkins and Mataric (2003), for example, who discuss a three level structure (motor level, skill level, task level), our architecture does not imply such a strict separation in levels. Rather, any combination of modules might, in principle, be possible in this architecture. Furthermore, this architecture is very flexible as it easily allows for later expansions to represent not only six-legged walking, but, for example, four-legged walking where both front legs could be used as grippers. How this could be done is illustrated in **Figure 10**. As depicted in this figure, to this end the front leg controller, in the figure leg 1, is equipped with a parallel procedure termed "grasp," that is controlled by an own motivation unit (**Figure 10**, gri1). This motivation unit is activated if the unit "4-legged walk" is active, which in turn inhibits the unit "6-legged walk."

Figure 11 indicates how the motivation unit network of Navinet (Cruse and Wehner, 2011; **Figure 1**) and that of the Walknet version depicted in **Figure 3** can be combined. To this end, we introduce a higher layer consisting of two motivation units "sleep" and "awake," which are then connected to the uppermost layer of Walknet (**Figure 3**), units "stand" and "walk," and to the uppermost layer of Navinet, units "nest" and "forage."

Our network provides an example showing that concatenation of modules required for control of complex behavior does not necessarily require explicit coding, but may emerge from local rules and the coupling through the environment. The heterarchical structure used in the expanded version of Walknet and in Navinet comprises a simple realization of "neural reuse" as proposed in Anderson's massive redeployment hypothesis 2010.

The network, as described, consists of a "hard-wired" structure, i.e., the weights connecting the artificial neurons are fixed. Nevertheless, the system is able to flexibly adapt to properties of the environment. However, there may also situations occur in

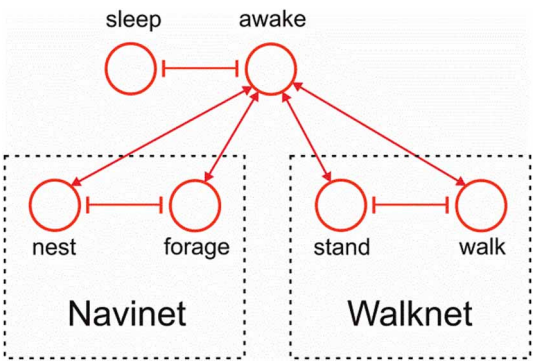

FIGURE 11 | Combination of the motivation unit network of Walknet as depicted in Figure 3 and of Navinet (Cruse and Wehner, 2011, Figure 1).

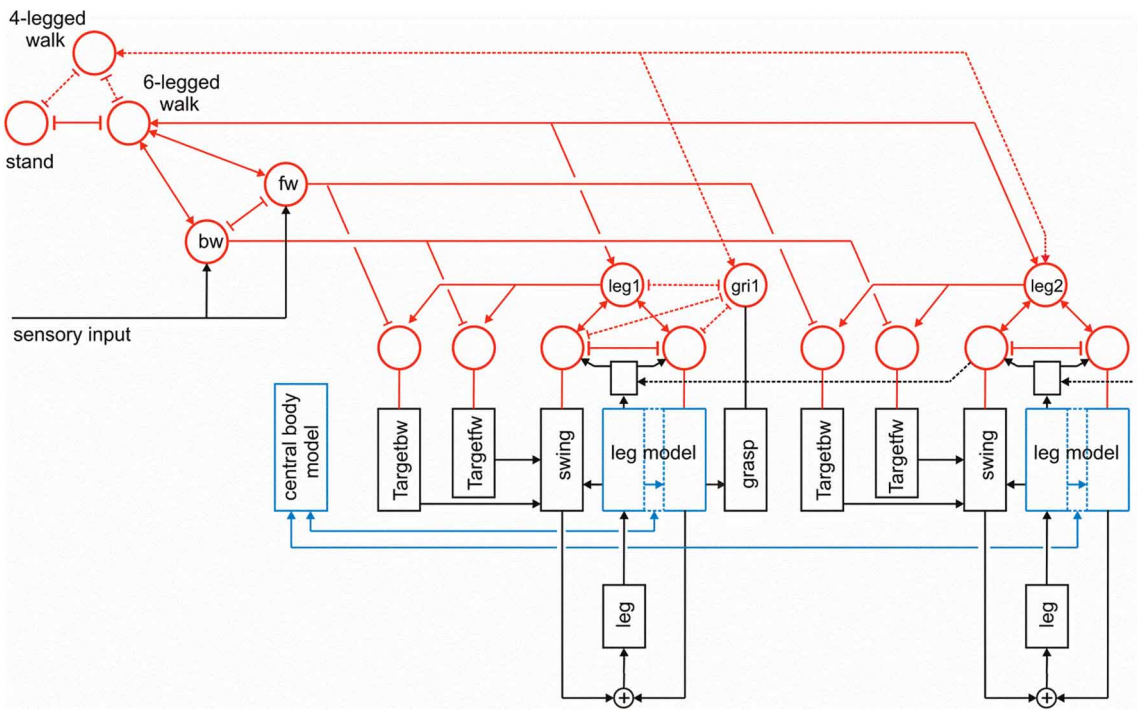

FIGURE 10 | The same network as shown in Figure 3, but now expanded by a procedure that allows for switching between 6-legged walk and 4-legged walk, where front legs (here leg 1) can be controlled by another procedure ("grasp," output not shown) via a motivation unit "gri1." The additional connections required are marked by dashed lines.

which the controller runs into a deadlock. Think for example of the situation in which, during forward walking, by chance all legs but the right hind leg are positioned in the frontal part of their corresponding range of movement, whilst the right hind leg is positioned very far to the rear. When this leg starts a swing movement, the body may fall backward as the center of gravity is not anymore supported by the legs on the ground. Such a "problem" might be signaled by specific sensory input, for example a specific load distribution of the legs. To find a way out of this deadlock, a random selection of a behavioral module not belonging to the actual context, in our case forward walking, may help. A possible example might be a backward step of the right middle leg. Such a backward step of the middle leg would make it possible to support the body, then allowing the hind leg to start a swing. However, in our controller, backward steps are only permitted in the context of backward walking. How might it be possible for the system to find such a solution nonetheless?

In **Figure 12** we briefly illustrate a simple expansion allowing the system to search for such a solution (Schilling and Cruse, 2008). A third layer, essentially consisting of a recurrent WTA-net, is arranged in such a way that each motivation unit has a partner unit in the WTA-net (**Figure 12**, green units). The WTA units might be activated by various "problem detectors" not depicted in **Figure 12**. Motivation units activated in the actual context inhibit their WTA partner unit (T-shaped connections in **Figure 12**). Thus, a random activation of the WTA-net will, after relaxation, find one of the currently not activated modules. The WTA unit winning the competition can then be used to activate its partner motivation unit and thereby trigger a new behavior that can be tested for being able to solve the problem. In this way, realizing a special type of top down attention, the network has the capability of following a trial-and-error strategy.

As has been proposed (Schilling and Cruse, 2008) a further expansion of the system may permit to use the body model instead of the real body to test the new behavior via "internal trial-and-error" whilst the motor output to the real body is switched off. To this end, switches have to be introduced allowing the motor output signals to circumvent the real body and being passed directly to the body model (not depicted in **Figure 12**). Only if the internal simulation has shown that the new trial provides a solution to the problem, the behavior will actually be executed. McFarland and Bösser (1993) define a cognitive system in the strict sense as a system that is able to plan ahead, i.e., to perform internal simulations to predict the possible outcome of a behavior. Therefore, the latter expansion would, according to McFarland and Bösser, make the system a cognitive one (for details see Schilling et al., 2013).

Furthermore, inspired by Steels and Belpaeme (2005); Steels (2007), the possibility to expand the network by a forth layer, that contains specific procedures, namely networks that represent verbal expressions has been discussed by Cruse (2010). These "word-nets" may likewise be used to utter or to comprehend the word stored. The underlying idea is to connect each word-net with a unit of the motivation network of which it carries the

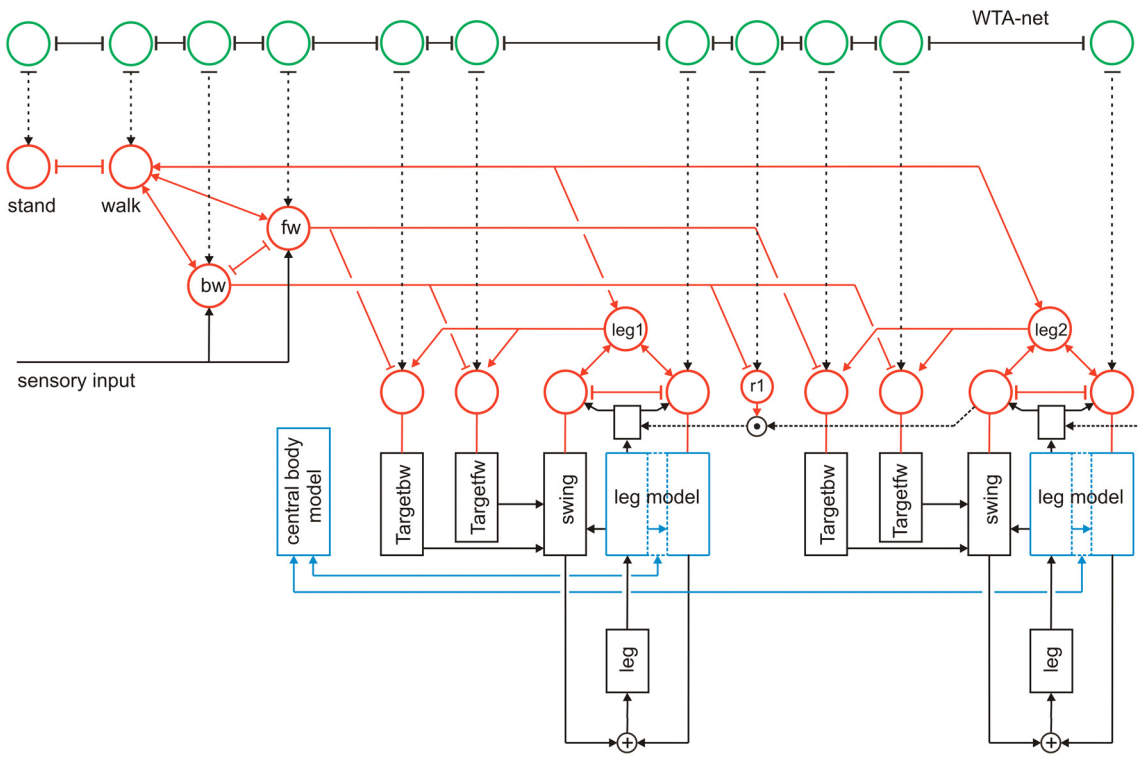

FIGURE 12 | Walknet as depicted in Figure 3, with a body model (blue) and a motivation unit network (red), but now expanded by a further layer (WTA, marked green, not all connections are depicted). The body is represented by the boxes "leg."

meaning (e.g., the word-net "walk" should be connected with the motivation unit walk), thereby grounding the symbolic expression (Cruse, 2010). Interestingly, Jenkins and Mataric (2003) draw an analogy between the structure for what they call a "motor vocabulary" to linguistic grammar or "verb graphs," a property that is reflected in our network.

Although the latter two levels (WTA-net and word-nets) are still quite speculative as they have not yet been tested, together with the two lower layers they illustrate the principal idea of this architecture (**Figure 13**). Horizontally arranged modules (procedures, motivation units, WTA neurons and procedures for words), are ordered in the horizontal layers in such a way that the corresponding elements in the different layers appear in a vertical order, leading to modules arranged in a columnar fashion (**Figure 13**, dashed rectangles). Addressing this columnar structure does not mean that each lower level procedure or each motivation unit has to have a partner in the upper layers, but only means that such connections are in principle possible. Similarly, not every unit or procedure in the upper layers necessarily has a partner procedure in the lowest layer. As a column in this architecture is characterized by a motivation unit, we name our architecture MUBCA.

Interestingly, Schack and Ritter (2009) and Schack (2010) have, too, proposed a four layer model to describe an architecture for the control of complex movements, which makes a comparison tempting. The four layers of this model are characterized as (i) sensorimotor control, (ii) sensorimotor representation, (iii) mental representation, and (iv) mental control. Although this architecture is settled at a more abstract level of description, our procedural layer might well be compared with Schack's sensorimotor control layer. Further, our motivation network has relations to Schack's sensorimotor representation layer (ii). Schack's layers (iii) and (iv) are not directly comparable, as "mental" is defined in his approach by consciously accessible, an aspect not considered here. Nonetheless, our WTA layer may be related with Schack's uppermost layer (iv), the mental control layer. Our uppermost layer might better be related with the mental representation layer of Schack's model, i.e., his layer (iii). This layer is characterized by containing the so called basic action concepts, behavioral elements to which verbal expressions can be assigned. So, there appear to exist some interesting relations between Schack's model and ours, but obvious differences can be observed in detail.

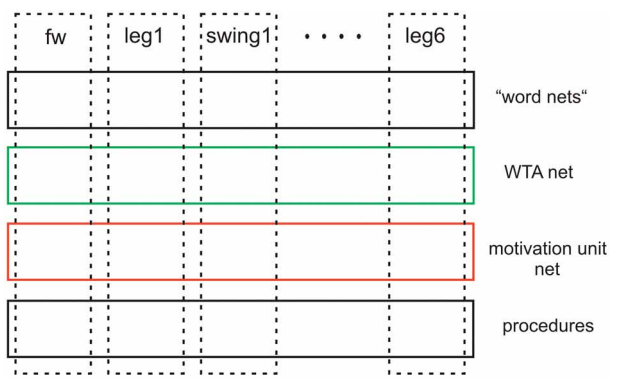

FIGURE 13 | Schematic showing the horizontal and columnar arrangement of the modules used by the architecture proposed.

Another proposal, the DAC architecture developed by Verschure and cooperators (review Verschure, 2012), is at first glance formally very similar to our approach, as it consists of four layers and (three) columns. The four layers show some relation to our layers. DAC differentiates between soma (body including sensors and actuators) and three layers characterizing the brain, the reactive layer, the adaptive layer and the contextual layer. The reactive layer roughly corresponds to our procedural layer, the adaptive layer controls (classical and operant) learning, not addressed in our approach. The contextual layer has some relation to our motivation unit network. The contextual layer of the DAC architecture also contains memory elements (STM, LTM) in contrast to our system where these memories are only stored in the lower, procedural layer. The motivation units only contribute to selecting the different procedures containing the memory content. The three columns, however, are quite different from the columns used in our architecture. They concern (i) the state of the world, (ii) the state of the self, and (iii) control of action. In our network, these functions are implicitly embedded in the different layers making our architecture much simpler. Learning is, in our model, foreseen to be implemented as explorative learning (Schilling et al., 2013) and will be realized by a cooperation of our third layer (WTA net) and the second layer (motivation unit network).

Our architecture follows the concept of D'Avella et al. (2003) assuming that natural motor patterns are constructed by combination of discrete elements ("modules," "motor programs"). To simplify the simulation, we assume that different modules are constructed of separate, non-overlapping neuronal elements. The situation might, however, be more complicated. As reviewed by Briggman and Kristan (2008), "morphologically defined circuits could be reconfigured into many distinct functional circuits [. . .] generating recognizable discrete behaviors." To cope with this case, for example Tani et al. (2004) studied how a number of different behaviors can be represented by different states of one RNN. A similar question can be asked with respect to the motivation units. Are they better described by individual units or do they form a distributed structure? Tani (2007) showed interesting studies of models, where not individual motivation units are responsible to modulate a given behavior. In contrast, a higher level RNN adopts different attractor states which as such influence the properties of lower level RNN. As, however, distributed systems containing recurrent connections appear to be more difficult to be stabilized, we have chosen to deal with distinct modules on the lower level and single units at the higher level. This is in particular helpful when dealing with a large number of modules and aiming to control relatively complex behaviors as is the goal of Walknet and Navinet.

Two further approaches should be mentioned that address the problem of how various sensory input can be used to select between different behaviors. The architecture of Arena et al. (2009) essentially consists of a number of "basic behaviors" (e.g., phonotaxis, phototaxis, obstacle avoidance) and a "representation

layer." The former compare with our procedures, the latter is related to our motivation unit network layer. Whereas the motivation unit layer comprises a simple, sparsely coded Hopfield-like network forming a decentralized structure with local, dedicated sensory inputs for some of the units, the Representation Layer of Arena et al. (2009) is quite different as it receives all sensory inputs to form a "central representation of the actual environmental situation" being represented by a Turing pattern. The Turing pattern emerges from a structure consisting of sensory neurons and two layers of Reaction-Diffusion Cellular Non-linear Networks (CNN) which, through temporal dynamics leads to static Turing patterns. The attractors represented by these patterns depend on the actual activation of the sensory cells. An additional selector network computes, after learning is finished, the relative contribution of the different basic behaviors to the overall behavioral output. A comparable selection process is, in our system, performed directly by the motivation unit network, that allows for parallel activation of different procedures except for those that are directly connected via inhibitory weights. As an important functional difference to our approach, learning plays a crucial role for the system developed by Arena et al. (2009), requiring a more complex architecture. As in our system no (online) learning is taking place, the network can be dramatically simplified and allows a simple way of finding sensible combinations of procedures. A central representation of the actual situation given by the current sensory input is not required.

An, on a general level, similar architecture, that transforms sensory input data into a vector that then is used to drive the single behaviors is given by Steingrube et al. (2010). Not counting on details, the representation layer of Arena et al. (2009) is here replaced by a network showing chaotic properties. The neuronal chaos controller requires a preprocessor and a postprocessor for sensorimotor mapping able to select between 11 different basic behaviors, whereby at least six of them are considered as "typical walking patterns emerging in insects." Although this solution is from a mathematical point of view quite interesting, the biological grounding is not well justified. The different gaits used should not be interpreted as discrete "basic behavioral patterns." Rather, as discussed earlier, these "gaits" are arbitrarily selected patterns out of a continuum and should therefore be considered as one basic behavior. Furthermore, although being claimed as allowing for fast switching between behaviors, the chaos controller is slower than our very simple motivation unit network which requires one or at the most two iteration for finding another attractor.

Both approaches are characterized by application of centralized structures to solve the problem of combining a large amount of sensor data and use this information to control various different behaviors. As an alternative, here we propose a decentralized solution. Our approach of using individual motivation units is supported by evidence for the existence of discrete neurons on the higher level, at least for invertebrates. For example, Briggman et al. (2005) show that in the leech a specific neuron drives crawling, while experimental inhibition of this neuron supports swimming. In Aplysia feeding behavior, a "command-like neuron" influenced by motivational states normally elicits ingestion behavior. After experimental application of a specific neuropeptid, this neuron elicits egestive behavior, thus deciding between two mutually excluding behaviors (Jing et al., 2007). Briggman and Kristan (2008) reviewed further examples including units releasing neuromodular substances.

Application of motivation units for controlling the selection of different procedures arranged in parallel have been introduced by Maes (1991, see also Hassenstein (1983), both inspired by K. Lorenz). Maes also included connections between motivation units that allow to control temporal relationships between the procedures, a property not applied here. Instead, we introduced a heterarchical structure to allow for the selection of various combinations of modules. Simple, non-heterarchical structures have already been applied in Walknet to select between procedures (Swing—Stance, Schilling et al., 2007) and between higher-level states (forward—backward, (Schilling and Cruse, 2008), then called "distributor net"). In the form of so-called command neurons the selection between forward walking and backward walking has already been applied by Ayers and Davis (1977). Similarly, mutually inhibitory units used to decide between forward and backward walking have also been used in a model of Tóth et al. (2012). In both cases, the units controlling forward or backward walking are directly connected with the motor units on the muscle level, in contrast to our approach. More generally, these models are based on strictly hierarchical structures what makes it difficult to use individual modules in other ways than allowed in the actual context. Therefore, these hard-wired hierarchical structures prohibit trial-and-error variations in cases of emergency. Our heterarchical system with selective access to individual modules makes this possible (**Figure 12** and related text).

Although our approach has originally been derived from studying insect behavior, the neuronal architecture is purposefully abstracted from any neuroanatomical constraints given by the insect brain. Therefore, concentrating on the functional aspect and searching for some kind of minimal model, this architecture may be applied to different types of brains. Nonetheless, in the following we will briefly discuss to what extent this model may be mapped to the neuronal system of insects. Some motivation units clearly should be part of local, thoracic ganglia. These are the motivation units for swing and stance, target_fw, target_bw, PEP_fw, PEP_bw of the different legs, as well as most probably the six "leg" motivation units. Less clear is the localization of the motivation units controlling the different coordination influences acting between the legs. All other motivation units, like stand, walk, forage, (stay in) nest, forward, backward, are to be attributed to the brain of the insects.

Finally, a nomenclatural question that might be briefly discussed is whether it is sensible to attribute a higher level term as "motivation" to such simple units as used here to control microbehaviors like swing or stance, for example. Generally accepted examples for motivational states are, for instance, aggression controlling fight, or fear controlling flight. However, in our network, there is functionally no principal difference between motivation units controlling behaviors at any level of our network. Therefore, we believe it is justified to apply this term also to such lower level elements, or "microbehaviors," like swing or stance of a leg, for example. Of course, this usage of the term motivation often applied in robotics and animal behavior, is still quite

different from that used in psychology, focusing on systems with cognitive abilities. Motivation in psychology is generally considered as a (multiplicative) combination of desire and expectancy. In our case, only the aspect of "desire" is addressed.

CONCLUSION

Our architecture, MUBCA, integrates often discussed properties postulated to exist in neuronal systems, as are modularity, hierarchy, cross modal influences (e.g., path integration and landmark navigation in Navinet), bottom–up and top–down attention control, i.e., selection of relevant input data establishing priorities, application of internal models for prediction, and redundant structures. Due to the fact that some central structures as the motivation unit network and the body model are realized as RNN, the complete network forms a holistic system. Therefore, this architecture can be considered as modular and holistic at the same time. As this architecture does not follow strict rules for construction, it is very flexible and can be expanded in various ways. To verify these capabilities further, our next step to do is to implement the cognitive layer as sketched in **Figure 12**. In parallel, all versions of the model will be tested on the physical robot Hector. The versatility of this approach is further underlined by a proposal as to how this architecture could be expanded to show properties of a mirror system and Theory of Mind (Cruse and Schilling, 2011). Recently, these authors have argued that even higher-level properties as are intention, (bottom–up and top–down) attention, volition as well as some aspects of consciousness can be attributed to a network based on this architecture. Interestingly, these properties are not explicitly implemented but appear as emergent properties of the network (Cruse and Schilling, 2013).

APPENDIX

MOTIVATION UNIT NETWORK

The motivation unit network as applied here represents a recurrent neural network with piecewise linear summation units and bounded activation function (output ≥ 0 and ≤ 1). Each unit has a fixed self-activation weight [w/(w + 1)], which gives each unit the property of a first order low-pass filter with a time constant tau = w − 1 (here we used w = 3). The used weights are given in the matrix shown in **Table A1**. Note that all values are multiplied by (w + 1). In **Table A1** several submodules can be identified. One consists of the two units Stance and Walk, the other of units Walk, Fw, Bw, leg1 . . . leg6. In addition, there are six leg submodules consisting of leg#, Sw# and St#, (# = 1–6). Motivation units for Target-net, PEP-net and Coordination Rules only receive top–down influence. This is done to simplify the net dynamics, but in principle recurrent connections were possible, too.

Training of such a network is possible for linear and non-linear activation functions (Makarov et al., 2008; Cruse and Schilling, 2010). To obtain sparse coding, only those weights were allowed to be learned that in **Figure 3** are represented by (red) connections. By this way, the different procedures controlling the six legs were kept separate which simplifies the number of attractors to be trained. For training the leg network we used four vectors characterized by activation of units (1) walk, fw, leg1, sw, (2) walk, fw, leg1, st, (3) walk, bw, leg1, sw, and (4) walk, bw, leg1, st. Application of the procedure proposed by Makarov et al. (2008) guarantees to find stable attractor solutions even for a piecewise-linear activation function showing no upper limit. However, following this procedure, stability of the network would depend on the exactness of the weight values, i.e., noise would deteriorate the stability. We therefore, made this network more stable against noisy weights by introduction of an upper limit of 1 for each activation function. In this way, the network shows a Hopfield-like structure, apart from asymmetric weights being possible. Introduction of this activation function further allows in a second step, to increase the weight values in order to decrease relaxation time. To this end, within a leg, positive weights were increased to 1, negative weights decreased to −3. The weight values of the upper motivation unit "walk" that connects all leg units, were only increased to a value of 0.2, but the inhibitory weights decreased to −5, to cope with the different number of positive (five) and negative (one, in the example of **Figure 3**) input channels. This two-step procedure makes the already stable trained net solution more stable with respect to noisy weight values and allows for faster relaxation. Note that the figures for the weight values given here and in **Table A1** are multiplied by a factor (w + 1) with w = 3.

With the weights given in **Table A1**, the motivation network shows the following dynamic properties. Motivation units connected via mutual inhibition (e.g., Walk—Stand, Swing—Stance) change from zero to one (and back) within one iteration. Motivation units which receive only feedforward input (e.g., motivation units of Target-nets or PEP-nets) change their output value following a low-pass filter dynamic with a time constant of four iterations.

An important aspect is that (sensory) input driving the motivation unit has to show a transient component, i.e., has to be endowed with high-pass filter like properties. The amplitude of the first pulse is tuned by hand and depends on the value of the inhibitory weight stabilizing the WTA elements.

Table A1 | The weights required for the motivation unit network (Figure 3, marked red).

	St	wa	fw	bw	leg1	sw1	st1	Tfw1	Tbw1	Pfw1	Pbw1	R1fw	R1bw	leg2 . . .
st	W	−1												
wa	−5	W	1	1	0.2									0.2
fw		1	w	−3										
bw		1	−3	W										
leg1		1			W	1	1							
sw1					1	W	−3							
st1					1	−3	w

*Upper row and left column refer to the individual motivation units. Weights arranged in a horizontal row mark input weights of the unit shown at the left. Units marked in **Figure 3** by "stand," or "walk" are abbreviated here by "st" or "wa," respectively. Units shown in **Figure 3** as "fw," "bw," "leg1," "leg2" . . . are shown as marked in **Figure 3**. Units not explicitly marked in **Figure 3** are the motivation units for the swing procedure (here abbreviated by sw plus the number for the corresponding leg), the motivation unit for the stance procedure (marked by "leg model" in **Figure 3**) here abbreviated by st plus the number for the leg. The motivation units for the target nets are abbreviated by Tfw and Tbw for forward walking and backward walking, respectively plus the number for the leg. Correspondingly, the motivation units for the PEP nets, not shown n **Figure 3**, are abbreviated by Pfw and Pbw plus the number for the leg. Furthermore, motivation units for coordination rule 1 is abbreviated by R1fw and R1bw for forward walking and backward walking, respectively. All weights multiplied by (w + 1); w = 3.*

ROBOT SIMULATION

As mentioned in the Introduction, to test the capability of our controller, a physical robot or, as a first step, a physics engine is required that is able to simulate the robot and its interaction with the environment. The robot named Hector (Schneider et al., 2011), currently being developed, has 22 DoFs. The spatial arrangement of the joints corresponds to that found in stick insects, however, all measurements are scaled by a factor of 20. The distance between the onset of the front leg and the middle leg is 360 mm, the corresponding distance between middle leg and hind leg is 218 mm. The three leg segments have a length of 30, 260, and 280 mm (coxa, femur, tibia, respectively). For the robot, all legs are constructed identically in order to simplify the design. The nominal step length of a leg is 310 mm, i.e., about 85% of the scaled up step length as found in stick insects (Stick insects have a step length of about 18 mm which would correspond to 360 mm in the scaled robot.). The step amplitude is limited mainly because in the stick insects, different to the robot, front legs and hind legs are longer than the middle legs. Nevertheless, step amplitude is quite large compared to usual 6-legged robots.

For the simulation the Open Dynamics Engine is used as a physics engine to simulate the interaction between all the moving parts and with the environment. The simulation basically consists of a rigid body dynamics simulation engine and a collision detection engine. Within this virtual environment the robot is rebuilt and the inertias of the sub-assemblies of the robot are set according to their real complement. The geometry of the housings and the movement ranges correspond to the real robot. The joints in the real robot will consist of a joint drive coupled with elastic properties in order to model muscle-like characteristics (Annunziata and Schneider, 2012). In the computer simulation the elasticity is also incorporated into the joint actuators and corresponds to a spring-damper-system. As the nature of the friction between the legs and the environment is generally quite complex in real systems, these contacts are hard to simulate. Therefore, these interactions can only be approximated and this will lead to differences between the virtual and the real system. This makes the application of the real robotic system important. The weight of the three simulated body segments is 2000 g, each.

All simulation experiments were made on flat terrain, however, due to (in particular for fast walking) considerable up- and down movements of the body, irregular ground was mimicked. In addition, as friction is limited, eventually legs showed slipping in various directions during stance. The resulting irregularities are also visible in the footfall patterns

The existence of dedicated neuronal modules such as those organized in the cerebral cortex, thalamus, basal ganglia, cerebellum, or spinal cord raises the question of how these functional modules are coordinated for appropriate motor behavior. Study of human locomotion offers an interesting field for addressing this central question. The coordination of the elevation of the 3 leg segments under a planar covariation rule (Borghese et al., 1996) was recently modeled (Barliya et al., 2009) by phase-adjusted simple oscillators shedding new light on the understanding of the central pattern generator (CPG) processing relevant oscillation signals. We describe the use of a dynamic recurrent neural network (DRNN) mimicking the natural oscillatory behavior of human locomotion for reproducing the planar covariation rule in both legs at different walking speeds. Neural network learning was based on sinusoid signals integrating frequency and amplitude features of the first three harmonics of the sagittal elevation angles of the thigh, shank, and foot of each lower limb. We verified the biological plausibility of the neural networks. Best results were obtained with oscillations extracted from the first three harmonics in comparison to oscillations outside the harmonic frequency peaks. Physiological replication steadily increased with the number of neuronal units from 1 to 80, where similarity index reached 0.99. Analysis of synaptic weighting showed that the proportion of inhibitory connections consistently increased with the number of neuronal units in the DRNN. This emerging property in the artificial neural networks resonates with recent advances in neurophysiology of inhibitory neurons that are involved in central nervous system oscillatory activities. The main message of this study is that this type of DRNN may offer a useful model of physiological central pattern generator for gaining insights in basic research and developing clinical applications.

Keywords: central pattern generator (CPG), human locomotion, biological oscillations, dynamical recurrent neural network (DRNN), kinematics, neurophysiology of walking

INTRODUCTION

Neuronal modules profoundly influence many aspects of motor behavior. However, little is currently known about the control mechanisms that allow the coordination of these modular entities. In this theoretical context, human locomotion is a challenging movement because of the numerous neuroanatomical modules implicated in the different aspects of whole body movement, ranging from the cyclic propulsion of the limb to balance control. In spite of these intricate movement components and neuronal modules involved, it has been proposed that the overall control can be realized by reducing the number of degrees of freedom of the system into global variables (Bernstein, 1967; Lacquaniti et al., 1999, 2002; Flash and Hochner, 2005; Latash, 2008). The fact that the elevation angles of the three main lower limb segments are coordinated during gait within a covariation plane (Borghese et al., 1996), forming an elliptic loop corroborates the idea that control of locomotion is also submitted to the general law of reducing variables (Barliya et al., 2009). This general law is also applicable for different walking speeds (Bianchi et al., 1998), for forward and backward directions (Grasso et al., 1998), rectilinear or curvilinear walking paths (Courtine and Schieppati, 2004), walking with stilts (Dominici et al., 2009; Leurs et al., 2011), or with a transfemoral prosthesis walk (Leurs et al., 2012), with different levels of body weight unloading (Ivanenko et al., 2002) and for running (Ivanenko et al., 2007). Notably, this inter-segmental coordination is not present in newly walking toddlers (Cheron et al., 2001a,b; Ivanenko et al., 2005), but covariation planarity rapidly emerges over the first few days of independent walking experience, while the shape of the loop and plane orientation "mature" gradually over several years.

This evolution indicates that the attractor plane and the shape of the loop are neurophysiologically defined, rather than being imposed by biomechanical constraints (see Hicheur et al., 2006; and Ivanenko et al., 2008 for discussion). More recently, the developmental study of this complex behavior in a new born baby (Dominici et al., 2011) has permitted revisiting the concept of locomotor modules coding for the control of movement primitives.

This modular approach raises the question of the dynamic coordination of modules in the context of oscillatory properties of neuronal ensembles. Indeed, the dynamical structure of these modules must logically obey a common principle for movement generation: the production of oscillatory activity. Although this principle is well accepted in case of the rhythmic nature of locomotion (Georgopoulos and Grillner, 1989; Grillner, 2006), the recent study of Churchland et al. (2012) surprisingly demonstrates that non-periodic movements such as reaching are also generated by neuronal oscillation. This means that there is a strong possibility that the spinal modules organized in a central pattern generator (CPG) could be dynamically controlled by cortical and/or supraspinal oscillations. Interestingly, Barliya et al. (2009) recently modeled the time course of elevation angles of the three lower limb segments in terms of simple oscillators coupled with appropriate time shifts reproducing the orientation of the plane and their elliptical shape. The oscillators were obtained by taking, after Fourier transform, the first three harmonics of the elevation angle kinematics. Each of these oscillators could be interpreted in term of oscillatory module acting in such a way that the orientation of the plane and the elliptic shape of the coordination are conserved. It could thus be possible that oscillatory signals derived from these harmonics are used for activating CPG modules.

The existence of CPG in the spinal cord in mammals has been proposed a century ago (Brown, 1911). In essence, it represents a group of neurons acting as a network to produce coordinated patterns of rhythmic activity. New evidence has shown the presence of CPG in the spinal cord in humans (Calancie et al., 1994; Bussel et al., 1996). The characteristics of such CPG modules are their adaptability and robustness that lead to the production of different gait patterns adapted to their current environmental context. For example, young infants (less than 1-year old) are already able to walk over a split-belt treadmill with different types of coupling (Yang et al., 2005). Some of them were even able to walk in opposite directions. Mimicking physiology, the robotic and neuroscientific community developed artificial CPGs that are commonly used to animate robots from multi-legged insect-like to humanoids (for a review see Ijspeert, 2008). In their pioneering work in the cat, Patla et al. (1985) proposed an analytic model of limb locomotor pattern generator based on recorded muscle activity induced by electrical stimulation over the mesencephalic locomotor region (MLR) in the decerebrate cat. In this model, locomotor like patterns of six muscles resulted from six independent oscillators with dedicated parameters. These oscillators were reduced to simple sine and cosine functions fed by a tonic input. Since then, different methods have been used from coupled non-linear oscillators (Ijspeert et al., 2007; Duvinage et al., 2011, 2012a), to highly detailed biophysics of small groups of interconnected neurons (Hellgren et al., 1992) and rhythm genesis of larger groups of neurons (Wadden et al., 1997) mainly in animal models. While human locomotion has often been reproduced computationally in the robotic field using equations that are numerically integrated (Righetti et al., 2005; Righetti and Ijspeert, 2006; Ceccato et al., 2009; Duvinage et al., 2011, 2012a), few methods involving neuron modeling for human gait generation have been studied so far. Among them Prentice and coauthors (1998, 2001) have successfully transformed fundamental timing signals (sine and cosine inputs) into individual muscles activation bursts related to gait locomotion at different speeds using a feedforward neural network. Our group used the electromyographic (EMG) signals of the lower limb muscles as input for a dynamic recurrent neural network (DRNN) producing as output the lower kinematics during locomotion (Cheron et al., 2003, 2012). However, the possibility to produce the motion of the lower limb segments by means of oscillations derived from the three harmonics of the Fourier transform of walking kinematics has not yet been assessed by means of the same DRNN. We show here that after learning based on different walking velocities, the DRNN is able to reproduce the lower limb kinematics of both legs. The DRNN can also generalize to the unlearned walking velocities. The analysis of the required network structure (e.g., number of units, distribution of time constant, and synaptic sign) provides a basis for the discussion about the constraints required for the elaboration of a CPG.

METHODS

EXPERIMENTAL SETUP

Seven healthy subjects aged from 25 to 35 years (mean age: 28 years) participated in this experiment. The protocol consisted of walking on a treadmill at 11 different velocities [from 1 (0.28 m/s) to 6 km/h (1.67 m/s) stepped by 0.5 km/h (0.14 m/s)] leading to 11 trials per subject (total of 77 trials over all subjects). Whole body kinematics was recorded using Vicon system with six infrared Bonita cameras recording at 100 Hz during 40 s for each trial. The tracking consisted of recording 29 markers placed over the whole body. The position of the markers in an orthogonal reference was computed using a custom biomechanical model. From the position of the markers of both legs, the kinematic (elevation) angles relative to the vertical plane of the laboratory have been calculated bilaterally for thighs, shanks, and feet. In this study we performed two experiments. The first one, "proof of concept," was done to ascertain the feasibility of a DRNN to learn elevation angles from pure sine waves. This part only includes supervised learning on a single pattern (**Figure 1A**). The second experiment was performed in order to study the possibility to learn multiple patterns of walking (i.e., velocities) and to predict kinematics from unlearned patterns (**Figure 1B**). After that, the DRNN structures were analyzed.

DYNAMICAL RECURRENT NEURONAL NETWORK

The DRNN is capable of modeling time-varying input–outputs and has varying weights as well as varying time constants for the artificial neurons (Pearlmutter, 1990). The adaptive time

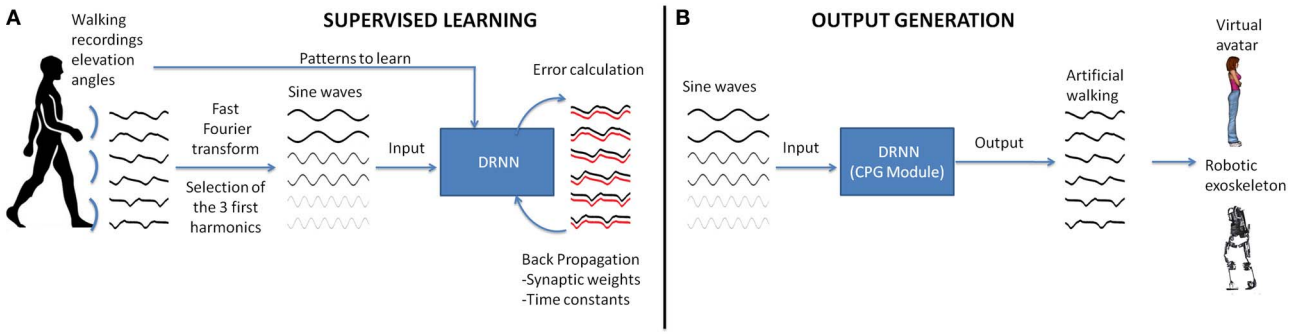

FIGURE 1 | Realization of a CPG module based on experimental recordings of human walking. (A) In the first step, the elevation angles of the thigh, shank, foot of the two legs are transformed in the time frequency domain using fast Fourier transform (FFT). Then the signal characteristics are computed for the first three harmonics and back-transformed into temporal space using sine waves formulation. These data are fed as input to the DRNN learning the transformation in kinematic signals (elevation angles). **(B)** A successful learning will permit the DRNN to predict kinematics based on sine wave inputs only. These output signals can produce biologically plausible walking patterns in a virtual reality avatar or an actual robotic exoskeleton.

constants make it dynamic (Draye et al., 1996). The DRNN is governed by the following equations:

$$T_i \frac{dy_i}{dt} = -y_i + F(x_i) + I_i \tag{1}$$

where $F(a)$ is the squashing function $F(a) = (1 + e^{-a})^{-1}$, y_i is the state or activation level of unit i, I_i, is an external input (or bias), and x_i is given by:

$$x_i = \sum_j w_{ij} y_i \tag{2}$$

which is the propagation equation of the network (x_i is called the total or effective input of the neuron i, w_{ij} is the synaptic weight between units i and j). The time constants T_i will act like a relaxation process. In order to make the temporal behavior of the network explicit, an error function is defined as:

$$E = \int_{t_0}^{t_1} q(y(t), t)dt \tag{3}$$

where t_0 and t_1 give the time interval during which the correction process occurs. The function $q(y(t), t)$ is the cost function at time t which depends on the vector of the neuron activations y and on time. We then introduce new variables p_i (called adjoint variables) that will be determined by the following system of differential equations:

$$\frac{dp_i}{dt} = \frac{1}{T_i} p_i - e_i - \sum_j \frac{1}{T_i} w_{ij} F'(x_j) p_j \tag{4}$$

with boundary conditions $p_i(t_1) = 0$. After the introduction of these new variables, we can derive the learning equations:

$$\frac{\delta E}{\delta w_{ij}} = \frac{1}{T_i} \int_{t_0}^{t_1} y_i F'(x_j) p_j dt \tag{5}$$

$$\frac{\delta E}{\delta T_i} = \frac{1}{T_i} \int_{t_0}^{t_1} p_i \frac{dy_i}{dt} \tag{6}$$

The sinusoid signals derived from the Fast Fourier transform (FFT) kinematic data are sent as input to a DRNN (**Figures 1**, **2** cf. Experiments 1, 2) that has to learn from these data to produce the kinematics specified as elevation angles (**Figure 1A**). Successful trainings were also used to produce kinematic patterns from unknown inputs (**Figure 1B**) aiming to produce walking for multiple purposes, such as virtual avatars or robotic exoskeletons. The training is supervised, involving learning rule adaptations of synaptic weights and time constant of each unit (Draye et al., 1995, 1996). A specific training procedure using Almeida algorithm was used to optimize learning performance (Cheron et al., 2011). The DRNN involves a looping mechanism (fully connected structure) which enables this network to learn and store information (memory). This equips the network with the ability to model complex situations with multiple influences. The DRNN was successfully used to map EMG signals into kinematics during walking (Cheron et al., 2003), for the identification of the triphasic EMG pattern in subjects performing fast elbow flexion movements (Cheron et al., 2007) or to predict specific muscular activity in elite fencers compare to amateurs (Cheron et al., 2011).

EXPERIMENT 1: PROOF OF CONCEPT

DRNN computation has been used to prove that simple sine waves with specified temporal characteristics can be used as input to an artificial neural network to be transformed into elevation angles obtained from kinematic recordings during locomotion (**Figure 3**).

Input: construction of sine waves

As the learning phase of the DRNN is a time-consuming process, we had to select appropriate sample from the whole available data as input. Moreover, even if the kinematics during walking is relatively stable, it may vary too much to feed the DRNN during the learning phase. For these reasons, we extracted two consecutive gait cycles from the 40 s of experimental data recorded in each trial (**Figure 2A**, black curves). They were chosen so as to be representative in terms of frequency of the whole recording set. Then, to determine the kinematic characteristics of gait, we transformed

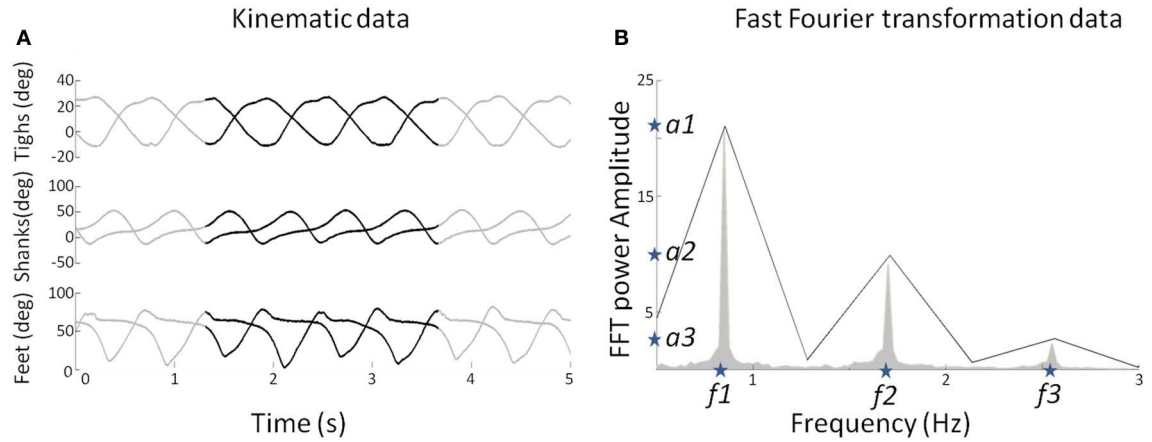

FIGURE 2 | (A) Elevation angles (in degree) of the three segments (thigh, shank, and foot) for each leg as a function of time for a subject walking at 3 km/h (0.83 m/s). The whole pattern is presented for duration of 5 s. The black lines represent a pattern for two gait cycles used to determine the FFT characteristics. **(B)** The mean FFT transformation for six joints for 40 s (in gray) and the two gait cycles (in black). Note that the two gait cycle patterns are selected so as to preserve the FFT characteristics in terms of amplitude and frequency (stars) for the overall pattern of 40 s. These characteristics are used as parameters to generate sine waves as input of the DRNN.

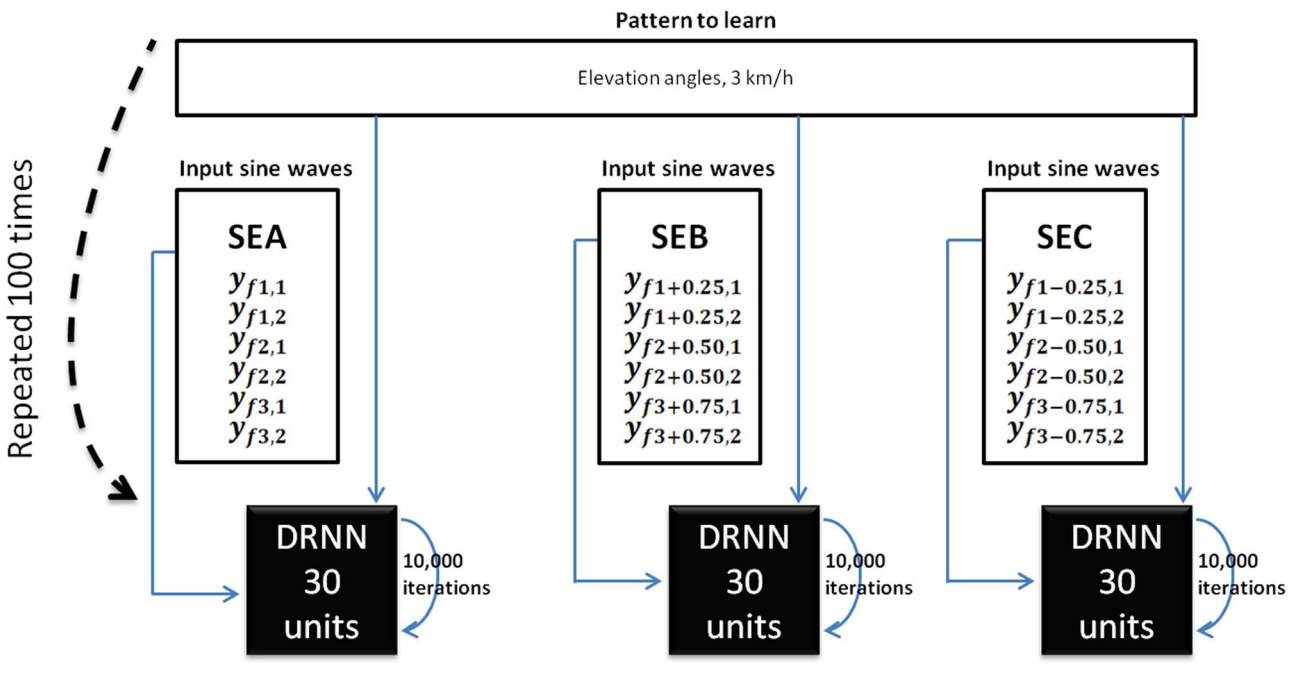

FIGURE 3 | DRNN learning method for Experiment 1. For each subject, we trained 100 DRNNs to learn a pattern of kinematic [corresponding to a velocity of 3 km/h (3.83 m/s)] from sine waves (Equations 7 and 8). Three sets of learning were defined as the input differed (SEA, SEB, SEC). The structures of DRNNs were modeled with 30 hidden units for each set of training. Each network iterated 10,000 times to change its synaptic weights and time constants. For each subject and structure we selected the network with the highest *SI* value. For each condition, the design of the network is then processed with 6 inputs, 30 hidden units, and 6 outputs.

the data of the lower limb segments elevation angles into the time frequency domain using the Matlab *fft* function to get the FFT power amplitude and their related frequency values of the first three harmonic peaks (**Figure 2B**). It has been shown previously that the first two Fourier harmonics accounted for approximately 98% of the experimental variance of the thigh, shank, and foot angles (Bianchi et al., 1998). We decided to create sine waves based on the characteristics of the first three harmonics to ensure that the signal proposed as learning input to the DRNN contains enough information to match the desired output precisely.

We extracted the values of the three frequencies ($f1$, $f2$, $f3$) corresponding to the maximal amplitudes ($a1$, $a2$, $a3$). It was

verified that $f2 = 2f1$ and $f3 = 3f1$. We then artificially produced six sinusoidal signals using frequency values as parameters (Equations 7 and 8).

$$y_{fi,1} = \sin(2\pi \times fi \times t) \quad (7)$$

$$y_{fi,2} = \sin(-(2\pi \times fi \times t)) \quad (8)$$

$$\text{For } i = 1,\ 2,\ 3$$

These six sine waves thus correspond to the frequency characteristics of the kinematic patterns that will be further used as pattern to be learned. For the sake of clarity we called the set of original inputs set SEA (for set of Equations A). Additionally, we produced six new sine waves using the preceding computations (Equations 7 and 8) where $f1' = f1 + 0.25$ Hz and six other sine waves where $f1'' = f1 - 0.25$ Hz, respectively called SEB (for set of Equations B) and SEC (for set of Equations C). Please note that in the latter two cases the original relations $f2 = 2f1$ and $f3 = 3f1$ were respected and hence $f2' = 2f1 + 0.50$ Hz; $f3' = 3f1 + 0.75$ Hz in the set SEB and $f2'' = 2f1 - 0.50$ Hz; $f3'' = 3f1 - 0.75$ Hz in the set SEC. Three different input sets (SEA, SEB, SEC) were thus defined for learning.

Pattern to learn: kinematic data

The pattern to learned corresponds to the elevation angles of the right and left thigh, shank, foot segments in the two gait cycles of a 3 km/h (0.83 m/s) walk, normalized between −1 and 1. The outputs were the same for SEA, SEB, and SEC whereas inputs differed.

DRNN learning phase

It was expected that the DRNN would learn how to transform the input to output thanks to its dynamical and recurrent structure of 30 hidden neurons. For each of the seven subjects, the network iterated 10,000 times. This process was repeated 100 times, leading to 100 different networks. At the end of the learning phase, we selected for each subject the network for which the difference between predicted and real kinematics was minimal. This computation was performed by calculating a similarity index (*SI*) (Bengoetxea et al., 2010) defined by the following equation:

$$SI = \frac{\int_{-\frac{Tc}{2}}^{\frac{Tc}{2}} p_1(t)p_2(t)dt}{\left[\int_{-\frac{Tc}{2}}^{\frac{Tc}{2}} p_1(t)^2 dt \int_{-\frac{Tc}{2}}^{\frac{Tc}{2}} p_2(t)^2 dt\right]^{\frac{1}{2}}} \quad (9)$$

where Tc is the period of the limit cycle, p_1 and p_2 being synchronized, i.e., the matching between both patterns is based on the maximum of each pattern. Note that if both functions are identical, $SI = 1$. *SI* was calculated with the recorded pattern of elevation angles and the output of the DRNN.

EXPERIMENT 2: MULTIPLE PATTERN LEARNING AND PREDICTION

In this experiment sine waves were modulated in frequency and amplitude and transformed into kinematic data using multi-pattern training. The prediction of kinematic pattern from unknown sine wave pattern was also tested.

Input

As for the proof of concept methods, we extracted two gait cycles of each trial for multiple velocities (in km/h) ($v = \{1.5,\ 2.5,\ 3.5,\ 4.5,\ 5.5\}$). We transformed the kinematic data into the time-frequency domain to get their frequency ($f1,\ f2,\ f3$) and amplitude ($a1,\ a2,\ a3$) (**Figure 2B**) parameters using the following set of Equations (10 and 11).

$$y_v, fi_v, ai_{v,1} = ai_v \times (sin(2\pi \times fi_v \times t)) \quad (10)$$

$$y_v, fi_v, ai_{v,2} = ai_v \times (sin(-(2\pi \times fi_v \times t))) \quad (11)$$

$$\text{For } i = 1,\ 2,\ 3$$

Patterns to learn: kinematic data

The patterns to be learned consisted of elevation angles of the right and left thigh, shank, and foot segments corresponding to the two gait cycles, normalized between –1 and 1. These patterns were obtained from recordings at multiple velocities (in km/h) ($v = \{1.5,\ 2.5,\ 3.5,\ 4.5,\ 5.5\}$).

DRNN training phase

We used the possibility to train the DRNN in a multi-pattern purpose (Bengoetxea et al., 2005). For each subject, the DRNN was trained to match the inputs/outputs patterns corresponding to five different velocities within a single DRNN structure. Hundred networks were made per subject, each of them iterating 50,000 times. This operation was assigned for 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 20, 30, 40, 50, 60, 70, and 80 hidden units. When this was completed, we selected the best network for each subject and each number of hidden units using the maximal *SI* values.

Output prediction

We built sine waves from intermediary pattern velocities (km/h) ($v = \{2,\ 3,\ 4,\ 5\}$) as explained above. We fed the best DRNN structures previously obtained after the training phases with these unlearned inputs sine waves and analyzed DRNN behavior by calculating the predicted output with experimental data using *SI* values.

NEURONAL PROPERTIES AND CONNECTIVITY AFTER LEARNING

Introduction of timing allows modeling of more complex frequency behavior, improves the non-linearity effect of the sigmoid function and the memory effect of time delays (Draye et al., 1995). The distribution of the time constant and the synaptic weights between units (Draye et al., 1996) after learning was analyzed after multiple pattern learning and prediction. In particular, we recorded the number of positive and negative connections inside DRNN structures of the best networks. Additionally we studied the distribution of neuronal time-constants.

STATISTICAL ANALYSIS

Statistical analysis was performed using Statistica software (Statsoft, www.statsoft.com). For each test performed and described in the result section, we firstly verify whether the

data were distributed normally using Kolmogorov–Smirnov test. When the data were normally distributed we use ANOVA with repeated measures and *post-hoc* Fisher analyses. When it was not possible to use ANOVA we used non-parametric tests such as Friedman ANOVA or sign tests.

COMPUTATIONS

All DRNN computations were performed in the Hydra computing center hosted in ULB (https://cc.ulb.ac.be/hydra/). We allocated 1 node and 10 Gb of memory per computation (i.e., per subject per condition in the Experiment 1, per subject per structure in the Experiment 2). The computations were run in parallel to optimize the learning duration. Afterwards we simulated 5% of the overall experiment in the same conditions to estimate the learning time. The overall duration of the process was obtained by linear interpolation (**Figure 4**).

RESULTS

EXPERIMENT 1: PROOF OF CONCEPT

A statistical test was designed to compare *SI* values from different input types (SEA, SEB, or SEC) (**Figures 3**,**5**). The Kolmogorov–Smirnov did not reject the hypothesis that *SI* values were normally distributed ($D = 1.4414$, $p > 0.20$) when analyzing together values of the different inputs (SEA, SEB, or SEC). We used an ANOVA with repeated measures where dependant variable was *SI* and the independent variable chosen was the type of input. The analysis showed an effect of the input frequency in the DRNN prediction (*SI* value) [$H\ F_{(2,\ 12)} = 38.110$, $p = 0.00001$]. *Post-hoc* analysis confirmed that *SI* values of original group of unchanged frequency input (SEA) were higher than the 2 modified groups where frequency inputs have changed (SEB and SEC).

EXPERIMENT 2: PREDICTION OF INTERMEDIARY VELOCITIES

As we decided to use frequency ($f1, f2, f3$) and amplitude ($a1, a2, a3$) characteristics to modulate inputs for multiple learning procedures (Equations 10 and 11), we have verified that there was a statistical significance of these parameters for different velocities. The Kolmogorov–Smirnov test for $f1$ ($D = 0.14370$, $p < 0.1$), $f2$ ($D = 0.14370$, $p < 0.1$), and $f3$ ($D = 0.14370$, $p < 0.1$) was not clear enough to reject the fact their population may follow a normal law. When looking at the distribution, they tend to be normal and it is possible that the significance of the test is due to the weak number of values. According to similar test,

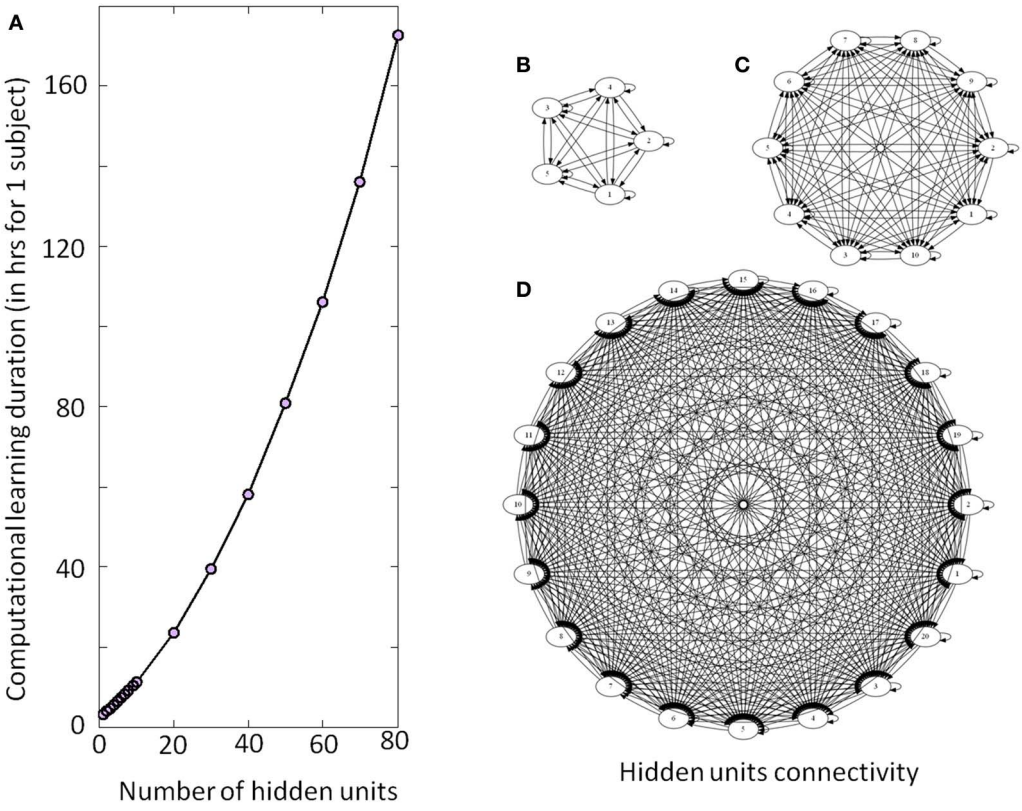

FIGURE 4 | Illustration of the DRNN structure and computational time. (A) Computational learning duration for one subject for experiment 2 (in hours). The gray circles represent the estimation of time required per number of hidden units from a recalculation of 5% of the procedure. Please note that the overall process for the seven subjects has taken approximately 200 days to be computed. **(B)**, **(C)**, and **(D)** represent the connectivity of the hidden layer with 5, 10, and 20 neurons, respectively. As the number of neurons increases, the number of connections increases by a factorial multiplication as well as the time required to adjust connection weight and time constant. Please note that only the units of the hidden layers are represented without input or output neurons.

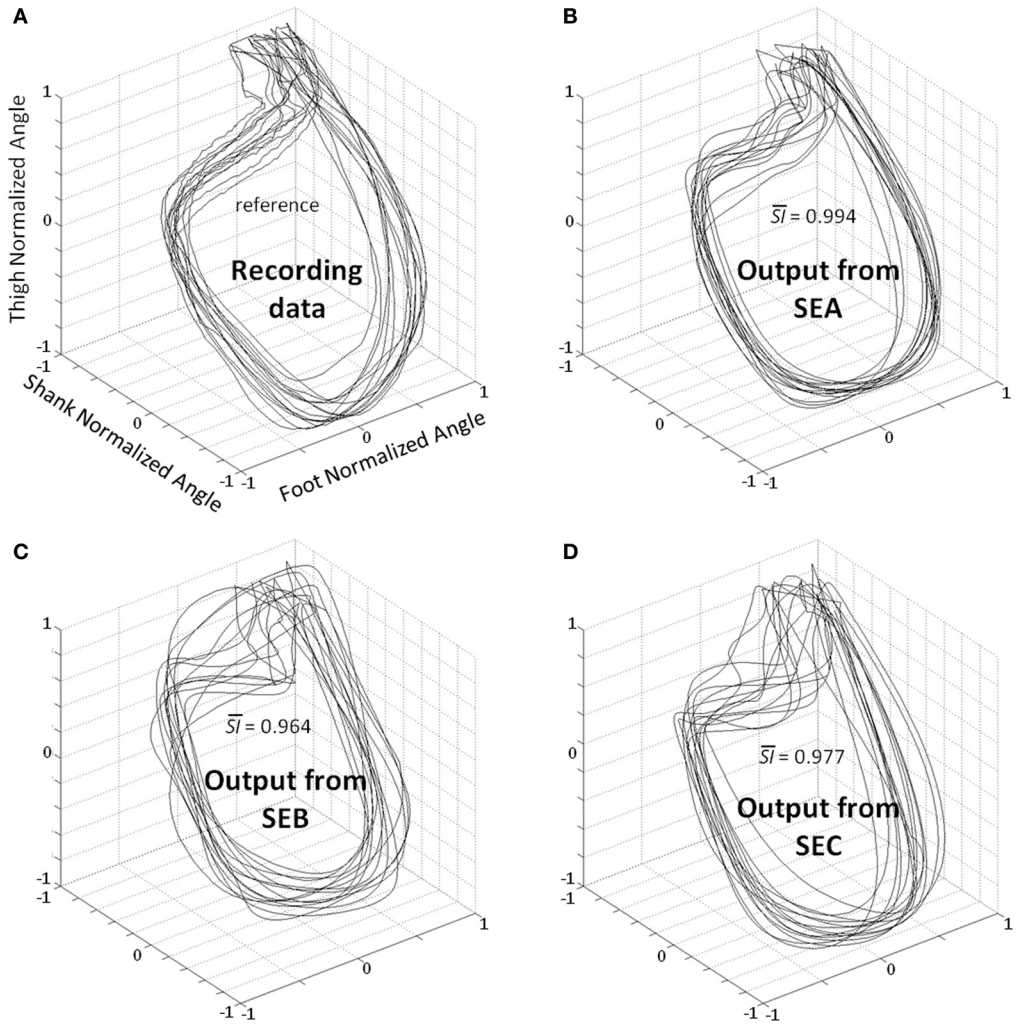

FIGURE 5 | Planar covariation between normalized thigh, shank, and foot for all participants. (A) Recording data—the patterns correspond to the real kinematics of 2 gait cycles for all participants. Best kinematic patterns predicted by the DRNN for each subject where SEA **(B)**, SEB **(C)**, and SEC **(D)** were fed as input. $\overline{SI}$ is the average of similarity index value (*SI*) in each condition for all subjects when compared with the recording data.

the values for parameters $a1$ ($D = 0.08476$, $p > 0.2$), $a2$ ($D = 0.08758$, $p > 0.2$), and $a3$ ($D = 0.09035$, $p > 0.2$) were normally distributed. We then used two ANOVA with repeated measures where the dependent variables were, respectively, the amplitude and frequency values and the within-subject factors were velocity of walking and the specific harmonic (1, 2, or 3).

ANOVA shows significant changes in amplitude [$F_{(10,\ 60)} = 31.351$, $p < 0.0001$] and frequency [$F_{(10,\ 60)} = 69.276$, $p < 0.0001$] with an increase in velocity. *Post-hoc* analyses revealed an increase in $f1$, $f2$, $a1$, $a2$, $a3$ and a decrease of $f3$ with an increase in the velocity. These significant differences justified their use for building specific sine waves for different walking velocities (**Figure 6**).

Concerning the performance of the DRNN outputs, we wanted to verify if the *SI* value applied for the best networks was different for learning and prediction. Additionally we wanted to statistically check if the number of hidden units of the networks increases the *SI* value (**Figure 7**). The Kolmogorov–Smirnov did not verify that the populations of *SI* values among the learning ($D = 0.18467$, $p < 0.01$) or the prediction ($D = 0.20684$, $p < 0.01$) were normal. Thus, to compare the *SI* values between learning and prediction process we chose to use a sign test as the structure of the network (weights and time constant) were the same. This test reveals no significant differences in *SI* values between the two populations except when the network contains 1, 2, 4, 5, 6, and 7 neurons. Moreover we use a Friedman test to analyze *SI* values (dependent variable) according to the number of hidden units (independent variables) of the network. There is an effect of the number of hidden units to the *SI* both for learning [$\chi^2_{(16)} = 111.5630$, $p < 0.0001$] and for prediction [$\chi^2_{(16)} = 109.3721$, $p < 0.0001$].

We also analyze the output of the DRNN for specific velocities where the hidden layer was the biggest with 80 units. A Kolmogorov–Smirnov run together with learning and prediction values did not verify that the populations of *SI* was normal ($D = 0.18342$, $p < 0.05$).

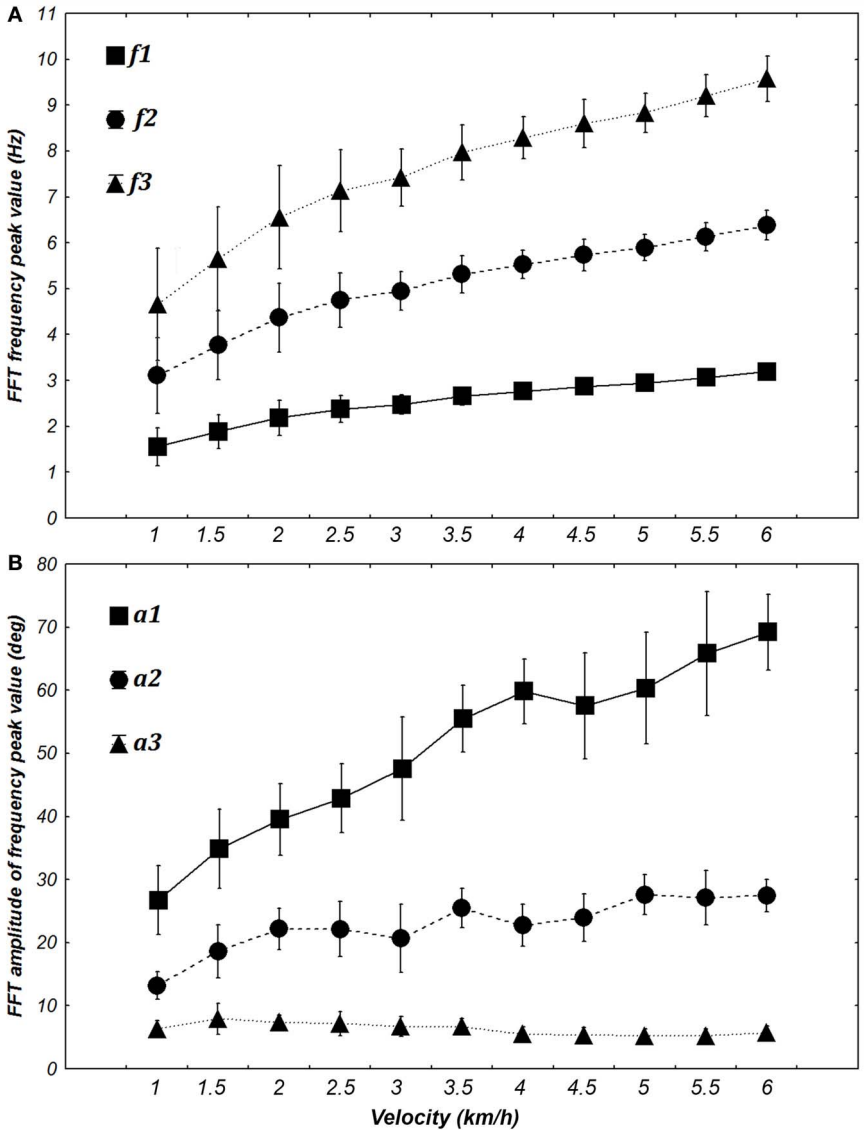

FIGURE 6 | Evolution of the frequency (A) and amplitude (B) of the first three harmonics when transforming elevation angles into the time frequency domain (FFT) at different walking velocities [from 1 to 6 km/h (0.28 to 1.67 m/s)]. The FFT peaks of each angle are averaged for each velocity for both frequency and amplitude. Squares, circles, and triangles represent the mean value for 7 subjects and whiskers represent the 95% confidence interval.

We use a Friedman test to analyze *SI* values (dependent variable) according to the velocity (independent variables) of the network. There is an effect of the velocity to the *SI* [$\chi^2_{(8)} = 30.22$, $p = 0.00019$] (**Figure 8**). A *post-hoc* analysis at 0.05 significance level reveals that *SI* values of 4.5 km/h were different from 1.5 and 2 km/h. *SI* values of 4 km/h were also different from 2 km/h. An example of prediction of intermediate velocities in one subject is illustrated in (**Figure 9**).

DRNN STRUCTURES FROM EXPERIMENT 2

Weight distribution analysis

The percentage of positive and negative weights was calculated for each best network per subject per condition. We wanted to verify if the distribution of the positive and negative weights were different (**Figure 10A**). The Kolmogorov–Smirnov test did not verify that the distribution of positive weights were normal ($D = 0.15022$, $p < 0.01$) nor the distribution of negative weights ($D = 0.15022$, $p < 0.01$). We then used a non-parametric sign-test to compare the two-distribution as the two samples were dependent. Regardless of the number of hidden units, the test shows a difference between the distributions of the two populations ($Z = 9.482$, $p < 0.0001$). When the number of units in the test were included, it appears that the population of negative weights is higher than population of positive weights when the network possesses more than 3 hidden units (for 4 hidden units, $Z = 2.268$, $p = 0.023342$). When the structure of the

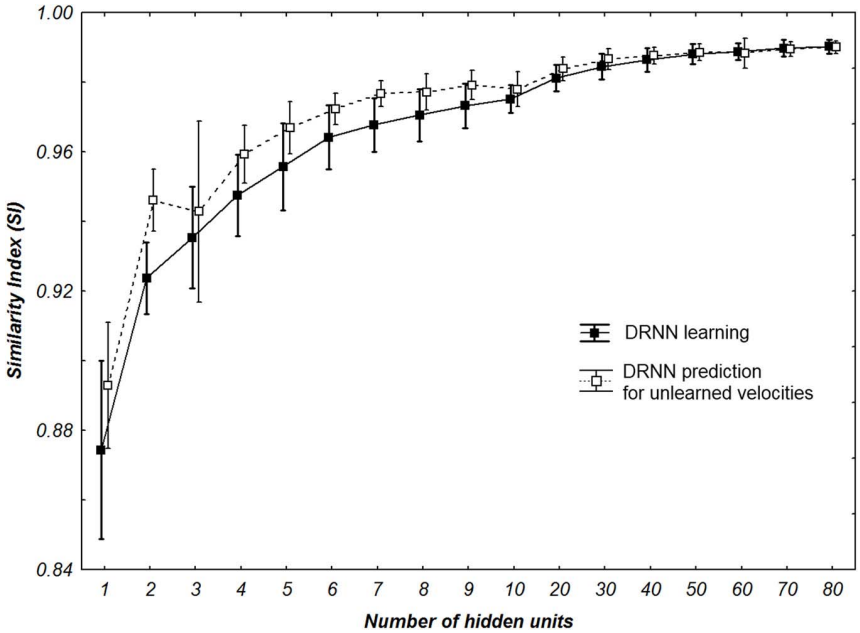

FIGURE 7 | *SI* values of all multi-patterns learning and prediction for all participants with different number of hidden neurons. Whiskers correspond to 95% confidence interval.

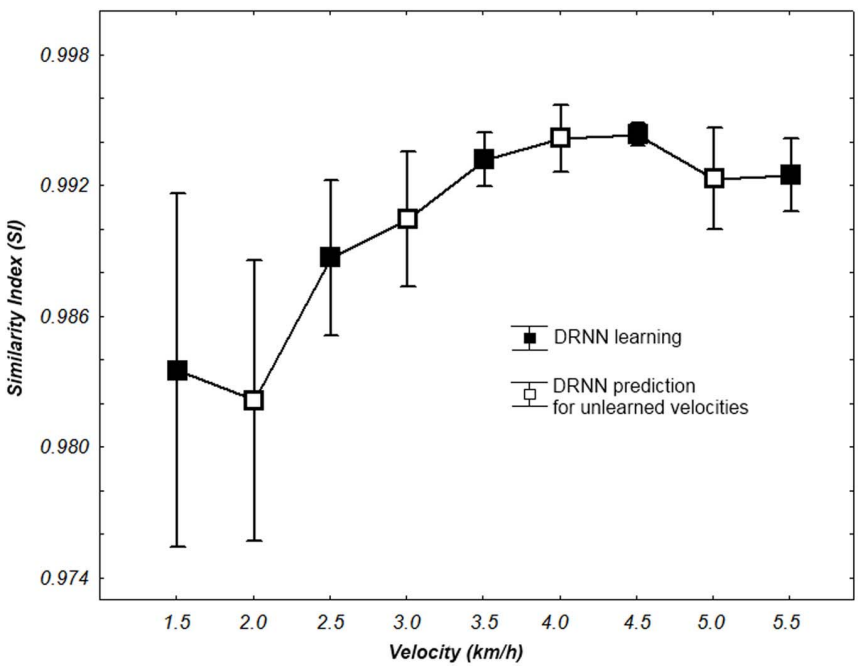

FIGURE 8 | *SI* values for learning and prediction with a 80 hidden units network according to walking velocity. Whiskers correspond to 95% confidence interval.

DRNN reaches 80 hidden neurons, $70.6 \pm 0.84\%$ of the synapses are negative.

Time constant distribution analysis

The distribution of the time constant was represented by the median of neuronal time constants of the best networks per subject and number of hidden units (**Figure 10B**). The Kolmogorov–Smirnov displayed a normal distribution of the time constant median ($D = 0.09110$, $p > 0.20$). ANOVA with repeated measures was designed with the number of hidden units as independent variable and time constant median as dependent variable. ANOVA analysis shows an interesting

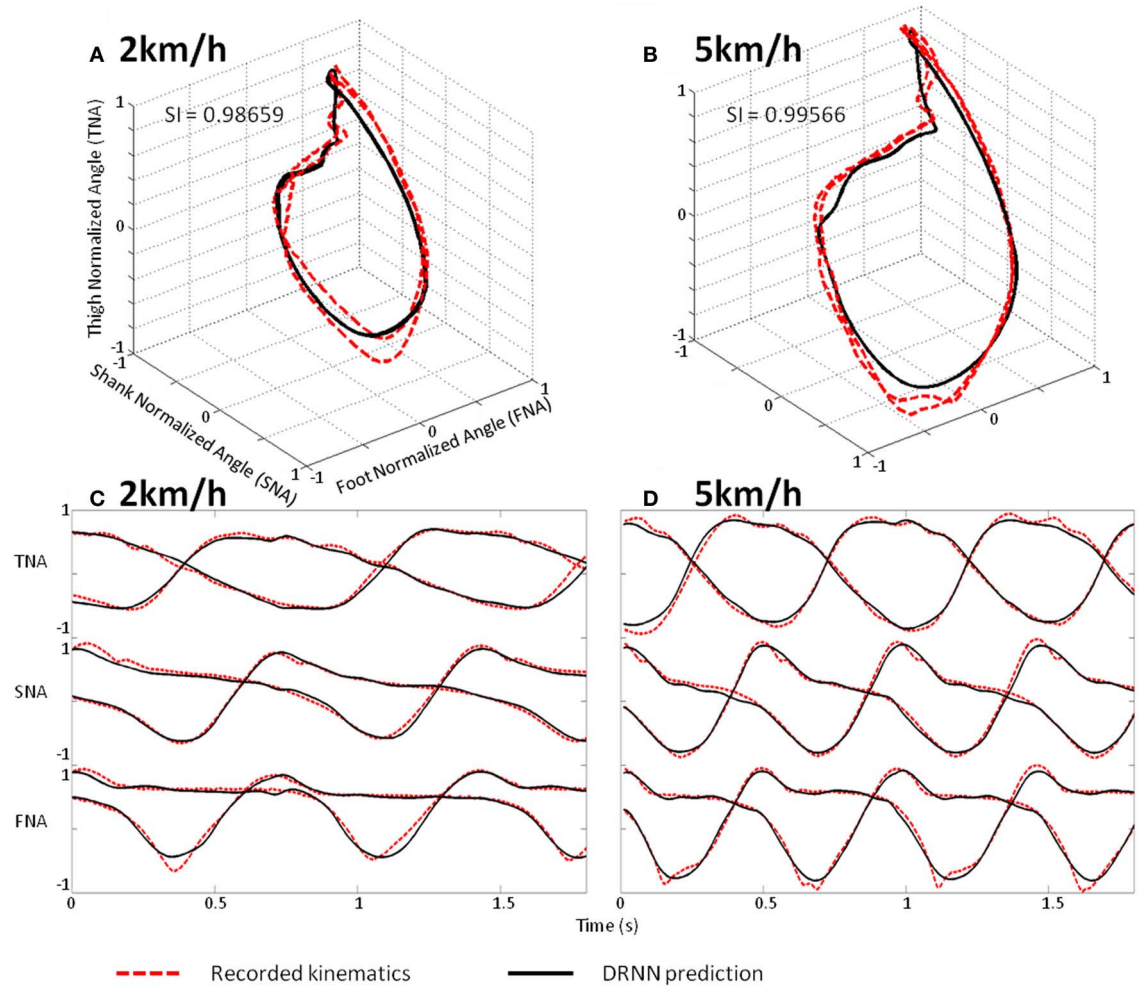

FIGURE 9 | Prediction of intermediate velocities in one subject. **(A)** Planar covariation of the normalized thigh, shank, and foot for one participant walking at 2 km/h. **(B)** Planar covariation of the normalized thigh, shank, and foot for the same participant walking at 5 km/h. **(C)** Kinematics of walking of the normalized thigh, shank, and foot for the same participant walking at 2 km/h. **(D)** Kinematics of walking of the normalized thigh, shank, and foot for the same participant walking at 5 km/h. In each subplot the red dotted line corresponds to the experimental data whereas black thick line corresponds to the output of the DRNN.

effect of the number of hidden neurons [$F_{(16,\ 96)} = 3.6245$, $p < 0.0001$]. Overall, *post-hoc* analysis revealed that the distribution of the time constants were different when the network was small (less than 5 hidden units). It also reveals that the networks with 80 hidden neurons were differently distributed than medium-sized network (8–10 hidden neurons).

DISCUSSION

MAIN FINDING

We show here that a fully connected recurrent neural network is able to reproduce human walking pattern based on oscillatory properties of kinematics. Although, this network is a black box model without prewired structure mimicking a physiological CPG, its actual performance allows direct comparison with CPG dedicated structure and related algorithm (Duvinage et al., 2012a). Moreover, by the inherent input-output mapping, the DRNN models not only the CPG but also neural feedback pathways and the musculoskeletal system. For simplicity, we consider this neural network as "CPG-like structure" here. We proved that the DRNN is capable of generating the kinematics as elevation angles pattern of walking for both limbs (six degrees of freedom) from simple oscillations corresponding to the three main harmonics of the walking kinematics. Moreover, by modulating those frequencies and tuning them in amplitude as input, the DRNN was able to learn and reliably predict walking kinematics at different velocities (**Figure 9**). After this appropriate learning the DRNN can thus be considered as a CPG-like structure that would continuously receive oscillation inputs to produce the relevant elevation patterns of the six leg segments. Another interesting result is observed when looking at the structure of best CPGs obtained after learning. Hence, it appears that all of them contain a major part of negative connection weight between units.

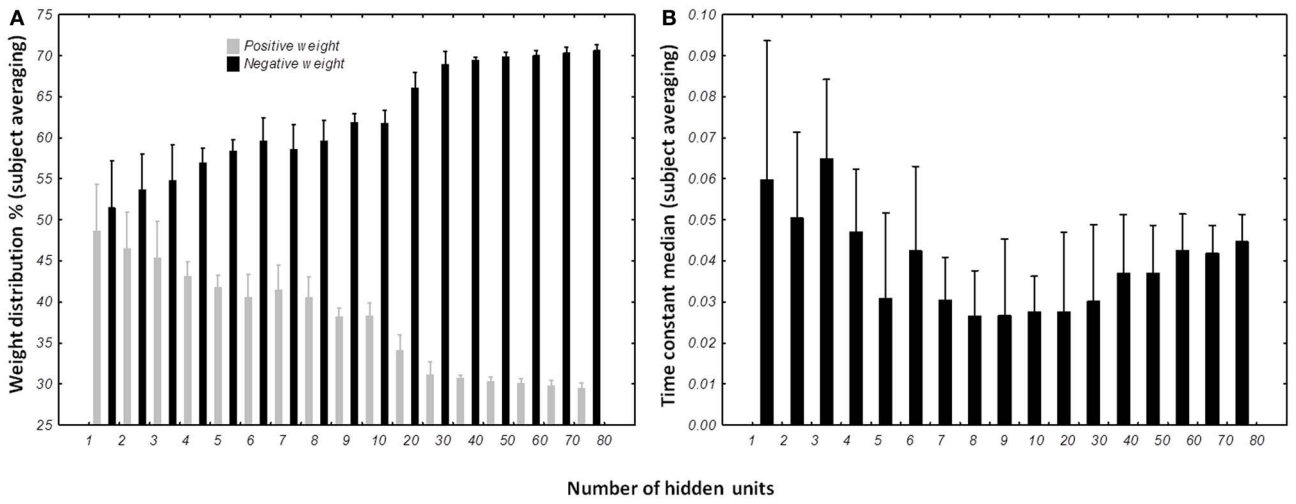

FIGURE 10 | Distribution of weights (A) and time constants (B) among the DRRN structures. The horizontal axis represents the number of hidden neurons and vertical the percentage of population. The bars represent the mean distribution among the best DRNN for each subject. Whiskers represent the 95% confidence intervals.

LIMITATIONS OF THE PRESENT APPROACH

Obviously, there are infinite different ways to train the DRNN and this is a strength of this approach. However, it implies a corollary limitation as not all possibilities could be tested in the present study. For example, in order to better document its generalization ability, the model could be trained for a defined low range of velocities, e.g., from 1 to 4 km/h, and then tested with unlearned oscillation input corresponding to higher velocities. A reverse procedure could also be made, i.e., from faster training to slower predictions. Furthermore, inter-subjects generalization has not been studied in the present investigation. The actual usefulness of performing this would largely depend on the basic or application purposes. Another limitation of the present work is the lack of feedback testing, which necessitates a priori identification of a reliable signal and a new operational strategy for learning. Future work will address these aspects specifically.

NEUROPHYSIOLOGICAL SIMILARITY BETWEEN MODELED CPG AND CPG IN HUMANS AND OTHER MAMMALS

The understanding of CPG mechanisms remains central in locomotion study (Grillner, 2006; Kiehn, 2006; Rossignol and Frigon, 2011). The CPG is a spinal network of neurons capable of generating a rhythmic pattern of alternate activities between flexor and extensor motoneurons on the same side with reciprocal activation of homologous motoneurons in the contralateral limb. This intrinsic spinal circuitry has been well described in many invertebrate and vertebrate animals, and is highly conserved even in humans, where greater cortical control of spinal modules is required working in conjunction with sensory feedback (Calancie et al., 1994; Bussel et al., 1996; Duysens and Van de Crommert, 1998; Drew et al., 2002; Rossignol et al., 2009). The unique characteristics of human walking probably reflect a complex neural mechanism responsible for pattern production. It is therefore difficult to directly extend experimental findings obtained in quadruped animals to human walking (Barbeau et al., 1998; Capaday, 2002).

The fact that some patients with incomplete spinal injury can move their legs in a rhythmic fashion (Dietz et al., 1995) and that the primary sensorimotor cortex provides oscillatory commands toward the spine during walking (La Fougère et al., 2010) motivates new experiments in which different types of oscillatory signals could be used as input to the CPG-like DRNN. In this context, recent studies have showed EEG oscillations in relation to the gait cycle phase including event-related spectral perturbation in the alpha-beta and gamma bands (Gwin et al., 2011; Haefeli et al., 2011; Cheron et al., 2012; Wagner et al., 2012).

These results are consistent with a top down control of locomotion (Capaday, 2002) and demonstrate the feasibility of extracting EEG signals from the sensorimotor cortex controlling the contralateral foot placement during walking. Although the distinction between the brain signals directly linked to the motor commands and those related to the treatment of multiple sensory signals is a hard task. In this context, Petersen et al. (2012) have found evidence of synchrony in the frequency domain between the primary motor cortex and the tibialis anterior muscle prior to heel strike during the swing phase of walking signifying that rhythmical cortical activity is transmitted via the corticospinal tract to the active muscles. Additionally Wagner et al. (2012), showed a significant difference in the alpha (8–12 Hz) and beta (18–21 Hz) rhythm recorded over the central midline area between passive and active walking with exoskeleton. The role played by specific oscillations related to the initiation and control of human locomotion coming from supraspinal structure was recently demonstrated by local field potential recordings performed in the pedunculopontine nucleus in parkinsonian patients during rest and unconstrained walking (Thevathasan et al., 2012). Alpha oscillation recorded in the caudal part of this nucleus is correlated with gait speed and permits to suppress "task irrelevant" distraction for improving gait performance.

Moreover, these authors showed that gait freezing of parkinsonian patient was associated with the attenuation of these alpha waves.

Consistent with this aspect of gait physiology, in our model, input sine waves are sufficient to predict successful output with the DRNN and offer the possibility to mimic such type of supraspinal oscillatory input. It could be advanced that nonlinear mapping of sinusoidal oscillations to kinematic pattern should be realized by other mathematical functions, such as by a Taylor series, but such multi-dimensional approximation seems to be highly difficult to obtain and does not permit testing different network configurations mimicking biological organization such as the CPG. In the present study, we focused on input oscillation derived from the first three harmonics of kinematic signals, which were slower than the alpha frequency range. However, it could be possible to extract slower oscillation from alpha or beta derived signals (envelope) in order to activate the DRNN in our future work.

STRUCTURAL SIMILARITIES OF MODELED CPG AND NEUROPHYSIOLOGICAL CPGs IN ANIMALS

It has been suggested that the biological CPG is considered to serve two basic functions: rhythm generation (RG) and pattern formation (PF).

Initially proposed by Perret and Cabelguen (1980), the idea that the biological CPG is composed of a rhythm and a pattern-amplitude generator is now widely accepted (Kriellaars et al., 1994; Guertin et al., 1995; Perreault et al., 1995; Grillner, 2006; Kiehn, 2006; Talpalar et al., 2011) and paved the way to more complex models of multi-level CPG (McCrea and Rybak, 2008, see below).

It is well-recognized that rhythm generating networks can be realized by means of (1) pacemaker neurons with intrinsic membrane properties such as those described in the stomatogastric ganglion of crustaceans or in the mammalian thalamus (Steriade and Llinás, 1988) or (2) most simplistic neurons without intrinsic pacemaker properties but interacting with inhibitory synapses for producing oscillation as emergent properties of this neuronal population (Geisler et al., 2005). Both neuronal systems thus present the fundamental ability to oscillate. Firstly described in the tadpole and lamprey CPGs, glutamatergic excitatory neurons distributed along the cord (Grillner, 2003) assume the function of rhythmic generator by driving motor neurons and other ipsilateral and commissural inhibitory neurons coordinating the different CPG modules. By blocking the inhibitory networking in the lamprey and also in rodent and cat, many authors (see Kiehn, 2006 for a review) have demonstrated that the glutamatergic burst neurons are the generators of the CPG rhythm.

In addition to intrinsic RG properties, the walking CPGs need to integrate the ipsilateral coordination of flexors and extensors across the same or different joints in a limb and perform inter-limbs coordination. It has been proposed (Zhong et al., 2012) that a subpopulation of neuronal CPG that drives extensor activity is tonically active and is regulated via inhibitory interactions with another CPG rhythmic structure responsible for flexors activity in the same hemicord. This assumption may explain why, during experimental recordings on the neonatal mouse isolated spinal cord, spontaneous deletions of extensor activity do not perturb rhythmic flexor activity. Thus, the inhibitory interneurons play a major role in the temporal sculpting and coordination of the CPG units. The interneurons and the Renshaw cells are involved in this function and in the regulation of walking speed. In addition, the left-right coordination is assumed by a complex network of excitatory and inhibitory commissural interneurons acting on both motor neurons and inhibitory interneurons of the contralateral side (Kiehn, 2006). Interestingly, we have shown that a great percentage of artificial neurons became inhibitory neurons (negative synaptic weight) when the number of neurons progressively increases in the DRNN structure. In this context, it was recently demonstrated in awake mice that the spiking activity of inhibitory neurons of the barrel cortex is organized in order to balance excitation and prevent explosive activity in the recurrently connected cortical microcircuit (Gentet et al., 2010). This physiological mechanism can also be proposed in the present case of the emergent structure of artificial DRNN circuit. Another, not exclusive explanation can reside in the prevalence of inhibitory recurrent connections for producing network oscillation (Geisler et al., 2005; Wildie and Shanahan, 2011). In their review, Nishimaru and Kakizaki (2009) have proposed that inhibitory interneurons play a major role in the CPG of rodent spinal cord. The interneurons are likely to control the bursting of motor neurons during locomotion and it appears that the synaptic transmission mediated by glycine and GABA shifts from excitatory to inhibitory during the prenatal period. It was recently demonstrated that in the absence of glutamatergic synaptic transmission, the flexor-extensor alternation appears to be generated by the inhibitory interneurons, mediating reciprocal inhibition from muscle proprioceptors to antagonist motor neurons (Talpalar et al., 2011).

The present artificial model does not pretend to mimic the complexity of the CPG structure. Instead, it presents a highly simplified recurrent organization from which CPG-like dynamic function emerges, following appropriate learning. Sinusoidal inputs serve as temporal referent to produce rhythmic angles patterns. This model could correspond to the RG structure described previously as a higher order structure that determines rhythmic output of the system (McCrea and Rybak, 2008; Zhong et al., 2012) since sine waves are transformed into kinematics. Another, lower order structure responsible for the phasing and intensity coordination (McCrea and Rybak, 2008; Zhong et al., 2012) could be assumed by another model of DRNN transforming theoretical kinematics into practical muscle orders. We have already studied such relation where EMG signals from walking where used to predict kinematics (Cheron et al., 2003). To conclude to this point, we propose that the two model driving two specific DRNNs (one for producing elevation angles from sine waves and one producing muscular patterns from elevation angles during walking) could act as a complementary top-down pathway to produce adequate coordinated patterns as it has been proposed to model the locomotion in spinal mouse (Zhong et al., 2012).

The present results can also be discussed in the light of the electrical stimulations performed in the MLR) inducing locomotor behavior in decerebrate cat (Shik et al., 1969) or in lamprey (McClellan and Grillner, 1984). In mice, prolonged rhythmic stimulation on the midline of the caudal hindbrain or the ventral

spinal cord (C1–C4) induces a stable locomotor activity (Talpalar et al., 2011). Typically, low-frequency stimulation leads to slow-frequency movements and inversely fast-frequency stimulation leads to fast-frequency movements. Our model is in accordance with this physiological behavior, when amplitude of the artificial sine wave inputs increases, the amplitude of stepping increases as well, leading to a change in walking velocities (**Figure 6B**). In terms of neurological development, there is some evidence for the existence of CPG very early in CNS maturation (Yang et al., 1998; Dominici et al., 2011). Neonatal, so-called "infant" stepping has been ascribed to similar EMG patterns activity in different directions inducing stereotyped yet non-functional walking patterns (Lamb and Yang, 2000). This leads the authors to conclude that the same CPG controls different stepping in human infants in contrast with some studies in adults (Thorstensson, 1986; Grasso et al., 1998). Interestingly, we found that DRNN with only four hidden artificial neurons can generate walking pattern, whereas at least 50 hidden neurons are the prerequisite to generate accurate movements (**Figure 7**). Obviously, recruitment and training of such high numbers of neurons requires long computational time. For example, with a 4 hidden units DRNN structure, the learning process lasts about 5 min based on our computer performance while 160 min are necessary for a DRNN containing 80 units (**Figure 4**).

PERSPECTIVES

Such a tool can be used to produce gait kinematics in numerous and various applications. For rehabilitation it can be used to train people for recovering a walking pattern corresponding to their physical characteristics by training with an appropriate feedback. Specifically dedicated DRNN based on the proper dynamics of participants could be used for medical applications such as in prosthesis and exoskeleton control (Cheron et al., 2012). It can also be integrated in BCI applications in which higher order commands can be used, e.g., from steady state visual or somatosensory evoked potentials (Cheron et al., 2012) or P300 (Castermans et al., 2011; Duvinage et al., 2012b). This neuronal avenue might lead to the decoding of higher neuronal commands that govern CPG mechanisms. Since these CPG can be trained using specific sinusoidal frequency signals, it might be possible to extract this type of signals from specific EEG rhythms since the brain itself is an effective machine for producing oscillations (Buzsáki and Draguhn, 2004). One of the strengths of this approach is that it is not necessary to determine in advance the topology and the timing sequences between the artificial neurons. This contrasts with other CPGs, such as a recently developed ones (Duvinage et al., 2011) based on coupled oscillators (Righetti and Ijspeert, 2006), where adjustment of intrinsic parameters by optimization techniques was necessary.

In future studies, by introducing an informational delay (Draye et al., 1997) or an artificial distance based on a Gaussian factor modulating the weights between the different neurons (Draye et al., 2002), it will be possible to analyze the self-tailored organization of the links between neurons and the possible emergence of specific topologies. In this case it will also be possible to select different modular architectures of the DRNN.

This paper addresses the question of how the brain maintains a probabilistic body state estimate over time from a modeling perspective. The neural Modular Modality Frame (nMMF) model simulates such a body state estimation process by continuously integrating redundant, multimodal body state information sources. The body state estimate itself is distributed over separate, but bidirectionally interacting modules. nMMF compares the incoming sensory and present body state information across the interacting modules and fuses the information sources accordingly. At the same time, nMMF enforces body state estimation consistency across the modules. nMMF is able to detect conflicting sensory information and to consequently decrease the influence of implausible sensor sources on the fly. In contrast to the previously published Modular Modality Frame (MMF) model, nMMF offers a biologically plausible neural implementation based on distributed, probabilistic population codes. Besides its neural plausibility, the neural encoding has the advantage of enabling (a) additional probabilistic information flow across the separate body state estimation modules and (b) the representation of arbitrary probability distributions of a body state. The results show that the neural estimates can detect and decrease the impact of false sensory information, can propagate conflicting information across modules, and can improve overall estimation accuracy due to additional module interactions. Even bodily illusions, such as the rubber hand illusion, can be simulated with nMMF. We conclude with an outlook on the potential of modeling human data and of invoking goal-directed behavioral control.

Keywords: modular body schema, sensor fusion, multisensory perception, multisensory processing, multimodal interaction, probabilistic inference, population code, conflicting information

1. INTRODUCTION

Humans and other animals appear to learn and maintain a body schema[1] (Graziano and Botvinick, 1999; Haggard and Wolpert, 2005), which is used to realize goal-directed behavior control. Evidence for having knowledge about the own body schema and associated body image is already found in 2-month old children, indicating that this knowledge is acquired very early in life (von Hofsten, 2004; Rochat, 2010). The more accurate the own body schema is, the more the infant is able to separate the external world (von Holst and Mittelstaedt, 1950) from its own body and, consequently, the more the infant is able to actively and goal-directedly explore the world (Konczak et al., 1995; Butz and Pezzulo, 2008). Developmental as well as neuroscientific evidence indicates that developing a body schema is critical for developing flexible, goal-directed behavioral control. In this paper we propose a computational neural model of how knowledge about the body can be represented, processed, and learned.

When learning such a body schema, specific challenges must be met. First, sensory information about the body is available in different modalities and frames of reference. Thus, mappings between these modalities need to be established. Second, uncertainty due to noise, external forces, and changes of the body and the environment has to be handled effectively. Third, different information signals about the body may contradict each other, so that the maintenance of the present body state estimate is non-trivial.

The human brain has solved these challenges. In particular, the brain appears to be able to flexibly integrate multimodal sensory information about the body into a current estimate of its body state. This body state estimate seems to be modularized in two fashions: sensory modality-respective modularizations and body part-respective modularizations.

Evidence for sensor-specific modularizations can be found in brain imaging studies, which suggest that cross-modal sensory information fusion is common when perceiving the own body (Shams et al., 2000; Shimojo and Shams, 2001; Beauchamp, 2005). Related research suggests that body state representations are separated into body parts to certain degrees (Andersen et al.,

[1]Note that **Table 1** lists the terminology utilized in this paper.

Table 1 | MMF-terminology.

Body image	A usually conscious representation of the way the body appears from the outside (Haggard and Wolpert, 2005)
Body model	Static knowledge about the body: segmentation into body parts, metrics, and mappings between modules
Body schema	A group of body representations relevant for action (Haggard and Wolpert, 2005). This includes body state, body space, and body model. It allows for updates of the body state. The term body schema has been used across disciplines and with varying degrees of precision (Sekiyama et al., 2000; Buneo et al., 2002; Battaglia-Mayer et al., 2003; Maravita et al., 2003; Makin et al., 2008; Burns and Blohm, 2010; Hoffmann et al., 2010; Sober and Körding, 2012)
Body space	Teachable space of a particular body part in a particular modality
Body state	An estimate of the current body configuration. May refer to the body state encoded in a single module or spread over multiple modules
Distal-to-proximal	Mapping direction: fingertip → wrist → elbow → shoulder
Forward	Mapping direction: joint angles → local orientation → global orientation → location
Frame of reference	The coordinate system of a module: "global" (shoulder centered) or local (respective the next proximal body part)
Information fusion	Bayes optimal fusion of multiple probability distributions. These may include multiple sensors, multiple body states in different modules, or both
Inverse	Mapping direction: location → global orientation → local orientation → joint angles
Mappings	The set of connections between neurons in one or two input modules and neurons in one output module. There are three "types" of mappings: forward kinematics, inverse kinematics, and distal-to-proximal kinematics. They are used to propagate neuronal activity to other modules
Modality	Which information is encoded in which frame of reference: nMMF uses position-vectors, orientation-vectors in a "global" (i.e., respective the shoulder) or "local" (i.e., respective the next proximal body part) frame of reference, or joint-angles
Module	A state space of the body, such as the wrist location in space. Modules may differ with respect to modalities, frames of reference, and body parts
Neural population	A set of neurons that encode the spatial distribution in a particular module. The population as a whole encodes a probability distribution
nMMF	neural Modular Modality Frame model: the model presented in this work
Proximal-to-distal	Mapping direction: shoulder → elbow → wrist → fingertip (cf. **Figure 4**)
q_l^i	Probability mass of the l-th neuron in module i's population. The probability mass is the same as the Voronoi volume V_l (cf. Appendix A.2) times neuron l's probability density, normalized to 1
Sensor integration	The special case where sensory information is fused with the body state. Also, the result becomes the new body state
Transformation step	Projects input information from one or two modules to a neighboring module

1997; Gentner and Classen, 2006; Latash et al., 2007; Shadmehr and Krakauer, 2008; de Vignemont et al., 2009). Thus, a highly modularized body state estimate is maintained by our brain.

For maintaining such a modularized but consistent body state estimate, information is effectively interchanged and fused across the modularizations (Tononi et al., 1998; Ernst and Bülthoff, 2004; Stein and Stanford, 2008). Hereby, the information exchange typically depends on how the body is currently positioned and oriented in space (Holmes and Spence, 2004; Butz et al., 2010). Neurological disorders further indicate that both sensory input and body state estimates are fused across modules (Giummarra et al., 2008). To combine incoming sensory information with the most accurate body state estimate, the brain also anticipates body state changes and consequent sensory feedback during movement execution (von Holst and Mittelstaedt, 1950; Blakemore et al., 2000; Sommer and Wurtz, 2006). Many of these interactions seem to take place in early stages of the cortical processing hierarchy (Stein and Stanford, 2008), probably before the sensory information is fully integrated into the own body state estimate. Further evidence for sensory information comparisons and the flexible fusion of this information for maintaining body state estimates is given by multimodal illusions like the rubber hand illusion (Botvinick et al., 1998; Haggard and Wolpert, 2005; Makin et al., 2008) and the Pinocchio illusion (Lackner, 1988). Thus, it appears that while the brain's body state estimate is highly modularized, many interactions ensure

an effective estimate maintenance and sensory information integration. However, it remains unclear how, when, and which information is compared and selectively fused.

We recently proposed the Modular Modality Frame (MMF) model (Ehrenfeld and Butz, 2011, 2012, 2013), which models the maintenance of a body state estimate given noisy, multimodal sensory information sources. The MMF model fully relies on hard-coded kinematic knowledge of the simulated body and estimates body states by means of Gaussian probability densities. Here we present a neural extension of MMF—the neural Modular Modality Frame (nMMF) model. The novel contributions of nMMF are as follows:

First, body spaces, current body state estimation modules, and mappings between body modules are now implemented neurally. As a result, nMMF is able to encode arbitrary, even multimodal body state estimations. Moreover, the neural population encodings for body state estimates are plausible from a computational neuroscience perspective (Deneve and Pouget, 2004; Knill and Pouget, 2004; Denève et al., 2007; Doya et al., 2007). Second, we now ensure that the Shannon entropy of a distribution remains unchanged during multi-body state fusion, in order to avoid excessive information gain when fusing dependent sources of information. Third, information exchange is no longer restricted to forward and inverse kinematic mappings. Distal-to-proximal mappings are also included. This means that information about the hand in space can, for example, influence the estimate of the elbow location, of the orientation of the upper arm, or even of the shoulder joint angles.

The remainder of this paper is structured as follows. First, the nMMF model is detailed. Next, nMMF is evaluated on a simulated two degree of freedom arm in a two-dimensional setup. The evaluations show that nMMF is able to detect faulty sensory information on the fly and is able to propagate information appropriately distal-to-proximal, i.e., from hand to upper arm. In the final discussion, we compare nMMF to related models and sketch-out future research directions.

2. MATERIALS AND METHODS

nMMF is inspired by those processes of human body state estimation which are detailed above. In a computational framework, these processes can be approximated by five key assumptions: (1) the body state is continuously estimated probabilistically over time; (2) multimodal, redundant sensory information sources are integrated based on Bayesian principles; (3) the body state representation is modularized along body parts as well as along modalities and their corresponding frames-of-reference; (4) the body modules are locally interactive in that information about the body state is compared and fused locally; (5) the redundant, modularized representation of the body is exploited for autonomous sensor failure detection and subsequent avoidance of the failing sensor's influence.

We now detail how these key aspects are realized in nMMF. First, we describe which modules are used, second, how neurons encode the sensory inputs and the body state, third, how information is fused, fourth, how information is projected across modules, fifth, how conflicting information is detected and blocked out, and, finally, how the overall information flow unfolds over time. In the subsequent evaluation section we show how nMMF processes sensory information, how faulty sensory information can be ignored to a certain degree, but also how such faulty sensory information can influence the complete body state estimation.

2.1. MODULES

nMMF represents a body state by a collection of modules, where each module represents an aspect of the overall body state. In particular, nMMF's modules differ with respect to (1) the encoded joint (or the next distal limb) and (2) the modality frame in which the joint or limb is encoded. The term modality frame defines which modality is perceived (location, orientation, or joint angle) and in which frame of reference the modality is encoded (shoulder-centered or "local" with respect to the next proximal limb).

In the following, we focus on a general description of a humanoid arm, although the same principle may apply for a complete body description. First, we specify the state of an arm in general. Next, we detail how nMMF encodes the arm state in its respective modules.

2.1.1. Arm specification

An arm state may be encoded by the arm's location in space, its limb orientations, or the joint angles. With respect to the arm's location, we denote the shoulder (elbow, wrist, fingertips) location by $\boldsymbol{\lambda}_0$ ($\boldsymbol{\lambda}_1$, $\boldsymbol{\lambda}_2$, $\boldsymbol{\lambda}_3$) (cf. **Figure 1** for an illustration). To

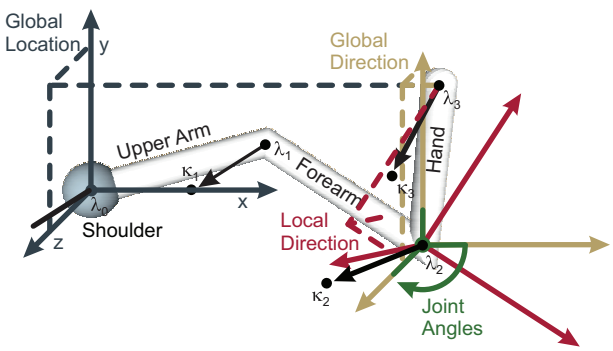

FIGURE 1 | Schematic of the four "hand"-limb-encoding modules. Three coordinate systems (solid axes) are shown, together with the components (dashed lines) of the respective encoded vector. Dark gray (Global Location module): the coordinate system is centered around the shoulder with fixed orientation. Encoded is the global location vector, which goes from shoulder to the end-effector. Yellow (Global Orientation module): the coordinate system has the same orientation as the gray one but in this case the limb orientation is encoded by the means of two vectors: a unit vector parallel to the "hand" limb (shown, dashed lines), and a perpendicular vector (not shown). Red (Local Orientation module): the local coordinate system is oriented along the forearm. Relative to this forearm orientation, the orientation of the "hand" limb is encoded—by a unit vector parallel to the "hand" limb (shown), and a perpendicular vector (not shown). Green (Local Angle module): the fourth module encodes angles. The same four modules and respective coordinate systems exist for the forearm and the upper arm (not shown). Modified based on Ehrenfeld and Butz (2012, 2013).

derive the arm limb orientations we simply subtract successive limb locations. To additionally encode the inner rotations of the respective limbs, we define a point $\boldsymbol{\kappa}_i$ for each limb i, where $\boldsymbol{\kappa}_i$ is locked relative to the limb. Essentially, $\boldsymbol{\kappa}_i$ always lies somewhere on the unit circle around $\boldsymbol{\lambda}_i$, where the unit circle's plane is perpendicular to the orientation of limb i. Finally, the joint angles of each arm joint i are denoted by the Tait-Bryan angles $(\phi_{i,1}, \phi_{i,2}, \phi_{i,3})$, which rotate about the intrinsic rotation axes ${}^{i-1}\boldsymbol{x}$, ${}^{i-1}\boldsymbol{y}'$, ${}^{i-1}\boldsymbol{z}''$, where one (two) apostrophes denote that the rotation axis has been rotated by the angles $\phi_{i,1}$ (and $\phi_{i,2}$).

2.1.2. nMMF's arm encoding

nMMF encodes probabilistic arm states by means of distributed population codes in redundant modules. In particular, each limb is encoded in four modality frames: global location (*GL*), global orientation (*GO*), local orientation (*LO*), and local (joint) angles (*LA*). Note that other modalities could be used in addition and other combinations of modalities and frames of reference are possible—such as a local location. It is crucial, however, that the chosen combinations form a redundant estimate of the overall body state. nMMF's implemented modules and their interactions are shown in **Figure 4**; **Figure 1** shows the employed modality frames for an exemplar arm.

To encode each modality frame, respective coordinate systems need to be defined. In order to provide a consistent notation for all nMMF modules, we introduce $\mathbf{x}^{Z_i}$ as the estimated arm state of limb i in modality frame Z, where $Z \in \{GL, GO, LO, LA\}$[2].

The first modality frame encodes the global location (*GL*) of an arm limb. Limb i's end point $\boldsymbol{\lambda}_i$ in the *GL* modality frame is the 3D vector from the shoulder to the end-point of limb i:

$$\mathbf{x}^{GL_i} \equiv \boldsymbol{\lambda}_i - \boldsymbol{\lambda}_0. \tag{1}$$

The global orientation (*GO*) is a 6D vector. It concatenates both a 3D unit-vector in the direction of the arm limb, and a 3D unit-vector perpendicular to the arm limb dependent on its inner rotation:

$$\mathbf{x}^{GO_i} \equiv \begin{pmatrix} \text{unit}\,(\boldsymbol{\lambda}_i - \boldsymbol{\lambda}_{i-1}) \\ \text{unit}\,(\boldsymbol{\kappa}_i - \boldsymbol{\lambda}_{i-1}) \end{pmatrix}, \tag{2}$$

As both vectors are unit vectors and are perpendicular to each other, three degrees of freedom are canceled out and all remaining orientation vectors form a 3D manifold in 6D space.

The local orientation (*LO*) is analogous, but expresses both subvectors in a local coordinate system (e.g., LO_2 is expressed in a coordinate system whose axes are defined by GO_1). Again, only a 3D manifold remains:

$$\mathbf{x}^{LO_i} \equiv \begin{pmatrix} \text{unit}\left({}^{i-1}\boldsymbol{\lambda}_i - {}^{i-1}\boldsymbol{\lambda}_{i-1}\right) \\ \text{unit}\left({}^{i-1}\boldsymbol{\kappa}_i - {}^{i-1}\boldsymbol{\lambda}_{i-1}\right) \end{pmatrix}. \tag{3}$$

Note that we use the pre-superscript to denote a particular, relative coordinate system, whereas we use the subscript to denote a particular limb. Furthermore, note that ${}^{i-1}\boldsymbol{\lambda}_{i-1} \equiv (0, 0, 0)^T$ due to the definition of the coordinate system relative to limb $i-1$.

Finally, the local angles (*LA*) are encoded as Tait-Bryan angles

$$\mathbf{x}^{LA_i} \equiv \left(\phi_{i,1}, \phi_{i,2}, \phi_{i,3}\right)^T, \tag{4}$$

which is identical to the arm encoding itself.

Note that all modality frames are maximally 3D. Thus, the locality of the modular architecture ensures that the amount of neurons needed to represent a particular modality frame with a neural population code of n neurons per dimension scales in $O\left(n^3\right)$.

2.2. PROBABILISTIC REPRESENTATION

In complex tasks, uncertainty is ubiquitous due to sensory and motor noise, external forces, changes in the environment, and changes of the body schema. To deal with this uncertainty, humans apply probabilistic body state estimations (Ernst and Banks, 2002; Körding and Wolpert, 2004). In computational models (e.g., Ma et al., 2006), state estimates are often simplified by confining probability density estimates to one type of distribution (such as the Gaussian, Gamma or Poisson distributions). However, shapes may vary greatly due to non-linear influences of mappings across modules, constraints (like joint restrictions or obstacles), varying shapes of sensory input to begin with, or even neural disorders. Moreover, in certain circumstances the brain may actually maintain multimodal alternatives about the current body state.

In contrast to MMF, nMMF approximates probability distributions with neural population codes (Deneve et al., 1999) to enable the representation of probability distributions with arbitrary shapes. Each neuron in such a code is responsive to specific values of the input data (preferred value) and thus has a local receptive field of a particular size. Note that by using population codes, the shapes of the encoded probability distributions become unconstrained. The modularity of nMMF ensures a scalable neural encoding of the arm or even the full body. In the following, we describe how the receptive fields and the preferred values of the population neurons are determined.

2.2.1. Sampling of neural populations

In order to create neurons only within the reachable manifolds, we let the populations of neurons grow while observing simulated arm states. This is done in the following way: A simulated arm is set to a random arm position, which is uniformly distributed in angular space. Then, noiseless measurements $\mathbf{z}^j$ are obtained in each module j. If

$$||\mathbf{z}^j - \mathbf{x}_l^j|| > d_{\min} \,\forall\, l \in \{1, \ldots, N^j\}, \tag{5}$$

[2]Without any additional specification, arm states are encoded in a "global", i.e., shoulder-respective coordinate system. In the case of the local orientation (*LO*) modality frame, however, the coordinate system used to encode the state is relative to the next proximal arm limb. We use the pre-superscript to denote the encoding of a location in a limb-relative coordinate system. For example, ${}^{i-1}\boldsymbol{\lambda}_i$ denotes the location of limb i relative to the location $\boldsymbol{\lambda}_{i-1}$ and orientation of limb $i-1$.

a new neuron is added at $\mathbf{z}^j$, where $\mathbf{x}_l^j$ denotes the preferred value of neuron l and N^j the current number of neurons that exist in module j. Next, the arm is set to a new random position. Thus, all sampling positions are independent of each other and the resulting neurons in each module are approximately uniformly distributed, covering the reachable manifold.

2.2.2. Tuning function

Each neuron has an associated tuning function (Deneve et al., 1999), which specifies how the neuron responds to a signal. We use Gaussian tuning functions with mean $\mathbf{x}_l$ and covariance $\mathbf{R}$. For instance, if a measurement signal occurs at position $\mathbf{z}$, the probability density function (PDF) at $\mathbf{x}_l$ is:

$$\mathrm{p}_l = N(\mathbf{z}, \mathbf{R})(\mathbf{x}_l). \tag{6}$$

In effect, a Gaussian PDF is activated over the whole neural population (cf. **Figure 2**, yellow bars for an illustration). If the covariance $\mathbf{R}$ of all tuning functions is equal to the sensor covariance, then Equation (6) is the same as the inverse measurement model (Thrun et al., 2005).

Since probability mass has to be conserved when information flows from one module to another in nMMF, we derive the probability mass function (PMF) from the PDF. Note that the neural PMF encoding will typically slightly differ from the PDF encoding in nMMF, because the population codes in nMMF may not be uniformly distributed. This is illustrated in **Figure 2**.

2.2.3. Probability mass

Let $\mathbf{X}$ be a multivariate random variable, and ω a subset of a sample space Ω. The probability mass q in ω corresponds to the probability that X lies in ω:

$$q_\omega \equiv Pr[\mathbf{X} \in \omega] = \int_\omega \mathrm{p}(\mathbf{x})\, d\mathbf{x} \tag{7}$$

Just as N neurons are spread over Ω, Ω is discretized into N subsets ω_l, $l \in (1..N)$, which are simply the Voronoi cells R_l of those neurons (cf. Appendix A.2). The probability mass of a neuron can then be approximated by the Volume V of the cell times the density (Equation 6) at the neuron's position

$$q_l = \int_{R_l} \mathrm{p}(\mathbf{x})\, d\mathbf{x} \approx \frac{V_l \cdot \mathrm{p}(\mathbf{x}_l)}{\sum_{l^*=1}^{N} V_{l^*} \cdot \mathrm{p}(\mathbf{x}_{l^*})}, \tag{8}$$

where the denominator normalizes the probability mass to 1. An illustration of a probability mass is shown in **Figure 2**, blue bars. To handle potential approximation errors, we ensure that the sum of the probability mass over all neurons N in a module is always normalized to 1, by

$$q_l \leftarrow \frac{q_l}{\sum_{l^*} q_{l^*}}, \tag{9}$$

where the symbol "$\leftarrow$" is used as a value update assignment.

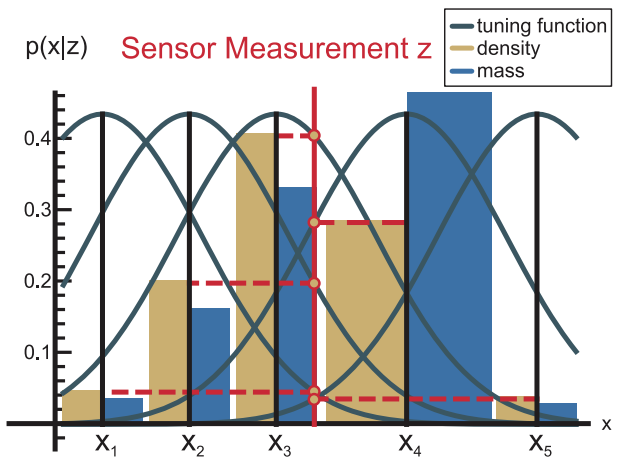

FIGURE 2 | Each neuron has a tuning function (Deneve et al., 1999) that defines how the neuron responds to a signal. Generally, these tuning functions are considered to be bell-shaped, such as the shown Gaussian kernels. As a consequence of this encoding, the PDF encoded by the neural population becomes Gaussian as well (yellow bars), while the probability mass (blue) is somewhat distorted because it accounts for the local neural density.

2.3. INFORMATION FUSION

With a neural, modularized, probabilistic body state representation in hand, we now focus on information processing and information exchange. In this section, we first detail the fusion of different neurally-represented PDFs, and consecutively derive the fusion of different PMFs. Two cases are considered: that the information carried by the different PMFs is dependent or independent.

The Bayesian fusion (Bloch, 1996) of multiple independent neurally-encoded probability distributions is the neuron-wise product of the respective PDFs. Thus, the fusion yields:

$$\mathrm{p}_{\mathrm{fused},l} \propto \prod_{j=1}^{M} \mathrm{p}_{j,l}, \tag{10}$$

where M specifies the number of modality frames that are fused, l is the index of a specific neuron, and $\mathrm{p}_{j,l}$ encodes the probability density that stems from modality frame j and that is covered by neuron l. As the density can be converted to a mass by $\mathrm{p}_l = q_l \cdot V_l^{-1}$, applying this identity to both sides of Equation (10) yields the fusion of PMFs

$$q_{\mathrm{fused},l} = \frac{(V_l)^{-(M-1)} \prod_{j=1}^{M} q_{j,l}}{\sum_{l^*} (V_{l^*})^{-(M-1)} \prod_{j=1}^{M} q_{j,l^*}}. \tag{11}$$

When Equations (10) or (11) is used to fuse partly or fully dependent information, the resulting distribution is overconfident (i.e., too narrow).

To correct for this overconfidence, the PDF can be raised to the power of an exponent $\alpha < 1$. However, since we encode PMFs, additional conversions are again necessary to account for the Voronoi volumes covered by the

respective neurons. The correction for overconfidence is thus accomplished by:

$$q_{\text{fused},l} \leftarrow \frac{V_l^{1-\alpha}\left(q_{\text{fused},l}\right)^{\alpha}}{\sum_{l^*} V_{l^*}^{1-\alpha}\left(q_{\text{fused},l^*}\right)^{\alpha}}; \tag{12}$$

where the denominator normalizes the mass to 1. The effect is a widening of the encoded PMF, which is illustrated in **Figure 3**.

To infer the exponent α, a measure of information content is required. We use the Shannon entropy h to estimate the amount of information in a PMF:

$$h \equiv -\sum_l q_l \cdot \ln\left(q_l\right), \tag{13}$$

where q_l may denote the fused distribution as in Equation (11) or any other arbitrary distribution. If all distributions were Gaussian, the exponent could be derived from Equation (12) by requiring that the Shannon entropy in a module before fusion should be equal to the Shannon entropy after fusion:

$$\alpha = \mathrm{e}^{-2\left(\min_j h_j - h_{\text{fused}}\right)}. \tag{14}$$

Due to the lack of a rigorous derivation of α in the general case, we utilize this approximation to determine α for our population-encoded probability masses in each module.

2.4. CROSS-MODULE CONNECTIONS

With notations for modules in nMMF, neurally-encoded probability masses, and information fusion of redundant sources of information at hand, we now specify how the neural, cross-module connections are implemented in nMMF.

Modules may differ along two axes: the limb-axis (proximal-to-distal, shown horizontally in **Figure 4**), and the modality frame axis (forward and inverse, shown vertically in **Figure 4**). Information may flow from one or two input modules to a neighboring output module. This may happen diagonally: Out of the four diagonal directions, only three are single transformation steps: proximal-to-distal-forward, proximal-to-distal-inverse, and distal-to-proximal-forward. [3] Together, all three form a triangle in **Figure 4**—e.g., (GL_2, GL_3, GO_3). In robotics, proximal-to-distal-forward and proximal-to-distal-inverse are typically termed forward and inverse kinematics, respectively, while distal-to-proximal mappings are often ignored.

2.4.1. *Single transformation steps*

Rather than learning the neural connections, here we use hard-coded kinematic mappings

$$\mathbf{x}^{j,k\to i}(m,n) = \mathbf{f}^{j,k\to i}\left(\mathbf{x}_m^j, \mathbf{x}_n^k\right), \tag{15}$$

where i, j, k are neighboring modules of nMMF. A derivation of the closed form of $\mathbf{f}^{j,k\to i}$ can be found in Ehrenfeld and Butz (2013).

For all pairs of input neurons m and n, connections are built to those neurons l in the output module, which are sufficiently close to the transformation result $\mathbf{x}^{j,k\to i}(m,n)$. The Gaussian

[3] In contrast, the fourth diagonal direction, distal-to-proximal-inverse, is not a single transformation step: the fingertip location and the hand orientation simply do not influence the proximal arm's orientation directly.

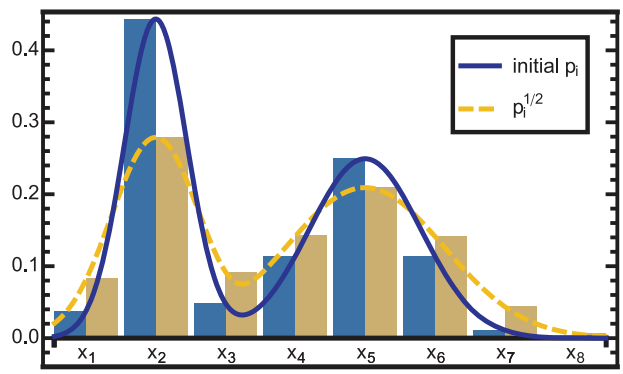

FIGURE 3 | The solid blue curve is modified by raising the PDF to the power of $\frac{1}{2}$ neuron-wise, resulting in the dashed yellow curve. As the exponent is <1, the distribution is widened, i.e., information is diffused. This effect is used in two cases: (1) to correct for overconfidence due to the combination of dependent information sources and (2) to reduce the influence of a module that is in conflict with other modules.

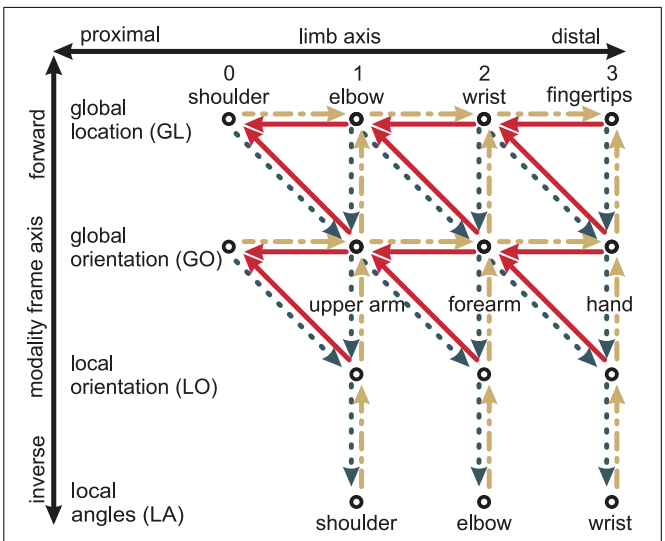

FIGURE 4 | Transformation steps between different modules: The modules (shown as circles) differ with respect to limbs (horizontal axis) and with respect to modalities and frames of reference (vertical axis). Every transformation step consists of one or two input modules and one output module. An example is the two solid lines on the top right: together, they encode how the wrist location GL_2 depends on both the fingertip location GL_3 and the global hand orientation GO_3. Yellow dash-dotted lines are the forward kinematics, dark gray dotted lines the inverse kinematics, and red solid lines the distal-to-proximal kinematics. Modified based on Ehrenfeld and Butz (2012, 2013).

(Equation 30) value for the Euclidean distance of each neuron l in the output module i to the transformation result $\mathbf{x}^{j,k\to i}(m,n)$ is used as connection strength w:

$$w_{m,n\to l}^{j,k\to i} = V_l \cdot N\left(\mathbf{x}^{j,k\to i}(m,n), \mathbf{R}_{\text{Map}}^{i}\right)(\mathbf{x}_l^i), \tag{16}$$

where the receptive field covariance $\mathbf{R}_{\text{Map}}^{i}$ regulates how much the mapping itself widens the encoded probability distribution. It models an information loss during a transformation, either due to inaccurate mappings or due to discretization errors. Since we use accurate mappings, we only need to consider the latter and therefore base $\mathbf{R}_{\text{Map}}^{i}$ on the neuron distance in the output module.

If the transformation step has two inputs from the location modality GL (e.g., an elbow location GL_1 and a wrist location GL_2) the distance of both neurons' preferred values $\left|\mathbf{x}_m^{GL_2} - \mathbf{x}_n^{GL_1}\right|$ must be approximately equal to the length of the forearm. We introduce a modifying factor F with respect to neurons m and n, which reflects how well the constraint is met:

$$F_{mn} = \mathrm{e}^{-\frac{1}{2}\frac{\Delta\mathbf{x}_{mn}^T}{|\Delta\mathbf{x}_{mn}|}\left(\mathbf{R}_{\text{Map}}^{i}\right)^{-1}\frac{\Delta\mathbf{x}_{mn}}{|\Delta\mathbf{x}_{mn}|}\cdot(|\Delta\mathbf{x}_{mn}|-d_{\text{limb}})^2}, \tag{17}$$

where d_{limb} is the length of the respective arm limb, and $\Delta\mathbf{x}_{mn} \equiv \mathbf{x}_m^{GL_2} - \mathbf{x}_n^{GL_1}$ the relative position of both input neurons. Intuitively, $(|\Delta\mathbf{x}_{mn}| - d_{\text{limb}})^2$ results in a penalization of larger deviations from the limb length, and the first factors scale this penalization dependent on the covariance in the mapping. For all other transformation steps, no constraints are necessary, and $F_{mn} = 1$ in these cases. In consequence, the connection weights w are normalized by

$$w_{m,n\to l}^{j,k\to i} \leftarrow \frac{F_{mn}\cdot w_{m,n\to l}^{j,k\to i}}{\sum_{l^*} w_{m,n\to l^*}^{j,k\to i}} \;\forall\, m, n, \tag{18}$$

where the modifying factor F_{mn} blocks the influence of pairs of location neurons that do not correspond with the arm length sufficiently well.

Finally, the projection of two probability distributions q^j, q^k along the connections $f^{j,k\to i}$ into module i yields

$$q_l^i = \frac{\sum_m \sum_n q_m^j\, q_n^k\, w_{m,n\to l}^{j,k\to i}}{\sum_{l^*}\sum_m \sum_n q_m^j\, q_n^k\, w_{m,n\to l^*}^{j,k\to i}}, \tag{19}$$

where the denominator normalizes the overall activity again to 1.

2.4.2. Chain of transformation steps

As nMMF's modules are strongly interconnected, information flows from any module to all other modules. This requires that multiple information transformation steps be done successively.

In nMMF, information is projected into other modules by means of two different approaches. The first approach is used when information needs to stay independent for determining plausibility estimates (cf. section 2.5). In this case, the forward or inverse kinematic mappings are used without fusing other information on the way. Thus, information is not mixed and projections of independent information sources into a common module stay independent. For example, sensory input from a local angle module may be projected to the corresponding global location module by the forward kinematics chain $LA \to LO \to GO \to GL$. Meanwhile, sensory information from the global orientation may also be projected into GL by $GO \to GL$. These two information sources remain independent of each other but are now represented in a common module and can thus be directly compared.

The second approach is used when information is fused across modules (cf. section 2.6). In this case, the information is projected across the modules of nMMF by alternating between local projection and information fusion steps. For example, the LA information is projected to LO, where the result is fused with the LO input. The fused result is then projected further to GO, where the result is fused again, and so on. This method enables the integration of even incomplete information[4] and it reduces computation time because fewer transformation steps are required.

2.5. CONFLICT RESOLUTION

The information, which is exchanged via the specified cross-module connections, has a specific certainty to it. This certainty is encoded implicitly in the neural population codes in each module. Sensory signals are encoded in a population code by making assumptions about the noise in the signal, typically using a measurement model (Thrun et al., 2005). However, those assumptions can be violated by, for example, sudden occurrences of systematic sensor errors, unacquainted environmental conditions, or changes in the body schema due to growth or injury. To be able to account for such potentially unknown signal disturbances, nMMF estimates plausibilities for each signal. If a signal has low plausibility, it is mistrusted and its information content is consequently decreased.

Because the true state of the body is unknown, nMMF estimates signal plausibilities by comparing different, redundant information sources. The modular encoding of the body in nMMF is highly suitable for conducting such comparisons. Given several redundant distributions about a body state, a failing distribution can be detected when it systematically and strongly differs from the complementary, redundant sources of information.

2.5.1. Acquisition of plausibilities

Let m_{12} be a measure of how well two sources (or distributions) 1 and 2 match each other. Zhang and Eggert (2009) provide an overview of different potential measures for m_{12}. In nMMF, we use the scalar product as a matching measure. Given any neural module i, in which

[4]Incomplete information: If e.g., a location input GL is transformed into the global orientation module GO, the result specifies only one subvector in the direction of the arm, while the other, perpendicular subvector remains unspecified. The second approach can then easily fuse a complete GO input onto this incomplete information.

two PMFs (1 and 2) are encoded, their relative match is determined by:

$$m_{12}^i = \frac{q_1^i\left(\mathbf{x}^i\right) \cdot q_2^i\left(\mathbf{x}^i\right)}{\left|\left|q_1^i\left(\mathbf{x}^i\right)\right|\right| \cdot \left|\left|q_2^i\left(\mathbf{x}^i\right)\right|\right|} = \frac{\sum_l q_{1,l}^i \cdot q_{2,l}^i}{\sqrt{\sum_l q_{1,l}^i \cdot q_{1,l}^i} \cdot \sqrt{\sum_l q_{2,l}^i \cdot q_{2,l}^i}}, \tag{20}$$

where the dot $\cdot$ in the first line's numerator is the inner product of the two functions $q_1^i\left(\mathbf{x}^i\right)$ and $q_2^i\left(\mathbf{x}^i\right)$. The measure m_{12}^i is symmetric, i.e., $m_{12}^i \equiv m_{21}^i$. Thus, if one source has an offset, the matching measure can not determine which of the two sources has that offset. This can be solved by comparing multiple pair matches given at least three redundant sources of information.

To identify faulty sensory information, nMMF computes a plausibility value m^i for each information source i by comparing it to multiple other redundant information sources j. The most direct comparison is done by determining the mean of the matches of channel i with all other channels j, whose information was transferred to module i:

$$\left(m^i\right)^* = \frac{1}{N-1} \sum_{j=1, j\neq i}^{N} m_{ij}^i. \tag{21}$$

The measure may be termed an absolute plausibility measure of information source i. To obtain the final plausibility value, the relative matching quality is determined by dividing $\left(m^i\right)^*$ by the highest absolute plausibility measure $\left(m^j\right)^*$ of all related sources:

$$m^i = \frac{\left(m^i\right)^*}{\max_j \left(m^j\right)^*}. \tag{22}$$

The whole process is illustrated in **Figure 5**. In the illustration, sensor S_4^4 is assumed to have a systematic error. As the sensor is always included for comparisons in its own module m^4, but only once in each other module, the arithmetic mean of its matching value is lower than that of the others. In our experience, this approach of comparing pairs of information sources is more robust than, for example, comparing one sensor to the combined information of all other sensors.

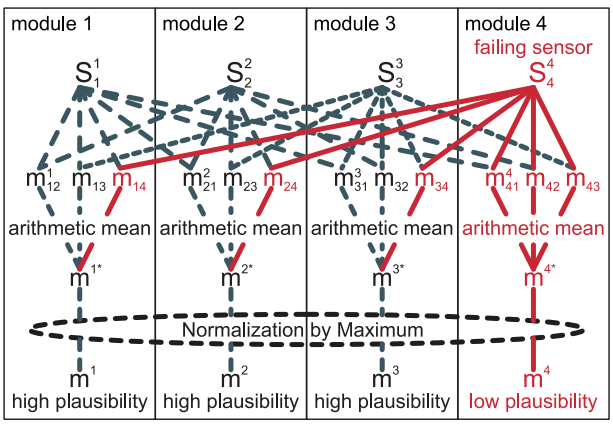

FIGURE 5 | Matches m_{ij}^i for pairs of two sources are obtained, then an arithmetic mean over all j yields $\left(m^i\right)^*$. Finally, a normalization by the maximum of all $\left(m^j\right)^*$ yields the final plausibility m^i.

In summary, if a channel i is in accordance with most of the other channels, the plausibility estimate m^i will be relatively high. In contrast, if a specific channel i systematically deviates from all other channels, its plausibility estimate will be relatively low.

2.5.2. Usage of plausibilities

To incorporate the plausibility estimates into the sensor fusion process, the contribution of each information source i is weighted by its plausibility estimate m^i. This is done by Equation (12), where the exponent α^i needs to depend on the plausibility m^i. Boundary constraints are $\alpha^i(0) = 0$, $\alpha^i(1) = 1$ and the mapping should strictly increase monotonically. We simply set $\alpha^i \equiv m^i$, which meets these constraints.

2.6. INTERACTIVE INFORMATION FLOW

With all options for information fusion at hand, we can finally specify the iterative information flow in nMMF. nMMF maintains an arm state estimate over time by executing four processing steps in each time step: a prediction step (A), a sensor fusion step (B), an update step (C), and a crosstalk step (D) (cf. **Figure 6**). The prediction step includes the impact of the movement on the estimates. The sensor fusion step first increases the dispersion of those sensory distributions that badly match other sensors. After that, the modified sensory distributions are fused. The next step integrates the sensor fusion result into the estimate of the body state. The last step enforces synchronization between the individual modules of the body state.

2.6.1. Prediction step

In order to be able to use the information from previous time steps, the impact of any movement of the arm on the state estimates $q^i(\mathbf{x})$ is predicted. First, the arm movement $\Delta\mathbf{y}$ and motor noise $\mathbf{P}_{\Delta\mathbf{y}}$ are projected from motor space to all nMMF modules by linear approximations, resulting in $\Delta\mathbf{y}^i$ and $\mathbf{P}_{\Delta\mathbf{y}}^i$. The involved Jacobians can be found in Ehrenfeld and Butz (2013).

Second, the impact of the movement is predicted by convolving the probability distribution of the last time step $q_{t-1|t-1}^i\left(\mathbf{x}^i\right)$ with the Gaussian $N\left(\Delta\mathbf{y}^i, \mathbf{P}_{\Delta\mathbf{y}}^i\right)$. This convolution can be understood as a translation of $q_{t-1|t-1}^i\left(\mathbf{x}^i\right)$ along the vector $\Delta\mathbf{y}^i$ and a blurring with the covariance $\mathbf{P}_{\Delta\mathbf{y}}^i$. Thus the activity q_n^i of some source neuron n in module i flows to all target neurons l in the same module. The consequent *a priori* activity of target neuron l after movement but before any sensor consideration can be determined by:

$$q_{l,t|t-1}^i \leftarrow \sum_n \left(q_{n,t-1|t-1}^i \cdot \frac{V_l\, N\left(\mathbf{x}_n^i + \Delta\mathbf{y}^i, \mathbf{P}_{\Delta\mathbf{y}}^i\right)(\mathbf{x}_l)}{\sum_{l^*} V_{l^*}\, N\left(\mathbf{x}_n^i + \Delta\mathbf{y}^i, \mathbf{P}_{\Delta\mathbf{y}}^i\right)(\mathbf{x}_{l^*})} \right), \tag{23}$$

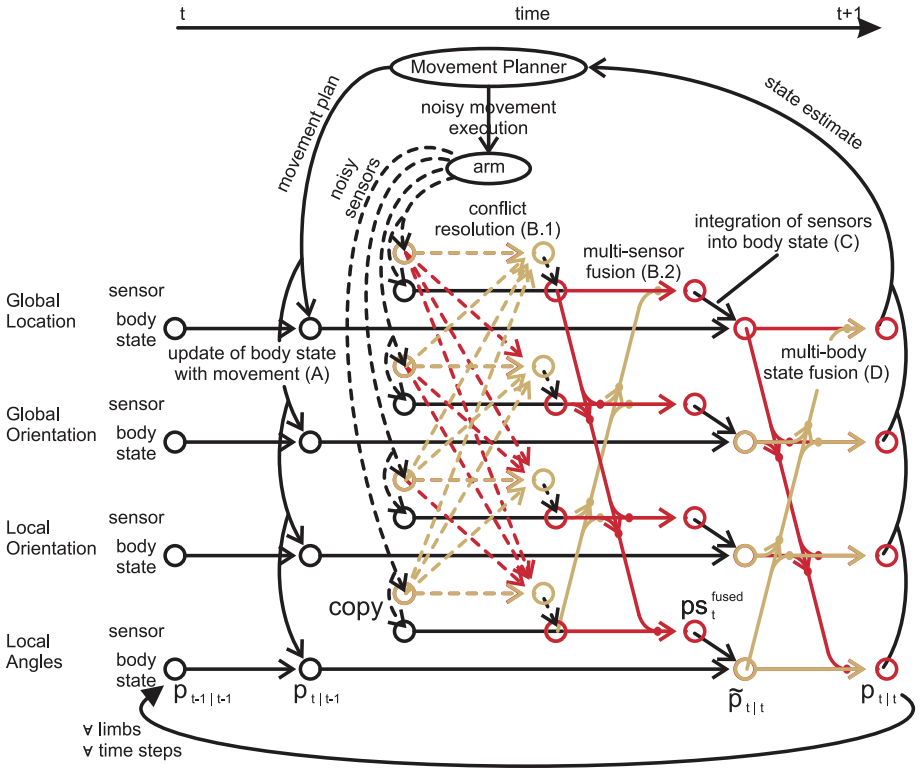

FIGURE 6 | Data flow for one limb: for simplicity, the inter-limb dependencies are not shown. First, the forward model predicts the state estimate after the movement **(A)**. Second, the measurements are transformed from all modality frames to all other frames (dashed lines), where their respective qualities are calculated **(B.1)**. Third, copies of the original measurements are fused weighted with both the quality and the quantity of their information **(B.2)**. These fused measurements are then integrated in their respective modality frame **(C)**. Lastly, the crosstalk shifts all state estimates toward all other estimates, synchronizing them **(D)**. **(A–D)** are then repeated for other limbs and other time steps. Modified based on Ehrenfeld and Butz (2012, 2013).

where the derivation is specified in the Appendix, cf. Equation (31). The equation sums up the activities from all source neurons n, where N is the Gaussian, which does the translation and blurring. The normalization in the denominator ensures that the activity that flows from each source neuron n is preserved.

2.6.2. Multi-sensor fusion

During multi-sensor fusion, conflicting information content is reduced by deriving sensory plausibilities for each module (Equation 22) and modifying the sensory inputs using (Equation 12). Second, the modified distributions are projected across modules (Equation 19) in order to provide each module with all the sensory input. During this projection, chains of transformation steps accumulate information from more and more modules along the way. Finally, in each module i, the underlying distribution is fused with the outputs from all three chains (forward, inverse, and distal-to-proximal). With Equation (11) the fusion is:

$$s^{i,\text{fused}}_{l,t} = \frac{V_l^{-3} s^i_{l,t} \cdot s^i_{l,t}|\text{for} \cdot s^i_{l,t}|\text{inv} \cdot s^i_{l,t}|\text{dis}}{\sum_{l^*} V_{l^*}^{-3} s^i_{l^*,t} \cdot s^i_{l^*,t}|\text{for} \cdot s^i_{l^*,t}|\text{inv} \cdot s^i_{l^*,t}|\text{dis}}, \quad (24)$$

where the notation |xyz is used to indicate the particular sensory information source that is projected into module i and $s^i_{l,t}$ denotes neuron l's share of this information[5]. The denominator normalizes the result.

2.6.3. Sensor integration

After sensor fusion, the fused sensor distributions $s^{i,\text{fused}}_{l,t}$ (Equation 24) are fused again, but this time with the *a priori* state estimate distributions $q^i_{l,t|t-1}$ resulting from the prediction step (Equation 23). The resulting posterior distribution before the final crosstalk step (denoted by $\sim$) thus equates to:

$$\tilde{q}^i_{l,t|t} = \frac{V_l^{-1} q^i_{l,t|t-1} \cdot s^{i,\text{fused}}_{l,t}}{\sum_{l^*} V_{l^*}^{-1} q^i_{l^*,t|t-1} \cdot s^{i,\text{fused}}_{l^*,t}}. \quad (25)$$

2.6.4. Multi-body state fusion

Finally, the module interaction in nMMF is applied to ensure that the state estimates stay consistent across the modules. This is done the same way as in multi-sensor fusion, except that afterwards the resulting distributions are modified such that each one has the same entropy as it had before (using Equations 12–14).

[5]While q denotes the probability mass of a body state estimate, s denotes the probability mass of a neurons response to sensory input.

Thus, during multi-body state fusion, information is first erroneously gained, and then corrected for by artificial information loss. The crosstalk step essentially shifts the means and shapes of each distribution toward other modules, ensuring consistency over modules. It does so without changing the distribution width. As a result, we have determined the final posterior distribution encoded by the probability masses in all neurons l for all modules i, denoted by $q^i_{l,t|t}$.

This step concludes the iterative information processing in nMMF, which continuously cycles over these processing (cf. **Figure 6**) steps over time. In the following, we validate the functionalities and capabilities of nMMF.

3. RESULTS

To test if nMMF is capable of maintaining a coherent body state estimate, we evaluated nMMF in a simple arm model setup, in which a simulated sensor failure occurs temporarily. We then analyzed whether the sensor failure can be detected (section 3.2); whether the sensor failure can be compensated for (section 3.3); how the available, partially conflicting information is propagated across modality frames (section 3.4); and if the distal-to-proximal mappings improve nMMF's state estimation (section 3.5).

3.1. ARM SETUP

To keep it simple, we use a minimally complex arm, which still shows all essential characteristics (i.e., modules that differ with respect to modalities, frames of reference and limbs, and cross-module interactions as in section 2.6). Specifically, a simulated planar arm with two limbs is used. The arm is controlled by a kinematic simulator, disregarding angular momentum or gravity. The simulator executes noisy movements with mean zero in the (x,y)-plane. The motor noise in the angular modules is

$$\boldsymbol{\sigma}^{LA_1}_{\text{movement}} = \boldsymbol{\sigma}^{LA_2}_{\text{movement}} = \left(0\ 0\ 0.1\,\text{rad}\right)^T. \tag{26}$$

Each limb has one degree of freedom and a length equal to 1. Results are averaged over 200 runs. In each run, the arm is initially set to a new random position, while the state estimates start with uniform distributions (i.e., no knowledge).

3.1.1. Distribution of neurons

Both neurons and mappings are built once before starting all 200 runs. The angles $\mathbf{x}^{LA_1}$ and $\mathbf{x}^{LA_2}$ can take on values in the interval $(-\pi, \pi)$ on the z-axis. The direction parts of the global (local) orientation $\mathbf{x}^{GD_1}$ ($\mathbf{x}^{LD_1}$) and $\mathbf{x}^{GD_2}$ ($\mathbf{x}^{LD_2}$), as well as the location of the elbow, are on the unit circle. Thus, the populations in the modules $LA_1, LO_1, GO_1, GL_1, LA_2, LO_2$, and GO_2 all need to cover **lines** with the length 2π. Only the wrist location deviates from this: it must cover a whole **disk** with radius 2.

Two hundred Neurons are sampled in each of the former modules. Thus the average Euclidean distance between two neighboring neurons equals to

$$d_{\text{avg}} = \frac{2\pi}{200} \approx 0.031 \tag{27}$$

The minimum allowed distance between two neurons (cf. section 2.2.1) is set to $d_{\min} = 0.7 \cdot d_{\text{avg}}$. In order to achieve the same average distance in GL_2, the number N^{GL_2} of neurons which need to be sampled is defined by

$$\sqrt{\frac{\pi r^2}{N^{GL_2}}} = \frac{2\pi}{200}. \tag{28}$$

The GL_2 neurons are distributed on a disc with radius $r = 2 + 3\sigma^{GL_2}_{\text{Map}} = 2.09$. The summand 2 accounts for the two limb lengths from shoulder to wrist, while $3\sigma^{GL_2}_{\text{Map}}$ (cf. section 3.1.2) guarantees that some neurons have receptive fields outside but close to the arm's reach. This slightly enlarged neural coverage avoids that boundary effects distort a probability distribution. The enforced equality (Equation 28) yields $N^{GL_2} = 14.0 \cdot 10^3$ neurons.

3.1.2. Mappings

We chose the standard deviation for the mapping's spreading (cf. Equation 16) so that it is equal to the average neuron distance, i.e., $\sigma^i_{\text{Map}} = d^i_{\text{avg}} \approx 0.031$. The mappings spread radially, i.e., $\mathbf{R}^i_{\text{Map}} = \text{diag}\left(\sigma_{\text{Map}}\right)$, where diag refers to a diagonal matrix. We discarded any mappings that fall outside a $3\sigma_{\text{Map}}$-range.

3.1.3. Tracking of information

In order to track the information influence stemming from one module (here GL_2), we (1) introduced an offset to GL_2 and (2) set its noise very low when compared to the other modules. The offset is introduced for two reasons: to distinguish the information that originates in GL_2 from all other information, and to observe how nMMF reacts to the sudden failure of a sensor. The offset has a magnitude of 0.5 limb length. It is switched on at time $t = 4$ and switched off again at $t = 7$. The offset is in a counterclockwise direction (i.e., from the arm's perspective, the offset is to the left). GL_2's noise is low compared to other modules, in order to increase GL_2's impact. We chose radial Gaussians for the sensor noise:

$$\sigma^i = \begin{cases} 0.05\ \text{limb length} & \text{if } i = GL_2 \\ 0.5\ (\text{in rad, limb length}, \dots) & \text{otherwise} \end{cases}, \tag{29}$$

where σ is the standard deviation.

Evaluating nMMF when conflict resolution is applied allows us to determine whether the sensor failure can be detected and how well nMMF compensates for it. When conflict resolution is turned off, the setup shows how information starting in GL_2 is generally propagated across modalities, frames of reference, and limbs.

3.2. DETECTION OF SENSOR FAILURE

A sensor failure is modeled by the GL_2-sensor offset during the interval $t \in [4, 6]$. By comparing all sensors, nMMF autonomously infers plausibility measures (Equation 22), which are displayed in **Figure 7**.

Even outside the offset-interval, GL_2 (top right) shows a low plausibility m as compared to other modules. This is because, in general, three aspects characterize a distribution: its mean, its

shape, and its dispersion. However, deciding which of these characteristics should be tested by a matching-measure m depends on the application. For instance, Equation (22) compares all three characteristics. As Gl_2's receptive field (Equation 29) is narrower than all other receptive fields, its dispersion is lower, and m^{GL_2} mainly detects the different dispersions, while it might be more interesting to instead detect systematic errors of the mean. Thus, for this application, a dispersion-independent measure (Ehrenfeld and Butz, 2012, 2013) might be more appropriate. This would yield much higher measures m^{GL_2} than shown in **Figure 7**, top-right.

Nevertheless, the measure is still able to detect sensor failure: while the offset is present ($t \in [4, 6]$), the plausibility measure drops in the setup with offset (red), as compared to the setup without offset (yellow) (**Figure 7**, top-right).

3.3. COMPENSATION OF SENSOR FAILURE

Plausibilities were introduced as a measure of quality of an information source. If all sources provide correct data, plausibilities introduce a random change on otherwise Bayesian fusion. Such a change can only worsen the state estimate. The results confirm this: With plausibilities switched on, state estimates get worse (cf. red vs. yellow, blue vs. green in **Figure 8**). If, however, a sensory source is conflicting the others (red and yellow in the interval $t \in [4, 6]$), plausibilities can suppress the influence of the false sensor information and improve the overall state estimate (red vs. yellow in **Figure 8**). This improvement is even visible under strong noise (red vs. yellow in **Figure 8**). Again, a dispersion-independent measure (Ehrenfeld and Butz, 2012, 2013) could improve the performance.

3.4. PROPAGATION OF INFORMATION ACROSS MODALITIES, FRAMES OF REFERENCE AND LIMBS

The setup without conflict resolution (**Figure 8**, yellow and green) shows how information is propagated across modality frames and limbs in general. The yellow peak, which starts in GL_2 (top right), is successfully propagated to all other modality frames (from top to bottom) and to the next proximal limb (from right to left). Shown is the estimation error (Euclidean distance between the real arm state and the estimated arm state).

3.5. PERFORMANCE IMPROVEMENT DUE TO DISTAL-TO-PROXIMAL MAPPINGS

In order to see if distal-to-proximal mappings improve or worsen the state estimation, two setups, one with mappings and one without are compared. **Figure 9** shows that the proximal limb's state estimate improves (yellow vs. blue, red vs. purple) because additional information flows to it from the distal limb. A

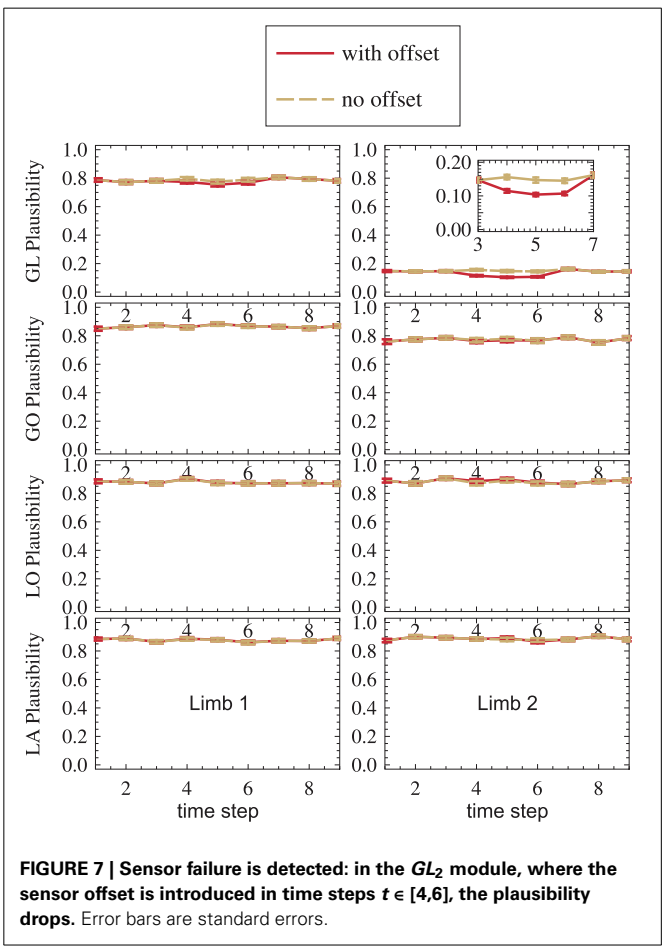

FIGURE 7 | Sensor failure is detected: in the GL_2 module, where the sensor offset is introduced in time steps $t \in [4,6]$, the plausibility drops. Error bars are standard errors.

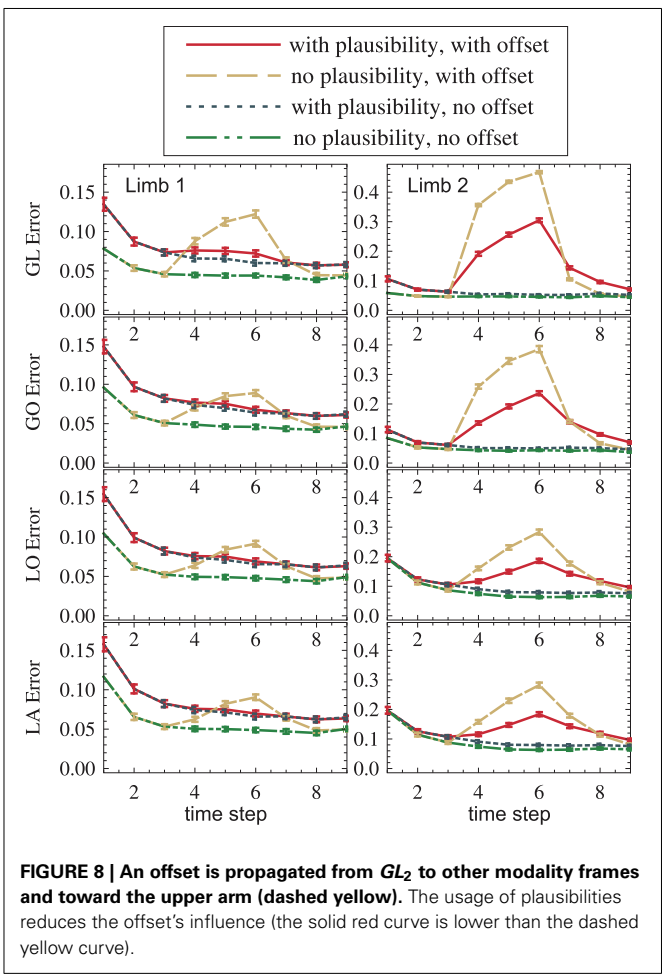

FIGURE 8 | An offset is propagated from GL_2 to other modality frames and toward the upper arm (dashed yellow). The usage of plausibilities reduces the offset's influence (the solid red curve is lower than the dashed yellow curve).

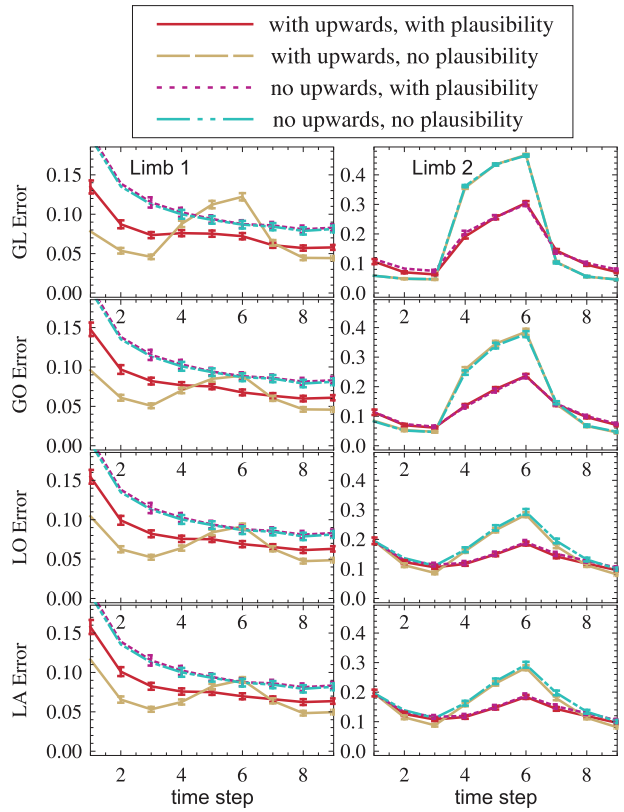

FIGURE 9 | (1) Distal-to-proximal mappings improve the state estimate (dashed yellow is lower than dash-dotted cyan, solid red is lower than dotted magenta). (2) Plausibilities worsen the state estimate if no failures exist and improve the state estimate if failures exist (red vs. yellow, magenta vs. cyan). Both effects (1) and (2) are found—though weaker—in other modules (not shown).

slight improvement can even be seen in the distal limb. This is the case because the distal limb profits from more accurate forward and inverse kinematic estimates in the proximal limb.

4. DISCUSSION

We introduced the neurally-encoded modular modality frame (nMMF) model, which maintains a consistent and robust but also highly distributed body state estimate over time. As in the previously published Gaussian MMF model (Ehrenfeld and Butz, 2011, 2012, 2013), nMMF represents the body (an arm in the current implementation) modularized into body parts and sensor-respective frames of reference. Local, body-state-dependent mappings allow for continuous interactions between modules, ensuring consistency. Bayesian information fusion principles are applied to fuse sensory information in the respective modules, to compare redundant information across modules, and to adjust the modular body state estimate for maintaining estimation consistency. Forward models are used to anticipate the sensory consequences of own movements and thus to fuse the consequent sensory information even more effectively.

In contrast to the MMF model, we showed that the same principles can be realized by means of a neural implementation, adding to the plausibility of the model. To succeed, population encodings principles of state estimates had to be employed. To establish a population code in one nMMF module, arm states were sampled randomly. To establish the neural mappings between the population codes, weight matrices were set based on the distances of the connected neurons, where the distances were currently determined by an informed kinematic model of the arm. To determine plausibility values, we used the scalar product to compare two neurally-encoded distributions. To avoid overconfidences in body states and to effectively realize information fusion, we normalized the resulting distributions maintaining respective Shannon entropies in the neural encodings.

In further contrast to the MMF model, nMMF also includes information exchanges from distal to proximal limbs and joints. This addition enables further-reaching information exchange. For example, information about the hand location can also influence estimates of the lower and upper arm, which was not the case in the MMF model (Ehrenfeld and Butz, 2013).

The evaluations confirmed that information from the wrist location influenced the whole arm estimate. First, we showed that due to the addition of the distal-to-proximal mappings, the location of the elbow or angles in the shoulder were adjusted by nMMF to generate an overall representation that is more consistent with the wrist estimate. We also showed that the additional mappings improve the state estimate due to the additional information exchange. Second, we showed that a systematic sensor error can be detected with the neural encoding. Third, although the inclusion of plausibilities slightly decreases the quality of the state estimate when all information sources are valid, if a sufficiently strong systematic error occurs in a sensor then the plausibility estimate can block this inconsistent information. Such sensor errors can be compared with situations in which visual information about the location of the hand is inaccurate, as is the case in the rubber hand illusion, thus leading to a misjudgment of the hand's location. The distal-to-proximal mappings in nMMF suggest, in addition to a misplacement of the hand, that the internal estimates of the elbow angles and lower arm orientations should be affected by the illusion.

4.1. RELATED MODELS

The original motivation to develop the nMMF model came from SURE_REACH (Butz et al., 2007), a neural, sensorimotor redundancy resolving architecture, which models human arm reaching. SURE_REACH and the strongly related posture-based motion planning approaches (Rosenbaum et al., 2001; Vaughan et al., 2006) focused on flexible goal reaching capabilities and on anticipatory behavior capabilities, such as modeling the end state comfort effect (Rosenbaum et al., 1990). The current state of the body, although incorporated during action decision making, was not explicitly represented. In contrast, nMMF primarily focuses on the probabilistic, distributed representation of the body and effective information exchange. However, we believe that the nMMF model is ready to be combined with goal-oriented behavioral decision making, planning, and control routines. Moreover, while the SURE_REACH model was also implemented by neural

grids, it represented the angular space of the arm in one module. Such a representation, however, is unfeasible for a seven degree of freedom, humanoid arm. nMMF's modularizations yield spatial encodings that are maximally three dimensional. Thus, nMMF is applicable to a seven degree of freedom arm. In particular, while SURE_REACH needs $O(x^7)$ neurons to cover the angular space of a humanoid arm with a density of $1/x$ neurons per dimension, nMMF only needs $O(3x^3)$ neurons to encode a comparable density.

The locality and modularity of nMMF relate the model to the mean of multiple computations (MMC) model (Cruse and Steinkühler, 1993; Schilling, 2011). However, nMMF additionally provides a probabilistic state representation, rigorous Bayesian-based information exchange, and plausibility-enhanced sensory information integration mechanisms. While the MMC model focuses on motor control, the nMMF model focuses on an effective, probabilistic body state representation. Nonetheless, the similarity to MMC suggests that similar motor control routines are implementable on a neural level in nMMF. Moreover, the fact that distributed, multisensory bodily representations serve well for goal-directed motor control (Andersen and Buneo, 2002) suggests that nMMF should be extended with adaptive motor control capabilities.

Various models use population codes for encoding probability distributions and exchange information in a comparable Bayesian fashion (Deneve and Pouget, 2004; Knill and Pouget, 2004; Doya et al., 2007). Information exchange across modalities and frames of reference take place in the brain. Gain fields are good candidates for realizing frame-of-reference conversions neurally (Andersen et al., 1985; Salinas and Abbott, 1995; Hwang et al., 2003; Deneve and Pouget, 2004). In the current nMMF implementation we used fully connected, direct transformations, which will need to be adjusted to gain-field transformations in order to map two three dimensional spaces into a third space. Nonetheless, in contrast to the related models, nMMF realizes a fully modularized, distributed probabilistic arm representation, which, to the best of our knowledge, has not been accomplished before. For example, Deneve and Pouget (2004) reviewed a multimodal gain field model that exchanged auditory, visual, and eye position information, enforcing consistency via population encodings. While nMMF has not considered auditory information so far, it goes beyond previous models in that it also incorporates a kinematic chain, relating body parts to each other along the chain. Thus, besides exchanging information across different frames of references, nMMF also exchanges information from distal-to-proximal body parts and vice versa.

In sum, nMMF focuses on estimating the own body state, incorporating multiple sources of information across sensory modalities and their respective frames of reference, as well as across neighboring body parts. While flexible goal-oriented behavior cannot be generated by nMMF at this point, the relations to the MMC model, the SURE_REACH model, and the posture-based motion planning theory suggest that behavioral decision making, planning, and control techniques can be incorporated.

4.2. FUTURE WORK

Although the plausibility measure used in this work is generally well-suited, our previous work showed that a more rigorous normalization can yield very little information loss but the same gain in robustness when plausibilities are applied (Ehrenfeld and Butz, 2012, 2013). A similar normalization in the neural implementation seems to be possible only by means of heuristics, lacking the computational rigor. We are currently investigating alternatives.

In the current nMMF implementation several choices had to be made about which information should be exchanged, how plausibilities should be computed, and which reference frames should be represented. Additional frames-of-reference could be represented, such as a local location frame. Synergistic body spaces may also be represented, potentially accounting for the synergistic properties of the human body, the muscle arrangements, and the neural control networks involved (Latash, 2008). Also, plausibilities may be determined by considering the internal state estimations in addition to the redundant sensory information sources. Finally, the transformations between limbs and frames-of-reference may also be endowed with uncertainties. In this way, the body model itself would become adjustable, potentially accounting for illusions such as the Pinocchio illusion (Lackner, 1988), where a body part (e.g., the nose) elongates phenomenally.

Due to its modularity and focus on bodily representations, we believe that nMMF can be easily integrated into a layered control architecture. In such an architecture, other layers may encode extended bodily motion primitives, plan the desired kinematics of bodily motions, or control the dynamics of the body. In particular, extended motion primitives may be incorporated in order to execute a motion sequence, potentially selectively with any limb or joint currently available, similar to us being able to push down a door handle by means of our hands but also potentially with one of our elbows. Meanwhile, kinematic planning mechanisms may utilize the nMMF representation to generate motion plans online. Finally, lower-level dynamic control layers may be included.

5. CONCLUSION

In conclusion, this paper has shown that a distributed, probabilistic bodily representation can be encoded by modularized neural population codes based on Bayesian principles. The presented nMMF architecture is able to mimic the capability of humans to integrate different sources of information about the body on the fly, weighted by the respective information content. Bodily illusions can also be mimicked. Besides the more rigorous modeling of human data with nMMF beyond qualitative comparisons, we believe that nMMF should be embedded in a layered representation and adaptive control architecture in order to generate flexible and adaptive goal-oriented behavior.

A APPENDIX

A.1 PSEUDOINVERSE AND ACTIVATION OF A GAUSSIAN

A multivariate Gaussian with mean $\boldsymbol{\mu}$ and Covariance-matrix $\mathbf{P}$ is given by:

$$N(\boldsymbol{\mu}, \mathbf{P})(\mathbf{x}) \equiv \frac{1}{\sqrt{(2\pi)^k |\mathbf{P}|}} e^{-\frac{1}{2}(\mathbf{x}-\boldsymbol{\mu})^T \mathbf{P}^{-1}(\mathbf{x}-\boldsymbol{\mu})}, \tag{30}$$

where k is the number of dimensions in the manifold.

In nMMF, three cases occur where activity is spread over neighboring neurons: when sensory inputs are encoded (Equation 6), when neural activity is propagated to other modules (Equation 16), and when the body estimate is updated with the movement (Equation 23). If the involved tuning functions are Gaussian, the activity mass spreads to all individual neurons l according to

$$q_l(\boldsymbol{\mu}, \mathbf{P}) = f \cdot \frac{V_l N(\boldsymbol{\mu}, \mathbf{P})(\mathbf{x}_l)}{\sum_{l^*} V_{l^*} N(\boldsymbol{\mu}, \mathbf{P})(\mathbf{x}_{l^*})}, \tag{31}$$

where $\boldsymbol{\mu}$ is the new mean, $\mathbf{P}$ the tuning functions covariance, and f the activity mass, which is spread. For instance, if a sensory input is activated, $\boldsymbol{\mu}$ is equal to the sensory reading and f is 1. If, on the other hand, the activity of a single neuron $\mathbf{x}_n$ is updated with a movement $\Delta\mathbf{x}$, $\boldsymbol{\mu}$ is equal to $\mathbf{x}_n + \Delta\mathbf{x}$, and f is equal to the neuron's probability mass q_n.

If no inverse $\mathbf{P}^{-1}$ exists, it is approximated with the pseudoinverse $\mathbf{P}^+$. The pseudoinverse is computed via a singular value decomposition, which factorizes the (real) $m \times m$ covariance $\mathbf{P}$ into

$$\mathbf{P} = \mathbf{U}\Sigma\mathbf{V}^T, \tag{32}$$

where $\mathbf{U}$ and $\mathbf{V}$ are unitary and Σ diagonal. $\mathbf{U}$ and $\mathbf{V}$ can be understood as rotation matrices while Σ is responsible for the scaling. Then the pseudoinverse $\mathbf{P}^+$ is

$$\mathbf{P}^+ = \mathbf{V}\Sigma^+\mathbf{U}^T, \tag{33}$$

where the pseudoinverse Σ^+ of the diagonal matrix Σ is obtained by taking the reciprocal of every non-zero element. If a diagonal element of Σ is equal to zero, this has to be interpreted as the probability distribution not depending on that element. Consistent with that interpretation is Σ^+: the corresponding diagonal element remains zero and deviations $(\mathbf{x}_l - \boldsymbol{\mu})$ of the mean in the direction of that element are multiplied with zero, i.e., they do not lower the result of the Gaussian (Equation 31). Unfortunately, this is a singularity. For diagonal elements close but unequal to zero, Σ^+ and consequently $\mathbf{P}^+$ explode. This occurs especially if a sub-manifold in a higher dimensional space needs to be activated (e.g., a sphere of elbow positions).

Thresholds are introduced to prevent discretization errors and small numerical errors from destabilizing the model. Matrix elements $\left(P^{-1}\right)_{ij}$ larger than the threshold 10^{12} are set to zero:

$$(\Gamma)_{ij} = \Theta\left(10^{12} - \left(P^{-1}\right)_{ij}\right)\left(P^{-1}\right)_{ij}, \tag{34}$$

where Θ is the heavyside function. Following, the distance vectors α_l and β_l are introduced as $\mathbf{x}_l - \boldsymbol{\mu}$ and $\Gamma(\mathbf{x}_l - \boldsymbol{\mu})$ and bound by the threshold 10^{-10}:

$$(\alpha_l)_i = \Theta\left([\mathbf{x}_l - \boldsymbol{\mu}]_i - 10^{-10}\right) \cdot [\mathbf{x}_l - \boldsymbol{\mu}]_i \tag{35}$$

$$(\beta_l)_i = \Theta\left([\Gamma(\mathbf{x}_l - \boldsymbol{\mu})]_i - 10^{-10}\right) \cdot [\Gamma(\mathbf{x}_l - \boldsymbol{\mu})]_i \tag{36}$$

Thus, Equation (31) becomes

$$q_l(\boldsymbol{\mu}, \mathbf{P}) = f \cdot \frac{V_l e^{-\frac{1}{2}\alpha_l^T \beta_l}}{\sum_{l^*} V_{l^*} e^{-\frac{1}{2}\alpha_{l^*}^T \beta_{l^*}}}, \tag{37}$$

A.2 VORONOI CELL AND VORONOI VOLUME

When N neurons are spread over a sample space Ω at positions $\mathbf{x}_l$, $l \in (1..N)$, the Voronoi-cell R_l of a neuron l is defined as the set of all points x that are closer to the neuron position $\mathbf{x}_l$ than to any other neurons, i.e.,

$$R_l \equiv \{\mathbf{x} \mid \forall m : ||\mathbf{x} - \mathbf{x}_l|| \leq ||\mathbf{x} - \mathbf{x}_m||\} \tag{38}$$

where $||\cdot||$ is the Euclidean norm. Intuitively, it is the subspace to which the neuron responds stronger than any other neurons. The Voronoi volume is defined as the volume of that cell. As only relative values are required, any normalization of the Volumes V_l is arbitrary.

To control targeted movements, such as reaching to grasp an object or hammering a nail, the brain can use divers sources of sensory information, such as vision and proprioception. Although a variety of studies have shown that sensory signals are optimally combined according to principles of maximum likelihood, increasing evidence indicates that the CNS does not compute a single, optimal estimation of the target's position to be compared with a single optimal estimation of the hand. Rather, it employs a more modular approach in which the overall behavior is built by computing multiple concurrent comparisons carried out simultaneously in a number of different reference frames. The results of these individual comparisons are then optimally combined in order to drive the hand. In this article we examine at a computational level two formulations of concurrent models for sensory integration and compare this to the more conventional model of converging multi-sensory signals. Through a review of published studies, both our own and those performed by others, we produce evidence favoring the concurrent formulations. We then examine in detail the effects of additive signal noise as information flows through the sensorimotor system. By taking into account the noise added by sensorimotor transformations, one can explain why the CNS may shift its reliance on one sensory modality toward a greater reliance on another and investigate under what conditions those sensory transformations occur. Careful consideration of how transformed signals will co-vary with the original source also provides insight into how the CNS chooses one sensory modality over another. These concepts can be used to explain why the CNS might, for instance, create a visual representation of a task that is otherwise limited to the kinesthetic domain (e.g., pointing with one hand to a finger on the other) and why the CNS might choose to recode sensory information in an external reference frame.

Keywords: sensory integration, motor control, maximum likelihood, reference frames

1. INTRODUCTION

Reaching to grasp an object requires that the CNS compare the position and orientation of the object with the position and orientation of the hand in order to generate a motor command that will bring the hand to the object. Depending on the situation, the CNS might use more than one sensory modality, such as vision and proprioception, to sense the position and orientation of the target and of the hand, with each source of information encoded in its own intrinsic reference frame. This raises the question as to how the CNS combines these different sources of information to generate the appropriate motor commands.

One school of thought contends that processes of sensor fusion for perception can be explained by the tenets of optimal estimation and control. According to the principles of maximum likelihood estimation, sensory signals that contain redundant information should be combined based on the expected variability of each so as to maximize the probability of producing a value close to the true value of what is being measured. This concept has been used with success in recent years to explain how humans combine different sources of sensory information to generate robust estimates of the position, size and orientation of external objects (Landy et al., 1995; Ernst and Banks, 2002; Kersten et al., 2004; Kording et al., 2007). Of greater interest for us, however, is the task of reaching an object with the hand, which adds additional aspects to the process beyond that of simple perception. The position and orientation of the object and of the hand must be effectively subtracted at some level, be it to compute a movement vector during task planning or to apply corrective actions based on real-time feedback during the course of the movement.This aspect of the task immediately brings to mind two additional issues that must be resolved: (1) To compare the position and orientation of two entities, sensory information about each must be expressed in a common coordinate frame. What reference frame(s) are used to perform the requisite computations? (2) The fusion of redundant sensory information might occur at various stages in the perception-action cycle. Where and how are the principles of maximum likelihood applied? In this article we will contrast two possible models of sensor fusion, which we will call *convergent* and *concurrent*, as illustrated in **Figure 1** for the task of hitting a nail with a hammer.

The convergent model shown in **Figure 1A** reflects the conventional idea that the CNS constructs a single representation of the

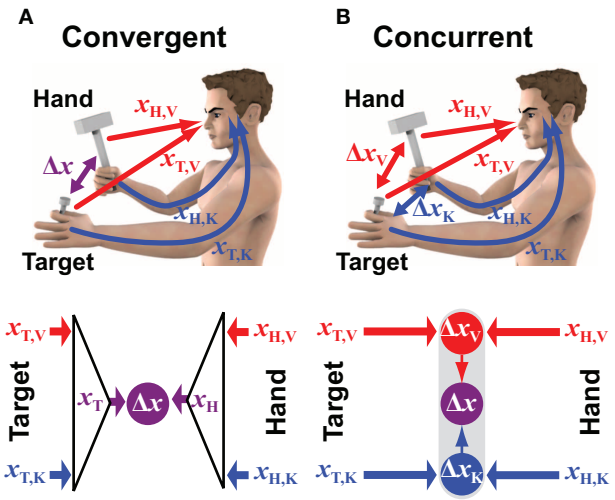

FIGURE 1 | Convergent vs. concurrent models of sensorimotor integration. The two conceptual models are applied to a case in which visual (V) and kinesthetic (K) information can be used to estimate the positions of both the target (T) and the hand (H) that hold the hammer. Red and blue colors correspond to information encoded in retinal and body centered reference frames, respectively. **(A)** In the convergent model the visual and kinesthetic information about the target ($x_{T,V}$ and $x_{T,K}$, respectively) are optimally combined to build a multimodal estimate of its position (x_T). Ditto for the hand/hammer position (x_H). The two optimal estimates are then compared (subtracted) to compute the movement vector Δx. **(B)** In the concurrent approach the positions of the target and the hand/hammer are compared simultaneously in visual and kinesthetic space. The two resulting unimodal movement vectors Δx_V and Δx_K are then optimally combined to compute the multimodal movement vector Δx.

target based on all available sensory information. In the example of hammering a nail, this includes the position of the nail-head in the visual field and the position of the fingertips holding the nail as sensed by kinesthesia. Weighting can be used to privilege either the visual or the kinesthetic information in the estimate of the target position; ditto for the estimation of the hammer's position and orientation, for which both visual and kinesthetic information are available. The combined representations are then compared in some reference frame that could be the reference frame intrinsic to one of the sensory modalities, or it could be some other, more generalized coordinate system. For instance, kinesthetic information could be transformed into retinal coordinates, or both visual and kinesthetic information could be transformed into a common reference frame centered on the head or on the trunk or referenced to external objects (McIntyre et al., 1997; Guerraz et al., 1998; Henriques et al., 1998; McIntyre et al., 1998; Carrozzo et al., 1999; Pouget et al., 2002a; Avillac et al., 2005; Obhi and Goodale, 2005; Byrne et al., 2010). Under this scheme, the CNS would combine all available sensory information about the target into a single, optimal representation of its position and orientation. Similarly, sensory information would be combined to form an optimal representation of the hand's position and orientation in the same general reference frame. The comparison of target and hand would then be carried out within this general reference frame and the difference between the two positions would be used to drive the motor response.

Figure 1B shows the alternative hypothesis by which the CNS performs a distributed set of concurrent comparisons within each reference frame first, and then combines the results to form a unique movement vector (Tagliabue and McIntyre, 2008, 2011, 2012, 2013; McGuire and Sabes, 2009, 2011; Tagliabue et al., 2013). In the example of hammering the nail, visual information about the nail-head is compared to visual information about the hammer while at the same time kinesthetic information about the hand holding the nail is compared with kinesthetic information about the hand swinging the hammer. Each comparison is carried out separately and thus may be carried out within the coordinate system intrinsic to the corresponding sensory modality. Under this formulation, a movement is programmed based on an optimal combination of the different movement vectors within each of the various reference frames. In this way the CNS accomplishes multimodal sensorimotor coordination in a modular fashion by performing a number of simpler target-hand comparisons in parallel.

The purpose of this article is to examine in greater detail these two hypotheses of convergent versus concurrent comparisons of target and hand for reaching movements, both at a theoretical level and through a targeted review of the pertinent literature. In section 2 we differentiate further the two models at the conceptual level by showing mathematically how the application of optimal estimation differs between them. Using these equations, we go on to present the experimental evidence supporting the hypothesis that the CNS functions according to the concurrent model. In section 3 we examine the conditions in which the CNS will transform information from the intrinsic reference frame of one sensor to the reference frame of another. Key to this discussion is an assessment of how coordinate transformations and memory processes affect the variability of the outcome, and we explicitly take into account how co-variation of transformed signals affects the choice of weighting. Section 4 examines the time course of the underlying sensorimotor processes, providing insight into when sensorimotor transformations are actually performed and, as a corollary, indicating that not only does the CNS perform multiple comparisons in parallel, it maintains parallel memory traces in multiple reference frames as well. In section 5 we generalize the concepts of convergent and concurrent processes to more than two sensory modalities, and in section 6 we use these formulations to consider trade-offs between using sensory information encoded in reference frames intrinsic to the sensors themselves or with respect to extrinsic reference frames such as the visual surrond or with respect to gravity. In the final section we describe some specific predictions made by different concurrent and convergent formulations and discuss how the models might be differentiated experimentally.

2. MULTIPLE, CONCURRENT vs. MULTIMODAL, CONVERGENT

The two models depicted in **Figure 1** can be described mathematically, in the linear case, as a set of weighted sums and differences. We use here linear formulations because they simplify the equations and are sufficient to make predictions about how the two models might differ computationally and experimentally. The main feature of the convergent model in **Figure 1A** is that a single

representation of the target is compared to a single representation of the hand in the common reference frame, and a movement is performed that reduces the difference of these two estimates, Δx, to zero. The equation describing this formulation is:

$$\Delta x = \left(w_{\mathrm{T,V}} x_{\mathrm{T,V}} + w_{\mathrm{T,K}} x_{\mathrm{T,K}}\right) - \left(w_{\mathrm{H,V}} x_{\mathrm{H,V}} + w_{\mathrm{H,K}} x_{\mathrm{H,K}}\right) \quad (1)$$

where $x_{\mathrm{T,V}}$ and $x_{\mathrm{T,K}}$ represent the position of the target detected by vision and kinesthesia, respectively, $x_{\mathrm{H,V}}$ and $x_{\mathrm{H,K}}$ represent the detected position of the hammer in each of those reference frames, and $w_{\mathrm{T,V}}$, $w_{\mathrm{T,K}}$, $w_{\mathrm{H,V}}$ and $w_{\mathrm{H,K}}$ are the weights given to each of these pieces of information. In the concurrent model of **Figure 1B**, target and hand are compared in the reference frame of each sensory modality first, and then the final movement vector Δx is computed as a weighted sum of the individual differences. This process can be described by the equation:

$$\Delta x = \lambda_{\mathrm{V}}\left(x_{\mathrm{T,V}} - x_{\mathrm{H,V}}\right) + \lambda_{\mathrm{K}}\left(x_{\mathrm{T,K}} - x_{\mathrm{H,K}}\right) \quad (2)$$

where λ_{V} and λ_{K} represent the weight given to the comparisons carried out in each of the two sensory modalities. Common to both Equations (1 and 2) is the idea that redundant information from the various sensory modalities can be weighted differently through the factors w and λ. In fact, Equation (2) is a special case of Equation (1), with the added constraint that within each sensory modality, signals about the target and the hand must have the same weight:

$$w_{\mathrm{T},i} = w_{\mathrm{H},i} = \lambda_i \quad (3)$$

In the linear formulation used here, therefore, the computational difference between the two models is not so much in terms of the order in which sensory information is added or subtracted, but rather in terms of how the weighting factors w and λ are chosen.

The principles of maximum likelihood estimation (MLE) can be applied to both Equations (1 and 2) to find weighting factors that are in some sense optimal, although they differ in terms of what is optimized. The optimal estimation of a parameter p given noisy measurements (m_1,...,m_n) corresponds to the value that maximizes the probability distribution $P(m_1, \ldots, m_n|p)$ which for independent measurements is equal to $P(m_1, \ldots, m_n|p) = \prod_{i=1}^{n} P(m_i|p)$. If each measurement is considered to be governed by Gaussian noise, the optimal estimate is analytically derived to be the weighted average such that the relative weight given to any one of the component quantities is equal to the inverse of it's variance relative to all the other quantities:

$$w_{m_i} = \frac{\sigma_{m_i}^{-2}}{\sum_{i=1}^{n} \sigma_{m_i}^{-2}} \quad (4)$$

where $\sigma_{m_i}^2$ is the variance of measurement m_i. Thus, noisy variables are given less weight compared to those that are more reliable (Ghahramani et al., 1997). If weighted in this manner, the linear combination of different sources of information results in a reduction of output variability (i.e., an increase in movement precision) compared to the use of any one source of information alone. For illustration purposes, therefore, we assume that the noise exhibited by each sensory signal is Gaussian so that we may apply the linear maximal likelihood solution (Equation 4) to find the optimal weights.

For the convergent model in **Figure 1A**, applying MLE in order to compute the weighting factors (w's) in Equation (1) means that an optimal estimate of the position of the hand, derived from all available sensory feedback about the hand, will be compared to (subtracted from) an optimal estimate of the target's position, similarly derived from all available sources of sensory information about the target. Applying Equation (4) to the convergent model, the sets of weights for $i = \mathrm{K}$ and $i = \mathrm{V}$ are:

$$w_{\mathrm{T},i} = \frac{\sigma_{\mathrm{T},i}^{-2}}{\sigma_{\mathrm{T,V}}^{-2} + \sigma_{\mathrm{T,K}}^{-2}} \text{and } w_{\mathrm{H},i} = \frac{\sigma_{\mathrm{H},i}^{-2}}{\sigma_{\mathrm{H,V}}^{-2} + \sigma_{\mathrm{H,K}}^{-2}} \quad (5)$$

The computation of weighting factors (λ's) for the parallel structure in **Figure 1B** is somewhat different. Here, target and hand are compared in both sensory modalities in parallel ($\Delta x_i = x_{\mathrm{T},i} - x_{\mathrm{H},i}$) and maximum likelihood then determines how much weight should be given to each of these comparisons, based on the expected variance of each of the computed differences. Given that the variance of a difference is simply the sum of the variances of its minuend and of its subtrahend ($\sigma_{\Delta_i}^2 = \sigma_{\mathrm{T},i}^2 + \sigma_{\mathrm{H},i}^2$) and applying Equation (4), the weight given to each difference is computed as:

$$\lambda_i = \frac{\sigma_{\Delta_i}^{-2}}{\sigma_{\Delta_{\mathrm{V}}}^{-2} + \sigma_{\Delta_{\mathrm{K}}}^{-2}} \quad (6)$$

Conceptually, therefore, the convergent and concurrent models differ primarily in terms of what is optimized. For the convergent model, an optimal estimate of the target and an optimal estimate of the hand are computed and then used to compute a movement vector. Under the concurrent model, multiple movement vectors are computed and then these vectors combined in an optimal fashion. Thus, even though Equations (1 and 2) are algebraically very similar, the choice of what to optimize when determining the various weights leads different results for the two different models. Note that the neural system may not operate in a strictly linear fashion, in which case differentiating between the two model structures would be even more important in terms of model predictions. But even the linear analysis presented here allows one to draw a distinction between the convergent and concurrent models, both conceptually, as we have described here, and experimentally, as we will show in the following paragraphs.

2.1. DISTINGUISHING BETWEEN MODELS

When both target and hand can be localized via all the same sensory modalities, the convergent and modular formulations differ very little in terms of the predicted outcomes. In the example of hitting a nail with a hammer, this corresponds to the situation in which one can simultaneously see and feel with the hand both the hammer and the nail. In these circumstances, both models predict that more weight will be given to the most reliable (e.g., the least noisy) sensory channels. However, when only a subset of sensory information is available (e.g., only vision of the target or only kinesthesia about the hand), the two different formulations predict two substantially different outcomes.

Consider the situation of a nail that is already imbedded in the wall, such that it need not be held by the non-dominant hand (**Figure 2A**). Information about the target would therefore be limited to the visual domain. Compare this to hammering a nail that is held by the non-dominant hand, but whose head is obscured from view (**Figure 2B**). This example is perhaps not a very wise thing to do in real life, but it illustrates the point. To generalize, we will refer to these two types of tasks by the notation V-VK (visual target, visual and kinesthetic hand feedback) and K-VK, respectively, and to the original case of hammering a hand-held nail with full vision of both target and hands as a VK-VK task. In the case of the convergent model (**Figures 2C,D**), the lack of one source of information about the target simply means that an optimal combination of the remaining sensory cues will be used to localize the target. Thus, in V-VK, a representation of the target based on visual cues, transformed into the common reference frame, will be compared with a representation of the hand in that same reference frame derived from both visual and kinesthetic feedback. Similarly, in K-VK a representation of the target derived from kinesthetic information will be compared with a representation of the hand that is based on an optimal combination of visual and kinesthetic cues.

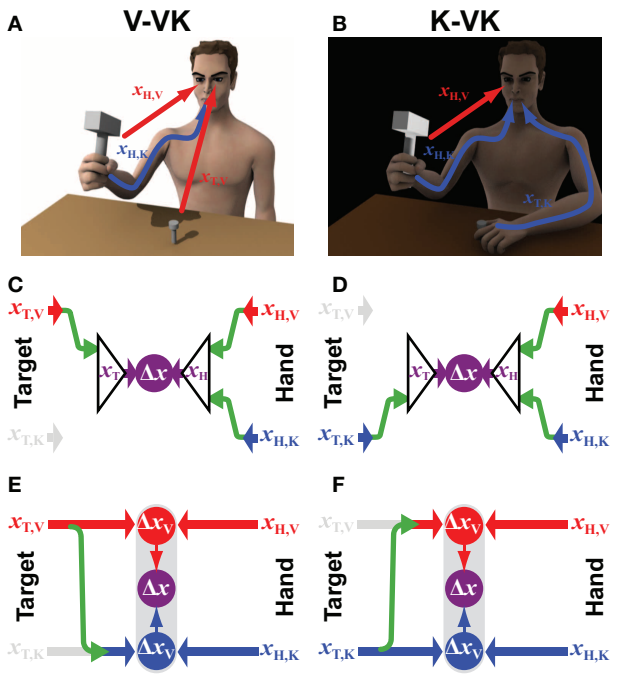

FIGURE 2 | Incomplete sensory information. The computational structure of the convergent and concurrent models are compared for situations in which the target position can be sensed through **(A)** visual ($x_{T,V}$) or **(B)** kinesthetic ($x_{T,K}$) information only, whilst information from both sensory modalities ($x_{H,V}$ and $x_{H,K}$) can be use to estimate the effector/hand position. Panels **(C,D)** represent how available sensory signals would be used following the Convergent Model in each of the two situations, respectively. Panels **(E,F)** illustrate the computational structure of the Concurrent Model for the same two situations. Green arrows represent the cross-modal sensory transformations that might be performed. Grayed out symbols indicate sensory inputs that are absent, as compared to the situation shown in **Figure 1**. All other notations and color conventions are the same as in **Figure 1**.

Applying the concurrent scheme to the situations shown in **Figures 2A,B**, however, begs the question: What is to be done with kinesthetic information about the hand when the target is presented only visually (V-VK) and what is done with visual information about the hand when the target is localized only kinesthetically (K-VK)? One possibility (not shown) is that the CNS simply ignores information about the hand in any sensory modality that is not also used to localize the target, relying only on sensory information that is directly comparable. Thus, only visual information about the hand would be used in the V-VK situation and only kinesthetic information about the hand would be used in the K-VK situation. But by doing so, one would forfeit the added precision that could be obtained by using both sources of sensory information about the hand holding the hammer. Alternatively, as illustrated in **Figures 2E,F**, the CNS could *reconstruct* the missing sensory information about the target by performing a cross-modal sensory transformation (green arrows). According to this arrangement, a kinesthetic representation of the target will be derived from visual information in V-VK, allowing both the visual and the kinesthetic information from the hand to be utilized. Analogously, the target can be reconstructed in visual space in K-VK, again allowing the comparison of target and hand to be carried out in both the visual and the kinesthetic domains.

The difference between the convergent and concurrent formulations becomes apparent if one compares the model predictions for V-VK versus K-VK in terms of the relative weighting given to visual or kinesthetic modalities. Consider first the concurrent models in **Figures 2E,F**. When computing the optimal weights λ_V and λ_K one must take into account not only the noise intrinsic to the sensory inputs, but also the noise added by cross-modal transformations (Soechting and Flanders, 1989; Tillery et al., 1991; Schlicht and Schrater, 2007) when a sensory input missing in one modality must be reconstructed from sensory signals in other. Taking into account this additional noise when applying Equation (6), one obtains for K-VK:

$$\lambda_V = \frac{\left(\sigma^2_{T,K} + \sigma^2_{H,K}\right)}{\left(\sigma^2_{T,K} + \sigma^2_{H,K}\right) + \left(\sigma^2_{T,K} + \sigma^2_{T,K\mapsto V} + \sigma^2_{H,V}\right)}$$
$$\lambda_K = \frac{\left(\sigma^2_{T,K} + \sigma^2_{T,K\mapsto V} + \sigma^2_{H,V}\right)}{\left(\sigma^2_{T,K} + \sigma^2_{H,K}\right) + \left(\sigma^2_{T,K} + \sigma^2_{T,K\mapsto V} + \sigma^2_{H,V}\right)} \quad (7)$$

and for V-VK:

$$\lambda_V = \frac{\left(\sigma^2_{T,V} + \sigma^2_{T,V\mapsto K} + \sigma^2_{H,K}\right)}{\left(\sigma^2_{T,V} + \sigma^2_{T,V\mapsto K} + \sigma^2_{H,K}\right) + \left(\sigma^2_{T,V} + \sigma^2_{H,V}\right)}$$
$$\lambda_K = \frac{\left(\sigma^2_{T,V} + \sigma^2_{H,V}\right)}{\left(\sigma^2_{T,V} + \sigma^2_{T,V\mapsto K} + \sigma^2_{H,K}\right) + \left(\sigma^2_{T,V} + \sigma^2_{H,V}\right)} \quad (8)$$

where $\sigma^2_{T,K\mapsto V}$ and $\sigma^2_{T,V\mapsto K}$ represent the noise added when reconstructing a visual representation of the target from kinesthetic information and the noise added when reconstructing the target in kinesthetic space from visual information, respectively. One can see from these sets of equations that changing what sensory information is available about the target has the potential of changing the weight given to each type of sensory feedback used to guide the hand. Indeed, less weight (smaller λ's) will be given to the component comparisons that require the reconstruction of sensory information, due to the noise that these reconstructions add to the signals. In most cases, however, the weighting of the two component comparisons will shift toward the visual information when the target is visual (V-VK) and will shift toward the kinaesthetic domain when the target is kinaesthetic (K-VK). In the limit, if the transformation noise is very high compared to the input noise, the comparison that requires a sensorimotor reconstruction will be given zero weight, leaving only the direct comparison to drive the response.

For the convergent model, there is no inherent need to reconstruct sensory information that is not available. The CNS would simply use all the available sensory information about the target and all available sensory information about the hand in order to compute an optimal estimate of the position of each. This does not mean, however, that no sensorimotor transformations are required to implement the concurrent formulation. On the contrary, in order to combine spatial information from different sources, the different pieces of information must be expressed in a common reference frame R. Thus, for the convergent model, coordinate transformations will be required even though no "reconstruction" of missing sensory information is needed. These transformations will also add noise which will affect the weighting between the different inputs and should therefore be explicitly considered when comparing the concurrent and convergent models. According to Equations (1 and 5), the estimate of the hand's position and orientation will be based on a weighted sum of the visual and kinesthetic feedback, with the weight determined by the variance of the two feedback signals and by the noise added by the two sensorimotor transformations:

$$w_{H,V} = \frac{\sigma^2_{H,K} + \sigma^2_{H,K\mapsto R}}{\sigma^2_{H,K} + \sigma^2_{H,K\mapsto R} + \sigma^2_{H,V} + \sigma^2_{H,V\mapsto R}}$$
$$w_{H,K} = \frac{\sigma^2_{H,V} + \sigma^2_{H,V\mapsto R}}{\sigma^2_{H,K} + \sigma^2_{H,K\mapsto R} + \sigma^2_{H,V} + \sigma^2_{H,V\mapsto R}} \quad (9)$$

One can see that even if one considers noise added by sensorimotor transformations, the convergent model, unlike the concurrent model, predicts that the weighting of sensory information will not change between V-VK and K-VK. Because the information available about the hand is the same in both V-VK and K-VK, the relative weight given to visual versus kinesthetic feedback about the hand will be the same in both circumstances, regardless of the sensory modality used to sense the target.

The convergent and concurrent models make two different predictions, therefore, about what happens when the modality of the target is changed while full feedback of the hand is available. These predictions allow one to differentiate between the two hypotheses experimentally. Indeed, a number of studies that have compared moving the hand to visual versus proprioceptive targets provide support for the hypothesis of concurrent comparisons shown **Figure 1B**. For instance:

- Sober and Sabes (2005) compared pointing to a visual target versus pointing with the one hand to the unseen index finger of the other. They used virtual reality to introduce conflict between visual and proprioceptive feedback about the initial position of the pointing finger. By measuring the bias toward the visual or the proprioceptive feedback about the position of the finger, they found a significant difference in the relative weighting of visual and kinesthetic hand feedback depending on the modality of the target.
- Sarlegna and Sainburg (2007) also used a virtual-reality technique to dissociate visual and proprioceptive feedback about the hand's initial position. The choice of target modality (moving to a visual target versus moving to the position of the other, unseen hand) had a significant effect on the contribution of vision versus proprioception to the control of the amplitude of rapid reaching movements.
- McGuire and Sabes (2009) made use of the well-known *retinal eccentricity effect* (Bock, 1986) and imposed changes in gaze direction to measure the reliance on visual versus kinesthetic information. They found that when visual and kinesthetic information about the hand was available, deviations due to changes in gaze direction, which would indicate coding of the movement in retinal space, depended on the target modality (pointing to a visual target versus pointing to the unseen left hand).
- Tagliabue and McIntyre (2011) asked subjects to align the hand with a target in the fronto-parallel plane. They used a virtual reality technique to introduce conflict between visual and kinesthetic reference frames during a memory delay. In these experiments the sensory modality used to present the target orientation had a significant effect on the weight given to visual versus kinesthetic comparisons when driving the response, with a shift toward visual information when the target was visual and kinesthetic information when the target was kinesthetic.

Because their data could not be reconciled with the encoding of movement parameters exclusively in either retinotopic space or kinesthetic space, the authors of the last two studies each proposed versions of the concurrent structure depicted in **Figure 1B**. The specifics of the models proposed by these different authors differ slightly from each other (more on the similarities and differences below) but both involve multiple comparisons in multiple reference frames and both can explain a shift in weighting toward visual information when the target was visible and toward kinesthetic information when the target was kinesthetic. Thus, compared to the hypothesis of convergent, multi-modal sensory integration shown in **Figure 1A**, the computational structure of multiple, concurrent comparisons depicted in **Figure 1B** provides a much more parsimonious explanation of the data reported from a number of different tasks and experimental paradigms.

3. TO RECONSTRUCT OR NOT TO RECONSTRUCT?

Inherent to the concurrent model is the concept of sensory reconstruction. According to this idea, a visible target could be compared with proprioceptive information about the location of the hand if the visible information is transformed into proprioceptive space. Some such reconstruction would be necessary when, for instance, reaching toward a visual target with the unseen hand (V-K). The question remains, however, as to whether the visual target should be transformed into kinesthetic space or whether a visual representation of the hand should be constructed based on proprioceptive information from the arm. Transforming target information into kinesthetic space would be optional in a V-VK situation, where a direct comparison of target and hand could be carried out in visual coordinates. It would be even more superfluous to transform into visual space a purely kinesthetic (K-K) task. Yet the implication of visual representations in purely kinesthetic tasks is known to occur (Pouget et al., 2002b; Sober and Sabes, 2005; Sarlegna and Sainburg, 2007; McGuire and Sabes, 2009; Jones and Henriques, 2010). A key question to be addressed, therefore, is that of how the CNS chooses which comparisons to apply to a given task, and how to weight the different computations to arrive at the overall response. Under what conditions should information from one sensory modality be transformed into the reference frame of another?

In our original publication (Tagliabue and McIntyre, 2011) we argued that the CNS avoids sensory transformations, and thus performs direct comparisons whenever possible. Indeed, we observed that a V-VK task was carried out in visual coordinates while the equivalent K-VK task was carried out in kinesthetic space. (Note that we observed this result when subjects held their head upright. We saw a somewhat different result when subjects were asked to move their head during an imposed memory delay. We will discuss these latter results further down in this section). In our V-K and our K-V tasks, however, we observed that both visual and kinesthetic comparisons were performed, even though just one of these (and just one transformation) would have been sufficient. For instance, in V-K, subjects could have performed a single transformation of visual information into kinesthetic space, or they could have only transformed the kinesthetic hand information so as to perform the task in visual space. The fact that both transformations and both comparisons were performed shows that the CNS does sometimes perform "unnecessary" transformations beyond what would be minimally necessary to achieve the task.

In order to explain our results, and others, we had to resort to additional, albeit reasonable, assumptions that went beyond the basic tenets of MLE. The first was that direct comparisons are absolutely best, even though estimates of noise in the visual and kinesthetic channels and the conventional application of maximum likelihood would predict a more graded weighting between visual and kinesthetic information for the V-V and K-K tasks. The second was that the necessity of a single transformation would provoke the execution of a whole range of transformations into a number of different reference frame or sensory modalities. This could explain why the CNS would reconstruct a visual representation of a task that is otherwise purely kinesthetic, as was observed in the studies mentioned above. In the discussion of our results, we argued that this could be because a common neural network might generate the same amount of noise, whether performing one or many transformations. While this is a reasonable, and even testable, hypothesis, it still remains unproven and thus still constitutes, as of this writing, an *ad hoc* assumption that we had to invoke in order to reconcile empirical data with MLE.

In a more recent study, however, we showed how MLE *can* explain much, if not all, of the available data without these additional assumptions, if one properly accounts for co-variation of noise in sensory signals that have been reconstructed in one sensory modality from another (Tagliabue and McIntyre, 2013). The issue of co-variation is important because it conditions how two signals should be optimally weighted. If two signals are stochastically independent, the principle of maximal likelihood estimation says that the two quantities should be weighted according to the inverse of their respective expected variance. This weighted average will tend to reduce the effects of the independent noise in each component. But if the noise in one is correlated with the noise in the other, computing the weighted average will be less effective in reducing the overall noise. In the limit, if the noise in the two variables in perfectly correlated, then computing the weighted average will not reduce the overall noise at all.

To correctly compensate for covariance between two signals in the computation of the optimal weights to be applied, one must essentially take into account only the independent components of noise within each variable. In the case of two non-independent variables that exhibit Gaussian noise, the weighted combination of x and y that will minimize the variance of the output:

$$z = \lambda x + (1 - \lambda)\, y \tag{10}$$

is given by the equation:

$$\lambda = \frac{\left(\sigma_x^2 - \mathrm{cov}_{x,y}\right)^{-1}}{\left(\sigma_x^2 - \mathrm{cov}_{x,y}\right)^{-1} + \left(\sigma_y^{-2} - \mathrm{cov}_{x,y}\right)^{-1}} \tag{11}$$

where $\mathrm{cov}_{x,y}$ is the covariance between x and y. Added insight can be achieved if one considers two components x and y are derived from two stochastically independent signals, p and q and a common component c:

$$\begin{aligned} x &= p + c \\ y &= q + c \end{aligned} \tag{12}$$

In this case, which is directly applicable to the sensorimotor transformations that are being considered in this paper, the covariance between x and y is precisely equal to the variance of the common component c:

$$\begin{aligned} \sigma_x^2 &= \sigma_p^2 + \sigma_c^2 \\ \sigma_y^2 &= \sigma_q^2 + \sigma_c^2 \\ \mathrm{cov}_{x,y} &= \sigma_c^2 \end{aligned} \tag{13}$$

and Equation (11) reduces to:

$$\lambda = \frac{\sigma_q^2}{\sigma_p^2 + \sigma_q^2} \tag{14}$$

In other words, the optimal weighting of x and y depends only on the variance of the independent components p and q.

One can see from Equation (14) that if one of the two constituent signals presents only noise that is common to both quantities x and y, e.g.,:

$$\begin{aligned} x &= p + c \\ y &= c \end{aligned} \tag{15}$$

then the weight given to the constituent with the added noise (x in the example) will be zero. This fact can be used to predict when the CNS might reconstruct a representation of the task in a reference frame different from that of either the target localization or the feedback about the motor response. If the task allows for a direct comparison of target and effector information, e.g., when moving the hand to a remembered posture, the reconstructed comparison will contain all the variability of the kinesthetic inputs plus the noise added by the coordinate transformations while the direct comparison will contain no noise that is not also included in the reconstructed comparison:

$$\begin{aligned} \sigma_{\Delta V}^2 &= \sigma_{T,K}^2 + \sigma_{H,K}^2 + \sigma_{T,K\mapsto V}^2 + \sigma_{H,K\mapsto V}^2 \\ \sigma_{\Delta K}^2 &= \sigma_{T,K}^2 + \sigma_{H,K}^2 \end{aligned} \tag{16}$$

Applying Equation (14) means that the comparison of the reconstructed signals, ΔV will be given no weight compared to the direct comparison ΔK. In other words, there is no advantage to transforming the task into an alternate reference frame (e.g., in visual space) in this situation. On the other hand, if the target and hand are sensed in two different reference frames, such that at least one sensory transformation is required, then reconstruction into a third reference frame might be beneficial. For example, if one is asked to reproduce with the right hand the remembered orientation of the left, a transformation will have to be applied to compare the hand orientation between the two limbs (see **Figure 3**), leading to the equations:

$$\begin{aligned} \sigma_{\Delta V}^2 &= \sigma_{T,K_L}^2 + \sigma_{H,K_R}^2 + \sigma_{T,K_L\mapsto V}^2 + \sigma_{H,K_R\mapsto V}^2 \\ \sigma_{\Delta K_L}^2 &= \sigma_{T,K_L}^2 + \sigma_{H,K_R}^2 + \sigma_{H,K_R\mapsto K_L}^2 \\ \sigma_{\Delta K_R}^2 &= \sigma_{T,K_L}^2 + \sigma_{H,K_R}^2 + \sigma_{T,K_L\mapsto K_R}^2 \end{aligned} \tag{17}$$

where K_L and K_R represent the kinesthetic information about the left and right hand, respectively. In this situation, each representation of the task, including representation that includes no direct inputs (ΔV) includes at least one source of noise that is independent from each of the others. Thus, one might expect to find that the task is carried out simultaneously in the intrinsic reference frame of each arm, and also in visual space. Indeed, when we compared precisely these two situations (matching the posture of the right hand to the remembered posture of the left versus matching the posture of the right hand to the remembered posture of the right hand) we observed exactly this behavior. The unilateral task showed no effect of deviations of the visual field, while the bilateral task did. This same reasoning can also be applied to a number of examples from the literature to explain why subjects appeared to reconstruct a visual representation of a task that could conceivably be carried out entirely in kinesthetic space (Pouget et al., 2002b; Sober and Sabes, 2005; Sarlegna and Sainburg, 2007; McGuire and Sabes, 2009; Jones and Henriques, 2010). Explicitly including the co-variation of reconstructed variable therefore increases the predictive value of the model structure depicted in **Figure 1B**.

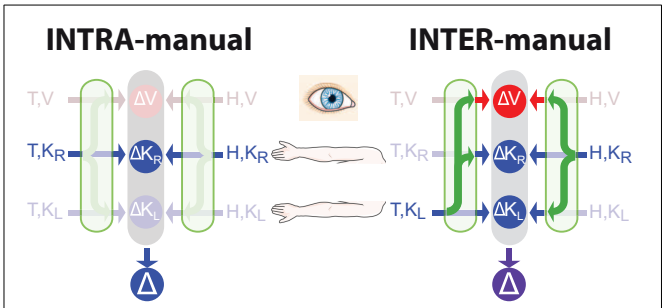

FIGURE 3 | Direct vs. indirect comparisons (modified from Tagliabue and McIntyre, 2013). The schematics represent the concurrent model applied to two tasks that are both purely kinesthetic (K-K). In the INTRA-manual task the subject feels the target position with the right hand (T,K_R) and reproduces it with the same hand (H,K_R). In the INTER-manual task the target is felt with the left hand (T,K_L) and its position is reproduced with the right (H,K_R). As in **Figures 1**, **2**, red and blue arrows represent visual and kinesthetic signals, respectively, circular nodes represent movement vectors computed in different reference frames and green arrows represent sensory transformations. Each task can potentially be carried out partially in visual space by reconstructing a visual representation of the target (T,V) and a visual representation of the hand (H,V) from available kinesthetic inputs. In the INTRA-, but not INTER-manual task, a direct comparison between the kinesthetic signals about target and response is possible. Taking into account co-variance between reconstructed signals, only in the INTER-condition would a reconstruction of an "unnecessary" visual representation reduce movement variability. Grayed-out symbols represent sensory inputs that are absent in each task while grayed-out green arrows depict sensory reconstructions that are given no weight when MLE is applied.

4. THE TIMING OF SENSORY RECONSTRUCTIONS

If one accepts the idea that the CNS transforms sensory information amongst multiple reference frames, one might also ask the question, when do such transformations occur? A number of studies have considered the performance of cross-modal transformations for the computation of a movement vector during planning (Sober and Sabes, 2003, 2005; Sarlegna and Sainburg, 2007; McGuire and Sabes, 2009; Burns and Blohm, 2010), but this is not the only time when such transformations may be needed. Sensory information about the target and limb continues to arrive throughout the movement, and the same issues about reference frames and sensor fusion arise when considering on-line corrections that are made based on this information. This question is of particular interest when one considers movements to memorized

targets. In a V-K task, for instance, which is a task that requires at least one cross-modal sensory transformation, what happens if the target disappears before the reaching movement is started? How is the information about the target stored? Is it encoded in memory in visual space, to be transformed into kinesthetic space for comparison with proprioceptive information from the arm? Or is it immediately transformed into kinesthetic space and stored during the memory delay for later use?

The results of one of our recent experiments (Tagliabue et al., 2013) can be used to address this question. In that study we analyzed the V-K tasks alluded to above and illustrated in **Figure 4**. We asked subjects to perform this task in two different conditions, which differed only in terms of the timing of head movements. In one condition (U-T) subjects memorized the target with the head upright and produced the motor response with the head tilted. In the other condition (T-U) they memorized the target with the head tilted and moved the hand with the head upright. The rationale for performing this experiment with head tilted at different times is based on the notion that transformations between visual and kinesthetic space are disrupted (noisier) when the head is not aligned with gravity (Burns and Blohm, 2010; Tagliabue and McIntyre, 2011). This assumption is supported by a study of orientation matching between a visual and haptic stimuli (McIntyre and Lipshits, 2008). Whereas tilting the subject's entire body had no effect on visual-visual and haptic-haptic comparisons, responses were more variable in the case of a visual-haptic comparison when the body was tilted versus when it was upright. The fact that the inter-modal comparison became more variable, but not the intra-modal ones indicates that it is the transformation between sensory modalities, and not the actual sensory inputs, that are noisier when tilted with respect to gravity. In light of this fact, the relative weight given to visual information (λ_V) in our more recent experiment and the overall variance (σ^2_Δ) will depend on whether each transformation is performed with the head upright or with the head tilted.

One can therefore differentiate between the different hypotheses **Figure 4** as follows. For a V-K task we have:

$$\begin{aligned} \sigma^2_{\Delta V} &= \sigma^2_{T,V} &&+\sigma^2_{H,K} + \sigma^2_{H,K\mapsto V} \\ \sigma^2_{\Delta K} &= \sigma^2_{T,V} + \sigma^2_{T,V\mapsto K} &&+\sigma^2_{H,K} \end{aligned} \tag{18}$$

Taking into account the co-variation between a transformed signal and its source, as described in section 3, one can compute the weight given to the visual comparison:

$$\lambda_V = \frac{\sigma^2_{T,V\mapsto K}}{\sigma^2_{T,V\mapsto K} + \sigma^2_{H,K\mapsto V}} \tag{19}$$

and given the formula for the variance of a weighted sum of two variables that are not independent:

$$\sigma^2_{ax+by} = a^2\sigma^2_x + b^2\sigma^2_y + 2\,ab\,\mathrm{cov}_{x,y} \tag{20}$$

the overall variance of the optimal estimate will be:

$$\sigma^2_\Delta = \lambda^2_V\sigma^2_{\Delta V} + (1-\lambda_V)^2\,\sigma^2_{\Delta K} + 2\lambda_V(1-\lambda_V)\,\mathrm{cov}_{\Delta V,\Delta K} \tag{21}$$

$$= \sigma^2_{T,V} + \sigma^2_{H,K} + \lambda^2_V\sigma^2_{H,K\mapsto V} + (1-\lambda_V)^2\,\sigma^2_{T,V\mapsto K} \tag{22}$$

$$= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\sigma^2_{T,V\mapsto K}\sigma^2_{H,K\mapsto V}}{\sigma^2_{T,V\mapsto K} + \sigma^2_{H,K\mapsto V}} \tag{23}$$

Now assume that the noise added when transforming from visual to kinesthetic or from kinesthetic to visual is the same, for a given orientation of the head, and that head tilt has the same additive effect on all transformations, i.e., we define:

$$\sigma^2_{T,V\mapsto K} = \sigma^2_{H,K\mapsto V} = \sigma^2_{\mapsto} \tag{24}$$

when the transformation is performed with the head upright, and:

$$\sigma^2_{T,V\mapsto K} = \sigma^2_{H,K\mapsto V} = \sigma^2_{\mapsto} + \sigma^2_{//} \tag{25}$$

when the transformation is performed with the head tilted to the side. Combining Equations (18–25), one can see that tilting the head will have no effect on λ_V if both transformations are

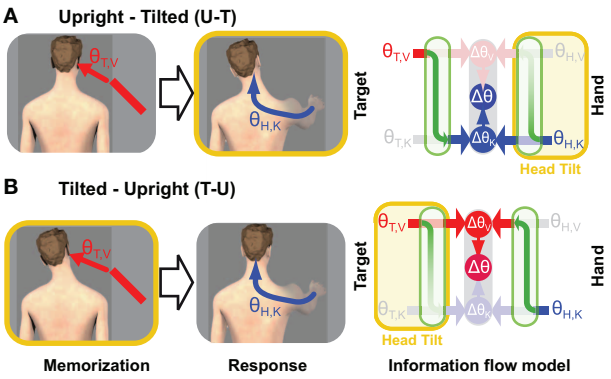

FIGURE 4 | Experimental manipulation of transformation noise (modified from Tagliabue et al., 2013). Two different experimental conditions are illustrated in which the subjects were asked to memorize the orientation (θ) of a visual target (red bar) and to reproduce it, after a delay, with their unseen hand. **(A)** In one condition (U-T) subjects memorized the target with the head upright and responded with the head tilted. **(B)** In the other condition (T-U), the target was memorized with the head tilted and the hand oriented with the head upright. On the right side of the figure are depicted the predictions of the Concurrent Model for each of the two experimental conditions. As in **Figures 1**, **2**, and blue arrows represent visual and kinaesthetic signals, respectively and green arrows represent cross-modal transformations. Gray symbols represent sensory inputs that are absent. Because having the head tilted (yellow areas) causes cross-modal transformations to be significantly noisier, comparisons requiring such transformations are given less weight (faded green arrows) and comparisons for which sensory reconstructions are performed with the head upright are privileged.

performed with the head upright or both are performed with the head tilted:

$$\begin{aligned}
\lambda_V|_{up,up} &= \frac{\sigma^2_{\mapsto}}{\sigma^2_{\mapsto} + \sigma^2_{\mapsto}} = \frac{1}{2} \\
\lambda_V|_{tilt,tilt} &= \frac{\sigma^2_{\mapsto} + \sigma^2_{//}}{\sigma^2_{\mapsto} + \sigma^2_{//} + \sigma^2_{\mapsto} + \sigma^2_{//}} = \frac{1}{2} \\
\lambda_V|_{up,up} &= \lambda_V|_{tilt,tilt}
\end{aligned} \tag{26}$$

Performing both transformations with the head upright or both with the head tilted will, however, have an effect on the overall variability:

$$\begin{aligned}
\sigma^2_{\Delta}|_{up,up} &= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\sigma^2_{\mapsto}\sigma^2_{\mapsto}}{\sigma^2_{\mapsto} + \sigma^2_{\mapsto}} \\
&= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\sigma^2_{\mapsto}}{2} \\
\sigma^2_{\Delta}|_{tilt,tilt} &= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\left(\sigma^2_{\mapsto} + \sigma^2_{//}\right)\left(\sigma^2_{\mapsto} + \sigma^2_{//}\right)}{\sigma^2_{\mapsto} + \sigma^2_{//} + \sigma^2_{\mapsto} + \sigma^2_{//}} \\
&= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\sigma^2_{\mapsto} + \sigma^2_{//}}{2} \\
\sigma^2_{\Delta}|_{tilt,tilt} &= \sigma^2_{\Delta}|_{up,up} + \frac{\sigma^2_{//}}{2} \\
\sigma^2_{\Delta}|_{tilt,tilt} &> \sigma^2_{\Delta}|_{up,up}
\end{aligned} \tag{27}$$

On the other hand, if one of the transformations is performed with the head upright, and the other with the head tilted, the opposite pattern should be observed. The weight given to visual information will depend on whether the transformation T,V $\mapsto$ K is performed with the head upright and the transformation H,K $\mapsto$ V is performed with the head tilted (up,tilt), or vice versa (tilt,up):

$$\begin{aligned}
\lambda_V|_{up,tilt} &= \frac{\sigma^2_{\mapsto}}{\sigma^2_{\mapsto} + \sigma^2_{\mapsto} + \sigma^2_{//}} = 0 \text{ as} \sigma^2_{//} \to \infty \\
\lambda_V|_{tilt,up} &= \frac{\sigma^2_{\mapsto} + \sigma^2_{//}}{\sigma^2_{\mapsto} + \sigma^2_{//} + \sigma^2_{\mapsto}} = 1 \text{ as } \sigma^2_{//} \to \infty \\
\lambda_V|_{up,tilt} &< \lambda_V|_{tilt,up}
\end{aligned} \tag{28}$$

while one would expect to see similar levels of overall variability between the two conditions, because in both cases one transformation is performed with the head tilted and one with the head upright:

$$\begin{aligned}
\sigma^2_{\Delta}|_{up,tilt} &= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\sigma^2_{\mapsto}\left(\sigma^2_{\mapsto} + \sigma^2_{//}\right)}{\sigma^2_{\mapsto} + \sigma^2_{\mapsto} + \sigma^2_{//}} \\
\sigma^2_{\Delta}|_{tilt,up} &= \sigma^2_{T,V} + \sigma^2_{H,K} + \frac{\left(\sigma^2_{\mapsto} + \sigma^2_{//}\right)\sigma^2_{\mapsto}}{\sigma^2_{\mapsto} + \sigma^2_{//} + \sigma^2_{\mapsto}} \\
\sigma^2_{\Delta}|_{up,tilt} &= \sigma^2_{\Delta}|_{tilt,up}
\end{aligned} \tag{29}$$

Note that the results remain valid even if $\sigma^2_{T,V\mapsto K} \neq \sigma^2_{H,K\mapsto V}$, for plausible values of $\sigma^2_{T,V\mapsto K}$, $\sigma^2_{H,K\mapsto V}$, $\sigma^2_{T,V}$, $\sigma^2_{H,K}$ and $\sigma^2_{//}$.

Using these mathematical considerations and the results of our experiment, one can distinguish between the three hypotheses about the timing of sensory reconstructions shown in **Figure 5**. If the movement vector is computed while the target is still visible (**Figure 5A**), then both transformations (T,V $\mapsto$ K and H,K $\mapsto$ V) will be performed with the head upright in the U-T condition and both will be performed with the head tilted in the T-U condition. According to Equations (26 and 27), the relative weight given to visual information should not change between the U-T and T-U conditions, while the overall variance should be greater for T-U than for U-T. Neither of these predictions is consistent with our empirical results in which we observed a significantly greater weight given to visual information in the T-U condition, compared to U-T, and similar levels of overall variability for both (Tagliabue et al., 2013). Note that this hypothesis can also be rejected by the strong effect of response modality that we observed in our previous study (Tagliabue and McIntyre, 2011). In all conditions tested in that study (K-K, K-VK, K-V, V-K, V-VK, and V-V) the subject's hand was outside the field of view during the time when the target was being presented. Therefore in all conditions the information available about the hand's orientation during target observation was *de facto* the same. If **Figure 5A** were correct, we would not have observed the strong effect of response modality on the weight given to visual versus kinesthetic information.

Figure 5B depicts an alternative hypothesis by which the CNS performs the requisite coordinate transformations starting at movement onset, relying on visual memory of the target after it disappears. In this case both transformations (T,V $\mapsto$ K and H,K $\mapsto$ V) would be performed with the head upright in the T-U condition and with the head tilted in the U-T condition. Applying once again Equations (26 and 27), one would expect to see similar weight given to visual information in both conditions and a significant difference in the overall variability, although according to this hypothesis, the higher variability would occur for U-T. As before, the empirical observations (Tagliabue et al., 2013) do not match the predictions of **Figure 5B**.

Our experimental findings can, however, be reconciled with a hypothesis by which cross-modal reconstructions of target and hand occur continuously, but *only long as the sensory input to be transformed is present* (**Figure 5C**). When the target disappears, as in our experiments, further reconstruction of its kinesthetic orientation from visual information is halted, and the remembered

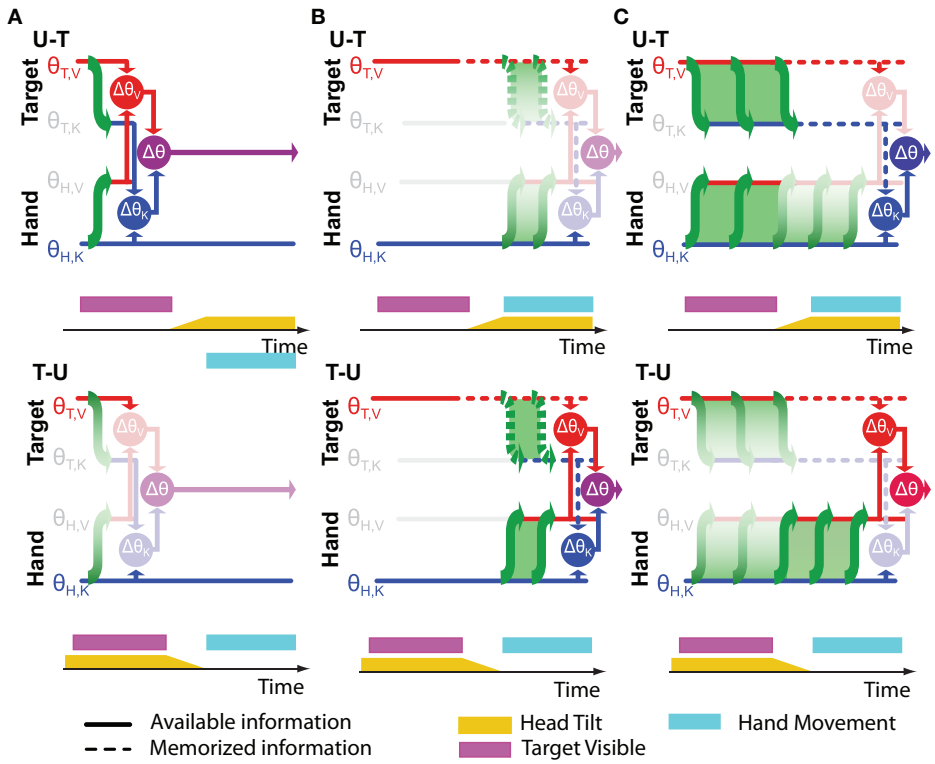

FIGURE 5 | Timing of cross-modal reconstructions. Hypotheses concerning the time course of sensorimotor reconstructions are represented for the task depicted in **Figure 4**. The visibility of the target (purple bar) and the tilt of the head (yellow bar) are shown as time progresses from left to right. The hand moves only after the rotation of the head is terminated. Horizontal lines represent internal representations of the target ($\theta_{T,V}$ and $\theta_{T,K}$) and of the hand ($\theta_{H,V}$ and $\theta_{H,K}$). Gray symbols indicate sensory inputs that are absent, while green arrows indicate cross-modal reconstructions that may be performed. Vertical arrows and nodes indicate when the comparisons of target and hand are carried out, according to three hypotheses: **(A)** Cross-modal reconstructions and concurrent target-hand comparisons ($\Delta\theta_V$,$\Delta\theta_K$) are performed while the target is visible and the resulting movement vector ($\Delta\theta$) is maintained and updated through the end of the movement. **(B)** Cross-modal reconstructions are performed during movement execution, relying on sensory inputs about the target stored in memory. **(C)** Cross-modal reconstructions are performed continuously as long as the sensory input is present; direct and reconstructed target representations are maintained in memory in parallel through the end of the movement. Faded nodes indicate target-hand comparisons that are noisier because they rely on cross-modal reconstructions that were performed with the head titled. Hypotheses **(A,B)** predict similar weighting of visual and kinesthetic information, and thus partial deviations of the response in both the U-T and T-U conditions, while hypothesis **(C)** predicts a significantly larger weighting of the visual comparison in the T-U than in the U-T conditions.

orientation is maintained in both spaces. Transformation of the continuously available hand kinesthesia into the visual domain proceeds, however, through the end of the movement. Here we fall into the situation in which the sensory transformations potentially used to control the movement do not all occur with the head at the same orientation. In the U-T condition, the last transformation of the target into kinesthetic space will occur with the head upright, while the latest transformations of the hand into visual space will occur throughout the movement, i.e., with the head tilted. Conversely, in the T-U condition, the last transformation of the target will occur with the head tilted, and the latest transformations of the hand with the head upright. Applying Equations (28 and 29), one expects to see a greater reliance on visual information in T-U than in U-T, with similar levels of overall variability between the two conditions, precisely as we observed (Tagliabue et al., 2013).

To summarize, we have shown that the reconstruction of sensory signals in alternate reference frames appears to occur only while the primary sensory input is available. An important corollary to this conclusion is that the CNS will also store spatial information concurrently in multiple reference frames, a prediction that can, in theory, be tested experimentally.

5. GENERALIZED CONVERGENT AND CONCURRENT MODELS

In the preceding sections we have discussed how the CNS might benefit from performing multiple, concurrent comparisons when, for instance, bringing the hand into alignment with a target. This discussion has highlighted a number of pertinent issues, including the evidence for single versus multiple comparisons, the importance of considering co-variation of signals when computing weights based on maximum likelihood and the timing of inter-modal transformations. The preceding sections leave open a number of questions, however, about when the various input signals are combined and about how to extend these concepts to situations where more than two sensory modalities may be involved. In this section we will formalize the distinction between convergent versus concurrent structures. In the section

that follows we will show how the various computational concepts can be broadened to include questions such as how the CNS makes use of intrinsic versus extrinsic reference frames.

5.1. FULLY CONVERGENT MODEL

Figure 6A shows the computational structure of the fully convergent model. A maximum likelihood estimate is made from all available inputs about the target's position and a similar process is applied to all available information about the position of the hand. As pointed out in section 2.1, the various sources of information must be transformed into a common reference frame in order for these optimal estimates to be computed and these transformations add noise. The calculations that describe the convergent model are therefore given by:

$$\Delta x = \sum_{i=1}^{n} w_{\mathrm{T},i}\Psi_{i\to r}\left(x_{\mathrm{T},i}\right) - \sum_{j=1}^{m} w_{\mathrm{H},j}\Psi_{j\to r}\left(x_{\mathrm{H},j}\right) \qquad (30)$$

where $x_{\mathrm{T},i}$ and $x_{\mathrm{H},j}$ are the sensory inputs about the target position in reference frame i and the hand position in reference frame j. Each input is associated with its own intrinsic variability ($\sigma^2_{\mathrm{T},i}$ or $\sigma^2_{\mathrm{H},j}$). The operator $\Psi_{a\to r}$ represents the a transformation of a position value from some reference frame a into the common reference frame r. Applying $\Psi_{a\to r}$ to an input value expressed in its intrinsic coordinate frame a creates a new value in the reference frame r with noise equal to the sum of the variance of the input (e.g., $\sigma^2_{\mathrm{T},a}$) and the variance added by the transformation ($\sigma^2_{a\to r}$). Note that the common reference frame r could be some abstract reference frame that is independent from any given sensory frame, or it could be one of the n reference frames intrinsic to the sensory modalities used to sense the target position or one of the m reference frames used to sense the hand position. In this latter case, no transformation will be required for at least one sensory input, and we define $\Psi_{r\to r}(x) = x$ and $\sigma^2_{r\to r} = 0$.

5.2. HYBRID CONVERGENT/CONCURRENT MODEL

According to the model presented in **Figure 6B**, it is presumed that the CNS will use all available information to represent the task in each of the component reference frames, and will then concurrently compare the target to the hand within each reference frame, before combining the results of each comparison to drive the motor response. We base this formulation on the model proposed by McGuire and Sabes (2009) for the combination of visual and kinesthetic information. From their discussion: *movements are always represented in multiple reference frames*, and from the Methods: *the model first builds internal representations of fingertip and target locations in both retinotopic and body-centered reference frames. These representations integrate all available sensory signals, requiring the transformation of non-native signals.* Extending these concepts to more than two sensory modalities and reference frames, the equation describing this formulation is:

$$\Delta x = \sum_{i=1}^{N} \lambda_i \left(\sum_{j=1}^{n} w_{i,\mathrm{T},j}\Psi_{j\to i}\left(x_{\mathrm{T},j}\right) - \sum_{j=1}^{m} w_{i,\mathrm{H},j}\Psi_{j\to i}\left(x_{\mathrm{H},j}\right) \right) \qquad (31)$$

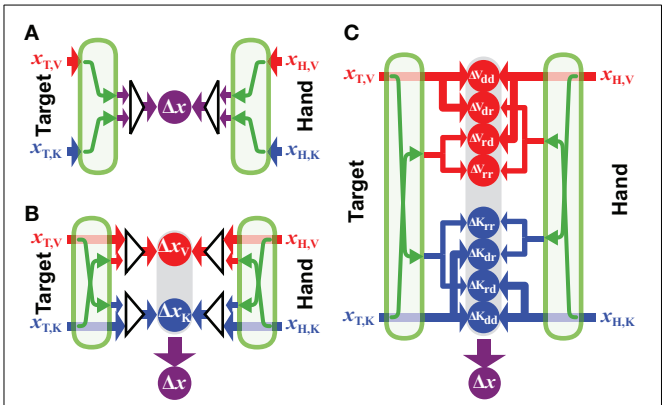

FIGURE 6 | Generalized models. Three possible formulations of the sensorimotor integration model, all based on principles of maximum likelihood. **(A)** *Fully-convergent model*: first, the position of the target and hand are optimally estimated independently; then, these optimal estimations are compared in a unique reference frame to compute a single movement vector Δx. Green arrows represent the sensory transformations necessary to encode the signals in a common reference frame before they can be combined. **(B)** *Hybrid-convergent/concurrent model*: available sources of information about the target are combined to build optimal estimations of its position in different reference frames. Ditto for the available hand information. Target-hand comparisons are then performed in each of these reference frames (Δx_{V} and Δx_{K}) and the results of these comparisons are optimally combined to produce the net movement vector (Δx). **(C)** *Fully-concurrent model*: available sources of information about target and hand are used to build concurrent target-hand comparisons in various reference frames. Information directly available in a given reference frame can be compared with both information directly available in the same reference frame and with information reconstructed from signal initially encoded in a different reference frame. It follows that, for each reference frame, all combinations between direct (d) and reconstructed (r) signals may be used to perform comparisons: ΔV_{dd}, ΔV_{dr}, etc.

where N is the total number of reference frames for which the comparison between target and hand will be made, $n \leqslant N$ is the number of reference frames in which target information is directly available and $m \leqslant N$ is the number of reference frames in which hand feedback is available. Implicit in this formulation is the idea that the CNS will always reconstruct sensory signals across modalities, even when sensory information is directly available within a given modality. One can see that this formulation allows for two sets of weights, those that determine the weight given to direct and reconstructed inputs within each reference frame [$w_{i,\mathrm{T},j}$ and $w_{i,\mathrm{H},j}$, comparable to the weights w described in the convergent model of Equation (1)] and those used to combine the results of the differences computed in each reference frame [comparable to the weights λ in the concurrent model of Equation (2)]. So, for instance, if both visual and kinesthetic information is available about the target, both the direct visual input and a transformed version of the kinesthetic information will be used to construct a representation of the target in visual space. Similarly, both the direct sensory input and the reconstructed visual input will be used to construct a representation of the target in kinesthetic space. The weight given to each source of information, however, will take into account the noise added by the cross-modal transformations. Thus, the representation of the movement in visual space will give more

weight to the direct visual input than to the visual representation that is reconstructed from kinesthetic signals, etc. According to this model, the CNS will read out the desired movement vector by combining the differences computed concurrently in each reference frame, also according to the expected variance of each of the differences.

5.3. A FULLY-CONCURRENT MODEL

Here we propose a third formulation, shown in **Figure 6C**, based on the concept that individual comparisons form the building blocks for multisensory control of hand-eye coordination. According to this proposal, each available sensory input may be transformed into any and all other potential reference frames, as in the hybrid model described above. The two models differ, however, in terms of how the various reconstructions are handled within each reference frame. According to the fully concurrent model, the direct and reconstructed signals are not combined into a single representation of the target and of the hand within each reference frame. Rather, the CNS would compute individually the differences between all possible permutations of target and hand representations, both direct and reconstructed, within each reference frame, on a pair-by-pair basis. Only then would the results of all the individual differences be combined through a weighted average according to MLE in order to compute the movement vector. The computations that describe such a fully distributed, concurrent model, based on individual differences can be described by:

$$\Delta x = \sum_{i=1}^{N} \sum_{j=1}^{n} \sum_{k=1}^{n} \gamma_{i,j,k} \left(\Psi_{j \to i} \left(x_{\mathrm{T},j} \right) - \Psi_{k \to i} \left(x_{\mathrm{H,K}} \right) \right) \quad (32)$$

A simple mathematical convenience serves to adapt Equation (32) to situations where direct sensory inputs about the target or the hand are missing in one or more of the n sensory modalities. According to MLE, a given signal is weighted according to the inverse of its expected variance. If the quantity $1/\sigma^2$ is a measure of the confidence that one has in a given signal—i.e., the greater the variability, the lower the confidence—one can therefore assign to a missing sensory input an infinite variance, in the sense that the confidence in a missing signal will be $1/\sigma^2 = 1/\infty = 0$. By doing so, the weight given to a missing input, or to a transformed version of a missing input will automatically fall to zero in the calculations derived from MLE.

Note that Model **6C** is "fully connected", allowing for the possibility that, for instance, the CNS will reconstruct and compare kinesthetic signals in a visual reference frame even though both target and hand may be visible. This means that there may be multiple comparisons of the target and hand within any one reference frame due to the reconstruction from more than one other reference frames. Nevertheless, given the noise inherent to the reconstruction, the application of MLE will favor the comparison of the directly sensed visual signals within the each reference frame, when such direct information is available. Indeed, some components may drop out of the equation because MLE gives them a weight of zero, as we will see in the following.

6. EXTRINSIC REFERENCE FRAMES

In the examples given above we have focused mainly on intrinsic reference frames native to the sensory modalities used to localize the target and the hand. This is due in part to the fact that the most widely documented studies of sensor fusion for eye-hand coordination, including those cited above, have considered two main reference frames: retinal for visual information and body centered for kinesthetic (a.k.a. proprioceptive) information. Depending on the task, however, other non-native reference frames are almost certainly of interest. For instance, ample evidence exists for the encoding of limb movements (Soechting and Ross, 1984; Darling and Gilchrist, 1991; Borghese et al., 1996; Luyat et al., 2001; Darling et al., 2008) or visual stimuli (Asch and Witkin, 1948b; Luyat and Gentaz, 2002) in a gravitational reference frames, as well as the encoding of information with respect to visual landmarks (Asch and Witkin, 1948a). In the following we examine the question of whether or not to make use of extrinsic reference frames in the context of each of the three models shown in **Figure 6**.

The convergent model of **Figure 6A** can accommodate the recoding of a sensorimotor task by realizing a change in the common reference frame r. Thus, the CNS may choose to combine sensory inputs in one possible reference frame or another, depending on the task conditions. Nothing in Equation (30), however, says anything about how r is chosen. Additional rules, not specified in Equation (30), would have to be found to resolve this outstanding question. As such, Model **6A** is incomplete. Models **6B,C** provide more elegant solutions to this question. An astute reader will have noticed the distinction between the lowercase n and m in Equations (31 and 32), representing the number of sensory inputs, from the uppercase N indicating the number of reference frames in which the comparison of target and hand is performed. These numbers could all be the same, but the two formulations allow for the use of additional reference frames not directly linked to a sensory input as well. According to these equations, each sensory input may be reconstructed in additional, non-native reference frames. Candidates include other, derived egocentric references such as the head or the shoulder or with respect to external references such as gravity or visual landmarks.

From the perspective of minimizing variability, however, recoding of sensory information in a non-native reference frame would not necessarily be advantageous, because the transformation of the information from a native to a non-native reference introduces additional noise. For instance, the variability of a visual target encoded with respect to gravity will include the variability of both retinal signals and of graviceptors. Moreover, all the variance of the target-hand comparison in the retinal reference frame will be included in the comparison encoded in the external reference frame. According to the analysis presented in section 3 the weight given to the external representation would drop to zero. One might therefore surmise that the recoding of spatial information in non-native reference frames will be avoided, when possible, in deference to direct comparisons of sensory information within the intrinsic reference frame of the different neural receptors. As we will show in the following examples, however, the native sensory representations may be affected by additional sources of noise, depending on the circumstances. The principle

of maximum likelyhood coupled with the concurrent structures of Models **7B,C**, can then predict which of the *N* reference frames, intrinsic or extrinsic, come into play in any given situation.

6.1. EXTERNAL REFERENCE FRAMES

Figure 7 shows an example of how the concurrent models may be applied to the question of whether or not to make use of an external reference frame for a given task. The model predicts that if the target and the hand can be sensed through the same modality and no movement of the sensor occurs between target memorization and response (**Figure 7A**), the brain should privilege a direct egocentric encoding of the movement. Since the transformation into the alternative reference frame would add noise, maximum likelihood will give the most weight to the direct comparison. This effect is amplified if one considers the co-variation between direct and reconstructed signals. Because a comparison performed in any other reconstructed reference frame would co-vary precisely with the inputs to the direct comparison, performing these additional encodings would not reduce the variability of the movement at all. On the other hand, if a movement occurs after the target is stored in memory (**Figure 7B**), an egocentric memory of the target would need to be updated to account for the sensor displacement (Droulez and Berthoz, 1992; Duhamel et al., 1992; Medendorp et al., 2008). In this situation, reconstructing additional, external encodings of the movement becomes advantageous, because the noise added by the updating of the intrinsic representation becomes comparable to the noise added when reconstructing in an external reference frame. This is especially true when the noise in the information used to update the egocentric representation of the target and the noise in the signals used as external references are independent.

The parallel structures of Models **6B,C** are interesting because they provide a theoretical basis for using a combination of intrinsic and extrinsic reference frames, which appears to well correspond to behavioral (Burgess et al., 2004; Vidal et al., 2004; Burgess, 2006; Byrne et al., 2010) and physiological (Dean and Platt, 2006; Zaehle et al., 2007) evidence. Indeed, in a task of reaching with the outstretched hand for a visual or kinesthetic target, with visual or kinesthetic feedback about the response, or both, we were unable to reconcile empirical data with a computational model that relied on intrinsic reference frames alone (Tagliabue and McIntyre, 2012). We surmised that due to the movement of the head in our experiment, subjects encoded the task in external reference frames as well. Psychophysical studies have also shown that subjects tend to use egocentric representations if they remain stable after memorization, but they combine egocentric and external representations if their body moves (Burgess et al., 2004; Burgess, 2006). Similarly, during reaching to visual targets, external visual landmarks appear to be neglected if the hand visual feedback is reliable; whilst they are integrated to build an allocentric representation of the movement if the hand visual feedback was absent or unpredictable (Obhi and Goodale, 2005; Neely et al., 2008).

6.2. MEMORY

The need to store target information in memory for some time before the movement occurs can also motivate the transformation of sensory information into a non-native reference frame. In eye-hand tasks with imposed memory delays, the variability of responses tends to increase with the length of the delay (McIntyre et al., 1997, 1998). Thus, the simple act of storing spatial information in memory adds noise. According to the hypothesis related in section 4, the target location will be stored in memory simultaneously in more than one reference frame. Assuming that each representation of the remembered target position will degrade independently (i.e., each will accumulate noise that is stochastically independent from the other), it becomes more and more interesting, a maximum likelihood perspective, to make use of the non-native representations, despite the added cost of reconstructing those representations in the first place. This reasoning is supported by a study in which subjects were asked to point to targets located along a straight line in 3D space (Carrozzo et al., 2002). As the memory delay increased, patterns of variability of the pointing position were more-and-more constrained

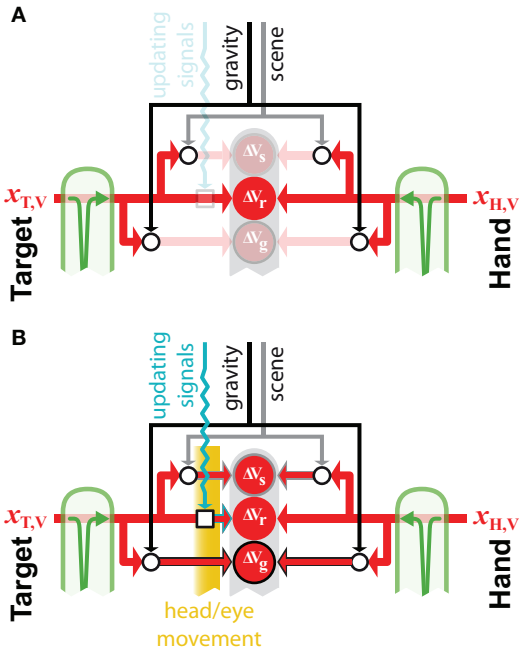

FIGURE 7 | External reference frames. Example of how external sources of information, such as gravity and the visual scene, can be combined to build external encodings of initially retino-centric signal about the target, $x_{T,V}$ and the hand, $x_{H,V}$. Open circular and square nodes represent the recoding of information with respect to an external reference (circles) or the updating of egocentric information to account for movements of the body. All other symbols for inputs and transformations are as defined in previous figures. **(A)** If no movement occurs after the memorization of the retinal information about the target, its direct comparison with the retinal signal about the hand is possible, therefore encoding these signal with respect to the external gravitational and scene references would not reduce movement variability. **(B)** If the head moves in space, or if the eye moves within its orbit, a direct comparison between retinal signals about the target and hand is not possible, because the retinal information about the target must be updated to take into account the sensor movement. In this case, encoding the initially retino-centric signals with respect to the gravity and visual scene become advantageous, because the egocentric and the external encodings become partially uncorrelated.

by the extrinsic reference provided by the direction of the line in 3D space. This can be interpreted as a shift in weighting between egocentric and allocentric reference frames, even when the body does not move. By simply substituting "memory processes" for "head/eye movement", however, **Figure 7** can be used to understand why the CNS may rely more on the encoding of a task in a external reference frame when memory processes are involved.

7. DISCUSSION

In this paper we have described three analytical models (see **Figure 6**) that share a number of defining features. One of these, the idea that the CNS can express spatial information in multiple reference frames while transforming information between them, is a common theme that is supported by numerous theoretical and experimental studies. To cite a few examples, Droulez and Cornilleau-Peres (1993) proposed a distributed model of "coherence constraint" by which spatial information may be encoded in reference frames intrinsic to each sensor and they described a computational structure by which information from one sensor can be reconstructed based on redundant information from other sensors when the primary source is not available. Bock (1986) identified a phenomenon of bias when pointing to targets that lie at a location peripheral to the center of gaze. This phenomenon has been used in a number of studies to argue that whether pointing to visual, auditory or even proprioceptive targets, the CNS carries out the task in retinotopic coordinates (Enright, 1995; Henriques et al., 1998; Pouget et al., 2002b). These observations can be linked to neural properties through models that solve the problem of recoding information in different reference frames by using basis functions and attractor dynamics (Pouget et al., 2002a) or restricted Boltzmann machines (Makin et al., 2013).

The premise that the CNS combines sensory information based on relative variance has also found considerable experimental support: van Beers et al. (1996) showed that the precision of pointing movements increased when the subject could use both visual and kinesthetic feedback signals, compared to when only one sensory feedback modality was available. They also showed that the relative weight given to the two sensory signals depended on their relative variability (van Beers et al., 1999). Ernst and Banks (2002) varied experimentally the noise in the sensory signals available to subjects when they grasped a virtual object that provided both visual and haptic cues about size. Using verbal judgments, they showed how the overall perceptual response shifted toward the haptic information when the precision of the visual inputs was degraded. Smeets et al. (2006) assumed that the CNS maintains both a visual and a kinesthetic representation of targeted movements. When vision of the hand was allowed, this sensory modality dominated due to its higher precision. But when vision of the hand was occluded and subjects were asked to make consecutive movements, the authors observed a gradual shift toward a reliance on proprioceptive information, as indicated by gradual drift in the direction of biases that are specifically associated with this modality. They attributed this shift to a re-weighting toward proprioceptive information as the visual representation of the occluded hand degrades over the course of sequential movements.

These themes of transformations and maximum likelihood come together when one considers the noise added when converting sensory information from one reference frame to another. As alluded to in section 2.1, the added noise inherent to sensory information that is reconstructed from other sources will cause a shift toward the alternative, directly sensed information. This principle has given rise to other empirical manifestations: Sober and Sabes (2003, 2005) postulated that the CNS combines visual and proprioceptive information at two different stages in the planning of targeted hand movements. First, the movement vector is calculated in visual space as the difference between the position of the visual target and the initial position of the hand. Kinesthetic information about the hand's position is also used at this stage, but because it must be transformed into visual space, it is given much less weight, in accord with MLE. At a second stage, the visual movement vector is converted into a motor vector, based primarily on proprioceptive information, but also accommodating a weaker influence of visual information about the target, hand and limb configuration transformed into motor coordinates. Burns and Blohm (2010), using the same model structure as Sober and Sabes, observed a reduction of the weight given to proprioceptive information in the calculation of the movement vector during planning when the head was tilted in a V-VK task. They attributed the shift to the fact that (a) the movement vector was calculated in visual space, requiring that the proprioceptive information about hand position be transformed in order to be useful and (b) tilting the head with respect to gravity increases the noise added by manual-to-visual transformations, thus further decreasing the weight given to the reconstructed signals. Tagliabue et al. (2013) examined the effects of head tilt on the weighting of sensory information. In a V-K task (**Figure 4**), if the head was tilted during target acquisition, but not the motor response, the CNS gave greater weight to the visual representation, presumably because transforming the visual target into kinesthetic space with the head tilted would be much noisier than transforming kinesthetic information about the hand into visual space with the head upright. Conversely, if the head was held upright when the target was acquired, but the head was tilted during the motor response, then the task was carried out in kinesthetic space so as to avoid the kinesthetic-to-visual transformation that would have to occur while the head was tilted.

Although the three computational models of **Figure 6** share a number of features, as described above, they vary in terms of the level of convergence or parallelism in the processing of sensory information. Model **6A** presents the highest level of convergence, combining all available inputs about the target and all available inputs about the hand before calculating a movement vector based on the two optimal estimates. Model **6A** provides no clue, however, as to what is the common reference frame for any given task, nor how the common reference frame might change from one task to another. Models **6B,C** provide more elegant solutions to this question by allowing the comparison of target and hand to be carried out simultaneously in multiple reference frames. The same rules that determine which sensory inputs will dominate in any given situation (maximization of likelihood) also determine the weight given to the comparison carried out in each of the component reference frames. The computational scheme

depicted in **Figure 6B** combines features of both the convergent model of **Figure 1A** and the concurrent model of **Figure 1B**. Whereas multiple comparisons of target and hand are performed in different reference frames, one can see nevertheless that there is a convergence of multimodal sensory signals about the target and about the hand before these two quantities are compared (subtracted) within each reference frame. In contrast, Model **6C** combines the results of binomial comparisons of a single sensory input about the target (direct or reconstructed in another reference frame) with a single sensory input about the hand (also direct or reconstructed). Model **6C** is the least convergent of the three and as such, lends itself to a modular approach to sensory integration for the coordination of eye and hand.

7.1. MODEL PREDICTIONS

Which of the three models depicted in **Figure 6** best represents human sensorimotor behavior and the underlying neurophysiology? The three computational structures that we have compared here can be distinguished on theoretical grounds and the differences between them lead to testable hypotheses, both at the behavioral level and in terms of the neural implementation as measured by electrophysiological or other methods.

7.1.1. Fully convergent vs. concurrent

The question as to whether sensory signals are combined in a unique reference frame that is defined *a priori* (i.e., in line with **Figure 6A**) prior to performing the comparison between hand and target has received considerable attention in recent years and can, perhaps, already be rejected. From a Bayesian perspective, it can be argued that it is advantageous to maintain multiple representations of movement parameters, expressed in diverse reference frames, in order to optimize motor performance. Electrophysiological evidence also supports the notion that motor planning and execution is carried out in multiple reference frames in parallel, both across different regions of the brain and within a single cortical area (Buneo et al., 2002; Beurze et al., 2010; Buchholz et al., 2013; Maule et al., 2013; Reichenbach et al., 2014). At the behavioral level, the fully convergent model depicted in **Figure 6A** cannot predict certain experimentally observed characteristics of movement planning and execution. As explained in the earliest sections of this article (2–2.1), such a computational model cannot explain why sensory information about the hand is weighted differently between K-VK and V-VK tasks, nor would Model **6A** be able to predict why the CNS would reconstruct a visual representation of kinesthetic pointing task when the task is bilateral, but not when it is unilateral (Tagliabue and McIntyre, 2013). Moreover, the combination of parallel comparisons in a variety of coordinate systems gives meaning to the concept of a *hybrid* reference frame (Carrozzo and Lacquaniti, 1994). Rather than considering that the task is executed in some abstract reference frame that has little or no physical meaning, one can instead understand that the characteristics of a so-called hybrid reference frame may in fact be the manifestation of a parallel, weighted combination of individual target-hand comparisons carried out in reference frames tied to identifiable objects or sensors.

Studies that have explicitly considered sensor fusion in the case of reaching or pointing tasks have often assumed, implicitly or explicitly, the fully convergent computational structure depicted in **Figure 1A**. One such example is the work carried out by van Beers et al. (1996, 1999) who postulated that a minimization of motor variability could be the driving factor behind the choice of one motor plan over another. They explicitly refer to a convergent maximum likelihood model structure along the lines of Equation (1). The work by Smeets et al. (2006) included the assumption that the CNS maintains both a visual and a proprioceptive representation of the hand and of the target, but did not include any explicit consideration of the transformation of visual information into proprioceptive space or vice versa. Furthermore, the equations that the authors used to make the model predictions in that study would appear to adhere to the computational structure evoked by the convergent model described by Equation (1). Nevertheless, the structure of concurrent comparisons described by Equation (2) can also accommodate both of these studies, without contradiction. Thus, even though Equation (1) has been used on occasion to explain the results of a number of studies, the ability of Equation (2) to explain those studies, and to also explain the effects of target modality that cannot be explained by Equation (1) means that Equation (2) provides a more parsimonious explanation of human sensorimotor behavior.

7.1.2. Hybrid concurrent/convergent vs. fully concurrent

Experiments testing the two concurrent hypotheses (**Figures 6B,C**) have been performed by various groups and reported in the literature. We believe that the hybrid formulation of Equation (31) is representative of the model proposed by McGuire and Sabes (2009). These authors used a more sophisticated Bayesian analysis to formulate their hypothesis, but as they point out, the convolutions required to represent a coordinate transformation in Bayesian notation are simply additions or subtractions and if there is no prior to be taken into account, the posterior is proportional to the likelihood. This model has been used to interpret a number of empirical results (McGuire and Sabes, 2009, 2011; Burns and Blohm, 2010). In our own studies and publications, we have implicitly used the computational structure of Equation (32) to interpret the results of a series of experiments on multi sensory integration (Tagliabue and McIntyre, 2008, 2011, 2012, 2013; Tagliabue et al., 2013). But whereas both models have been used with success to explain a wide range of empirical results, the differentiation between the hybrid concurrent/convergent formulation of **Figure 6B** and the fully concurrent formulation in **Figure 6C** has not, to our knowledge, been explicitly taken up in the literature. Yet it should be possible to distinguish between the two mechanisms, both in terms of potential theoretical advantages of one computational scheme over the other and in terms of empirical results, as we will discuss below.

One key difference between **Figures 6B,C** is that of when the difference between target and hand is actually computed. In a linear system, this distinction is not very important, since Model **6B** can be rearranged algebraically to match Model **6C**, and vice versa. But evidence suggests that the combination of sensory

signals occurs in a non-linear fashion, in part as a means to deal with sensory signals that may or may not come from the same stimulus or event (Roach et al., 2006; Knill, 2007; Hospedales and Vijayakumar, 2009). If sensory signals are separated in distance or in time, the Bayesian optimal may be to rely fully on one signal or the other, rather than an weighted sum of the two. A corollary of these non-linear processes is that as two redundant signal become more separated, the combined estimate may become noisier (Wallace et al., 2004). Model **6C** has an advantage over **6B** in this respect. By combining sensory signals only after computing the movement vector, disparity between reference frames will drop out, provided that the disparity is the same for the target and for the hand. One might therefore test this hypothesis by artificially modulating the disparity between reference frames. The prediction of Model **6C** is that such an operation will not affect motor precision.

The question of how the CNS takes into account covariance between signals could also provide the basis for favoring one model over the other. In Model **6B**, the combination of visual and kinesthetic information about the target are combined by using a "local" optimality criterion, that is by taking into account the variability of the signal to be combined (including the necessary cross-modal transformations), but neglecting how the resulting optimal estimation will be used in later stages. In particular, this local optimal weighting of the target information neglects the consequences of any covariance that may be generated between the two concurrent comparisons ΔV and ΔK. The very same considerations are valid, of course, for the hand information. It follows that the brain could tend to over-estimate the benefit of weighting a given signal, because, although it would "locally" provide a more precise estimation of the target and of the hand positions, "globally" it would increase the covariance between ΔV and ΔK, and if not corrected, will increase the variance of the final output. In other words, generating optimal estimates of target and hand does not necessarily lead to optimal targeted hand movements. Model **6C**, on the other hand, is based on the combination of pairwise comparisons of target and hand, with maximum likelihood being applied to minimize the variability of the combination of multiple movement vectors. Through this more modular approach, it is potentially easier to identify and adjust for co-variation between movement vectors.

An example of this is shown in **Figure 8**, in the case of a V-VK task. The hybrid model predicts that both visual and kinesthetic information about the hand will be used to construct representations of the hand in each of the two reference frames (**Figure 8A**). Due to the inter-modal transformations, the comparison carried out in kinesthetic space will be correlated with the comparison carried out in visual space. The optimal combination of ΔV and ΔK will need to be modified to take into account the resulting co-variation. Model **6C** applied in this situation instead predicts that comparison of the visual target position, reconstructed in kinesthetic space, with the representation of the hand, reconstructed from visual information, will simply drop out, due to the co-variance with the direct comparison of target and hand in visual space (**Figure 8B**). One might therefore ask the question, will the CNS, like Penelope waiting for Ulysses with her weaving (Homer, VIII century BC), perform cross-modal reconstructions, only to undo their effects at a later stage (**Figure 8A**)? Or, by maintaining a more modular approach, can the CNS more efficiently achieve the optimal solution by performing only those transformations and comparisons that are beneficial in any given situation (**Figure 8B**)?

Of course the ultimate test of the hypotheses presented here would be to find correlates of models **6B** or **6C** in electrophysiological studies of neuronal activity. Model **6B** predicts that one should find neurons that respond to multiple sensory inputs about the target and similar neurons encoding information about the hand. Model **6C** makes a novel prediction that certain cells will be sensitive to inputs about the target in one (and only one) sensory modality but that the spatial information will be expressed in the coordinate frame of another. For example, Model **6C** predicts the existence of a cell that encodes the movement vector in visual space, even though the cell may be sensitive to modulation of proprioceptive, but not visual, signals. This would not be the case for Model **6B**, where sensory signals from each available sensory modality are expected to converge prior to the computation of the movement vector.

8. CONCLUSIONS

In this article we have formulated computational models that rely on multiple concurrent computations carried out in multiple reference frames in order to optimally drive the hand to a target. We have compared these concurrent models to the more conventional viewpoint that presupposes the use of a single, common reference frame for combining multi-sensory information. The concurrent models are attractive because of their modular structure and because they better explain a variety of empirical studies. Moreover, they place the question of how to combine sensory information and how to choose the reference

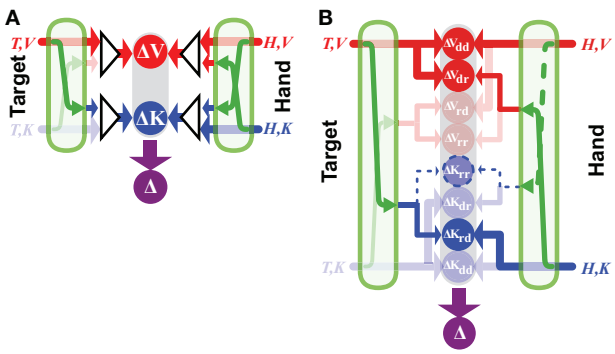

FIGURE 8 | Hybrid convergent/concurrent versus full concurrent. Information flow predicted by the hybrid convergent/concurrent **(A)** and fully-concurrent **(B)** models for a V-VK condition in which the target can be sensed only visually, but the subject has both visual and kinesthetic information about the hand. Missing sources of information are represented by faded colors. Dashed lines represent sensory transformations and comparisons that can be neglected without a decrease in motor performance, given the extent to which the noise in these calculations correlates with the other comparisons. The fully-concurrent model, but not the Hybrid model, predicts that in the V-VK condition the reconstruction of the kinesthetic representation of the hand from visual feedback can be avoided.

frame(s) for any given task into a common theoretical framework, that of maximum likelihood estimation. They also make specific, testable predictions about the sensory transformations that are performed and the representations of target and hand that are maintained in working memory during the performance of sensorimotor tasks. In the spirit of this special issue on modularity in motor control, we therefore propose that the CNS performs multisensory integration in a highly modular fashion, building up the required motor commands for targeted movements from a principled combination of elementary target-hand comparisons.

A promising idea for scaling robot learning to more complex tasks is to use elemental behaviors as building blocks to compose more complex behavior. Ideally, such building blocks are used in combination with a learning algorithm that is able to learn to select, adapt, sequence and co-activate the building blocks. While there has been a lot of work on approaches that support one of these requirements, no learning algorithm exists that unifies all these properties in one framework. In this paper we present our work on a unified approach for learning such a modular control architecture. We introduce new policy search algorithms that are based on information-theoretic principles and are able to learn to select, adapt and sequence the building blocks. Furthermore, we developed a new representation for the individual building block that supports co-activation and principled ways for adapting the movement. Finally, we summarize our experiments for learning modular control architectures in simulation and with real robots.

Keywords: robotics, policy search, modularity, movement primitives, motor control, hierarchical reinforcement learning

1. INTRODUCTION

Robot learning approaches such as policy search methods (Kober and Peters, 2010; Kormushev et al., 2010; Theodorou et al., 2010) have been very successful. Kormushev et al. (2010) Learned to flip pan-cakes and Kober and Peters (2010) Learned the game ball-in-the-cup. Despite these impressive applications, robot learning still offers many challenges due to the inherent high-dimensional continuous state and action spaces, the high costs of generating new data with the real robot, the partial observability of the environment and the risk of damaging the robot due to overly aggressive exploration strategies. These challenges have, so far, prevented robot learning methods to scale to more complex real world tasks.

However, many motor tasks are heavily structured. Exploiting such structures may well be the key to scale robot learning to more complex real world domains. One of the most common structures of a motor task is modularity. Many motor tasks can be decomposed into elemental movements or movement primitives (Schaal et al., 2003; Khansari-Zadeh and Billard, 2011; Rozo et al., 2013) that are used as building blocks in a modular control architecture. For example, playing tennis can be decomposed into single stroke-based movements, such as a forehand and a backhand stroke. To this end, we need a learning architecture that learns to select, improve, adapt, sequence and co-activate the elemental building blocks. Adaptation is needed as such building blocks are only useful if they can be reused for a wide range of situations, and, hence the building block needs to be adapted to the current situation. For example, for playing tennis, the ball will always approach the player slightly differently. Furthermore, we need to learn how to sequence such parametrized building blocks. Taking up our tennis example, we need to execute a sequence of strokes such that the opponent player can not return the ball on the long run. For sequencing the building blocks, we ideally want to be able to continuously switch from one building block to the next to avoid abrupt transitions, also called "blending" of building blocks. Finally, co-activation of the building blocks would considerably increase the expressibility of the control architecture. Coming back to the tennis example, co-activating primitives that are responsible for the upper body movement, i.e., the stroke, and primitives that are responsible for the movement of the lower body, i.e., making a side step or a forward step would significantly reduce the number of required building blocks.

In this paper we present an overview over our work that concentrates on learning such modular control architectures by reinforcement learning. We developed new policy search methods that can select and adapt the individual building blocks to the current situation, learn and improve a large number of different building blocks as well as to learn how to sequence building blocks to solve a complex task. Our learning architecture is based on an information-theoretic policy search algorithm called Relative Entropy Policy Search (REPS) proposed by Peters et al. (2010). The main insight used by REPS is that the relative entropy between the trajectory distributions of two subsequent policies during policy search should be bounded. This bound is particularly useful in robotics as it can cope with many of the mentioned challenges of robot learning. It decreases the danger of damaging the robot as the policy updates stay close to the "data" generated by the old policy and do not perform wild exploration. Moreover, it results in a smooth learning process and prevents the algorithm from getting stuck prematurely in local minima even for high dimensional parameter spaces that are typically used in robotics (Peters and Schaal, 2008; Daniel et al., 2012a). While there are several other policy search approaches which can either learn the selection (da Silva et al., 2012), adaptation (Kober et al.,

2010b; Ude et al., 2010) or the sequencing (Stulp and Schaal, 2011) of individual building blocks, to the best of our knowledge, our approach offers the first framework that unifies all these properties in a principled way.

A common way to implement the building blocks is to use movement primitives (MPs). Movement primitives provide a compact representation of elemental movements by either parameterizing the trajectory (Schaal et al., 2003; Neumann, 2011; Rozo et al., 2013), muscle activation profiles (dAvella and Pai, 2010) or directly the control policy (Khansari-Zadeh and Billard, 2011). All of these representations offer several advantages, such as the ability to learn the MP from demonstration (Schaal et al., 2003; Rozo et al., 2013), global stability properties (Schaal et al., 2003), co-activation of multiple primitives (dAvella and Pai, 2010), or adaptability of the representation per hyper-parameter tuning (Schaal et al., 2003; Rozo et al., 2013). However, none of these approaches unifies all the desirable properties of a MP in one framework. We therefore introduced a new MP representation that is particularly well suited to be used in a modular control architecture. Our MP representation is based on distributions over trajectories and is called Probabilistic Movement Primitive (ProMP). It can, therefore, represent the variance profile of the resulting trajectories, which allows us to encode the importance of time points as well as represent optimal behavior in stochastic systems (Todorov and Jordan, 2002). However, the most important benefit of a probabilistic representation is that we can perform probabilistic operators on trajectory distributions, i.e., conditioning for adaptation of the MP and a product of distributions for co-activation and blending of MPs. Yet, such a probabilistic representation is of little use if we cannot use it to control the robot. Therefore, we showed that a stochastic time-varying feedback controller can be obtained analytically, enabling us to use the probabilistic movement primitive approach as a promising future representation of a building block in modular control architectures. We will present experiments on several real robot tasks such as playing tether-ball and shooting a hockey puck. The robots used for the experiments are illustrated in **Figure 1**.

1.1. RELATED WORK

1.1.1. Movement representations

Different elemental movement representations have been proposed in the literature. The most prominent one is the dynamic movement primitive (DMP) approach (Ijspeert and Schaal, 2003; Schaal et al., 2003). DMPs encode a movement in a parametrized dynamical system. The dynamical system is implemented as a second order spring damper system which is perturbed by a non-linear forcing function f. The forcing function depends non-linearly on the phase variable z_t which denotes a clock for the movement. The evolution of the phase variable can be made faster or slower by the temporal scaling factor τ, which finally also changes the execution speed of the movement. The forcing function is linearly parametrized by a parameter vector $\mathbf{w}$ and can be easily learned from demonstrations. In addition to the high dimensional parameters $\mathbf{w}$, we can adjust meta-parameters of the DMPs such as the goal attractor $\mathbf{g}$ of the spring-damper system and temporal scaling factor. In Kober et al. (2010a), the DMPs have been extended to include the final desired velocity in its meta-parameters. DMPs have several advantages. They are easy to learn from demonstrations and by reinforcement learning, they can be used for rhythmic and stroke-based movements and they have build-in stability guarantees. However, they also suffer from some disadvantages. The can not represent optimal behavior in a stochastic environment. In addition, the generalization to a new end position is based on heuristics and not learned from demonstrations and it is not clear how DMPs can be combined simultaneously. Several other movement primitive representation have been proposed in the literature. Some of them are based on DMPs to overcome their limitations (Calinon et al., 2007; Rozo et al., 2013), but none of them can overcome all the limitations in one framework. Rozo et al. (2013) estimate a time varying feedback controller for the DMPs, however, how this feedback controller is obtained is based on heuristics. They also implement a combination of primitives as a product of GMMs which is similar to the work presented here on the probabilistic movement primitives. However, this approach is lacking a principled way of determining a feedback controller that exactly matches the trajectory distribution. Therefore, it is not clear what the result of this product is if we apply the resulting controller on the robot.

Most of the movement representations explicitly depend on time (Ijspeert and Schaal, 2003; Neumann and Peters, 2009; Paraschos et al., 2013; Rozo et al., 2013). For time-dependent representations, a linear controller is often sufficient to model complex behavior as the non-linearity is induced by the time dependency. In contrast, time-independent models such as the Stable Estimator of Dynamical Systems (SEDS) approach (Khansari-Zadeh and Billard, 2011) directly estimate a state dependent policy that is independent of time. Such models require more complex, non-linear controllers. For example, the SEDS approach uses a GMM to model the policy. The GMM is estimated such that the resulting policy is proofed to be stable. Due to the simplicity of the policy, time-dependent representations can be easily scaled up to higher dimensions as shown by Ijspeert and Schaal (2003). Due to the increased complexity, time-independent models are typically used for lower dimensional movements such as modeling the movement directly in task space. Yet, a time-independent model is the more general representation as it does not require the knowledge of the current time step. In this paper, we will nevertheless concentrate on time-dependent movement representations.

1.1.2. Policy search

The most common reinforcement learning approach to learn the parameters of an elemental movement representation such as a

DMP is policy search (Williams, 1992; Peters and Schaal, 2008; Kober and Peters, 2010; Kober et al., 2010a). The goal of policy search is to find a parameter vector of the policy such that the resulting policy optimizes the expected long-term reward. Many policy search methods use a stochastic policy for exploration. They can be coarsely categorized according their policy update strategy. Policy gradient methods (Williams, 1992; Peters et al., 2003) are one of the earliest policy update strategies that were applied to motor primitive representations. They estimate the gradient of the expected long-term reward with respect to the policy parameters (Williams, 1992) and update the policy parameters in the direction of this gradient. The main disadvantages of policy gradient methods are the necessity to specify a hand-tuned learning rate, the poor learning speed and that typically many samples are required to obtain a new policy without sample re-use.

More recent approaches rely on probabilistic methods. These methods typically base their derivation on the expectation-maximization algorithm (Vlassis et al., 2009; Kober and Peters, 2010) and formulate the policy search problem as inference problem by transforming the reward into an improper probability distribution, i.e., the transformed reward is required to be always positive. Such transformation is typically achieved by an exponential transformation with a hand-tuned temperature. The resulting policy update can be formulated as a weighted model fitting task where each sample is weighted by the transformed long-term rewards (Kober and Peters, 2010). Using a probabilistic model fitting approach to compute the policy update results in the important advantage that we can use a big toolbox of algorithms for estimating structured probabilistic models, such as the expectation maximization algorithm (Dempster et al., 1977) or variational inference (Neal and Hinton, 1998). Additionally, it does not require a user specified learning rate. These approaches typically directly explore in the parameter space of the policy by estimating a distribution over the policy parameters. Such approach works well if we have a moderate number of parameters.

Another algorithm that has recently gained a lot of attention is the policy improvement by path integrals (PI^2) algorithm (Theodorou et al., 2010; Stulp and Sigaud, 2012). The path integral theory allows to compute the globally optimal trajectory distribution along with the optimal controls without requiring a value function as opposed to traditional dynamic programming approaches. However, the current algorithm is limited to learning open-loop policies (Theodorou et al., 2010; Stulp and Sigaud, 2012) and may not be able to adapt the the variance of the exploration policy (Theodorou et al., 2010).

1.1.3. Generalization of skills

An important requirement in a modular control architecture is that we can adapt a building block to the current situation or task. We will describe a task or a situation with a context vector **s**. The context vector can contain the objectives of the agent, e.g., throwing a ball to a desired target location, or physical properties of the environment. e.g., the mass of the ball to throw. Ude et al. (2010) use supervised learning to generalize movement primitives from a set of demonstrations. Such approach is well suited to generalize a set of demonstrations to new situations, but can not be used to improve the skills upon the demonstration. To alleviate this limitation, da Silva et al. (2012) combines low-dimensional subspace extraction for generalization and policy search methods for policy improvement. Finding such low-dimensional sub-spaces is an interesting idea that can considerably improve the generalization of the skills. Yet, there is one important limitation of the approach presented in da Silva et al. (2012). The algorithms for policy improvement and skill generalization work almost independently from from each other. The only way they interact is that the generalization is used as initialization for the policy search algorithm when a new task needs to be learned. As a consequence, the method needs to create many roll-outs for the same task/context in order to improve the skill for this context. Such limitation is relaxed by contextual policy search methods (Kober et al., 2010b; Neumann, 2011). Contextual policy search methods explicitly learn a policy that choses the control parameters $\boldsymbol{\theta}$ in accordance to the context vector **s**. Therefore, a different context can be used for each roll-out. Kober et al. (2010b) us a Gaussian Process (GP) for generalization. While GPs have good generalization properties, they are of limited use for policy search as they typically learn an uncorrelated exploration policy. The approach in Neumann (2011) can use a directed exploration strategy, but it suffers from high computational demands.

1.1.4. Sequencing of skills

Another requirement is to learn to sequence the building blocks. Standard policy search methods typically choose a single parameter vector per episode. Hence, such methods can be used to learn the parameters of a single building block. In order to sequence building blocks, we have to learn how to choose multiple parameter vectors per episode. The first approach (Neumann and Peters, 2009) for learning to sequence primitives was based on value-function approximation techniques, which restricted its application on a rather small set of parameters for each primitive. Recently, (Stulp and Schaal, 2011) adapted the path integral approach to policy search to sequence movement primitives. Other approaches (Morimoto and Doya, 2001; Ghavamzadeh and Mahadevan, 2003) use hand-specified sub-tasks to learn the sequencing of elemental skills. Such an approach is limited in its flexibility of the resulting policy and the sub-tasks are typically not easy to define manually.

1.1.5. Segmentation and modular imitation learning

Segmentation (Kulic et al., 2009; Álvarez et al., 2010; Meier et al., 2011) and modular imitation learning (Niekum et al., 2012) is a very important and challenging problem to autonomously extract the structure of the modular control policy from demonstrations. In Meier et al. (2011) and Álvarez et al. (2010), the segmentation is done due to parameter changes in the dynamical system that is supposed to have created the motion. In Chiappa and Peters (2010), Bayesian methods are used to construct a library of building blocks. Repeated skills are modeled to be generated by one of the building-blocks, which are rescaled and noisy. Based on the segmentation of the demonstrations, we can infer the single building blocks from the data by clustering the segments. One approach that integrates clustering and segmentation is to use Hidden Markov Models (HMMs). Williams and Storkey (2007) used a HMM to extract movement primitives from hand-writing

data. While this is a very general approach, it has only been used to rather low-dimensional data, i.e., 2-D movements. Niekum et al. (2012) use a beta-process auto regressive HMM to estimate the segmentation which has the advantage the number of building blocks can also be inferred from data. DMPs are used to represent the policy of the single segments. Butterfield et al. (2010) use a HMM to directly estimate the policy. For each hidden state, they fit a Gaussian Process model to represent the policy of this hidden state. The advantages of these imitation learning approaches is that we can also estimate the temporal structure of the modular control policy, i.e., when to switch from one building block to the next. So far, such imitation learning approaches have not been integrated in a reinforcement learning framework, which seems to be a very interesting direction. For example, in current reinforcement learning approaches, the duration of the building blocks is specified by a single parameter. Estimating the duration of the building blocks from the given trajectory data seems to be a fruitful and more general approach.

2. INFORMATION THEORETIC POLICY SEARCH FOR LEARNING MODULAR CONTROL POLICIES

In this section we will sequentially introduce our information theoretic policy search framework used for learning modular control policies. We start our discussion with the adaptation of a single building block. Subsequently, we discuss how to learn to select a building block and, finally, we will discuss sequencing of building blocks.

After introducing each component of our framework, we briefly discuss related experiments on real robots and in simulation. In this paper, we can only give a brief overview over the experiments. For more details, we refer to the corresponding papers. In our experiments with our information theoretic policy search framework, we used Dynamic Movement Primitives (DMP) introduced in Schaal et al. (2003) as building blocks in our modular control architecture. In all our experiments, we used the hyper-parameters of a DMP as parameters of the building blocks, such as the final positions and velocities of the joints (Kober et al., 2010a) as well as the temporal scaling factor of the DMPs for changing the execution speed of the movement.

2.1. LEARNING TO ADAPT THE INDIVIDUAL BUILDING BLOCKS

We formulate the learning of the adaptation of the building blocks as contextual policy search problem (Kober et al., 2010b; Neumann, 2011; Daniel et al., 2012a), where we will for now assume that we want to execute only a single building block. Adaptation of a building block is implemented by an upper-level policy $\pi(\boldsymbol{\theta}|\mathbf{s})$ that chooses the parameter vector $\boldsymbol{\theta}$ of the building block according to the current context vector $\mathbf{s}$. The context describes the task. It might contain objectives of the agent or properties of the environment, for example, the incoming velocity of a tennis ball. After choosing the parameters $\boldsymbol{\theta}$, the lower level policy $\mathbf{u}_t = f(\mathbf{x}_t, \boldsymbol{\theta})$ of the building block takes over and is used to control the robot. Note that we use the symbol $\mathbf{x}_t$ to denote the state of the robot. The state $\mathbf{x}_t$ typically contains the joint angles $\mathbf{q}_t$ and joint velocities $\dot{\mathbf{q}}_t$ of the robot and it should not be confused with the context vector $\mathbf{s}$. The context vector $\mathbf{s}$ describes the task and contains higher level objectives of the agent. For example, such a lower level policy can be defined by a trajectory tracking controller that tracks the desired trajectory of a dynamic movement primitive (DMP) (Schaal et al., 2003).

Our aim is to learn an upper-level policy that maximizes the expected reward

$$J_\pi = \iint \mu(\mathbf{s})\pi(\boldsymbol{\theta}|\mathbf{s})R(\mathbf{s},\boldsymbol{\theta})d\mathbf{s}d\boldsymbol{\theta},$$
$$R(\mathbf{s},\boldsymbol{\theta}) = \int p(\tau|\mathbf{s},\boldsymbol{\theta})r(\tau,\mathbf{s})d\tau, \quad (1)$$

where $R(\mathbf{s},\boldsymbol{\theta})$ is the expected reward of the resulting trajectory τ when using parameters $\boldsymbol{\theta}$ in context $\mathbf{s}$ and $\mu(\mathbf{s})$ denotes the distribution over the contexts that is specified by the learning problem. The distribution $p(\tau|\mathbf{s},\boldsymbol{\theta})$ denotes the probability of a trajectory given $\mathbf{s}$ and $\boldsymbol{\theta}$ and $r(\tau,\mathbf{s})$ a user-specified reward function that depends on the trajectory τ and on the context $\mathbf{s}$. We use the Relative Entropy Policy Search (REPS) algorithm (Peters et al., 2010) as underlying policy search method, The basic idea of REPS is to bound the relative entropy between the old and the new parameter distribution. Here, we will consider the episode-based contextual formulation of REPS (Daniel et al., 2012a; Kupcsik et al., 2013) that is tailored for learning such an upper-level policy. The policy update step is defined as constrained optimization problem where we want to find the distribution $p(\mathbf{s},\boldsymbol{\theta}) = \mu(\mathbf{s})\pi(\boldsymbol{\theta}|\mathbf{s})$ that maximizes the average reward given in Eq. 1 with respect to $p(\mathbf{s},\boldsymbol{\theta})$ and simultaneously satisfies several constraints. We will first discuss these constraints and show how to compute $p(\mathbf{s},\boldsymbol{\theta})$. Subsequently, we will explain how to obtain the upper-level policy $\pi(\boldsymbol{\theta}|\mathbf{s})$ from $p(\mathbf{s},\boldsymbol{\theta})$.

Generally, we initialize any policy search (PS) method with an initial policy $q_0(\mathbf{s},\boldsymbol{\theta}) = \mu(\mathbf{s})q_0(\boldsymbol{\theta}|\mathbf{s})$, either obtained through learning from demonstration or by manually setting a distribution for the parameters. The variance of the initial distribution $q_0(\mathbf{s},\boldsymbol{\theta})$ defines the exploration region. Policy search is an iterative process. Given the sampling distribution $q_0(\mathbf{s},\boldsymbol{\theta})$, we obtain a new distribution $p_1(\mathbf{s},\boldsymbol{\theta})$. Subsequently, p_1 is used as new sampling policy q_1 and the process is repeated.

PS methods need to find a trade-off between keeping the initial exploration and constricting the policy to a (typically local) optimum. In REPS, this trade-off is realized via the Kullback-Leibler (KL) divergence. REPS maximizes the reward under the constraint that the KL-divergence to the old exploration policy is bounded, i.e.,

$$\epsilon \geq \mathrm{KL}\left(p(\mathbf{s},\boldsymbol{\theta})||q(\mathbf{s},\boldsymbol{\theta})\right). \quad (2)$$

Due to this bound, we can choose between exploitation with the greedy policy (high KL-bound) or continue to explore with the old exploration policy (very small KL-bound). The KL divergence in REPS bounds not only the conditional probability $\pi(\boldsymbol{\theta}|\mathbf{s})$, i.e., the differences in the policies, but also the joint state-action probabilities $p(\mathbf{s},\boldsymbol{\theta})$ to ensures that the observed state-action region does not change rapidly over iterations, which is paramount to a real robot learning algorithm. Using the (asymmetric) KL divergence $\mathrm{KL}\left(p(\mathbf{s},\boldsymbol{\theta})||q(\mathbf{s},\boldsymbol{\theta})\right)$ allows us to find a closed form solution of the algorithm. Such closed form would not be possible with the opposite KL divergence, i.e., $\mathrm{KL}\left(q(\mathbf{s},\boldsymbol{\theta})||p(\mathbf{s},\boldsymbol{\theta})\right)$.

We also have to consider that the context distribution $p(\mathbf{s}) = \int p(\mathbf{s}, \boldsymbol{\theta}) d\boldsymbol{\theta}$ cannot be freely chosen by the agent as it is specified by the learning problem and given by $\mu(\mathbf{s})$. Hence, we need to add the constraints $\forall \mathbf{s} : p(\mathbf{s}) = \mu(\mathbf{s})$ to match the given context distribution $\mu(\mathbf{s})$. However, for continuous context vector $\mathbf{s}$, we would end up with infinitely many constraints. Therefore, we resort to matching feature averages instead of single probability values, i.e., $\int p(\mathbf{s}) \boldsymbol{\phi}(\mathbf{s}) d\mathbf{s} = \hat{\boldsymbol{\phi}}$, where $\boldsymbol{\phi}(\mathbf{s})$ is a feature vector describing the context and $\hat{\boldsymbol{\phi}}$ is the mean observed feature vector.

The resulting constrained optimization problem is now given by

$$\max_{p} \iint_{\mathbf{s}, \boldsymbol{\theta}} p(\mathbf{s}, \boldsymbol{\theta}) R(\mathbf{s}, \boldsymbol{\theta}) d\mathbf{s} d\boldsymbol{\theta}, \quad \text{s.t.: } \epsilon \geq \mathrm{KL}\left(p(\mathbf{s}, \boldsymbol{\theta}) || q(\mathbf{s}, \boldsymbol{\theta})\right),$$

$$\int_{\mathbf{s}} p(\mathbf{s}) \boldsymbol{\phi}(\mathbf{s}) d\mathbf{s} = \hat{\boldsymbol{\phi}}, \quad \iint_{\mathbf{s}, \boldsymbol{\theta}} p(\mathbf{s}, \boldsymbol{\theta}) d\mathbf{s} d\boldsymbol{\theta} = 1. \tag{3}$$

It can be solved by the method of Lagrangian multipliers and yields a closed-form solution solution for p that is given by

$$p(\mathbf{s}, \boldsymbol{\theta}) \propto q(\mathbf{s}, \boldsymbol{\theta}) \exp\left(\frac{R(\mathbf{s}, \boldsymbol{\theta}) - V(\mathbf{s})}{\eta}\right), \tag{4}$$

where $V(\mathbf{s}) = \mathbf{v}^T \boldsymbol{\phi}(\mathbf{s})$ is a context dependent baseline that is subtracted from the the reward signal. The scalar η and the vector $\mathbf{v}$ are Lagrangian multipliers that can be found by optimizing the dual function $g(\eta, \mathbf{v})$ (Daniel et al., 2012a). It can be shown that $V(\mathbf{s})$ can be interpreted as value function (Peters et al., 2010) and, hence, estimates the mean performance of the new policy in context $\mathbf{s}$.

The optimization defined by the REPS algorithm is only performed on a discrete set of samples $D = \left\{\mathbf{s}^{[i]}, \boldsymbol{\theta}^{[i]}, R^{[i]}\right\}$, $i = 1, \ldots, N$, where $R^{[i]}$ denotes the return obtained by the ith rollout. The resulting probabilities $p\left(\mathbf{s}^{[i]}, \boldsymbol{\theta}^{[i]}\right)$, see Equation (4), of these samples are used to weight the samples. In order to obtain the weight $p^{[i]}$ for each sample, we need to divide $p\left(\mathbf{s}^{[i]}, \boldsymbol{\theta}^{[i]}\right)$ by the sampling distribution $q(\mathbf{s}, \boldsymbol{\theta})$ to account for the sampling probability (Kupcsik et al., 2013), i.e.,

$$p^{[i]} = \frac{p\left(\mathbf{s}^{[i]}, \boldsymbol{\theta}^{[i]}\right)}{q\left(\mathbf{s}^{[i]}, \boldsymbol{\theta}^{[i]}\right)} \propto \exp\left(\frac{R(\mathbf{s}, \boldsymbol{\theta}) - V(\mathbf{s})}{\eta}\right). \tag{5}$$

Hence, being able to sample from q is sufficient and q is not needed in its analytical form.

The upper-level policy $\pi(\boldsymbol{\theta}|\mathbf{s})$ is subsequently obtained by performing a weighted maximum-likelihood (ML) estimate. We use a linear-Gaussian model to represent the upper-level policy $\pi(\boldsymbol{\theta}|\mathbf{s}) = \mathcal{N}(\boldsymbol{\theta}|\mathbf{a} + \mathbf{A}\mathbf{s}, \boldsymbol{\Sigma})$ of the building block, where the parameters $\mathbf{a}$, $\mathbf{A}$ and $\boldsymbol{\Sigma}$ are obtained through the ML estimation. As a building block is typically reused only for similar contexts $\mathbf{s}$, a linear model is sufficient in most cases. **Figure 2** shows an illustration of how a linear model can adapt the trajectories generated by a DMP. In practice, we still need an initial policy q. This initial policy can either be obtained through learning from demonstration or by selecting reasonable parameters and variance if the experimenter has sufficient task knowledge.

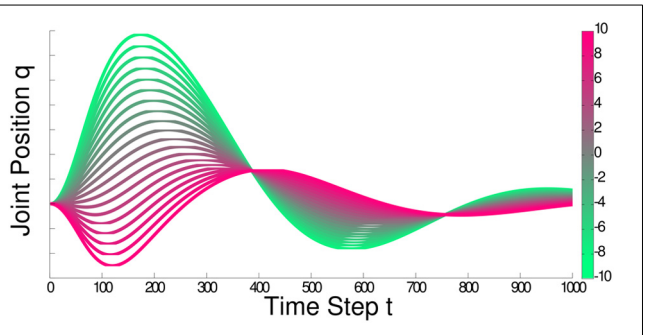

FIGURE 2 | The figure illustrates the joint trajectories that can be generated when using a linear Gaussian to adapt the DMP parameters according to a one dimensional context variable. In this illustration, we show the color coding for the context variable in the color bar on the right and show how the generated trajectories change in the main plot. For this plot, we assumed no exploration noise and adapted ten basis functions of the DMP. As we can see, complex behavior can emerge already with a linear adaptation model due to the high-dimensionality of the parameter space.

In Kupcsik et al. (2013), we further improved the data-efficiency of our contextual policy search algorithm by learning probabilistic forward models of the real robot and its environment. With these forward models, we can predict the reward $R\left(\mathbf{s}^{[j]}, \boldsymbol{\theta}^{[j]}\right)$ for unseen context-parameter pairs $\mathbf{s}^{[j]}$ and $\boldsymbol{\theta}^{[j]}$ and use these additional samples for computing the policy update. The data-efficiency of our method could be improved up to two orders of magnitude using the learned forward models. As we used Gaussian Processes (GPs) (Rasmussen and Williams, 2006) to represent the forward models, this extension of our method is called GPREPS. These forward models were used to generate additional data points that are used for the policy update. For each of these virtual data points, we generated 15 trajectories with the learned forward models. We used the average reward of these predicted trajectories as reward used in the REPS optimization. We used sparse GPs (Snelson and Ghahramani, 2006) to deal with the high number of data points within a reasonable computation time.

2.1.1. Experimental evaluation of the adaptation of building blocks - robot hockey target shooting

In this task we used GPREPS with learned forward models to learn how to adapt the building blocks such that the robot can shoot hockey pucks to different locations. The objective was to make a target puck move for a specified distance by shooting a second hockey puck at the target puck. The context $\mathbf{s}$ was composed of the initial location $[b_x, b_y]^T$ of the target puck and the distance d^* that the target puck had to be shoot, i.e., $\mathbf{s} = [b_x, b_y, d^*]^T$. We chose the initial position of the target puck to be uniformly distributed from the robot's base with displacements $b_x \in [1.5, 2.5]$m and $b_y \in [0.5, 1]$m. The desired displacement context parameter d^* is also uniformly distributed $d^* \in [0, 1]$m.

The reward function

$$r(\tau, \mathbf{s}) = -\min_t ||\boldsymbol{x}_t - \mathbf{b}||_2 - ||d_T - d^*||_2$$

consist of two terms with equal weighting. The first term penalizes missing the target puck located at position $\mathbf{b} = [b_x, b_y]^T$, where the control puck trajectory is $\boldsymbol{x}_{1:T}$. The second term penalizes the error in the desired displacement of the target puck, where d_T is the resulting displacement of the target puck after the shot. The parameters $\boldsymbol{\theta}$ define the weights and goal position of the DMP. The policy in this experiment was a linear Gaussian policy. The simulated robot task is depicted in **Figure 3**.

GPREPS first learned a forward model to predict the initial position and velocity of the first puck after contact with the racket and a travel distance of 20 cm. Subsequently, GPREPS learned the free dynamics model of both pucks and the contact model of the pucks. We assumed that we know the geometry of the pucks to detect a contact. If there is a contact, we used the contact model to predict the state of both pucks after the contact given the state of both pucks before the contact. From this state, we again predicted the final puck positions after they came to stop with a separate GP model.

We compared GPREPS in simulation to directly predicting the reward $R(\mathbf{s}, \boldsymbol{\theta})$, model-free REPS and CrKR (Kober et al., 2010b), a state-of-the-art model-free contextual policy search method. The resulting learning curves are shown in **Figure 3** (middle). GPREPS learned the task already after 120 interactions with the environment while the model-free version of REPS needed approximately 10000 interactions. Directly predicting the rewards from parameters $\boldsymbol{\theta}$ using a single GP model resulted in faster convergence but the resulting policies still showed a poor performance (*GP direct*). The results show that CrKR could not compete with model-free REPS. The learned movement is shown in **Figure 3** for a specific context. After 100 evaluations, GPREPS placed the target puck accurately at the desired distance with an error ≤ 5 cm.

Finally, we evaluated the performance of GPREPS on the hockey task using a real KUKA lightweight arm. The learning curve of this experiment is shown in **Figure 3** (right) and confirms that GP-REPS can find high-quality policies within a small amount of interactions with the environment.

2.2. LEARNING TO SELECT THE BUILDING BLOCKS

In order to select between several building blocks o, we add an additional level of hierarchy on top of the upper-level policies of the individual building blocks. We assume that each building block shares the same parameter space. The parameters are now selected by first choosing the building block to execute with a gating policy $\pi_G(o|\mathbf{s})$ and, subsequently, the upper level parameter policy $\pi_P(\boldsymbol{\theta}|\mathbf{s}, o)$ of the building block o selects the parameters $\boldsymbol{\theta}$. Hence, $\pi(\boldsymbol{\theta}|\mathbf{s})$ can be written as hierarchical policy

$$\pi(\boldsymbol{\theta}|\mathbf{s}) = \sum_o \pi_G(o|\mathbf{s})\pi_P(\boldsymbol{\theta}|\mathbf{s}, o). \tag{6}$$

In this model, the gating policy composes a complex, nonlinear parameter selection strategy out of the simpler upper level policies of the building blocks. Moreover, it can learn multiple solutions for the same context, which also increases the versatility of the learned motor skill (Daniel et al., 2012b). While a similar decomposition in gating policy and option policies has been presented in da Silva et al. (2012), their framework was not integrated in a reinforcement learning algorithm, and hence, generalization and improvement the building blocks is performed by two independent algorithms, resulting in sample-inefficient policy updates.

To incorporate multiple building blocks, we now bound the Kullback-Leibler divergence between $q(\mathbf{s}, \boldsymbol{\theta}, o)$ and $p(\mathbf{s}, \boldsymbol{\theta}, o)$. As we are interested in versatile solutions, we also want to avoid that several building blocks concentrate on the same solution. Hence, we want to limit the "overlap" between building blocks in the parameter space. In order to do so, we bound the expected entropy of the conditional distribution $p(o|\mathbf{s}, \boldsymbol{\theta})$, i.e.,

$$-\int p(\mathbf{s}, \boldsymbol{\theta}) \sum_o p(o|\mathbf{s}, \boldsymbol{\theta}) \log p(o|\mathbf{s}, \boldsymbol{\theta}) d\mathbf{s} d\boldsymbol{\theta} \leq \kappa. \tag{7}$$

A low entropy of $p(o|\mathbf{s}, \boldsymbol{\theta})$ ensures that our building blocks do not overlap in parameter space and, thus, represent individual and clearly separated solutions (Daniel et al., 2012a). The new optimization program results in the hierarchical version of REPS, denoted as HiREPS. We can again determine a closed form solution for $p(\mathbf{s}, \boldsymbol{\theta}, o)$ which is given in Daniel et al. (2012a). As in the

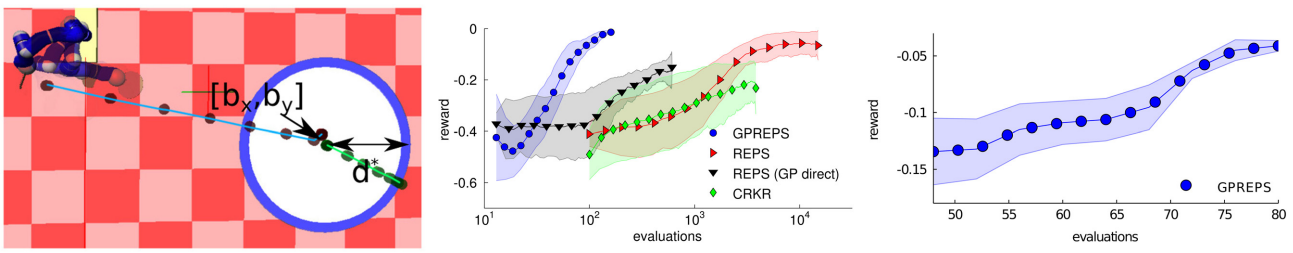

FIGURE 3 | (Left) Robot hockey target shooting task. The robot has to shoot a puck at the target puck such that the target puck moves for a specified distance. Both, the initial location of the target puck $[b_x, b_y]^T$ and the desired distance d^* to move the puck were varied. **(Middle)** Learning curves on the robot hockey task in simulation. GPREPS was able to learn the task within 120 interactions with the environment, while the model-free version of REPS needed about 10000 episodes. **(Right)** GPREPS learning curve on the real robot arm.

previous section, the optimization problem is only solved for a given set of samples that has been generated from the distribution $q(\mathbf{s}, \boldsymbol{\theta})$. Subsequently, the parameters of the gating policy and the upper-level policies are obtained by weighted ML estimates. We use a Gaussian gating policy and an individual linear Gaussian policy $\pi(\boldsymbol{\theta}|\mathbf{s}, o) = \mathcal{N}(\boldsymbol{\theta}|\mathbf{a}_o + \mathbf{A}_o\mathbf{s}, \boldsymbol{\Sigma}_o)$ for each building block. As we use a linear upper-level policy and the used DMPs produce only locally valid controllers, our architecture might require a large number of building blocks.

2.2.1. Experimental evaluation of the selection of building blocks - robot tetherball

In robot tetherball, the robot has to shoot a ball that is fixed with a string on the ceiling such that it winds around a pole. The robot obtains a reward proportional to the speed of the ball winding around the pole. There are two different solutions, to wind the ball around the left or to the right side of the pole. Two successful hitting movements of the real robot are shown in **Figure 5**. We decompose our movement into a swing-in motion and a hitting motion. As we used the non-sequential algorithm for this experiment, we represented the two motions by a single set of parameters and jointly learn the parameters $\boldsymbol{\theta}$ for the two DMPs. We start the policy search algorithm with 15 options with randomly distributed parameters sampled from a Gaussian distribution around the parameters of the initial demonstration. We use a higher number of building blocks to increase the probability of finding both solutions with the building blocks. If we use two randomly initialized building blocks, the probability that both cover the same solution is quite high. We delete unused building blocks that have a very small probability of being chosen, i.e., $p(o) < 0.001$. The learning curve is shown in **Figure 4** (left). The noisy reward signal is mostly due to the vision system and partly also due to real world effects such as friction. Two resulting movements of the robot are shown in **Figure 5**. The robot could learn a versatile strategy that contained building blocks that wind the ball around the left and building blocks that wind the ball around the right side of the pole.

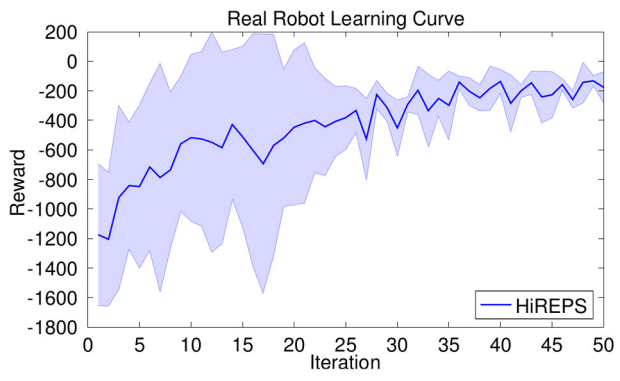

FIGURE 4 | Average rewards for learning tetherball on the real robot. Mean and standard deviation of three trials. In all of the three trials, after 50 iterations the robot has found solutions to wind the ball around the pole on either side.

2.3. LEARNING TO SEQUENCE THE BUILDING BLOCKS

To execute multiple building blocks in a sequence, we reformulate the problem of sequencing building blocks as Markov Decision Process (MDP). Each building block defines a transition probability $p(\mathbf{s}'|\mathbf{s}, \boldsymbol{\theta})$ over future contexts and an immediate reward function $R(\mathbf{s}, \boldsymbol{\theta})$. It is executed until its termination condition $t_o(\mathbf{s}, \boldsymbol{\theta})$ is satisfied. However, in our experiments, we used a fixed duration for each building block. Note that traditional reinforcement learning methods, such as TD-learning, can not deal with such MDPs as its action space is high dimensional and continuous.

We concentrate on the finite-horizon case, i.e., each episode consists of K decision steps where each step is defined as the execution of an individual building block. For clarity, we will only discuss the sequencing of a single building block, however, the selection of multiple building blocks at each decision step can be easily incorporated (Daniel et al., 2013).

In the finite horizon formulation of REPS we want to find the probabilities $p_k(\mathbf{s}, \boldsymbol{\theta}) = p_k(\mathbf{s})\pi(\boldsymbol{\theta}|\mathbf{s})$, $k \leq K$, and $p_{K+1}(\mathbf{s})$ that maximize the expected long term reward

$$J = \int_{\mathbf{s}} p_{K+1}(\mathbf{s}) R_{K+1}(\mathbf{s}) d\mathbf{s} + \sum_{k=1}^{K} \iint_{\mathbf{s},\boldsymbol{\theta}} p_k(\mathbf{s}, \boldsymbol{\theta}) R_k(\mathbf{s}_k, \boldsymbol{\theta}_k) d\mathbf{s} d\boldsymbol{\theta},$$

where $R_{K+1}(\mathbf{s}_{K+1})$ denotes the final reward for ending up in the state $\mathbf{s}_{K+1}$ after executing the last building block. As in the previous case, the initial context distributions is given by the task, i.e., $\forall \mathbf{s} : p_1(\mathbf{s}) = \mu_1(\mathbf{s})$. Furthermore, the context distribution at future decision steps $k > 1$ need to be consistent with the the past distributions $p_{k-1}(\mathbf{s}, \boldsymbol{\theta})$ and the transition model $p(\mathbf{s}'|\mathbf{s}, \boldsymbol{\theta})$, i.e.,

$$\forall \mathbf{s}', k > 1 : p_k(\mathbf{s}') = \iint_{\mathbf{s},\boldsymbol{\theta}} p_{k-1}(\mathbf{s}, \boldsymbol{\theta}) p(\mathbf{s}'|\mathbf{s}, \boldsymbol{\theta}) d\mathbf{s} d\boldsymbol{\theta},$$

for each decision step of the episode. These constraints connect the policies for the individual decision-steps and result in a policy $\pi_k(\boldsymbol{\theta}|\mathbf{s})$ that optimizes the long-term reward instead of the immediate ones. As in the previous sections, these constraints are again implemented by matching feature averages.

The closed form solution of the joint distribution $p_k(\mathbf{s}, \boldsymbol{\theta})$ yields

$$p_k(\mathbf{s}, \boldsymbol{\theta}) \propto q_k(\mathbf{s}, \boldsymbol{\theta}) \exp\left(\frac{A_k(\mathbf{s}, \boldsymbol{\theta})}{\eta_k}\right),$$
$$A_k(\mathbf{s}, \boldsymbol{\theta}) = R_k(\mathbf{s}, \boldsymbol{\theta}) + \mathbb{E}_{p(\mathbf{s}'|\mathbf{s},\boldsymbol{\theta})}\left[V_{k+1}(\mathbf{s}')\right] - V_k(\mathbf{s}).$$

We can see that the reward $R_k(\mathbf{s}, \boldsymbol{\theta})$ is transformed into an advantage function $A_k(\mathbf{s}, \boldsymbol{\theta})$ where the advantage now also depends on the expected value of the next state $\mathbb{E}_{p(\mathbf{s}'|\mathbf{s},\boldsymbol{\theta})}\left[V_{k+1}(\mathbf{s}')\right]$. This term ensures that we do not just optimize the immediate reward but the long term reward.

2.3.1. Experimental evaluation of sequencing of building blocks - sequential robot hockey

We used the sequential robot hockey task to evaluate sequential motor skill learning framework. The robot has to move the target

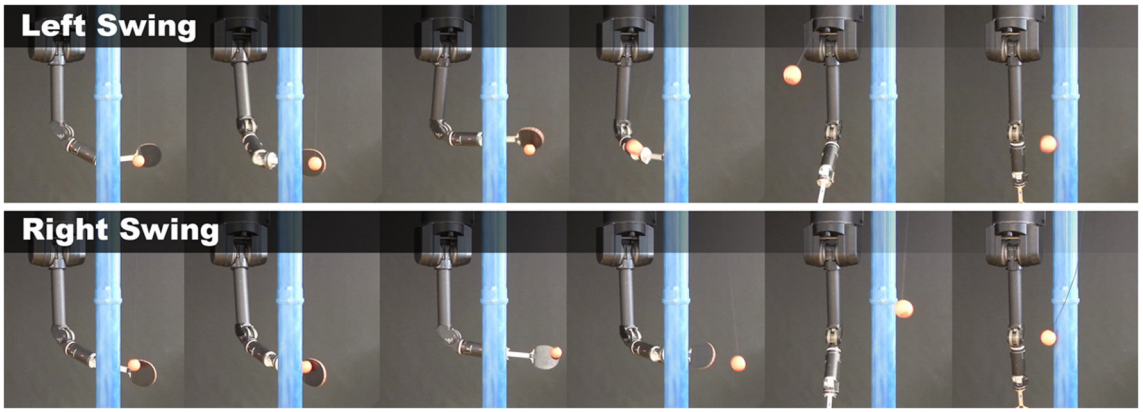

FIGURE 5 | Time series of a successful swing of the robot. The robot first has to swing the ball to the pole and, subsequently, when the ball has swung backwards, can arc the ball around the pole. The movement is shown for a shoot to the left and to the right of the pole.

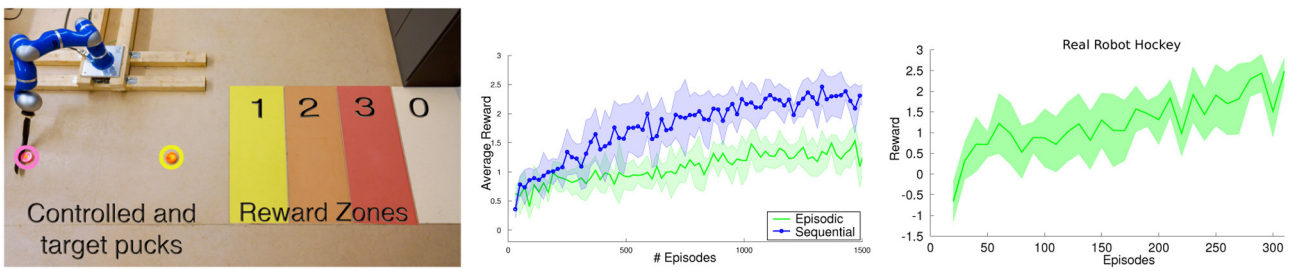

FIGURE 6 | (Left) The sequential robot hockey task. The robot has two pucks, the pink control puck and the yellow target puck. The task is to shoot the yellow target puck into one of the colored reward zones. Since the best reward zone is too far away from the robot to be reached with only one shot, each episode consists of three strikes. After each strike, the control puck is returned to the robot, but the target puck is only reset after one episode is concluded. **(Middle)** Comparison of sequential motor primitive learning to the episodic learning setup on the simulated robot hockey task. The sequential motor primitive learning framework was able to find a good strategy to place the puck in the third reward zone in most of the cases while the episodic learning scenario failed to learn such a strategy. **(Right)** One trial of the real robot hockey tasks. The robot starts with a negative initial reward and learns to achieve an average reward of 2.5 after 300 episodes.

puck into one of three target areas by sequentially shooting a control puck at the target puck. The target areas are defined by a specified distance to the robot, see **Figure 6** (left). The robot gets rewards of 1, 2, and 3 for reaching zone 1, 2 or 3, respectively. After each shot, the control puck is returned to the robot. The target puck, however, is only reset after every third shot.

The 2-dimensional position of the target puck defines the context $\mathbf{s}$ of the task and the parameter vector $\boldsymbol{\theta}$ defines the goal positions of the DMP that define the desired trajectory of the robot's joints. After performing one shot, the agent observes the new context to plan the subsequent shot. In order to give the agent an incentive to shoot at the target puck, we punished the agent with the negative minimum distance of the control puck to the target puck after each shot. While this reward was given after every step, the zone reward was only given at the end of the episode (every third step) as $r_{K+1}(\mathbf{s}_{K+1})$.

We compared our sequential motor primitive learning method with its episodic variant on a realistic simulation. For the episodic variant we used one extended parameter vector $\tilde{\boldsymbol{\theta}}$ that contained the parameters for all three hockey shoots. The comparison of both methods can be seen in **Figure 6** (middle). Due to the high-dimensional parameter space, the episodic learning setup failed to learn a proper policy while our sequential motor primitive learning framework could learn policies of much higher quality.

On the real robot, we could reproduce the simulation results. The robot learned a strategy which could move the target puck to the highest reward zone in most of the cases after 300 episodes. The learning curve is shown in **Figure 6** (right).

3. PROBABILISTIC MOVEMENT PRIMITIVES

In the second part of this paper, we investigate new representations for the individual building blocks of movements that are particularly suited to be used in a modular control architecture. In all experiments for our modular policy search framework, we so far used the Dynamic Movement Primitive (DMP) approach (Schaal et al., 2003). DMPs are widely used, however, when used for our modular control architecture, DMPs suffer from severe limitations as they do not support co-activation or blending of building blocks. In addition, the DMPs use

heuristics for the adaptation of the motion. Hence, we focus our discussion on our new movement primitive (MP) representation (Paraschos et al., 2013) on a these two important properties.

We use a trajectories $\tau = \{q_t\}_{t=0...T}$, defined by the joint angles q_t over time, to model a single movement. We will use a probabilistic representation of a movement, which we call probabilistic movement primitives (ProMP), where a movement primitive describes several ways how to execute a movement (Paraschos et al., 2013). Hence, the movement primitive is given as distribution $p(\tau)$ over trajectories. A probabilistic representation offers several advantages that make it particularly suitable to be used in a modular control architecture. Most importantly, it offers principled ways to adapt as well as to co-activate movement primitives. Yet, these advantages of a probabilistic trajectory representation are of little use if we can not use it to control the robot. Therefore, we derive a stochastic feedback controller in closed form that can exactly reproduce a given trajectory distribution, and, hence, trajectory distributions can be used directly for robot control.

In this section, we present two experiments that we performed with the ProMP approach. As we focused on the representation of the individual building blocks, we evaluated the new representation without the use of reinforcement learning and learned the ProMPs by imitation. In our experiments, we illustrate how to use conditioning as well as co-activation of the building blocks.

3.1. PROBABILISTIC TRAJECTORY REPRESENTATION

In the imitation learning setup, we assume that we are given several demonstrations in terms of trajectories τ_i. In our probabilistic approach we want to learn a distribution of these trajectories. We will first explain the basic representation of a trajectory distribution and subsequently cover the two new operations that are now available in our probabilistic framework, i.e., conditioning and co-activation. Finally, we will explain in Section 3.3 how to control the robot with a stochastic feedback controller that exactly reproduces the given trajectory distribution.

We use a weight vector $\mathbf{w}$ to compactly represent a single trajectory τ. The probability of observing a trajectory τ given the weight vector $\mathbf{w}$ is given as a linear basis function model $p(\tau|\mathbf{w}) = \prod_t \mathcal{N}\left(\mathbf{y}_t|\mathbf{\Psi}_t^T\mathbf{w}, \mathbf{\Sigma}_y\right)$, where $\mathbf{y}_t = [q_t, \dot{q}_t]^T$ contains the joint position q_t and joint velocity $\dot{q}_t$, $\mathbf{\Psi}_t = [\psi, \dot{\psi}_t]$ defines the time-dependent basis matrix and ϵ_y is zero-mean i.i.d. Gaussian noise.

We now abstract a distribution over trajectories as distribution $p(\mathbf{w};\boldsymbol{\theta})$ over the weight vector $\mathbf{w}$ that is parametrized by the parameter vector $\boldsymbol{\theta}$. The original trajectory distribution $p(\tau;\boldsymbol{\theta})$ can now be computed by marginalizing of the weight vector $\mathbf{w}$, i.e., $p(\tau;\boldsymbol{\theta}) = \int p(\tau|\mathbf{w})p(\mathbf{w};\boldsymbol{\theta})d\mathbf{w}$. We will assume a Gaussian distribution for $p(\mathbf{w};\boldsymbol{\theta}) = \mathcal{N}(\mathbf{w}|\mu_w, \mathbf{\Sigma}_w)$ and, hence, $p(\tau;\boldsymbol{\theta})$ can be computed analytically, i.e.,

$$p\left(\mathbf{y}_t;\boldsymbol{\theta}\right) = \mathcal{N}\left(\mathbf{y}_t|\mathbf{\Psi}_t^T\boldsymbol{\mu}_\mathbf{w}, \mathbf{\Psi}_t^T\mathbf{\Sigma}_\mathbf{w}\mathbf{\Psi}_t + \mathbf{\Sigma}_y\right).$$

As a probabilistic MP represents multiple ways to execute an elemental movement, we also need multiple demonstrations to learn $p(\mathbf{w};\boldsymbol{\theta})$. The parameters $\boldsymbol{\theta} = \{\mu_\mathbf{w}, \mathbf{\Sigma}_\mathbf{w}\}$ can be learned by maximum likelihood estimation, for example, by using the expectation maximization algorithm (Lazaric and Ghavamzadeh, 2010).

For multi-dimensional systems, we can also learn the coupling between the joints. Coupling is typically represented by the covariance of the joint positions and velocities. We can learn this covariance by maintaining a parameter vector $\mathbf{w}_i$ for each dimension i and learn a distribution over the combined weight vector $\mathbf{w} = \left[\mathbf{w}_1^T, \ldots, \mathbf{w}_n^T\right]^T$.

To be able to adapt the execution speed of the movement, we introduce a phase variable z to decouple the movement from the time signal (Schaal et al., 2003). The phase can be any function $z(t)$ monotonically increasing with time. The basis functions ψ_t are now decoupled from the time and depend on the phase, such that $\psi_t = \psi(z_t)$ and $\dot{\psi}_t = \psi'(z_t)\dot{z}_t$. The choice of the basis functions depends on whether we want to model rhythmic movements, where we use normalized Von-Mises basis functions that are periodic in the phase, or stroke-based movements, where we use normalized Gaussian basis functions,

$$\begin{aligned}\boldsymbol{\phi}_i^{\mathrm{G}}(z) &= \exp\left(-\frac{(z_t - c_i)^2}{2h}\right),\\ \boldsymbol{\phi}_i^{\mathrm{VM}}(z) &= \exp\left(h\cos\left(2\pi\left(z_t - c_i\right)\right)\right).\end{aligned} \tag{8}$$

The parameter h defines the width of the basis and c_i the center for the ith basis function. We normalize the basis functions $\boldsymbol{\phi}_i$ with $\psi_i(z_t) = \boldsymbol{\phi}_i(z)/\sum_j \boldsymbol{\phi}_j(z)$.

3.2. NEW PROBABILISTIC OPERATORS FOR MOVEMENT PRIMITIVES

The probabilistic formulation of MPs enables us to use new probabilistic operators on our movement primitive representation. Adaptation of the movement can be accomplished by conditioning on desired positions or velocities at time step t. Co-activation and blending of MPs can be implemented as as product of two trajectory distributions.

3.2.1. Adaptation of the building blocks by conditioning

For efficient adaptation, our building blocks should support the modulation of hyper-parameters of the movements such as the desired final joint positions or the joint positions at given via-points. For example, DMPs allow for the adaptation of the final position by modulation of the point attractor of the system. However, how the final position modulates the trajectory is hard-coded in the DMP-framework and can not be learned from data. This adaptation mechanism might violate other task constraints.

In our probabilistic formulation, such adaptation operations can be described by conditioning the MP to reach a certain state $\mathbf{y}_t^*$ at time t. Conditioning can be performed by adding a new desired observation $\mathbf{x_t} = \left[\mathbf{y}_t^*, \mathbf{\Sigma}_y^*\right]$ to our probabilistic model where $\mathbf{y}_t^*$ represents the desired position and velocity vector at time t and $\mathbf{\Sigma}_y^*$ specifies the accuracy of the desired observation. By applying Bayes theorem, we obtain a new distribution over $\mathbf{w}$, i.e., $p(\mathbf{w}|\mathbf{x}_t^*) \propto \mathcal{N}\left(\mathbf{y}_t^*|\mathbf{\Psi}_t^T\mathbf{w}, \mathbf{\Sigma}_y^*\right)p(\mathbf{w})$. As $p(\mathbf{w}|\boldsymbol{\theta})$ is Gaussian, the conditional distribution $p\left(\mathbf{w}|\mathbf{y}_t^*\right)$ is also Gaussian and can be

computed analytically

$$\boldsymbol{\mu}_{\mathbf{w}}^{[\text{new}]} = \boldsymbol{\mu}_{\mathbf{w}} + \boldsymbol{\Sigma}_{\mathbf{w}}\boldsymbol{\Psi}_t \left(\boldsymbol{\Sigma}_y^* + \boldsymbol{\Psi}_t^T\boldsymbol{\Sigma}_{\mathbf{w}}\boldsymbol{\Psi}_t\right)^{-1}\left(\mathbf{y}_t^* - \boldsymbol{\Psi}_t^T\boldsymbol{\mu}_{\mathbf{w}}\right), \quad (9)$$

$$\boldsymbol{\Sigma}_{\mathbf{w}}^{[\text{new}]} = \boldsymbol{\Sigma}_{\mathbf{w}} - \boldsymbol{\Sigma}_{\mathbf{w}}\boldsymbol{\Psi}_t \left(\boldsymbol{\Sigma}_y^* + \boldsymbol{\Psi}_t^T\boldsymbol{\Sigma}_{\mathbf{w}}\boldsymbol{\Psi}_t\right)^{-1}\boldsymbol{\Psi}_t^T\boldsymbol{\Sigma}_{\mathbf{w}}. \quad (10)$$

We illustrated conditioning a ProMP to different target states in **Figure 7A**. As we can see, the modulation of a target state is also learned from demonstration, i.e., the ProMP will choose a new trajectory distribution that goes through the target state, and, at the same time, is similar to the learned trajectory distribution.

3.2.2. Combination and blending by multiplying distributions

In our probabilistic representation, a single MP represents a whole family of movements. Co-activating two MPs should return a new set of movements which are contained in both MPs. Such operation can be performed by multiplying two distributions. We also want to weight the activation of each primitive o_i by a time-varying activation factor $\alpha_i(t)$, for example, to continuously blend the movement execution from one primitive to the next. The activation factors can be implemented by taking the distributions of the individual primitives to the power of $\alpha_i(t)$. Hence, the co-activation of ProMPs yields $p^*(\tau) \propto \prod_t \prod_i p_i(\mathbf{y}_t)^{\alpha_i(t)}$.

For Gaussian distributions $p_i(\mathbf{y}_t) = \mathcal{N}\left(\mathbf{y}_t|\mu_t^{[i]}, \boldsymbol{\Sigma}_t^{[i]}\right)$, the resulting distribution $p^*(\mathbf{y}_t)$ is again Gaussian and we can obtain its mean $\boldsymbol{\mu}_t^*$ and variance $\boldsymbol{\Sigma}_t^*$ analytically with variance and mean

$$\boldsymbol{\Sigma}_t^* = \left(\sum_i \left(\boldsymbol{\Sigma}_t^{[i]}/\alpha_i(t)\right)^{-1}\right)^{-1},$$

$$\boldsymbol{\mu}_t^* = \left(\boldsymbol{\Sigma}_t^*\right)^{-1}\left(\sum_i \left(\boldsymbol{\Sigma}_t^{[i]}/\alpha_i(t)\right)^{-1}\mu_t^{[i]}\right). \quad (11)$$

Both terms are required to obtain the stochastic feedback controller that is finally used to control the robot. We illustrated co-activating two ProMPs in **Figure 7B** and blending of two ProMPs in **Figure 7C**.

3.3. USING TRAJECTORY DISTRIBUTIONS FOR ROBOT CONTROL

In order to use a trajectory distribution $p(\tau|\boldsymbol{\theta})$ for robot control, we have to obtain a controller which can exactly reproduce the given distribution. As we show in Paraschos et al. (2013), such controller can be obtained in closed form if we know the system dynamics $\dot{\mathbf{y}} = f(\mathbf{y}, \mathbf{u}) + \epsilon_y$ of the robot[1]. We model the controller as time-varying stochastic linear feedback controller, i.e., $\mathbf{u}_t = \mathbf{k}_t + \mathbf{K}_t\mathbf{y}_t + \epsilon_u$, where $\mathbf{k}_t$ denotes the feed-forward gains, $\mathbf{K}_t$ the feedback gains and $\epsilon_u \sim \mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_u)$ the controller noise. Hence, the controller is determined by $\mathbf{k}_t$, $\mathbf{K}_t$ and $\boldsymbol{\Sigma}_u$ for each time point. All these terms can be obtained analytically by predicting the distribution $p_{\text{model}}(\mathbf{y}_{t+\text{dt}})$ from $p(\mathbf{y}_t|\boldsymbol{\theta})$ with the known model of the system dynamics and subsequently matching the moments of $p(\mathbf{y}_{t+\text{dt}}|\boldsymbol{\theta})$ and the moments of the predicted distribution $p_{\text{model}}(\mathbf{y}_{t+\text{dt}})$. The resulting controller exactly reproduces the given trajectory distribution $p(\tau|\boldsymbol{\theta})$ (Paraschos et al., 2013).

While the ProMP approach has many similarities to the approach introduced in Rozo et al. (2013) by Calinon and colleagues, there are also important differences to this approach. They also learn a trajectory distribution which is modeled with a GMM, where the output variables are the joint angles and the time step t. The probability for the joint angles at time step t is then obtained by conditioning on t. However, it is unclear how to condition on being at a certain state $\mathbf{q}_t^*$ at time step, which is very different then just conditioning on being in time step t. In this case, the mixture components need to be changed such

[1]Alternatively, we can assume that we use inverse dynamics control on the robot, and, hence, the idealized dynamics of the robot are given by a linear system. Such an approach is, for example, followed by the DMPs that also assumes that the underlying dynamical system, that represents the robot, is linear.

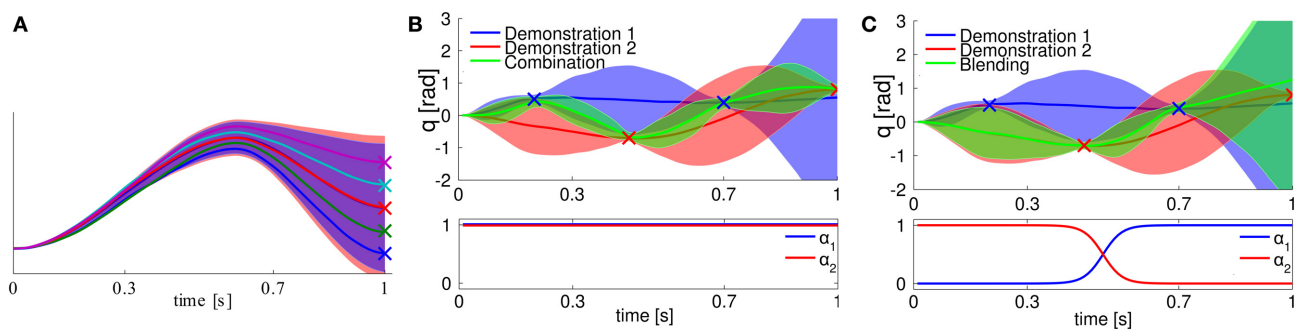

FIGURE 7 | (A) Conditioning on different target states. The blue shaded area represents the learned trajectory distribution. We condition on different target positions, indicated by the "x"-markers. The produced trajectories exactly reach the desired targets while keeping the shape of the demonstrations. **(B)** Combination of two ProMPs. The trajectory distributions are indicated by the blue and red shaded areas. Both primitives have to reach via-points at different points in time, indicated by the "x"-markers. We co-activate both primitives with the same activation factor. The trajectory distribution generated by the resulting feedback controller now goes through all four via-points. **(C)** Blending of two ProMPs. We smoothly blend from the red primitive to the blue primitive. The activation factors are shown in the bottom. The resulting movement (green) first follows the red primitive and, subsequently, switches to following the blue primitive.

that the trajectory distribution passes through $\mathbf{q}_t^*$ at time step t. How to implement this change with a GMM is an open problem. Note that the ProMP approach is very different from a GMM. It uses a linear basis function model and learns the correlation of the parameters of the basis functions for the different movements. Time is not modeled as random variable but as conditional variable right away. Due to the learned correlations, we can condition on reaching $\mathbf{q}_t^*$ at time step t and the trajectory distribution smoothly passes through $\mathbf{q}_t^*$ with high accuracy.

Furthermore, a trajectory distribution alone is not sufficient to control a robot as it requires a feedback controller that determines the control actions. How to obtain this feedback controller from the trajectory distribution is based on heuristics in Rozo et al. (2013). I.e., when we apply the feedback controller on the real robot, we will not reproduce the learned trajectory distribution. The produced trajectory distribution might be similar, but we do not know how similar. Therefore, for all operations performed on the trajectory distributions (i.e., a combination of distributions by a product), it is hard to quantify the effect of this operation on the resulting motions that are obtained from the heuristic feedback controller. In contrast, the ProMPs come with a feedback controller that exactly matches the trajectory distribution. Hence, for a combination of distributions, we know that the feedback controller will exactly follow the product of the two distributions.

3.3.1. Experimental evaluation of the combination of objectives at different time-points

In this task, a seven link planar robot has to reach different target positions in end-effector space at the final time point t_T and at a via-point t_v. We generated the demonstrations for learning the MPs with an optimal control law, (Toussaint, 2009) and adding noise to the control outputs. In the first set of demonstrations, the robot reached a via-point at $t_1 = 0.25$ s with its end-effector. We used 10 normalized Gaussian basis functions per joint, resulting in a 70-dimensional weight vector. As we learned a single distribution over all joints of the robot, we can also model the correlations between the joints. These correlations are required to learn to reach a desired via-point in task space. The reproduced behavior with the ProMPs is illustrated in **Figure 8** (top). The ProMP exactly reproduced the via-points in task space. Moreover, the ProMP exhibited the same variability in between the time points of the via-points. It also reproduced the coupling of the joints from the optimal control law, which can be seen by the small variance of the end-effector in comparison to the rather large variance of the single joints at the via-points. We also used a second set of demonstrations where the first via-point was located at time step $t_2 = 0.75$, which is illustrated in **Figure 8** (middle). We co-activated the ProMPs learned from both demonstrations. The robot could accurately reach both via-points at $t_1 = 0.25$ and $t_2 = 0.75$, see **Figure 8** (bottom).

3.3.2. Experimental evaluation of the combination of simultaneous objectives - robot hockey

In this task, the robot again has to shoot a hockey puck in different directions and distances. The task setup can be seen in **Figure 9A**. We record two different sets of demonstrations, one that contains straight shots with varying distances, while the second set contains shots with a varying shooting angle and almost constant distance. Both data sets contained ten demonstrations each.

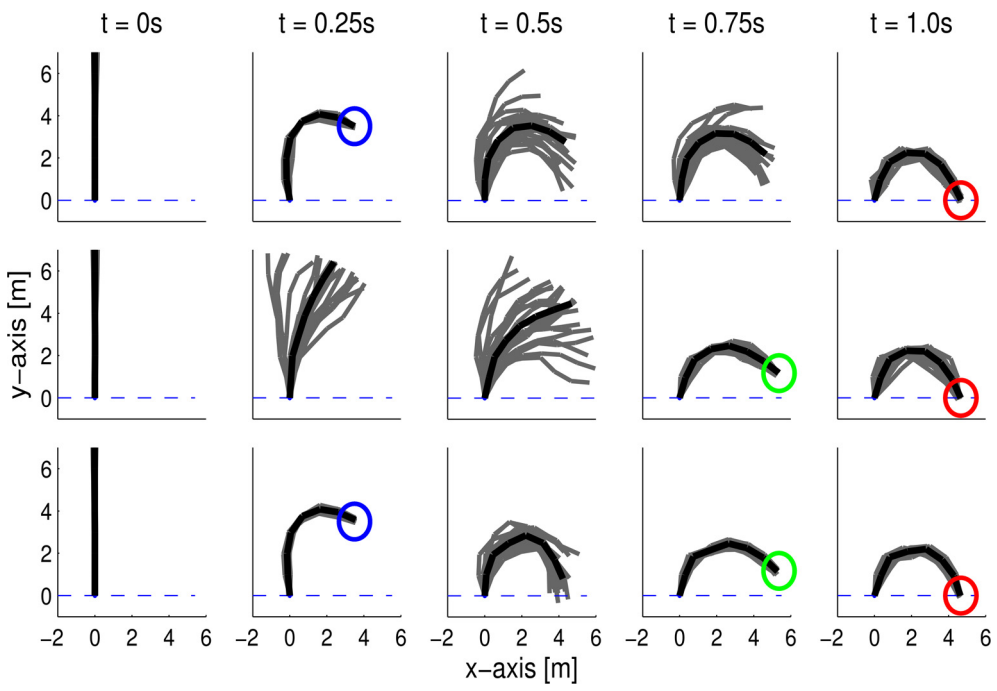

FIGURE 8 | A 7-link planar robot has to reach a target position at $T = 1.0$ s with its end-effector while passing a via-point at $t_1 = 0.25$ s (top) or $t_2 = 0.75$ s (middle). The plot depicts the mean posture of the robot at different time steps (black) and samples generated by the ProMP (gray). The demonstrations have been generated by an optimal control law. The ProMP approach was able to exactly reproduce the coupling of the joints from the demonstrations. The combination of both learned ProMPs is shown in the bottom. The resulting movement reached both via-points with high accuracy.

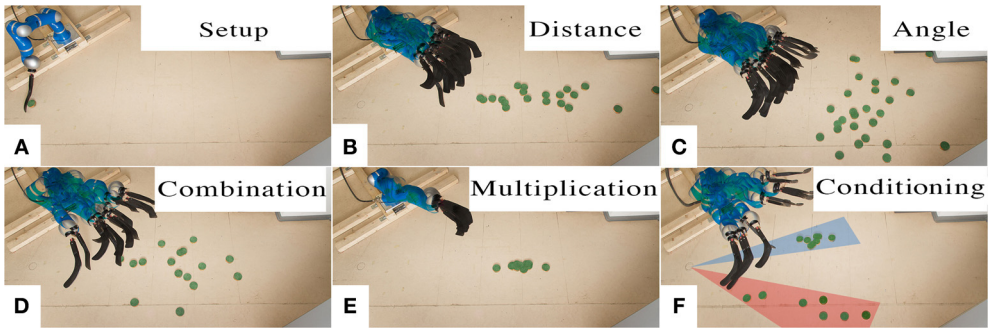

FIGURE 9 | Robot Hockey. The robot shoots a hockey puck. The setup is shown in **(A)**. We demonstrate ten straight shots for varying distances and ten shots for varying angles. The pictures show samples from the ProMP model for straight shots **(B)** and angled shots **(C)**. Learning from combined data set yields a model that represents variance in both, distance and angle **(D)**. Multiplying the individual models leads to a model that only reproduces shots where both models had probability mass, in the center at medium distance **(E)**. The last picture shows the effect of conditioning on only left or right angles, the robot does not shoot in the center any more **(F)**.

Sampling from the two models generated by the different data sets yields shots that exhibit the demonstrated variance in either angle or distance, as shown in **Figures 9B,C**. When combining the data sets of both primitives and learning a new primitive, we get a movement which exhibits variance in both dimensions, i.e., angle and distance, see **Figure 9D**. When the two individual primitives are combined by a product of MPs, the resulting model shoots only in the center at medium distance, i.e., the intersection of both MPs, see **Figure 9F**.

In this section, we present two experiments that we performed with the ProMP approach. As we focused on the representation of the individual building blocks, we evaluated the new representation without the use of reinforcement learning and learned the ProMPs by imitation. In our experiments, we illustrate how to use conditioning as well as co-activation of the building blocks.

4. CONCLUSION AND FUTURE WORK

Using structured, modular control architectures is a promising concept to scale robot learning to more complex real-world tasks. In such a modular control architecture, elemental building blocks, such as movement primitives, need to be adapted, sequenced or co-activated simultaneously. In this paper, we presented a unified data-efficient policy search framework that exploits such control architectures for robot learning. Our policy search framework can learn to select, adapt and sequence parametrized building blocks such as movement primitives while coping with the main challenges of robot learning, i.e., high dimensional, continuous state and action spaces and the high costs of generating data. Moreover, we presented a new probabilistic representation of the individual building blocks which show several beneficial properties. Most importantly, they support efficient and principled ways of adapting a building block to the current situation and we can co-activate several of these building blocks.

Future work will concentrate on integrating the new ProMP approach into our policy search framework. Interestingly, the upper-level policy would in this case directly specify the trajectory distribution. The lower level control policy is automatically given by this trajectory distribution. We will explore to incorporate the co-activation of individual building blocks also in our policy search framework. Additional future work will concentrate on incorporating perceptual feedback into the building blocks and using more complex hierarchies in policy search.

Walking, catching a ball and reaching are all tasks in which humans and animals exhibit advanced motor skills. Findings in biological research concerning motor control suggest a modular control hierarchy which combines movement/motor primitives into complex and natural movements. Engineers inspire their research on these findings in the quest for adaptive and skillful control for robots. In this work we propose a modular architecture with control primitives (MACOP) which uses a set of controllers, where each controller becomes specialized in a subregion of its joint and task-space. Instead of having a single controller being used in this subregion [such as MOSAIC (modular selection and identification for control) on which MACOP is inspired], MACOP relates more to the idea of continuously mixing a limited set of primitive controllers. By enforcing a set of desired properties on the mixing mechanism, a mixture of primitives emerges unsupervised which successfully solves the control task. We evaluate MACOP on a numerical model of a robot arm by training it to generate desired trajectories. We investigate how the tracking performance is affected by the number of controllers in MACOP and examine how the individual controllers and their generated control primitives contribute to solving the task. Furthermore, we show how MACOP compensates for the dynamic effects caused by a fixed control rate and the inertia of the robot.

Keywords: reservoir computing, echo state networks, motor primitives, movement primitives, motor control, MOSAIC, robot control

1. INTRODUCTION

Catching a ball, reaching for a cup of coffee and drawing a figure on a blackboard are all tasks in which humans exhibit advanced motor control. We are able to perform such tasks robustly and adaptively, constantly anticipating an uncertain environment. Robots are most commonly used in environments which are fully deterministic, and are programmed in such a way that all possible situations are foreseen by the engineer. However, inspired by humans and biology in general, more and more techniques emerge in which robots can be used in dynamic environments without explicitly defining a set of rules to achieve advanced and adaptive motor control. The study of motor skills in nature also has sparked the interest of modular representations in both planned and actual motor commands. For instance, research performed on frogs (Bizzi et al., 1991) showed that electrical microstimulation of different areas of the lumbar cord generated distinct types of force fields in the frog's isometric leg movement. Similar research on frogs (Mussa-Ivaldi et al., 1994; Kargo and Giszter, 2000) and rats (Tresch and Bizzi, 1999) has shown that simultaneous stimulation of such areas result in a superposition of the separate recorded force fields, suggesting a modular control system. In Mussa-Ivaldi and Bizzi (2000), this work has been extended to the planning of limb movements and how to transform this planning into a sufficient set of motor commands.

Instead of using invasive and/or stimulation techniques to investigate the existence of a modular control system, researchers (d'Avella et al., 2003) also developed methods to find out if a large set of natural movements is the result of a combination of a limited set of *motor primitives*, solely based on muscle activity observations. By measuring such activations with Electromyography (EMG) and applying a decomposition technique over multiple EMG recordings, they found primitive representations, called synergies. These experiments were first conducted on frogs and later on humans (Hart and Giszter, 2004; Cheung et al., 2005; d'Avella and Bizzi, 2005).

Also on the behavioral level it has been demonstrated that humans try to follow mental templates of motion when executing a task (Bernstein, 1967). The presence of these mental templates or *movement primitives* can also be detected as velocity bumps (Doeringer and Hogan, 1998) during online movement corrections. A more detailed overview of primitives at the neural, dynamic and kinematic level can be found in Flash and Hochner (2005).

The idea of movement primitives also inspired research in robotics (Schaal et al., 2003). In Muelling et al. (2010) they demonstrate a robot that learned to play table tennis based on a set of primitives learned by imitating human table tennis movements. In Schaal et al. (2005), a flexible and reactive framework for motor control was presented which uses dynamic movement primitives (DMPs) (Schaal, 2006). This framework showed to be useful in the generation of walking motion of a biped based on oscillating DMPs or the generation of the swimming and walking motions of a salamander robot (Ijspeert et al., 2007) when DMPs are used as central pattern generator.

Most of these approaches define the primitives as oscillators or learned movements, and learn how to adapt them to get the desired objective. In this work, however, we take a different

approach in which a similar decomposition emerges naturally, such that their combination converges to the objective. For this, we inspired our work on MOSAIC (modular selection and identification for control), originally proposed by Wolpert and Kawato (Wolpert and Kawato, 1998; Haruno et al., 2001) which suggest a feasible strategy on how a human motor control system learns and adapts to novel environments. For instance, when moving an empty cup or one filled with coffee. As both objects have different dynamics, MOSAIC learns a different controller for each object and assigns a "responsibility"-function, which allows for smooth switching between the controllers' individual contributions. When a new object is introduced, MOSAIC will generalize, by combining the contribution of each controller. To determine which controller should be used, each controller contains a forward model that predicts the next state of the object based on the previous control commands. If a controller's forward model is predicting well compared to the others, that controller is used. This architecture, however, can not be related to the idea of movement or motor primitives, as the number of controllers roughly depends on the number of objects, such that when handling a known object, a single controller's output is used.

Many variants of MOSAIC have been studied. The original implementation uses a gradient based method and later hidden Markov models. In Lonini et al. (2009), an alternative architecture based on locally weighted projection regression (LWPR) (Vijayakumar and Schaal, 2000) was presented which allows a better incremental learning of new tasks. Another approach (Oyama et al., 2001) uses a separate performance prediction network to determine which module should be used to learn the inverse kinematics of an arm. Likewise, in Nguyen-Tuong et al. (2009), they propose a localized version of Gaussian Process Regression in which a different model is trained for different regions in task-space.

The *modular architecture with control primitives* (MACOP) which we propose in this work is also inspired on MOSAIC. However, we want to build upon the idea of using a limited set of controllers whose contributions are continuously combined to produce the desired objective. Each controller's contribution should be mixed in a manner which permits all controllers to contribute to the objective, while still allowing for each controller to specialize in a part of the task. Due to the similarity with motion/motor primitives we will call the contributions of the individual controllers *control primitives*. We will provide a more detailed explanation on the similarities and differences with the common notion of primitives in the Discussion section of this paper.

Based on some interesting observations we omit the use of forward models (unlike MOSAIC) and use a simple heuristic to achieve the desired mixing mechanism which determines the "responsibility". The controllers are constructed from Echo State Networks (ESNs) (Jaeger, 2001) which are inherently dynamic and therefore provide a natural platform for modeling and controlling a dynamic system such as a robot arm. After giving a description of MACOP we validate it by letting it learn the inverse kinematics (IK) of a 6 degrees-of-freedom (DOF) robot arm and we analyze its behavior. In the discussion we will address the following key points and differences with other techniques:

- Unsupervised learning of the mixing mechanism given some high-level requirements.
- Learning an inverse kinematic mapping which includes dynamical effects.
- How it allows to solve a task with control primitives where the complexity of a single controller is insufficient to solve the full task.
- How a control primitive compares with the notion of motor/motion primitives.

2. MATERIALS AND METHODS

2.1. DIFFICULTY OF CONTROLLING AN UNKNOWN SYSTEM

When controlling a system we want to find a way to control the states of that system by changing its input without actually knowing how the system internally works. All we can do is observe how the system responds to a certain input. Consider for instance the scenario in which we have a student trying to manipulate a cup of coffee with a robot arm. The actions that are under direct control of the student are the joint-torques, and this at a fixed control-rate. The variables that the student wishes to control, however, represents the trajectory of the cup of coffee. The student needs to use trial and error to learn to produce the desired result. In this process, he or she will need to implicitly learn the connection between his or her actions and the resulting trajectory of the cup. The main difficulties concerning this task can be summarized as:

- Learning an implicit mapping from actions to the resulting trajectory without prior knowledge.
- Handling redundancies because controlling multiple joints results in a mapping which is not unique.
- Because of a fixed control rate, the dynamic behavior of the robot needs to be anticipated.

Similar to this scenario, the system we use is a multi-jointed robot arm that needs to trace out a desired trajectory in its task-space.

2.2. ROBOT ARM PLATFORM

In this work we perform all our experiments on a dynamic Webots simulation model of the PUMA 500 robot arm which has 6 DOF. This numerical model allows us to apply joint-angles and measure its actual values in the dynamical environment of the robot. We interact with this simulation model every 32 ms (default Webots configuration), which means that between every sample we take, 32 ms passed in the simulation environment, regardless of the computation time needed for the proposed algorithm. We control the joint-angles of the robot arm which are converted to joint-torques by PID (proportional-integral-derivative) controllers. Each joint is equipped with an encoder which allows us to measure the actual joint-angles. Additionally, the simulation environment provides us with the euclidean end-effector position of the robot arm.

2.3. MACOP

As mentioned before, controlling a system such as a robot arm poses some difficulties when the internal mechanisms of the robot

are unknown. Although classical kinematic models are known for most commercial robots available, the increasing use of soft materials with passive compliant properties requires an adaptive modeling approach. Often a learning algorithm is used to create a model of the robot such that the model exhibits the same behavior (outcome) when perturbed by the same inputs (actions), which is called a forward model. By using for instance a neural network as model, the known structure of this network can be exploited to calculate a gradient which can be used to determine the actions that are needed to change the outcome as desired. Another approach is to learn an inverse model which maps a desired outcome to an action. However, learning such a model is difficult when the correct actions to a certain outcome are unknown. A more detailed overview on training and using such models can be found in Jordan and Rumelhart (1992).

Often the modeling complexity of a control problem can be reduced by decomposing the problem into less complex parts. For instance, if we again consider the cup lifting scenario for which we want to learn a model. This model will approximate the underlying dynamics of the particular task. If we extend this problem to lifting other objects, the resulting model needs to be able to approximate a single function that includes both tasks with different dynamics each.

One of the approaches that can solve such problems is called MOSAIC (Wolpert and Kawato, 1998; Haruno et al., 2001), which suggest a feasible strategy on how a human motor control system learns and adapts to new dynamic characteristics of the environment. MOSAIC learns a different controller for each different task, and uses a "responsibility"-function to decide which controller will be used, while still allowing for smooth switching between the controllers individual actions. When introducing a new task, MOSAIC will generalize, by combining the actions of each controller. To determine each controller's "responsibility", every controller contains a forward model that predicts the next state of the object based on the previous control actions. If a controller's forward model is more accurate compared to the others, that controller's inverse model is trained further with the new observations and used to control the robot arm.

One potential weakness of this approach is that the performance of a forward model is not necessarily a good indicator of the modeling performance of the inverse model. To confirm this we have tried an approach directly based on MOSAIC. For each controller, we trained a reservoir (see section 2.4.2) to serve as both an inverse and forward model at the same time. We found that all forward models had initially roughly the same prediction error, leading to an equal responsibility factor for each controller as a result. During the training phase, however, small variations in performance error influenced both the training of the forward and the inverse models. Eventually this always causes one controller to be fully responsible at all times, making the other controllers redundant. These findings confirm the observations made in Haruno et al. (2001) even though in the original MOSAIC setup, the inverse and forward models are completely separate from each other, meaning that there is no relation at all between the modeling performance of the inverse and forward model. Based on these experiments one can argue that the responsibility of a controller is fully determined by noise on the forward modeling performance of a controller. Any other controller selection mechanism might thus be as useful as the one used by MOSAIC.

Therefore we propose a Modular Architecture for Control with Primitives (MACOP) which is inspired on MOSAIC, and depicted in **Figure 1**. Instead of using both an inverse and forward model, we only use inverse models to produce actions for our robot arm. Determining when a controller (inverse model) should contribute to the task is learned unsupervised given the robot's state and some desired mixing properties. This can be related to a Kohonen map (Kohonen, 1998).

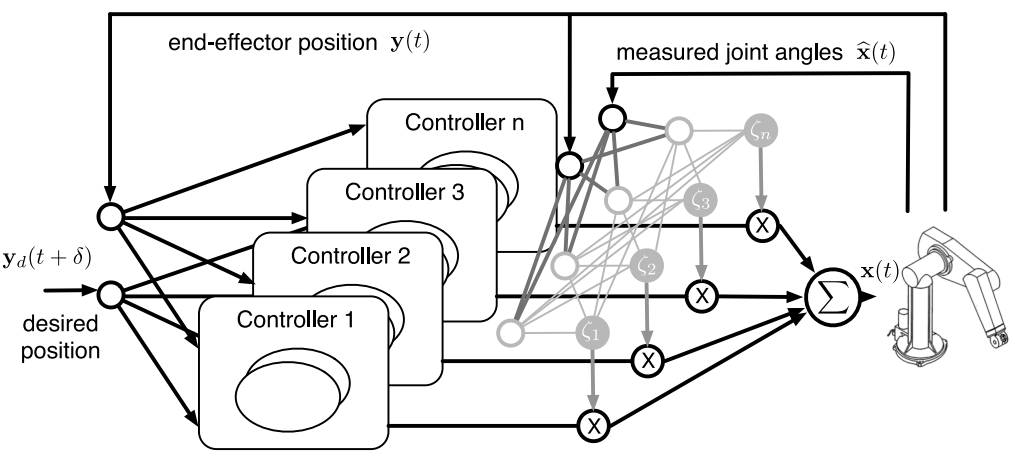

FIGURE 1 | Illustration of MACOP which consists of an ensemble of controllers depicted in Figure 2. The desired (objective) and the current end-effector position are used as external inputs to each controller. The controller outputs are weighted by a scaling factor ζ_i and superimposed with each other such that the resulting joint-angles control the robot. The used ζ_i represent the responsibility of a controller and is determined by the measured joint-angles and end-effector position.

2.3.1. Controller selection

As depicted in **Figure 1**, the actual control signal is a weighted sum of the outputs of a limited number of controller outputs. The weight (or scaling) factors (which are the equivalent of MOSAIC's "responsibility"), depend on observable properties of the robot. Each controller learns to control the robot arm by creating an inverse robot model. Simultaneously, the mixing mechanism is trained, also online. In order for a controller to distinguish itself from others, the rate at which each controller is trained will be modulated according to its corresponding responsibility. This will be explained in more detail when we describe the operation of a single controller.

Suppose we have N_c controllers. We denote the output of the i-th controller as $\mathbf{x}_i(t)$. The controlled joint-angles $\mathbf{x}(t)$ are then given by:

$$\mathbf{x}(t) = \sum_{i=1}^{N_c} \zeta_i(t)\mathbf{x}_i(t), \tag{1}$$

where $\zeta_i(t)$ is the scaling factor, or "responsibility" of a controller, which decides how much each controller is expressed in the final control signal. Ideally, we would like to let $\zeta_i(t)$ express the momentary accuracy of each controller. For example, if each controller is randomly initialized before training, certain controllers may be better than others when the arm is near a certain pose, and we would like to use the ζ_i to scale up the control signal of these controllers, and suppress that of the others. In reality, however, we cannot directly measure the accuracy of each individual controller, as the robot is driven with the weighted sum of the control signals, and not the individual controllers.

Therefore, we will apply a different strategy. We will introduce a way in which the scaling factors will automatically start to represent local parts of the operating regime of the robot, and next we will specialize the associated controllers to be more accurate within this local area.

We wish for $\zeta_i(t)$ to only depend on the current end-effector position $\mathbf{y}(t)$ and the measured joint-angles $\widehat{\mathbf{x}}(t)$, both of which are observable properties of the robot arm. As each controller will attempt to learn an inverse model, the combined control signal will need to be of the same magnitude as the individual control signals. Therefore, we will make sure that the scaling factors are always positive, and always sum to one:

$$\sum_{i=1}^{N_c} \zeta_i(t) = 1 \quad \text{and} \quad 0 \leq \zeta_i(t) \leq 1. \tag{2}$$

Both these qualities can be ensured if ζ_i is calculated by a *softmax* function. First we use a linear projection from the joint-angles and end-effector position to a vector $\mathbf{r}$:

$$\mathbf{r}(t) = \begin{bmatrix} r_1(t) \\ r_2(t) \\ \vdots \\ r_{N_c}(t) \end{bmatrix} = \mathbf{V}(t) \begin{bmatrix} \mathbf{y}(t) \\ \widehat{\mathbf{x}}(t) \end{bmatrix}, \tag{3}$$

Next, we compute the softmax function.

$$\zeta_i(t) = \frac{\exp(r_i(t))}{\sum_{j=1}^{N_c} \exp(r_j(t))}, \tag{4}$$

The projection matrix $\mathbf{V}(t)$ is a matrix of size N_c by $N_\mathbf{y} + N_{\widehat{\mathbf{x}}}$, where $N_\mathbf{y}$ and $N_{\widehat{\mathbf{x}}}$ are the dimensions of $\mathbf{y}(t)$ and $\widehat{\mathbf{x}}(t)$, respectively. Dependence on time comes from the fact that, like all parameters, $\mathbf{V}$ is trained online.

$\mathbf{V}(t)$ is randomly initialized, with elements drawn from a normal distribution $\mathcal{N}(0, 0.1)$. It will determine how the responsibilities are distributed. We need to train $\mathbf{V}(t)$ in such a way that MACOP learns to generate the target trajectories by mixing all contributions as we desire. In this work we wish to obtain the following two qualitative properties:

- Each controller should contribute in a unique way to the movement generation of the robot. In order for a controller to distinguish itself from the others, its corresponding $\zeta_i(t)$ should peak over the others. We wish that there is sufficient variation, such that at each moment in time some controllers are significantly more responsible than others.
- On the other hand we wish to make sure that there are no responsibilities that are close to zero at all times, such that all controllers are put to good use, and we fully exploit the potential power of the ensemble. We wish to avoid the situation we observed when we implemented the MOSAIC-based controller ensemble, where eventually only one controller contributed to the task.

Based on these two desired properties, we will construct a learning algorithm for training $\mathbf{V}(t)$. The first property of our mixing mechanism can be achieved by gradually increasing the magnitude of $\mathbf{V}$. This results in a more strongly peaked distribution for the scaling factors. This can be understood by looking at the limit situations. If all elements of $\mathbf{V}(t)$ are zero, all scaling factors are equal. If the magnitude goes to infinity, the softmax function will be equal to one for the highest element, and zero for all others. Controlling the magnitude of $\mathbf{V}(t)$ allows us to make a smooth transition between these extremes. We chose to increase the magnitude of $\mathbf{V}(t)$ linearly each time step by adding a small increment, equal to $\mathbf{V}(t)$ divided by its Frobenius norm.

The second mixing property requires that all controllers contributes significantly to the robot motion. The manner in which we chose to do this was to suppress the scaling of the momentary maximal scaling factor. This ensures that no single scaling factor can remain dominant for a long time. Suppressing one scaling factor automatically scales up the others, such that in the end none of the scaling factors remains very small at all times. In order to train $\mathbf{V}(t)$ to get this effect, we need to set target values for the $\zeta_i(t)$ at each time step. We set the target value of the highest $\zeta_i(t)$ equal to N_c^{-1} (which would be the long-term time average of all scaling factors if they all contribute equally). At the same time we have to make sure that the sum of the target values is equal to one (i.e., a target that can be reached by a softmax function). To obtain this, the target values of the other $\zeta_i(t)$ are equal to themselves, scaled

up to ensure that the sum of the targets equals one. If we denote the target value for $\zeta_i(t)$ as $\theta_i(t)$, we can write

$$\theta_i(t) = \begin{cases} h(t)\zeta_i(t), & \text{if } i \neq \text{argmax}(\zeta_i(t)) \\ \frac{1}{N_c} & \text{if } i = \text{argmax}(\zeta_i(t)) \end{cases}, \quad (5)$$

with

$$h(t) = \frac{1 - N_c^{-1}}{1 - \max(\zeta_i(t))}. \quad (6)$$

To train $\mathbf{V}$ according to these target values, we calculate the gradient of the cross-entropy[1] $H(\theta_i, \zeta_i)$ with respect to $\mathbf{V}$. For both desired properties we have defined an update rule and each time step we add up both contributions, resulting in the following update rule:

$$\mathbf{V}(t+1) = \mathbf{V}(t) + \eta_g \frac{\mathbf{V}(t)}{||\mathbf{V}(t)||_F} + \eta_s[\mathbf{y}^\mathsf{T}(t), \widehat{\mathbf{x}}^\mathsf{T}(t)](\boldsymbol{\zeta}(t) - \boldsymbol{\theta}(t)), \quad (7)$$

where $\boldsymbol{\zeta}(t)$ and $\boldsymbol{\theta}(t)$ are column vectors with the responsibility factors and their targets, respectively, and η_g and η_s are two learning rates. In order to prevent one mixing property to dominate the other, we set these learning rates such that both properties are present. Left on its own, Equation (7) never converges. What will happen is that the magnitude of $\mathbf{V}$ slowly keeps on increasing, and in the long term, the scaling factor distribution will become highly peaked (at each moment, one will be close to one, the others close to zero). Therefore, during all our experiments, unless mentioned differently, we calculate the root mean-square-error (RMSE) between the desired and the measured end-effector position[2] over a moving time-window of 1000 samples. When this RMSE becomes smaller than 1 mm we start to linearly decrease both η_g and η_s over the course of 5000 samples until they reach 0. After this point the elements of $\mathbf{V}$ no longer change.

2.4. SINGLE CONTROLLER

As described before, we will use inverse models for controlling our multi-jointed robot arm. Rather than finding the mapping from joint-angles (actions) to end-effector position (outcome), we will approximate the inverse mapping: from outcome to action. Essentially, this means that we train a model to directly provide us with the correct joint-angles for any given desired end-effector position.

2.4.1. General setup

As described before, the end-effector position (outcome) is denoted by $\mathbf{y}(t)$, and the joint-angles (the actions) by $\mathbf{x}(t)$. We assume that we can train a model (model A in **Figure 2**) to approximate the past joint-angles $\mathbf{x}(t-\delta)$, δ being a fixed delay period, given that it receives the current and the delayed end-effector position $\mathbf{y}(t)$ and $\mathbf{y}(t-\delta)$, respectively. This part of the control mechanism is the inverse model.

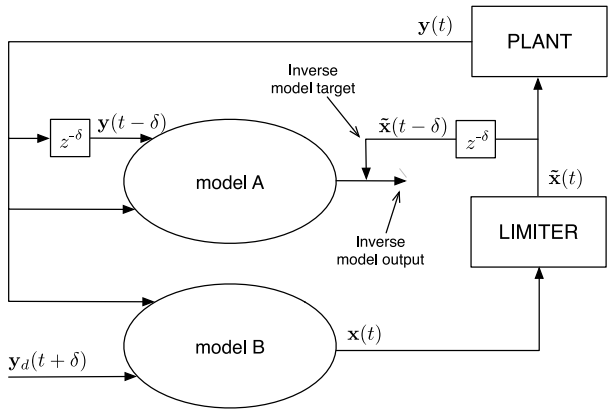

FIGURE 2 | Schematic representation of a single controller. Model A and B are identical at every moment in time, but receive different input signals. The optional limiter limits the values $\mathbf{x}(t)$ to a desired range which, for example, represent imposed motor characteristics. Afterwards, the limited values $\tilde{\mathbf{x}}(t)$ excite the plant (robot in this work). The signal $\tilde{\mathbf{x}}(t-\delta)$ is the desired output which model A is trained to generate from the plant output, i.e., it learns the inverse model. This inverse model is then simultaneously employed as a controller to drive the plant (model B), which receives a desired future plant state $\mathbf{y}_d(t+\delta)$ as input, instead of the actual one.

Simultaneous with training the inverse model, we use it as a controller. In order to do this, we use an identical copy of the model (model B in **Figure 2**), which has as input the current end-effector position $\mathbf{y}(t)$, and a desired future end-effector position $\mathbf{y}_d(t+\delta)$. This model, given that the inverse model performs sufficiently well, provides the required joint-angles $\mathbf{x}(t)$ to reach the set target after the delay. For some plants it might be necessary to limit these values to a certain range. For instance, when controlling a joint, the angle in which it can be positioned is bounded. In **Figure 2** this bounding is represented by a limiter which converts $\mathbf{x}(t)$ values to $\tilde{\mathbf{x}}(t)$.

In general, the optimal δ depends on the rate at which the dynamics are observed (sample rate) and the kind of dynamics (fast or slow) that are inherent to the control task. Plants (the system under control) with fast dynamics usually require a smaller δ than slower dynamical systems when using the same sample rate. In this work we chose $\delta = 1$, because one time step delay is sufficient to capture the dynamics of the task at hand. More details concerning this parameter can be found in Waegeman et al. (2012).

In order to train the inverse model we will use online learning, i.e., the inverse model is trained during operation. Initially the untrained inverse model will not be able to provide the desired joint-angles, and the driving signal $\mathbf{x}(t)$ is essentially random. Model A will use the resulting end-effector position to learn what signal was provided by model B. The random driving signal will assure that in this initial training phase model A is provided with a sufficiently broad set of examples. However, to further improve

[1] Here we treat the scaling factors and their target values as if they were probabilities, which stems from the common use of a softmax function: to model a multinomial distribution function (Bishop and Nasrabadi, 2006). We could as well use mean-square error to train $\mathbf{V}(t)$ on the target values, but the resulting update equations would be more complicated, whereas cross-entropy leads to a simple formula.

[2] This is the average distance, such that we can express RMSE in millimeter or centimeter.

exploration and to speed up training in the initial training phase, we add a small amount of noise [initially drawn from $\mathcal{N}(0, 7)$ in mm] to the desired end-effector position, of which the standard deviation linearly diminishes to 0 over the course of 50, 000 samples of training. As soon as model A becomes sufficiently accurate, model B will begin providing the actions for obtaining the desired end-effector positions. In this phase, the inverse model will learn to become especially accurate in the operating regime in which the robot provides the resulting end-effector positions.

In principle, there is no need to ever stop training the inverse model in the proposed controller. Indeed, if the experimenter knows that the conditions of the setup may change over time, it could be desirable to keep the online learning mechanism active at all times in order to let it keep track of changes in the system. For this paper, however, we chose to gradually slow down the learning algorithm and at some point in time let it stop, such that all parameters in the controller architecture remain fixed during testing. More details are provided in section 2.4.4.

2.4.2. Echo state networks

We use an *Echo State Network* (ESN) (Jaeger, 2001) as inverse model. An ESN is composed of a discrete-time recurrent neural network [commonly called the *reservoir* because ESNs belong to the class of Reservoir Computing techniques (Schrauwen et al., 2007)] and a linear readout layer which maps the state of the reservoir to the desired output. A schematic overview of this is given in **Figure 3**. An ESN has an internal state $\mathbf{a}(t)$ (often referred to as reservoir state), which evolves as follows:

$$\mathbf{a}(t+1) = \tanh\left(\mathbf{W}_{\mathrm{r}}^{\mathrm{r}}\mathbf{a}(t) + \mathbf{W}_{\mathrm{i}}^{\mathrm{r}}\mathbf{u}(t) + \mathbf{W}_{\mathrm{o}}^{\mathrm{r}}\mathbf{o}(t) + \mathbf{W}_{\mathrm{b}}^{\mathrm{r}}\right). \quad (8)$$

Here, $\mathbf{u}(t)$ is the reservoir input signal and $\mathbf{o}(t)$ the output produced by the ESN (see below). The weight matrices $\mathbf{W}_g^k$ represent the connections from g to k between the nodes of the network, where r, i, o, b denote *reservoir*, *input*, *output*, and *bias*, respectively. In the case of the controller setup we discussed earlier, the reservoir input $\mathbf{u}(t)$ of model A consists of the concatenation of the past and present end-effector positions, and that of model B of the present and desired end-effector position. During our experiments we scale the input and training signal to the ESN such that

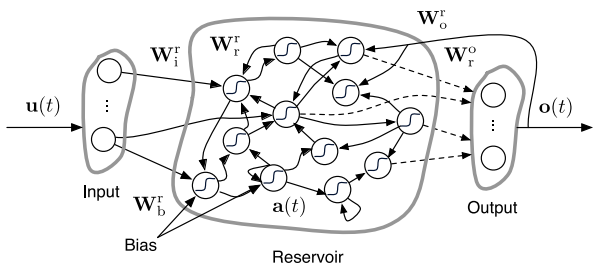

FIGURE 3 | Description of an ESN. Dashed arrows are the connections which can be trained. Solid arrows are fixed. $\mathbf{W}_g^k$ is a matrix representing the connections from g to k, which stand for any of the letters r, i, o, b denoting *reservoir, input, output,* and *bias*, respectively. $\mathbf{u}(t)$, $\mathbf{o}(t)$ and $\mathbf{a}(t)$ represent the input, output, and reservoir states, respectively.

their values are between −1 and 1. Consequently, we will need to undo this scaling before the generated network output represents actual joint-angles which can control the robot.

The ESN output $\mathbf{o}(t)$ is generated by:

$$\mathbf{o}(t) = \mathbf{W}_{\mathrm{r}}^{\mathrm{o}}(t)\mathbf{a}(t), \quad (9)$$

i.e., a linear transformation of the reservoir state over $\mathbf{W}_{\mathrm{r}}^{\mathrm{o}}(t)$. The core idea of ESNs is that only this weight matrix is explicitly trained. The other weight matrices have fixed, randomly chosen elements of which only the global scaling is set. As we use a continuously operating online learning strategy, $\mathbf{W}_{\mathrm{r}}^{\mathrm{o}}(t)$ is time depending. In the more common ESN setup they are trained offline using, e.g., ridge regression, and remain fixed once they are determined.

Each ESN in this paper is initialized by choosing the elements of $\mathbf{W}_{\mathrm{r}}^{\mathrm{r}}$, $\mathbf{W}_{\mathrm{i}}^{\mathrm{r}}$, and $\mathbf{W}_{\mathrm{b}}^{\mathrm{r}}$ from a standard normal distribution $\mathcal{N}(0, 1)$. Next, $\mathbf{W}_{\mathrm{r}}^{\mathrm{r}}$ is scaled such that its spectral radius equals one, and the matrices $\mathbf{W}_{\mathrm{o}}^{\mathrm{r}}$, $\mathbf{W}_{\mathrm{i}}^{\mathrm{r}}$ and $\mathbf{W}_{\mathrm{b}}^{\mathrm{r}}$ are multiplied with a factor 0.1 (hand tuned).

The reservoir serves as a random non-linear dynamical system which can extract useful information of its input. Due to its recursion, a reservoir has *fading memory*, i.e., it retains information of the past input signal but gradually forgets it over time and allows ESNs to be used for processing time series.

2.4.3. Linear controllers

In order to check how much the operation of MACOP depends on the type of controller, we also conducted an experiments in which we used linear controllers. Here, the output of the inverse model is a direct linear combination of its input, so no non-linearity or memory is present in these controllers, and learning the non-linear part of the full inverse kinematics will largely need to be accounted for by training the scaling factors. Here too, we will train the system online, according to the algorithm described in section 2.4.4.

2.4.4. Recursive least squares

In order to train the inverse model online we will use Recursive Least Squares. With each iteration the output weights are adjusted such that the network converges to the desired output. However, the rate at which these weights are changed is controlled by the corresponding responsibility factor ζ_i. Within the proposed MACOP architecture, such adaptive learning rate allows each controller's inverse model to distinguish itself from the other controllers. Additionally, in order to allow the weights to converge to fixed values, the training speed is modulated with a factor $l(t)$. Because our description of a controller is equal for all controllers within MACOP we will omit the use of the index i which refers to the i-th controller. We can therefore write the weight update equation as follows:

$$\mathbf{W}_{\mathbf{r}}^{\mathbf{o}}(t) = \mathbf{W}_{\mathbf{r}}^{\mathbf{o}}(t-1) - l(t)\zeta(t)\mathbf{e}(t)(\mathbf{Q}(t)\mathbf{a}(t))^{\mathsf{T}}, \quad (10)$$

where

$$\mathbf{Q}(t) = \frac{\mathbf{Q}(t-1)}{\lambda} - \frac{\mathbf{Q}(t-1)\mathbf{a}(t)\mathbf{a}^T(t)\mathbf{Q}(t-1)}{\lambda(\lambda + \mathbf{a}^T(t)\mathbf{Q}(t-1)\mathbf{a}(t))}, \quad (11)$$

and

$$\mathbf{Q}(0) = \frac{\mathbf{I}}{\alpha}. \quad (12)$$

Here, $\mathbf{a}(t)$ are the current states, λ a forgetting factor and α an initially chosen value. $\mathbf{Q}(t)$ is a running estimate of the Moore–Penrose pseudo inverse $(\mathbf{a}^T\mathbf{a})^{-1}$, (Penrose, 2008). $\mathbf{Q}(0)$ denotes the initial value of $\mathbf{Q}$. The error $\mathbf{e}(t)$ is the difference between the actual and the desired joint-angles. To allow $\mathbf{W}_\mathbf{r}^\mathbf{o}(t)$ to converge together with the projection matrix $\mathbf{V}$ from Equation (7), $l(t)$ is decreased linearly from 1 to 0 in the same fashion as the learning rates η_g and η_s in Equation (7), i.e., as long as the average error over the last 1000 time steps is larger than 1 mm, it is equal to one, and as soon as it is smaller, it linearly decreases to zero over the course of 5000 time steps.

2.5. ANALYZING MACOP

Each controller learns to produce a set of joint-angles online, which contribute to solving the IK problem. We define such a set of joint-angles as being a control primitive. Mixing these primitives results in a set of joint-angles to which the robot is positioned. To analyze each controller and its contribution we define several methods which we will describe in the remainder of this section. The results of these analyses can be found in section 3.

2.5.1. Tracking a trajectory

As described above we designed MACOP such that the scaling of a controller depends on the location of the end-effector and the robot's pose. A control primitive that has the largest "responsibility" [biggest $\zeta_i(t)$], we will call the dominant primitive (generated by the dominant controller). Furthermore, we study the time course of the scaling factors, and how they relate to the motion of the robot. We color the trajectory of the end-effector according to which controller is the dominant one at that position, this in order to show which controllers specialize in which regions of task-space. We show the resulting trajectories using both ESN and linear controllers.

2.5.2. Selecting a single controller: control primitives

Even when the scaling factors strongly fluctuate in time, this does not necessarily mean that the controllers are sending different control signals. Indeed, even though the learning speed is modulated according to the scaling factors, all of them still are trained to perform the same task. In order to verify if specialization indeed occurs, we conduct experiments in which after the training phase, only one controller is used (i.e., we set its scaling factor to 1 and all others to 0). We show the resulting trajectories, and we study individual model performance compared to its true scaling factor.

2.5.3. One vs. multiple controllers

One of the main research questions of this paper is of course how much we can profit from using MACOP versus a single controller. In order to answer this, we measure how well the setup performs as a function of the number of controllers. In order to keep this comparison fair, we make sure that for each setup the number of trainable parameters (the total number of output weights of the ESN) remains constant.

2.6. DYNAMIC EFFECTS OF KINEMATIC CONTROL

An inverse kinematic mapping maps a desired task-space position to the corresponding joint-angles. In most evaluations of learning inverse kinematics, a new command is only sent when the previous desired joint-angles are reached. For this, a direct inverse mapping without memory suffices. However, in our experiments we do not wait for the robot to reach the commanded joint-angles and send new joint-angles at a constant rate (every 32 ms). As shown in **Figure 4**, a PID-controller, which applies the necessary torque to reach a desired joint-angle, has a dynamic transition before reaching a new target angle. These dynamic transitions need to be compensated by the controllers as well, in order to reach the desired outcome in time[3]. Such transitions require memory instead of a direct mapping. We evaluate the MACOP's ability to cope with these dynamic effects by changing the *P*-parameter of each joint's PID-controller (which determines how fast the robot can react to changes in the desired joint-angles) such that these dynamic effects become more important.

3. RESULTS

All training parameters for the experiment are provided in **Table 1**. The RLS parameters λ and α we chose based on previous experience. The learning rates η_g and η_s we found by trial and error, but we experimentally verified that performance does not change much in a broad region around the provided values.

3.1. TRACKING A TRAJECTORY

To investigate the overall behavior of MACOP, we applied multiple desired trajectories of the robot end-effector. In both

[3]This means that the control signal the robot receives can no longer be simply interpreted as joint-angles, but more as a type of motor commands.

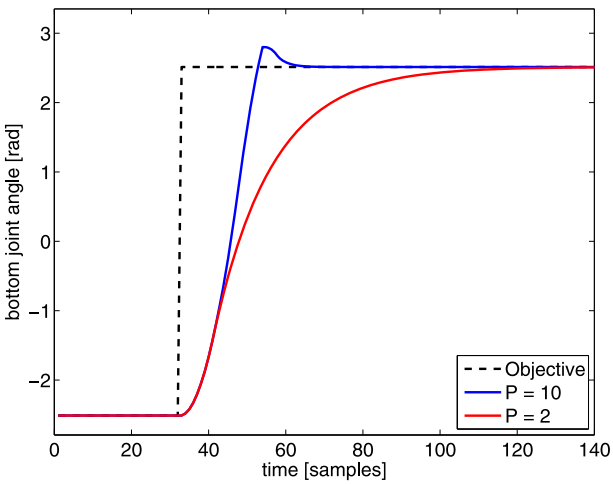

FIGURE 4 | Illustration of a sudden change in desired joint-angle of the bottom joint (black dashed line) of the PUMA 500. The robot response is shown for this particular joint with different *P*-parameters, to illustrate the effect of a changed *P* value. By decreasing the *P*-parameter the dynamic transition time from one position to the other increases.

Table 1 | Simulation parameters.

Parameter	Value
λ	$1 - 10^{-4}$
α	0.01
η_g	0.00008
η_s	0.0002

Figures 5, **6**, we show the resulting trajectories (after convergence) of following a rectangular and circular-shaped target trajectory. In both experiments an RMSE of 10 cm was achieved within 10,000 samples and a RMSE of 1 mm (point of convergence) within 100,000 samples, demonstrating that the system is able to follow a desired trajectory closely.

In the first experiment, we train the robot to generate a rectangular trajectory which spirals back and forth into the X-direction over several passes. For this we used 5 controllers, each with 50 neurons. In the top panel of **Figure 5** we show the trajectory generated by the robot after convergence (all learning rates are 0 and RMSE = 1 mm). Each part of the trajectory is colored according to which controller is dominant (has the maximum scaling factor) at that time. The responsibilities $\zeta_i(t)$ themselves are shown in the bottom panel of **Figure 5**. It appears that the 5 controllers have formed a specialization for certain regions of task-space, their responsibilities ζ_i peaking at the corresponding parts of the trajectory.

Notice that the depth of the trajectory in the X-direction is rather small (20 cm), and yet the scaling factors strongly vary as a function of it (as is especially apparent in the green and blue parts of the trajectory). This strong change in scaling factor is caused mostly by the pose of the robot, and not so much the end-effector position, as we have verified by experimentally testing the sensitivity of the scaling factors as a function of the joint-angles and position. This suggest that the control architecture effectively uses information of the robot pose to solve the task.

A second experiment ($N_c = 4$, 50 neurons each) extends the difficulty of the previous trajectory to demonstrate responsibility/task-space correlations over a larger time period of the desired movement. The trajectory describes four passes of a circle in a single direction during 8 s, after which the trajectory smoothly switches to describing a shifted circle in the opposite direction of the previous circle.

We show the result after convergence in **Figure 6**. The rotation direction in which the trajectory is followed is indicated by the arrows. In the left part of the circular trajectory the blue controller is contributing a significant part to the control of the robot. This contribution is reduced when the robot is performing the right circular movement. In this part of the trajectory, the red controller is contributing more. In order to verify MACOPs robustness we consider the double circle trajectory after training, and suddenly jump ahead in time in the desired trajectory such that there is a discontinuous jump in the target end-effector position. The result is shown in **Figure 7**. It appears that after a large initial overshoot, the robot recovers and is eventually capable of tracking the desired trajectory again. The overshoot can be largely explained by the fact that the controller never saw a discontinuous jump during training, such that it has seen no examples of what happens when large torques are applied on the joints. Furthermore, the sudden jump forces the robot arm into a region of task-space where it never resided during training, causing unpredictable behavior.

After training MACOP (same configuration as before) with the double circle trajectory we define a test grid on the plane of the training trajectory with a resolution of 1 cm. The test target points of this trajectory are visited by sweeping the grid back and forth

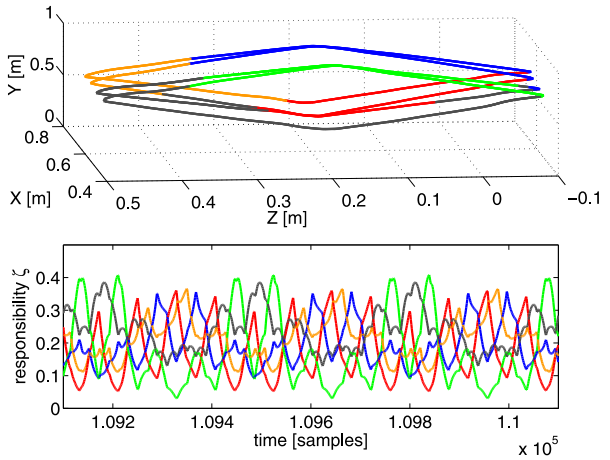

FIGURE 5 | Top panel: the resulting end-effector trajectory generated by the robot arm for the rectangular target trajectory after convergence (RMSE < 1 mm for the full trajectory). The corresponding color of the dominant controller is shown. **Bottom panel:** the responsibility factors $\zeta_i(t)$ as a function of time.

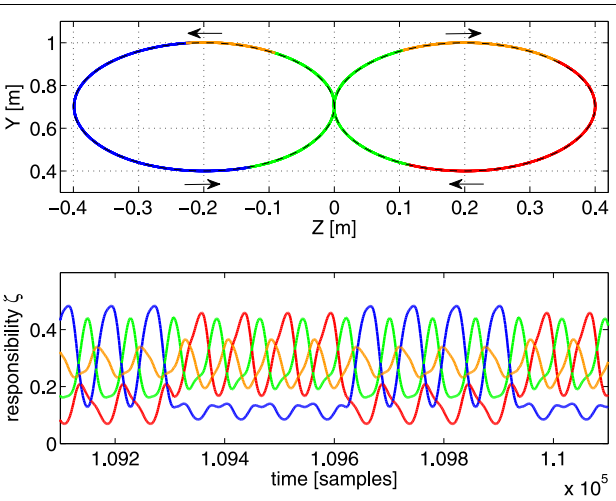

FIGURE 6 | Top panel: the resulting end-effector trajectory generated by the robot arm for the circular target trajectory after convergence. The corresponding color of the dominant controller is shown. The arrows indicate the direction of the trajectory. **Bottom panel:** the responsibility factors $\zeta_i(t)$ as a function of time.

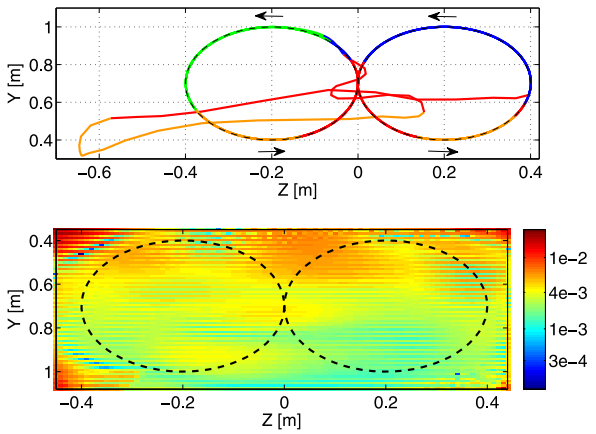

FIGURE 7 | Top panel: a part of the generated trajectory before the switch and after a jump, where the dominant controllers are represented by a corresponding color. The direction in which the trajectory is tracked is indicated by the arrows. **Bottom panel:** visualization of the generalization performance of the learned IK (circular training trajectory: dashed line) on a test grid. Color scale is the RMSE in m.

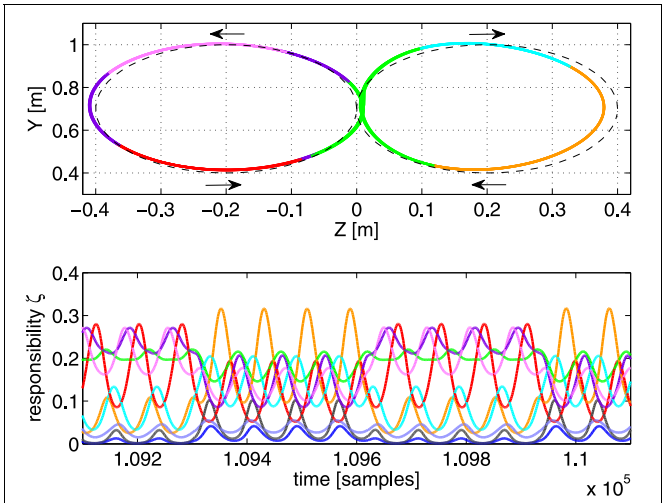

FIGURE 8 | Illustration of the tracking performance of MACOP with 9 linear controllers after convergence. Top panel: the resulting trajectory, colored according to the dominant controller. The dashed line is the target. **Bottom panel:** the corresponding responsibilities as a function of time.

in the Z-direction. The result of such an experiment is shown in the bottom panel of **Figure 7**. Each pixel represents the RMSE (in meters) of a specific grid point. Averaged over 10 experiments (different initialization and training) a mean RMSE = 4.4 mm with a standard deviation of 3.1 mm is achieved. Note that the RMSE in the grid corners are bigger because they are harder to reach.

In the final experiment of this paragraph, we tried a set of linear controllers to see if MACOP is able to still control the robot arm to generate a trajectory with very low-complexity controllers. We found that we need at least 9 controllers to approximate the target trajectory with a final RMSE = 1.5 cm. Using MACOP with fewer controllers does not work. **Figure 8** shows the resulting trajectory and the scaling factors of the individual controllers. The fact that MACOP is capable of solving the tracking task with such basic controllers is a strong indicator that the presented training algorithm for the scaling factors is quite successful in distributing the complexity of the full task. It also demonstrates that MACOP can be easily extended to include any kind of inverse model.

3.2. ONE VS. MULTIPLE CONTROLLERS

One of the main assumptions underlying MACOP is that we assume it is beneficial to distribute the full control task over multiple controllers. The first check we performed was to make sure that the mixing using the softmax function is in fact responsible for the increase in performance, and not just having several distinct controllers in the first place. We have tested this by keeping the responsibility factor $\zeta_i(t)$ constant and equal to N_c^{-1} for each model, and this in the case of 5 ESN-controllers. It turns out that this situation leads to the same performance that is attained by using a single, large reservoir (which performs worse, as we will show next), showing that the variable responsibility factors directly increases performance.

To investigate how much the tracking performance depends on the number of controllers we conducted an experiment in which we measure the mean error on the trajectory for different number of controllers. We measure the distance from the end-effector to the target averaged over 5000 samples after training. We linearly reduce all learning rates to 0 after 100,000 samples of training (because some experiments will never reach the requirement of an RMSE less than 1 mm). For an increasing number of controllers we apply MACOP on trajectories which are based on all 26 letters in the English alphabet, which we have drawn by hand and of which we recorded position as a function of time. As the trajectory is repeated periodically, we also made sure that the end and starting point are the same in each trajectory (to avoid sudden jumps). After recording we scaled the trajectories and placed them in the YZ-plane in reach of the robot.

In each experiment we train a randomly initialized controller ensemble to produce a single letter, and we measure the RMSE after convergence. For each number of controllers, we measure the average RMSE over 50 instantiations of each letter, such that the measured result for each N_c is averaged over $50 \times 26 = 1300$ experiments. In order to keep the comparison fair, we keep the number of trainable parameters (the total number of output weights of all the ESNs) constant. In practice this means we used 250 neurons for a single controller, 125 for 2 controllers, etc. In **Figure 9** we present the results. A single controller performs rather poorly. The optimal number of controllers for the entire English alphabet is around 6 controllers. When the number of controllers increases further, the number of neurons, and hence the modeling power, of each controller becomes smaller. Similar to the experiment with the linear controller, this experiment shows that great deal of the modeling complexity is covered by the mixing mechanism.

It should be noted that in some cases, due to the random initialization, the robot can get stuck in a certain pose (as some

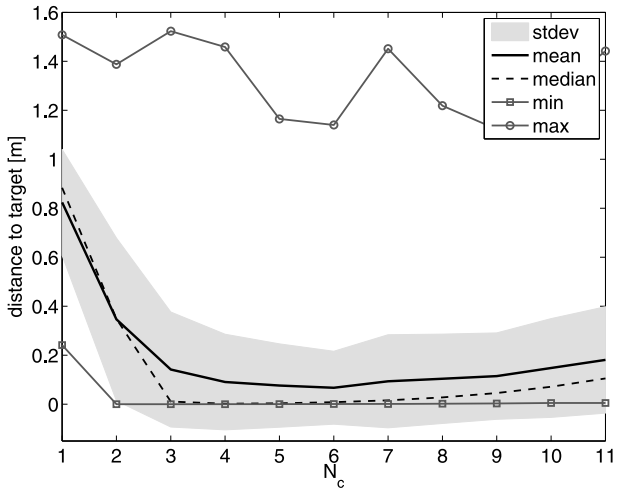

FIGURE 9 | Effect of the number of controllers on the tracking performance of MACOP on the English alphabet trajectories. The mean, median, standard deviation, minimum and maximum values over 1300 experiments are shown for each controller configuration.

joint-angles are limited between certain values), and never reach the desired trajectory. This is the reason why the maximum values in **Figure 9** are much bigger than the mean over all its experiments. If we disregard these cases we get an RMSE of 1 mm within 100,000 training samples.

3.3. CONTROL PRIMITIVES

As we have mentioned in the introduction, what we call control primitives in this paper differs from the regular notion of primitives. In this section, we investigate how the actual individual contributions of the controllers behave. Due to the MACOP setup it is not straightforward to get a good understanding of the role of a single controller. At all points in time, all controllers influence the robot, and due to the feedback, each controller influences all other controllers. We can think of two ways in which to study the individual controller contributions. Either we use a single controller in the ensemble (with scaling set to one) for steering the robot, which then ignores potential feedback by the influence of the other controllers, and as such emergent synergies are not expressed. Alternatively, we could record the control signals of the individual controllers during normal operation, and use these recordings to steer the robot afterwards. Even though this approach will take into account potential synergies between the controllers, during testing it has no feedback at all, such that the trajectory could start to drift from the objective. In our setup, however, it seems that such an effect does not occur. Therefore we will use this approach. We have tried the other approach as well, and the results were qualitatively similar.

To get a qualitative idea of how the individual contributions look, we revisit the task inspired on the English alphabet, and train a controller ensemble to draw the letters of the word "amarsi"[4] one after another. After training, we use the recorded contributions of a single controller (unscaled) to steer the Webots simulation, and record the robot response.

The result is shown in **Figure 10A**, the five rows starting from the top show what trajectory each individual control primitive produces if it alone is present in the control architecture (in a corresponding color), plotted over the target value (gray). The bottom row shows the trajectory of the full ensemble, colored according to the most dominant controller. It is interesting to note that, even though all individual controllers produce a trajectory that resembles the target, all of them strongly deviate from the true target, and each of them produces a distinctly different response. The scaled combination of them, however, tracks the objective far more closely, which again indicates that the mixing mechanism works well to combine contributions of several controllers.

A second experiment we perform is to see whether true specialization occurs. After all, even though one controller is dominant, the other controllers will also strongly contribute to the total motion. In order to check this, we have performed a similar experiment to the double-circle objective, depicted in **Figure 6**. We used four controllers, and used the individual recordings to drive the robot. Next, we record the distance error of the end-effector as a function of time, which we compare with the corresponding scaling factor of the controller. If specialization occurs, we would expect to see some negative correlation between the error on the trajectory and the corresponding scaling of the controller. If the scaling factor of a certain controller is high, this would indicate that it specializes in the current region of task-space, and the resulting error should be low. Vice versa, if the scaling is low the controller should perform worse, as it is not its region of specialization.

The result for each controller is shown in **Figure 10B**. For some controllers there seems to be a strong relation between the error and the scaling of the corresponding model. Especially in the case of the red and blue controller. The relation is weaker, however, for the other two. Indeed, the scaling factor for these two controllers fluctuate less, such that they are able to train their corresponding inverse models throughout the full trajectory, leading to better overall generalization. From this we can conclude that MACOP uses both specialization and signal mixing to obtain good control over the robot arm.

3.4. COPING WITH DYNAMIC EFFECTS

As mentioned before, during training MACOP is capable of handling dynamic effects/transitions caused by the inherent inertia of the robot and the fixed control signal rate. To demonstrate this ability, we apply MACOP to the robot with the square objective we used in **Figure 5**, but reduce the velocity of each joint. The *P*-parameter in the PID-controllers is reduced from 10 to 2, of which the effect is shown in **Figure 4**. Furthermore, in order to assess the effect of a sudden jump, we periodically shift the square by half a meter, which introduces discontinuous moments in the objective.

In **Figure 11** we show the Z-coordinate as a function of time for the desired trajectory and resulting trajectories for the different *P*-parameters. The top panel depicts the results during the beginning of the experiment (30.4–38.4 s), while the

[4]AMARSi is an EU project concerning adaptive motor skills for robots.

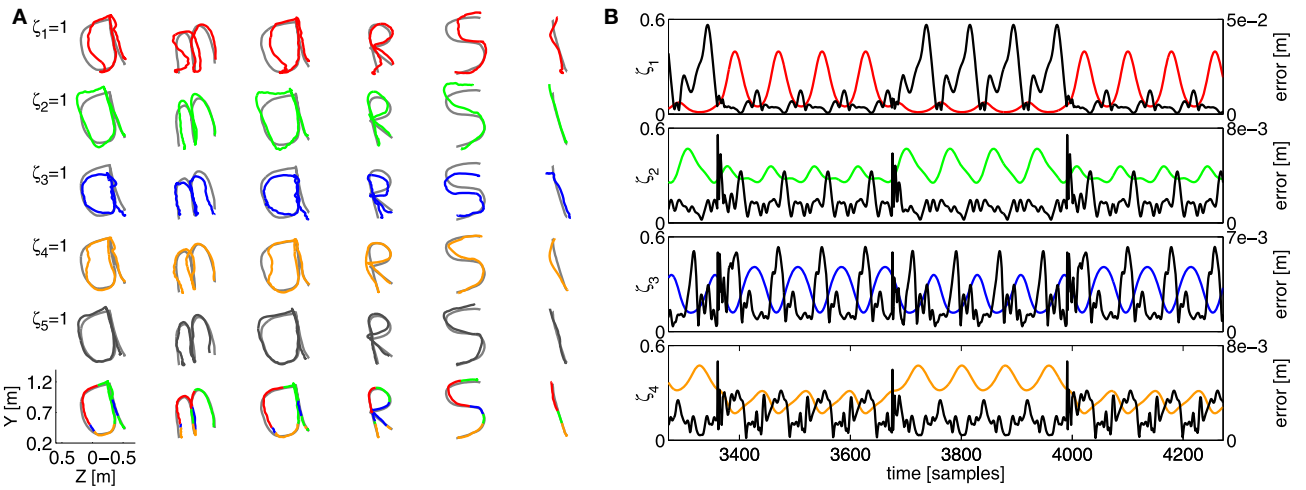

FIGURE 10 | (A) Overview of the resulting trajectory with the "amarsi" target by using a single controller contribution. Each row shows the resulting end-effector trajectory of the robot arm. From left to right a part of the continuous writing is shown such that every letter of the word "amarsi" is presented. The coloring of the trajectory illustrates which controllers contribution is used (one for each row). The bottom row show the target trajectory, together with the actual generated trajectory. **(B)** The error of a single controller contribution (the black curves), plotted with their corresponding scaling factors (colored) as a function of time. The vertical scale of the error is provided on the left vertical axis, and that of the scaling on the right.

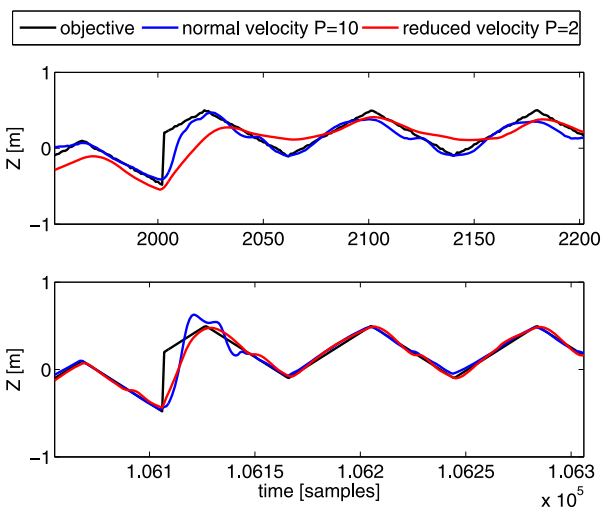

FIGURE 11 | Comparison of the Z-coordinate of the generated trajectories for the shifted-squares objective. Shown are the desired Z-coordinate (black), and those generated by robots with $P = 10$ (blue), and $P = 2$ (red). The top panel is during the early parts of the training, and the bottom one after convergence. The abrupt change in the desired trajectory corresponds to the shift of the squares.

bottom panel depicts the results after convergence. The robot with the standard velocity (blue line) is able to follow the objective more closely during the beginning of the experiment but exhibits some fluctuations. The Z-position trajectory of the reduced velocity configuration is unable to reach the objective closely during the first part an clearly needs more time to learn the inverse model, indicating that the control problem is harder when the robot reacts more slowly. If we look at the result after convergence, we notice that the small fluctuations in the blue trajectory are reduced, and that MACOP has learned to follow the objective closely. Interestingly, due to a larger maximum velocity, the blue trajectory has a large overshoot when the applied objective exhibits a sudden jump. The red trajectory exhibits almost no overshoot in the beginning of the experiment but after convergence, the red curve also exhibits some overshoot. In the beginning of the experiment it's clear that the limited velocity of the joints causes the robot's end-effector to not reach its target in time, as opposed to the version with fast control. This indicates that the desired trajectory is more difficult to obtain if the robot has slow dynamics. Indeed, the sudden changes in direction can be made far more easily if the robot has a fast control response, and actuating a single joint may be enough, which is a simple task. If it has a slow response, the robot will need to use synergies between several joints in order to cause the end-effector to switch its direction so suddenly. This makes the control problem far more complicated.

Reducing the velocity of each robot joint has its advantages in terms of power consumption and safety. However, a trade-off must be made between faster convergence, as in closely following the objective, and the amount of overshoot allowed. In some tasks it might be possible that the objective changes very fast, and in such cases, reducing the reaction speed will restrict the robot in reaching its targets.

4. DISCUSSION

In this work we described a modular architecture with control primitives (MACOP), which learns to control a robot arm

based on a pre-set number of controllers. The inspiration for this architecture stems from MOSAIC (Haruno et al., 2001), which is a control framework, inspired by a plausible model on how human motor control learns and adapts to novel environments. MOSAIC uses a strategy in which an ensemble of inverse-model controllers is trained, one for each environment with different properties. On top of this, a selection mechanism selects which controller needs to be active at which moment in time. Each controller is associated with a forward model of the system that needs to be controlled, and controller selection happens by choosing the forward model which is the most accurate.

Our [and others' (Haruno et al., 2001)] observations show that such a strategy may not be optimal. There is no reason why the accuracy of a forward model should be correlated to that of the inverse model. Another selection mechanism of the controllers might thus be possible. In this work, we want to build upon the idea of a fixed number of control primitives which are continuously combined to produce a desired motion. Each controller used in MACOP consists of an inverse model which is trained online and consists of an Echo State Network. Given some high-level controller mixing requirements, an unsupervised division of the task and joint-space is achieved, which can be related to a Kohonen map (Kohonen, 1998). The mixing mechanism learns a subdivision of the entire task and joint-space and produces one scaling factor for each controller which are associated with the current end-effector and joint-angle position of the robot. The training error of each controller is scaled with the same factor such that training data within a controller's associated part of the subdivision becomes more important than other data. As a result of this data selection mechanism, every controller can specialize its function within its appointed part of the joint and task-space. The used mixing requirements prescribe that all controllers should contribute significantly to the task, while still allowing for a controller to specialize itself for a certain subregion.

We validated MACOP on an inverse kinematic learning task where we controlled a 6 DOF robot arm by producing joint-angles which are sent at a fixed control rate. This is in contrast with other approaches such as Oyama et al. (2001) where a static mapping from task-space position to joint-space is learned and where a separate feedback control loop to approach the target joint-angles is needed. Such a separate feedback control system results in high control gains when their is an external perturbation of the robot's movement. Achieving a compliant kinematic control thus argues for a dynamic learning approach which learns the control at a fixed control rate. In this work we rely on the approach proposed in Waegeman et al. (2012) for such a dynamic control method. As a result MACOP is well suited to cope with the dynamical effects introduced by the non-instantaneous control of the robot: even when the robot responds slowly to the control signal, the MACOP architecture is able to compensate for it and produce the target trajectory.

We replaced each controller with a simple linear controller to validate MACOP's independence of the chosen ESN-controller. Such a linear controller is constructed by learning a linear combination of the architecture's input. When the number of linear controllers within MACOP is large enough, the end-effector will start to track the target. However, the tracking performance of MACOP with the ESN-based controllers is better due to its non-linear nature.

In this work, the contribution of a single controller to all the robot's joint-angles is called a control primitive. Motor and motion primitives generally refer different building blocks at different levels of the motor hierarchy. They can be kinematic (e.g., strokes, sub movements), dynamic (e.g., joint torque synergies, control policies) or both. According to Flash and Hochner (2005) their crucial feature is that a wide variety of movements can be derived from a limited number of stored primitives by applying appropriate transformations. Within this definition a controller's contribution to the joint-angles can be called a primitive. Their organization is stored within the mixing transformation such that after convergence a consistent controller selection is achieved. What is different from the common interpretation of primitives is that in our case, the control primitives are mixed and rescaled constantly, instead of truly being selected and weighted statically.

MACOP learns to spread a set of controllers in the vicinity of the target trajectory such that primitives produced by controllers can help in tracking this trajectory. Even when the complexity of these controller is reduced (using linear controllers), the task is still solvable. Unlike in Nori and Frezza (2004), the MACOP control primitives and their mixing values both depend on the state of the robot, and because they are adapted online they become dependent on the task. After convergence (all learning rates are 0) this task dependency is removed.

In future work we wish to investigate how well MACOP is able to simplify the full dynamic control (e.g., controlling torques) of such systems including real-world robot platforms. Secondly, we wish to investigate how the mixing mechanism adapts to new tasks when the controllers are assumed to be fixed (training completed).

One interesting observation needs more scrutiny. Even though we showed that a single controller is unable to learn the inverse kinematics, we still found that for the controller ensemble, individual controller contributions perform relatively well in tracking the target trajectory. We suspect that this is caused by the used mixing mechanism and its effect on the controller's learning rate. The training data used to update a controller is weighted such that a good local model can be learned more easily instead of polluting the controller with data from other positions. Later, generalization to other positions in task-space can be performed more gradually, simplifying the full training problem. Further tests will be needed to confirm this hypothesis.

ACKNOWLEDGMENTS

We thank J. P. Carbajal for the valuable and inspiring discussions and useful suggestions. The behaviors of the animals or embodied agents are characterized by the dynamic coupling between the brain, the body, and the environment. This implies that control, which is conventionally thought to be handled by the brain or a controller, can partially be outsourced to the physical body and the interaction with the environment. This idea has been demonstrated in a number of recently constructed robots, in particular from the field of "soft robotics". Soft robots are made of a soft material introducing high-dimensionality, non-linearity, and elasticity, which often makes the robots difficult to control. Biological systems such as the octopus are mastering their complex bodies in highly sophisticated manners by capitalizing on their body dynamics. We will demonstrate that the structure of the octopus arm cannot only be exploited for generating behavior but also, in a sense, as a computational resource. By using a soft robotic arm inspired by the octopus we show in a number of experiments how control is partially incorporated into the physical arm's dynamics and how the arm's dynamics can be exploited to approximate non-linear dynamical systems and embed non-linear limit cycles. Future application scenarios as well as the implications of the results for the octopus biology are also discussed.

Keywords: reservoir computing, octopus, soft robotics, morphological computation

1. INTRODUCTION

Biological systems have certain morphologies[1] and material characteristics that improve their adaptivity and increase their probability to survive. This suggests that control is not only located in the brain, but that there is a tight coupling between the brain, the body, and the environment, an idea that is usually termed *embodiment* (Pfeifer and Bongard, 2006; Pfeifer et al., 2007, 2012; Li et al., 2011b; Nakajima et al., 2011c, 2012a,b). Recently, motivated by the fact that soft material is ubiquitous in the body structures of living creatures, a new family of robots, *soft robots*, has been constructed with the aim of incorporating flexible elements (Trivedi et al., 2008; Steltz et al., 2009; Brown et al., 2010; Shepherd et al., 2011; Pfeifer et al., 2012). These robots have significant advantages over traditional articulated robots in terms of morphological flexibility and interactional safety (Trivedi et al., 2008; Li et al., 2011b). However, controlling them with conventional techniques is difficult because of their high-dimensional body structures and their diverse body dynamics, which are due to their non-linearity and elasticity. In this context, the octopus has been a good source of inspiration for roboticists to learn a control strategy for soft robots. An octopus has hyper-redundant limbs with a virtually unlimited number of degrees of freedom (DOF), and its movements are known to be highly sophisticated (Sumbre et al., 2001, 2005; Trivedi et al., 2008). From a conventional control perspective, the octopus's method of controlling movement and harnessing its non-linear body dynamics is outstanding and far-reaching.

It is well known that the nervous system of the octopus is highly distributed throughout the entire body. It has a relatively small central brain (about 50 million neurons), a central nervous system (CNS), which controls the large peripheral nervous system (PNS) of the arms (about 300 million neurons), integrates information from the visual system, and then issues commands to lower motor centers controlling the elaborate neuromuscular system of the arms. A typical example showing the effectiveness of this distribution of the nervous system is the reaching behavior (Gutfreund et al., 1996; Gutfreund, 1998; Sumbre et al., 2001; Yekutieli et al., 2005a,b). Reaching behavior consists of a *bend propagation* along the arm toward the tip in a highly stereotypical and invariant way. Sumbre et al. showed that the arm extensions can be evoked in arms whose connection with the brain have been severed (Sumbre et al., 2001). Because the evoked motions in denervated octopus arms were qualitatively and kinematically identical to natural bend propagations, an underlying motor program appears to be embedded in the neuromuscular system of the arm, which does not require continuous central control (Li et al., 2011a, 2012, 2013; Nakajima et al., 2011a,b; Kuwabara et al., 2012). In addition, the muscular organization of the octopus's arm has a characteristic structure called *muscular-hydrostats* (Kier and Smith, 1985; Smith and Kier, 1989; Taylor and Kier, 2003;

[1] By morphology, we do not only refer to the shape, but also sensor and actuator distributions, and physical properties, such as stiffness, etc.

Feinstein et al., 2011). In such structures, the volume of the organ remains constant during all movements, enabling the muscles themselves to perform all the functions usually performed by the skeleton (Sumbre et al., 2001, 2005; Taylor and Kier, 2003). This suggests that the body of the octopus arm is highly involved in the production of movements. Accordingly, in robotics, there have been several attempts to characterize the role of the muscular-hydrostat system in terms of its anatomical structure (Mazzolai et al., 2007; Laschi et al., 2009, 2012; Vavourakis et al., 2012a,b) and functionality (Nakajima et al., 2013).

In this paper, along the lines of these biological findings, we aim to provide one quantitative evidence that the structure of the octopus's arm has the potential to embed multiple motor programs without any support from the external controller. Recently, it has been shown that non-linear mass-spring networks can be used as a computational resource (Caluwaerts and Schrauwen, 2011; Hauser et al., 2011, 2012; Sumioka et al., 2011; Caluwaerts et al., 2013; Nakajima et al., 2013). These works imply that the non-linear and elastic body dynamics of soft robots are not drawbacks for control, but rather can be directly exploited as a computational resource. In this paper, we build on theoretical models (Hauser et al., 2011, 2012) that have been proposed in the context of *reservoir computing*.

The term reservoir computing has been proposed by Schrauwen et al. (2007) for a set of machine learning techniques used to emulate complex, non-linear computations. The idea is to drive a high-dimensional, non-linear dynamical system (which has been randomly initialized, but afterwards fixed) with a low-dimensional input stream. This dynamical system, typically referred to as the *reservoir*, provides highly complex, but reproducible responses in its state space to the input. It operates as a type of temporal and finite "kernel" by projecting non-linearily the low-dimensional input into the high-dimensional state space of the reservoir. Furthermore, since a reservoir consists of dynamical systems, it exhibits a memory, which fades out exponentially (i.e., fading memory)[2]. A remarkable property of the approach is, if the reservoir is complex enough (i.e., high-dimensional and non-linear), it can been shown that it is sufficient to add a simple *linear*, *static* readout from the high-dimensional state space to emulate *non-linear complex* computations. Such reservoir computing setups have been proven to outperform other machine learning techniques in a number of difficult tasks; see Jaeger (2003) for example. Another remarkable property of this setup is that the requested properties for computationally powerful reservoirs turn out to be rather general. Hence, a number of different implementations for reservoirs have been proposed (Schrauwen et al., 2007). For example, simple, abstract dynamical systems are used for echo state networks (Jaeger, 2002; Verstraeten et al., 2007; Lukoševičius and Jaeger, 2009), or models of neurons are used in liquid state machines (Maass et al., 2002). Lately, it has been demonstrated that complex, compliant bodies of biological systems and robots have the potential to serve as such a reservoir as well, see Hauser et al. (2011) and Hauser et al. (2012).

[2]The memory is due to the integration capability of dynamical systems (i.e., It accumulates information over time).

Here, we demonstrate that the soft robotic arm inspired by the octopus can be used as a reservoir. This means, by simply attaching a static, linear readout from the high-dimensional non-linear dynamics of the octopus arm, one can emulate complex, non-linear computation without altering the physical system itself. That is, we employ the physical body as part of a computational device. In this paper, a 3D dynamic model of this soft robotic arm is used as a test platform. Compared with the model used in Hauser et al. (2011) and Hauser et al. (2012), our model is more biologically inspired and physically feasible. It is a mass-spring-damper system, where the springs are aligned to emulate the octopus's muscular organization, and embeds the characteristic properties of a muscular-hydrostat. The arm is also assumed to be immersed in an underwater environment, in which the water friction constants are approximated by the computational fluid dynamics (CFD) simulations. As a result, the arm reveals highly non-linear body dynamics when actuated. By using this platform, we demonstrate that its body dynamics can be exploited as a computational resource. To test its power, we defined two types of tasks: first, to emulate complex non-linear dynamical systems, where we investigate whether the body dynamics are exploited as a computational resource; second, to implement a closed-loop control. We used several non-linear limit cycles to see how they can be embedded directly into the soft robotic arm without any support from an external controller. The choice of example functions adopted for each type of task is motivated to evaluate the non-linearity and memory that the body dynamics contains.

This paper is organized as follows. In section 2, we start by explaining the overall setting of the 3D dynamic model of the soft robotic arm platform and show how the arm emulates the muscular organization of the octopus in detail. The input–output relations adopted and the experimental procedures are also provided in detail. In section 3, we explain the results for a series of tasks in detail, and in section 4, we give concluding remarks, including future extension scenarios of our proposed approach.

2. MATERIALS AND METHODS

In this section, we provide a detailed description of the soft robotic arm simulator model and explain how to exploit the system as a computational resource by introducing input–output relations. The experimental procedure is also explained in detail.

2.1. DYNAMIC MODEL OF A SOFT ROBOTIC ARM INSPIRED BY THE OCTOPUS

In this paper, we use a 3D dynamic model of a soft robotic arm inspired by the octopus (Kang et al., 2011, 2012). The model is currently applied for testing purposes for control architectures of soft robotic arms (Kuwabara et al., 2012; Nakajima et al., 2012a), and has been validated to have good agreement with a physical soft robotic arm platform (Zheng et al., 2012). The overall structure of the entire arm is shown in **Figure 1F**. It is assumed to be immersed in an underwater environment, and the base of the arm is able to rotate in any direction. It consists of 20 compartments, and each compartment implements the unique characteristics of octopus muscles, called muscular-hydrostats. In an octopus arm,

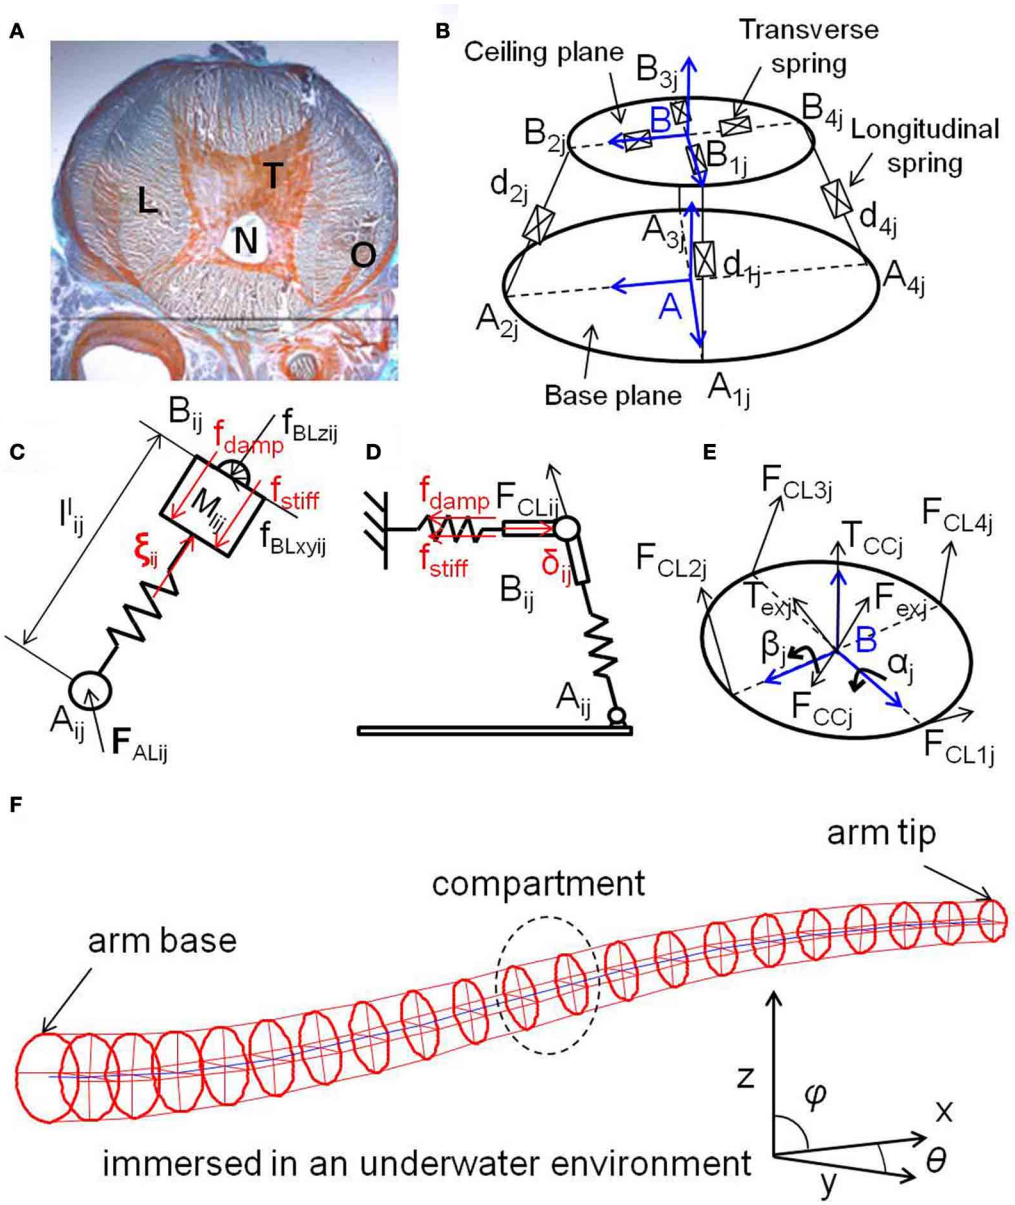

FIGURE 1 | (A) Histological transverse section of an octopus arm, showing the longitudinal muscles (L), the transverse muscles (T), the nerve fibers (N), and the oblique muscles (O). **(B)** Overall structure of the muscular-hydrostat system (a single compartment) used in this paper. **(C)** Schematics showing a longitudinal spring, a transverse spring **(D)**, and a ceiling plane **(E)**. In **(C)**, $f_{\mathrm{damp}} = C_{lij}\dot{l}^{l}_{ij}$, $f_{\mathrm{stiff}} = K_{lij}(l^{l}_{ij} - l^{l}_{0ij})$, and $\xi_{ij} = \xi_{cij} + \xi_{vij}$. In **(D)**, $f_{\mathrm{damp}} = C_{rij}\dot{l}^{r}_{ij}$, $f_{\mathrm{stiff}} = K_{rij}(l^{r}_{ij} - l^{r}_{0ij})$, and $\delta_{ij} = \delta_{cij} + \delta_{vij}$. See the text for details. **(F)** The entire soft robotic arm inspired by the octopus. It consists of 20 compartments, which are numbered from 1 to 20 from the base to the tip. Each compartment contains four longitudinal springs and one transverse disk. The blue line represents the line connecting the centers of each transverse disk. The base of the arm is able to rotate in any direction. See the text for details.

muscles are organized into transverse, longitudinal, and obliquely oriented groups (**Figure 1A**). This special muscular organization forms the structures of the muscular-hydrostats. Their main property is that their volume remains constant during muscle contractions. The result is that if the diameter of the muscular-hydrostats decreases, then their length increases, and vice versa. Several proposed models deal with the muscular-hydrostat system of the octopus [e.g., See Yekutieli et al. (2005a,b) and Kang et al. (2012)]. The overall structure of the muscular-hydrostat system adopted in this paper is shown in **Figure 1B**. We begin our description by focusing on the model of a single compartment, and then progress to describing an entire arm.

A single compartment is a mass-spring-damper system, shaped like a circular truncated cone, consisting of a base plane, a ceiling plane with four transverse springs, a central strut, and four longitudinal springs, which emulate the anatomical structure of the muscle alignment in a real octopus arm. (Note that, although we use the term "spring," it is a model for a muscle,

so it has mass and damping.) The longitudinal springs control the position and orientation of the ceiling plane, while the transverse springs control the radius of the ceiling plane. The central strut provides kinematic constraints to guarantee the unique position of the ceiling plane. It is considered as an ideal prismatic joint without mass, damping, and stiffness. The system has an isovolmetric structure, which provides forces constantly aiming to maintain its volume and is an expression of the property of the muscular-hydrostats, and thus, all the springs are assumed to be implicitly or explicitly coupled with each other. The values for all the parameters of the model (e.g., spring coefficients, damping, etc.) are either inspired by the octopus or directly drawn from biological data (Kier and Curtin, 2002; Lieber, 2002; Shinohara et al., 2010). Standard SI units are used for the variables, and all of the ordinal differential equations presented are solved using the 4th order Runge–Kutta method, where dt is set to 0.001 s for the system throughout this paper.

Coordinates are defined on a base plane and a ceiling plane, denoted by $A_j(x_j, y_j, z_j)$ and $B_j(u_j, v_j, w_j)$, respectively (**Figure 1B**), where j is the index number of the compartment. A vector expressing a longitudinal spring ($\mathbf{d}_{ij}$) is: $\mathbf{d}_{ij} = \mathbf{p}_j + \mathbf{b}_{ij} - \mathbf{a}_{ij}$, where $\mathbf{p}_j = \overline{A_jB_j} = [0\ 0\ h_j]^T$ is the position vector of the center of the ceiling plane, $\mathbf{b}_{ij}$ is the position vector of joint B_{ij}, and $\mathbf{a}_{ij} = \overline{A_jA_{ij}}$ is the position vector of joint A_{ij}. The length of the ith spring in compartment j is l^l_{ij} and can then be obtained by $l^l_{ij} = \sqrt{\mathbf{d}^T_{ij} \cdot \mathbf{d}_{ij}}$. The dynamics of a longitudinal spring is expressed by:

$$\xi_{cij} + \xi_{vij} - f_{\mathrm{BL}zij} = M_{lij}\ddot{l}^l_{ij} + C_{lij}\dot{l}^l_{ij} + K_{lij}\left(l^l_{ij} - l^l_{0ij}\right), \quad (1)$$

where ξ_{cij} is the control force, ξ_{vij} is the isovolumetric constraint force, which will be also explained further in Equation (7), $f_{\mathrm{BL}zij}$ is the component force of joint B_{ij} acting along the spring i of compartment j, l^l_{0ij} is the initial length of the spring, M_{lij} is the mass of the spring, C_{lij} is the damping coefficient, and K_{lij} is the stiffness coefficient (**Figure 1C**). Then, the rotation of the longitudinal springs can be formulated in frame A by:

$$I_{ij}\dot{\omega}_{lij} = \mathbf{d}_{ij} \times \mathbf{f}_{\mathrm{BL}_{xyij}}, \quad (2)$$

where $\mathbf{f}_{\mathrm{BL}xyij}$ is the component force of joint B_{ij} acting perpendicular to the spring, I_{ij} is the inertia moment of the spring about A_{ij}, and ω_{lij} is the angular velocity of the spring about A_{ij}, where $\omega_{lij} = (\mathbf{d}_{ij}/l^l_{ij}) \times (\mathbf{v}_{Bij}/l^l_{ij})$, and $\mathbf{v}_{Bij}$ is the velocity of B_{ij}.

To interlink several compartments serially the reaction forces between the longitudinal springs and the base, $\mathbf{F}_{ALij}$, need to be calculated. These reaction forces are obtained by:

$$\mathbf{F}_{ALij} = M_{lij}\ddot{\mathbf{d}}_{ij} - \mathbf{F}_{\mathrm{BL}ij}, \quad (3)$$

where $\mathbf{F}_{ALij}$ is the joint force on A_{ij}, and $\mathbf{F}_{\mathrm{BL}ij} = \mathbf{f}_{\mathrm{BL}xyij} + \mathbf{f}_{\mathrm{BL}zij}$ is the joint force on B_{ij}.

The four transverse springs spread around the central point of the ceiling plane. **Figure 1D** shows the illustration of a transverse spring. The dynamics of the length of the transverse spring are described as:

$$\delta_{cij} + \delta_{vij} - \mathbf{F}_{\mathrm{CL}ij} \cdot \mathbf{u}_{bij} = M_{rij}\ddot{l}^r_{ij} + C_{rij}\dot{l}^r_{ij} + K_{rij}\left(l^r_{ij} - l^r_{0ij}\right), \quad (4)$$

where δ_{cij} is the control force, δ_{vij} is the isovolumetric constraint force (which will be discussed in detail later), $\mathbf{F}_{\mathrm{CL}ij} = -\mathbf{F}_{\mathrm{BL}ij}$ is the joint force of B_{ij} acting on the ceiling plane, $\mathbf{u}_{bij}$ is the unit vector of $\mathbf{b}_{ij}$, M_{rij} is the mass of the spring, l^r_{0ij} is the initial radius of the ceiling plane, C_{rij} is the damping coefficient, and K_{rij} is the stiffness coefficient (**Figure 1D**). **Figure 1E** shows the illustration of the ceiling plane. The equation for the motion of the ceiling plane is:

$$M_{\mathrm{ceil}j}\left[0\ 0\ \ddot{h}_j\right]^T = \mathbf{F}_{\mathrm{CL}1j} + \mathbf{F}_{\mathrm{CL}2j} + \mathbf{F}_{\mathrm{CL}3j} + \mathbf{F}_{\mathrm{CL}4j} + \mathbf{F}_{\mathrm{CC}j} + \mathbf{F}_{\mathrm{ex}j}, \quad (5)$$

where h_j is the height of the ceiling plane of compartment j, $\mathbf{F}_{\mathrm{CC}j} = -\mathbf{F}_{\mathrm{BC}j}$ is the joint force on B_j acting on the ceiling plane, and $\mathbf{F}_{\mathrm{ex}j}$ is the external force. The rotation is formulated as:

$$^{B_j}\mathbf{I}_{\mathrm{ceil}j}\left[\ddot{\beta}_j\ \ddot{\alpha}_j\ 0\right]^T = \sum_{i=1}^{4} {}^{B_j}\mathbf{b}_{ij} \times {}^{A_j}\mathbf{R}^T_{B_j}\mathbf{F}_{\mathrm{CL}ij} + {}^{B_j}\mathbf{T}_{\mathrm{CC}j} + {}^{B_j}\mathbf{T}_{\mathrm{ex}j}, \quad (6)$$

where ${}^{B_j}\mathbf{T}_{\mathrm{CC}j}$ is the constraint torque of joint B_j acting on the ceiling plane, ${}^{A_j}\mathbf{R}^T_{B_j}$ is the Euler rotation matrix, ${}^{B_j}\mathbf{b}_{ij}$ is the position vector of B_{ij} expressed in frame B_j, and ${}^{B_j}\mathbf{I}_{\mathrm{ceil}j}$ is the inertia matrix of the ceiling plane.

As explained previously, the system is isovolumetric due to its muscular hydrostat structure. This means that an increase in the longitudinal length will result in a reduction in the cross-sectional area and vice versa. A pair of antagonistic forces are applied to the longitudinal and transverse springs to guarantee the isovolumetric constraints. These are expressed as:

$$\xi_{vij} = -K_{lv} \times |\delta_{cij}| \times (V_{cj} - V_{0j}), \quad (7)$$

$$\delta_{vij} = -K_{rv} \times \left|\sum_{i=1}^{4} \xi_{ij} + \mathbf{F}_{exj} \cdot \mathbf{p}_j/h_j\right| \times (V_{cj} - V_{0j}), \quad (8)$$

where V_{cj} is the actual volume of compartment j, V_{0j} is the initial volume of the compartment, K_{lv} is the constraint force gain for the longitudinal springs, and K_{rv} is the constraint force gain for the transverse springs. From Equation (7), it can be seen that the constraint force ξ_{vij} is a function of the transverse spring force, δ_{cij}, and the compartment volume change, $V_{cj} - V_{0j}$. By applying ξ_{vij} to Equation (1), the longitudinal springs will act against the transverse springs to drive the volume change to zero. Similarly, another constraint force δ_{vij} is obtained by Equation (8) and applied to Equation (4) for the transverse springs to cancel the volume change induced by the longitudinal springs. Note that the external force, $\mathbf{F}_{exj}$, is included in Equation (8) because

it is acting on the compartment on joint B_j, which may also change the length of the longitudinal springs and the volume of the compartment.

In addition to the forces generated by the muscles, typical external forces applied to the soft robotic arm in an underwater environment are gravity, buoyancy, and hydrodynamic forces. These are considered as distributed forces acting on each compartment as:

$$\begin{aligned}\mathbf{F}_{exj} &= \mathbf{F}_{gj} + \mathbf{F}_{bj} + \mathbf{F}_{\mathrm{hyd}j} \\ &= \mathbf{F}_{gj} + \mathbf{F}_{bj} + \left(\mathbf{F}_{\mathrm{hydD}j} + \mathbf{F}_{\mathrm{hydL}j}\right), \end{aligned} \tag{9}$$

where $\mathbf{F}_{\mathrm{ex}j}$ is the total external force acting on compartment j, $\mathbf{F}_{gj}$ is the gravity force, $\mathbf{F}_{bj}$ is the buoyancy force, and $\mathbf{F}_{\mathrm{hyd}j}$ is the hydrodynamic force composed of the water drag force, $\mathbf{F}_{\mathrm{hydD}j}$, and the water lift force, $\mathbf{F}_{\mathrm{hydL}j}$.

The direction of buoyancy always opposes gravity. Thus, the resulting force due to gravity and buoyancy is:

$$\mathbf{F}_{gj} + \mathbf{F}_{bj} = (\rho_o - \rho_w) V_{cj} g \mathbf{u}_{gj} = \rho_o V_{cj} g_e \mathbf{u}_{gj}, \tag{10}$$

where ρ_w is the density of water, ρ_o is the density of the octopus arm, V_{cj} is the volume of compartment j, $\mathbf{u}_{gj}$ is the unit vector indicating the direction of gravity for compartment j, g is the gravity constant, and g_e is the equivalent gravity constant defined as:

$$g_e = \left(1 - \frac{\rho_w}{\rho_o}\right) g. \tag{11}$$

By adjusting the value of g_e, both gravity and buoyancy forces are included in the model.

The hydrodynamic forces applied to an octopus arm during a movement through a fluid medium are shown in **Figure 2**. For compartment j, the drag force $\mathbf{F}_{\mathrm{hydD}j}$ is parallel to the velocity vector $\mathbf{V}_j$ of the fluid (or the uniform arm velocity in a stationary fluid) and the lift force $\mathbf{F}_{\mathrm{hydL}j}$ is perpendicular to $\mathbf{V}_j$, according to

$$\mathbf{F}_{\mathrm{hydD}j} = \frac{1}{2} C_{Dj} A_{rj} \rho_w ||\mathbf{V}_j||^2 \mathbf{u}_{vj}, \tag{12}$$

$$\mathbf{F}_{\mathrm{hydL}j} = \frac{1}{2} C_{Lj} A_{rj} \rho_w ||\mathbf{V}_j||^2 \mathbf{u}_{vj}^{\perp}, \tag{13}$$

where C_{Dj} and C_{Lj} are the drag and lift coefficients, respectively, A_{rj} is the reference area of compartment j, $\mathbf{u}_{vj}$ is the unit vector indicating the direction of $\mathbf{V}_j$, and $\mathbf{u}_{vj}^{\perp}$ is the unit vector of normal direction for $\mathbf{V}_j$. The hydrodynamic force coefficients, C_{Dj} and C_{Lj}, for a segmented arm are obtained from high fidelity CFD simulations (Kazakidi et al., 2012). They were found to be dependent on the flow incidence angle θ_j, and the configuration of the arm (e.g., straight vs. bended). As a first approximation of the hydrodynamic forces common in robotic literature (Ijspeert, 2001; Kazakidi et al., 2012), dependence on arm configuration was ignored. Therefore, a single value for each coefficient at specific angles of θ_j for a straight arm was identified by CFD simulations and approximated by a 4th order polynomial in the simulator, expressed as follows:

$$C_{Dj} = e_1^D \theta_j^4 + e_2^D \theta_j^3 + e_3^D \theta_j^2 + e_4^D \theta_j + e_5^D, \tag{14}$$

$$C_{Lj} = e_1^L \theta_j^4 + e_2^L \theta_j^3 + e_3^L \theta_j^2 + e_4^L \theta_j + e_5^L, \tag{15}$$

where e_{1-5}^D and e_{1-5}^L are the parameters identified by CFD simulations. The hydrodynamic forces for each compartment were then computed according to Equations (12) and (13), where $\mathbf{V}_j$ was taken as the velocity of B_j. All the parameters used in this study are shown in **Table 1**.

This model is intrinsically non-linear. The non-linearities of the system are partly introduced by its kinematics (Kang

e_1^D	-5.5×10^{-9}	e_1^L	1.8×10^{-9}
e_2^D	6.3×10^{-7}	e_2^L	-5.9×10^{-7}
e_3^D	-7.7×10^{-6}	e_3^L	2.8×10^{-5}
e_4^D	0.0015	e_4^L	0.0011
e_5^D	0.017	e_5^L	0.00089

Note that, for l_{0ij}^r and V_{0j}, they decrease monotonically, according to the compartment number in the given range in the table.

et al., 2012). The relation between the spring length and the ceiling plane posture (position and orientation) is non-linear. Therefore, the system dynamics become non-linear as well. Also, the calculation of the isovolumetric forces and hydrodynamic forces introduces non-linearities. See Kang et al. (2012) for a detailed discussion of the model. In the majority of cases, these non-linearities are undesirable from the viewpoint of classical control theory. However, as previously mentioned in section 1, such a complex body could potentially be used as part of a computational device, if appropriate inputs and readouts are applied.

2.2. EXPERIMENTAL PROCEDURE

Our aim in this paper is to demonstrate whether a soft robotic arm can be exploited as a computational resource, as well as a controller. Accordingly, we need to define inputs ($\mathrm{In}(t)$) to the system and how to generate corresponding outputs ($\mathrm{O}(t+1)$). In this paper, we apply the position control of the base rotation as an input, and an output is generated by the weighted sum of the longitudinal spring lengths of all 20 compartments (**Figure 3**).

Based on this I/O scheme, we set two types of tasks for our demonstrations. First, we consider the emulation tasks of non-linear dynamical systems (**Figure 3A**), which aims to show whether the soft robotic arm can be exploited as a computational resource, including sufficient non-linearity and memory. The second task is to embed closed-loop control onto the soft robotic arm itself (**Figure 3B**). In particular, we aim to embed non-linear limit cycles, which are especially appealing for the control of robots. Typically, such limit cycles are implemented using non-linear oscillators, such as central pattern generators (CPGs), or a network of such oscillators (Righetti and Ijspeert, 2008). We here aim to demonstrate that the body of the soft robotic arm itself can be used to generate such limit cycles.

As explained in section 1, our approach is comparable to a reservoir computing approach, which normally uses randomly coupled non-linear elements as a computational resource (Jaeger, 2002; Maass et al., 2002; Jaeger and Haas, 2004). In the conventional reservoir computing approach, since each computational element is coupled randomly, each element possess a uniform role in the computation in the statistical sense. On the other hand, if we exploit the robot's body as a reservoir, according to the intrinsic structure of the body, each part of the body shows qualitatively different dynamics, which may lead to specific role distributions corresponding to each body part. Accordingly, in this paper, we will investigate how the computational role is distributed through the arm in each task. In the following subsections, we provide detailed descriptions for each task.

2.2.1. Task 1: non-linear dynamical system emulation tasks

In order to evaluate the computational power of the system, we here set non-linear dynamical system emulation tasks, which are often used as benchmark tasks (Jaeger, 2002; Verstraeten et al., 2007; Hauser et al., 2011) in the context of recurrent neural network learning (Atiya and Parlos, 2000) and the reservoir computing approach (Jaeger, 2002; Maass et al., 2002; Jaeger and Haas, 2004). Each task requires a certain degree of non-linearity and memory to be performed by the system. As explained above,

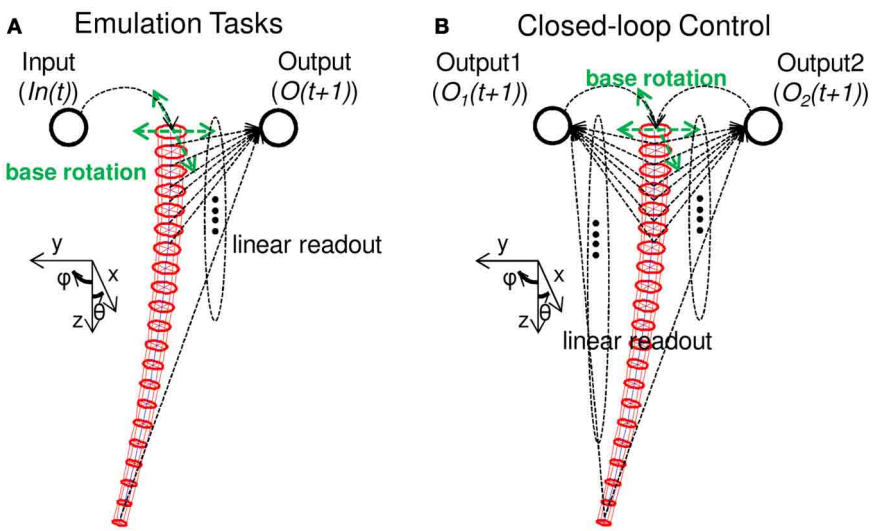

FIGURE 3 | Schematics explaining the tasks adopted in this paper. **(A)** Schematics showing the nonlinear dynamical system emulation tasks (Task 1). An input ($\mathrm{In}(t)$) is projected as a base rotation angle, and accordingly, the soft robotic arm shows passive body dynamics. By setting a linear readout for each longitudinal spring length in each compartment, an output ($\mathrm{O}(t+1)$) is calculated as a weighted sum of all the spring lengths. By adjusting only the linear readout, we demonstrate whether the system can emulate complex nonlinear dynamical systems. **(B)** Schematics showing the implementation of closed-loop control (Task 2). Similar to Task 1, by adjusting the linear readouts, two variables of a nonlinear limit cycle are emulated and fed back as the next input to the system to generate the base rotation movement. Accordingly, the nonlinear limit cycle is embedded onto the arm in a closed-loop manner. See the text for details.

we first apply position control of the base rotation as an input (**Figure 3A**), expressed as follows:

$$\theta(t) = \phi(t) = \text{Scale} \times \text{In}(t), \quad (16)$$

$$\text{In}(t) = 0.2\sin(2\pi f_1 t \times dt)\sin(2\pi f_2 t \times dt)\sin(2\pi f_3 t \times dt), \quad (17)$$

where $\theta(t)$ and $\phi(t)$ are base rotations at timestep t along the x-axis and y-axis, respectively. The parameter *Scale* linearly scales the raw input, $\text{In}(t)$, to the specific range of the base angle [degree], $-R \leq \theta(t), \phi(t) \leq R$. This scaling parameter can be freely chosen, but should be fixed throughout the experiment. The detailed setting will be explained in the section 3. The parameters f_1, f_2, and f_3 are set to 2.11, 3.73, and 4.33, respectively. Similar inputs were adopted in Hauser et al. (2011), Sumioka et al. (2011), and Nakajima et al. (2013).

According to the base rotation, the arm generates passive body dynamics. The output of the system is calculated by using the resulting spring dynamics as follows:

$$\text{O}(t+1) = \sum_{j=1}^{20}\sum_{i=1}^{4} w_{\text{out}}^{ij} s_{ij}(t), \quad (18)$$

where $s_{ij}(t)$ is the length of the longitudinal spring i ($i = 1, 2, 3,$ and 4) in compartment j ($j = 1, 2, \ldots, 20$) at timestep t. When the input is projected as the base rotation at timestep t, the corresponding length of the spring, l_{ij}^{l}, is collected to $s_{ij}(t)$. The linear readout weight, w_{out}^{ij}, corresponds to each spring length. Overall, the dynamics of 80 ($= 4 \times 20$) spring lengths are the expression of the body dynamics in this paper.

In order to achieve the required computation, we only train the linear readout (w_{out}^{ij}). Since we have 80 nodes, $s_{11}(t), s_{21}(t), s_{31}(t), s_{41}(t), s_{12}(t), \ldots, s_{420}(t)$, for the lengths of the spring at timestep t, by collecting the lengths of the springs for M timesteps, we can generate an 80 $\times M$ matrix **L**. We also collect the corresponding target outputs for M in a matrix **T**. Then, the optimal readout weights, $\mathbf{W} = [w_{\text{out}}^{11}, w_{\text{out}}^{21}, w_{\text{out}}^{31}, w_{\text{out}}^{41}, w_{\text{out}}^{12}, \ldots, w_{\text{out}}^{420}]^T$, can be obtained by $\mathbf{W} = \mathbf{L}^*\mathbf{T}$, where $\mathbf{L}^*$ is the Moore-Penrose pseudo-inverse, since **L** is not a square matrix in general.

According to the sent input, the system should emulate the following three non-linear dynamical systems as outputs. We prepared three corresponding output nodes to the system whose linear readouts are trained separately for each task. (This procedure is often called *multitasking*.) The first task is a 2nd order non-linear dynamical system, expressed as follows:

$$y(t+1) = 0.4y(t) + 0.4y(t)y(t-1) + 0.6\text{In}^3(t) + 0.1, \quad (19)$$

where $y(t)$ denotes the output of the system. The second task is a 10th order non-linear dynamical system, expressed as follows:

$$y(t+1) = 0.3y(t) + 0.05y(t)\left(\sum_{i=0}^{9} y(t-i)\right) \quad (20)$$

$$+ 1.5\text{In}(t-9)\text{In}(t) + 0.1, \quad (21)$$

where $y(t)$ denotes the output of the system. The third task is a discrete Volterra series, expressed as follows:

$$y(t+1) = A \times \sum_{\tau_1=0}^{200}\sum_{\tau_2=0}^{200} h(\tau_1, \tau_2)\text{In}(t-\tau_1)\text{In}(t-\tau_2), \quad (22)$$

$$h(\tau_1, \tau_2) = \exp\left(\frac{(\tau_1 \times dt - \mu_1)^2}{2\sigma_1^2} + \frac{(\tau_2 \times dt - \mu_2)^2}{2\sigma_2^2}\right), \quad (23)$$

where A is a scaling parameter set to 0.0001, $y(t)$ and $h(\tau_1, \tau_2)$ denote the output of the system and a Gaussian kernel, respectively. The parameters, μ_1, μ_2, σ_1, and σ_2 are set as $\mu_1 = \mu_2 = 0.1$ and $\sigma_1 = \sigma_2 = 0.05$. Any computational model that can emulate the above dynamical systems should have a certain degree of memory and non-linearity. Simply put, emulation of a 10th order system requires more memory and non-linearity than a 2nd order system, and emulation of the Volterra task requires more than the 10th order system.

For the experimental procedure, the soft robotic arm is first set in the resting state with $\theta(t) = \phi(t) = 0$, and before beginning the experiment, we start to run the arm with Equation (16) for T_{ini} timesteps. This phase is to set the different initial positions of the arm for each experimental trial; T_{ini} is randomly determined from 0 to 1000 timesteps for each trial. The actual experimental trial consists of 16,000 timesteps, where the first 1000 timesteps are for washout, the following 10,000 timesteps are for the training phase, and the final 5000 timesteps are for the evaluation phase. After T_{ini} timesteps, we continue running the arm with Equation (16) and the actual experiment begins. By collecting the lengths of the spring and the corresponding target outputs for each task in the training phase, we train the linear readouts for three outputs by adopting the previously explained procedure. By using the trained linear readouts, we evaluate the performance of the system output by calculating the mean squared error (MSE), $\text{MSE} = \frac{1}{n}\sum_{t=1}^{n}(\text{O}(t+1) - y(t+1))^2$, where $n = 5000$. We here compare the performance of the system with outputs generated by simple linear regression, $\text{O}(t+1) = a \times \text{In}(t) + b$, where a and b are trained by using the same time series as in the training phase. As is clear from the equation, since the linear regressor only uses the input to generate the output, which does not contain non-linearity and memory, any task performance of the system better than the linear regressor can be said that the required non-linearity and memory to perform the task is positively exploited from the system.

2.2.2. Task 2: closed-loop control—embedding non-linear limit cycles

As previously explained, in this task, we aim to embed non-linear limit cycles in a closed-loop manner. The major difference from Task 1 is that the outputs generated by the system are fed back to the system itself as a motor command (an input) for the next timestep (**Figure 3B**). In particular, as will be explained later, we here aim to embed several limit cycles, which each have two variables. Accordingly, the outputs generated for the next motor commands (namely, $\text{In}_1(t)$ and $\text{In}_2(t)$ for each variable) are

projected to $\theta(t)$ and $\phi(t)$, respectively. The situation is expressed as follows:

$$\begin{cases} \theta(t) = \mathrm{In}_1(t), \\ \phi(t) = \mathrm{In}_2(t), \end{cases} \tag{24}$$

$$\begin{cases} \mathrm{In}_1(t) = \mathrm{O}_1(t), \\ \mathrm{In}_2(t) = \mathrm{O}_2(t), \end{cases} \tag{25}$$

$$\begin{cases} \mathrm{O}_1(t+1) = \sum_{j=1}^{20} \sum_{i=1}^{4} w_{\mathrm{out},1}^{ij} s_{ij}(t), \\ \mathrm{O}_2(t+1) = \sum_{j=1}^{20} \sum_{i=1}^{4} w_{\mathrm{out},2}^{ij} s_{ij}(t), \end{cases} \tag{26}$$

where $w_{\mathrm{out},1}^{ij}$ and $w_{\mathrm{out},2}^{ij}$ are the linear readouts corresponding to the two outputs, $\mathrm{O}_1(t)$ and $\mathrm{O}_2(t)$, respectively. (Note that, in Equation (24), unlike Equation (16) in Task 1, the scaling parameter *Scale* is not introduced. As will be explained later, this is because we here aim to emulate the limit cycles, which are already scaled with a certain parameter value. So the scaling procedure is already included in the target outputs.)

As in the procedure explained in Task 1, to train the system, we only adjust the linear readouts, $w_{\mathrm{out},1}^{ij}$ and $w_{\mathrm{out},2}^{ij}$. However, the procedures differ in two points; first, during the training phase, we clamp the feedbacks from the system outputs, and provide the target outputs as inputs, which means, in Equation (25), we set $\mathrm{In}_1(t) = x_1(t)$, $\mathrm{In}_2(t) = x_2(t)$, where $x_1(t)$ and $x_2(t)$ are the target outputs at timestep t. Thus, the training phase is carried out with an open-loop, where the system was forced into the desired operative state by the target signals (this is called, *teacher forcing*) (Hauser et al., 2012). Second, when collecting the lengths of the springs in the training phase, we add white noise in the range of $[-\nu, \nu]$. By doing this, we can expect that the obtained optimal readouts will generate the target outputs even under the influence of noise (Hauser et al., 2012). The appropriate degree of ν is determined heuristically for each task.

Here, we aim to embed three non-linear limit cycles. The first one is the dynamical systems of the Van der Pol equations, expressed as follows:

$$\begin{cases} \dot{x_1} = x_2, \\ \dot{x_2} = -x_1 + \left(1 - x_1^2\right) x_2. \end{cases} \tag{27}$$

The second one is a limit cycle, which we call the *quadratic limit cycle* (Hauser et al., 2012; Khalil, 2002), expressed as follows:

$$\begin{cases} \dot{x_1} = x_1 + x_2 - 5x_1\left(x_1^2 + x_2^2\right), \\ \dot{x_2} = -2x_1 + x_2 - x_2\left(x_1^2 + x_2^2\right). \end{cases} \tag{28}$$

The third one is a Lissajous curve with a frequency ratio of $f_1/f_2 = 2$, expressed as follows:

$$\begin{cases} x_1 = \sin(f_1 t), \\ x_2 = \sin(f_2 t). \end{cases} \tag{29}$$

Since each limit cycle is symmetric about the point $(0, 0)$, we select the variable with the larger range, and scale both variables to the desired range of the base rotation [degree], $-R \leq \theta(t), \phi(t) \leq R$. As in Task 1, this scaling parameter can be freely chosen, but should be fixed throughout the experiment. Thus, what the system should emulate here is $x_1'(t+1) = \mathrm{Scale} \times x_1(t+1)$ and $x_2'(t+1) = \mathrm{Scale} \times x_2(t+1)$ as $\mathrm{O}_1(t+1)$ and $\mathrm{O}_2(t+1)$, respectively. Further settings on the parameter *Scale* will be explained in the section 3. For the Van der Pol system and the quadratic limit cycle, the ordinal differential equations are solved for each simulation timestep by using the 4th order Runge–Kutta method, where *dt* is set to 0.01. Note that the timescale of the arm model and these limit cycle is different. When we refer to time *s*, we always fixed our expression to the timescale to the arm model, otherwise we use the expression of simulation *timestep* to avoid the confusion.

In the experimental procedure, the soft robotic arm is first set in the resting state with $\theta(t) = \phi(t) = 0$, as in Task 1. We run the system with the teacher forcing condition for 70,000 timesteps, and by discarding the first 10,000 timesteps, we use 60,000 timesteps as for the training phase with white noise of degree ν added in the spring lengths. After obtaining the optimal readout weights from these collected data, we initialize the arm's state to the resting state and again start to run the system with the teacher forcing condition. After 5000 timesteps of running, we switch the inputs to the system output generated by the trained readout weights (Equations 25 and 26) and check whether it could embed the target limit cycle. Unlike Task 1, multitasking cannot be adopted (due to the feedback control), so each limit cycle is trained separately as a different trial.

3. RESULTS

In this section, we present the results of each task applied to indicate the performance of our system. We would like to note again that all the tasks presented in this section is performed with "one body", the same soft robotic arm explained in section 2.1, where all the parameter settings of the arm is fixed throughout the experiments. In addition, for Task 1, emulations of three non-linear dynamical systems are simultaneously performed for each experimental run (i.e., multitasking).

3.1. TASK 1: NON-LINEAR DYNAMICAL SYSTEM EMULATION TASKS

Figure 4 shows a typical example of the time series of $\mathrm{In}(t)$, the lengths of the springs, and the performance of each task during the evaluation phase. The plots show the case when R is set to 60. We can clearly see that, according to the input projected to the base rotation, our soft robotic arm shows diverse passive body dynamics (**Figures 4A,B**). Regarding the task performance, the system output shows better performances than the linear regressor in all the tasks (**Figure 4C**). In the emulation task for the 2nd order system, the linear regressor also showed relatively good performance. However, as we can see in the plots, as the degree of non-linearity and memory of the task increases in the 10th order system and Volterra task, the performance of the linear regressor decreases significantly (**Figure 4C**). On the other hand, our system shows relatively good performance even in the Voletrra series emulation task (**Figure 4C**). **Table 2** shows the statistical comparisons between the MSE of the output of the system and that of the linear regressor for each task. The values show the averaged

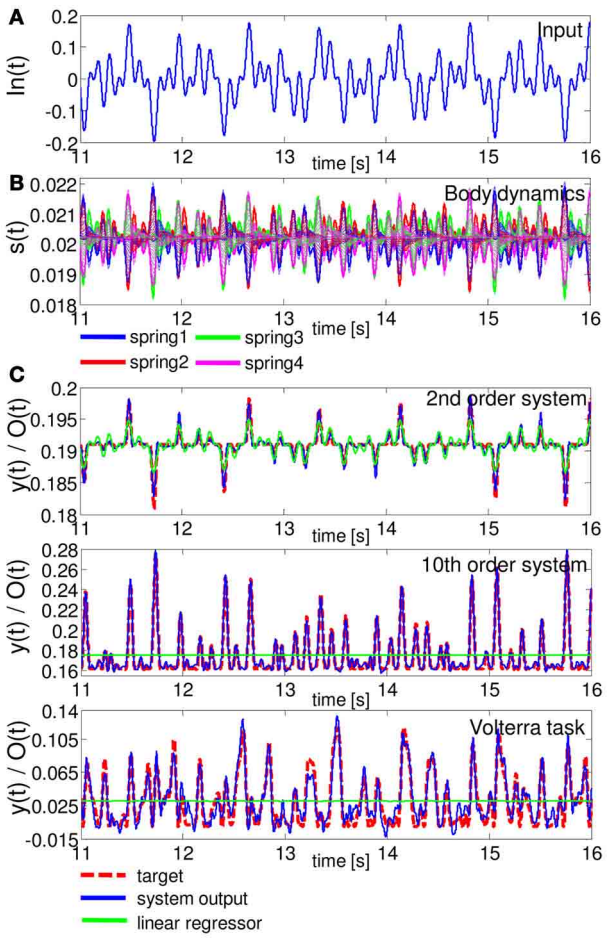

FIGURE 4 | A typical example of the task performance for Task 1 in terms of time series in the evaluation phase. (A) The time series of $\mathrm{In}(t)$. **(B)** Corresponding body dynamics, which are expressed as the time series of the lengths of springs 1, 2, 3, and 4. The spring dynamics of all 20 compartments are overlaid. **(C)** Comparisons of the performance of the system output and the linear regressor for the emulation tasks of the 2nd order system (upper diagram), 10th order system (middle diagram), and Volterra task (lower diagram). In the plots, for the 2nd and 10th order systems, and the Voletrra task, the MSEs of the system output were 1.89×10^{-7}, 3.80×10^{-6}, and 8.90×10^{-5}, respectively, and those of the linear regressor were 9.96×10^{-7}, 4.95×10^{-4}, and 9.48×10^{-4}, respectively. For each task, the system output showed better performance than the linear regressor. Note that the output of the linear regressor is not a straight line, but a scaled version of the input with an offset (this outcome is due to the scaling of the figure).

MSEs over 20 trials. In each task, our system showed significantly low MSE. These results suggest that our system is able to exploit the non-linearity and memory originates from the passive body dynamics of the soft robotic arm to perform the task.

Unlike a conventional computational network or device, our system receives input as a mechanical rotation of the base, which generates the physical motion of the arm. Thus, we can easily imagine that, for example, if the input scaling of the base rotation range, R, is small, then the arm can only vibrate slightly, which does not generate diverse body dynamics. Moreover, since the input is linearly scaled to the base rotation range in our setting, the degree of this scaling changes not only the amplitude of the rotation but also the speed of the rotation. Considering that the water friction on the arm shows non-linear dependence on the velocity and the angle of the compartments (Equations 12, 13, and 14), the property of the body dynamics would change according to the degree of input scaling, R. Accordingly, the performance of our system would also change for each task. In order to validate this, we varied R from 15 to 90, and observed how the performance of the system changed for each R. **Figure 5A** shows the results. We can confirm the different individual error profile with respect to R for each task. First, small R values (around 15) show the highest errors; errors gradually start to decrease according to increases in R values in all tasks. But, for example, in the case of the 2nd order system, the error starts to increase again at around $R = 30$ and has a local maximum at around $R = 45$. In the case of the 10th order system, the error just decreases monotonically as the value of R increases. In the case of the Volterra task, the error shows the minimum at around $R = 55$ and start to increase monotonically as the value of R increases. This suggests that, even if the mechanical structure of the arm is the same, certain behaviors of the arm can reveal especially high computational power in some tasks, but not in others.

Table 2 | Comparisons of MSE between the output of the system and that of the linear regressor for each task.

	System output ($X \pm SD$)	Linear regressor ($X \pm SD$)	p value
2nd order	1.84 ± 0.05 ($\times 10^{-7}$)	1.01 ± 0.03 ($\times 10^{-6}$)	$p < 0.001$
10th order	3.77 ± 0.03 ($\times 10^{-6}$)	5.05 ± 0.11 ($\times 10^{-4}$)	$p < 0.001$
Volterra task	8.89 ± 0.18 ($\times 10^{-5}$)	9.28 ± 0.11 ($\times 10^{-4}$)	$p < 0.001$

As explained in section 1, our system is essentially classified as a reservoir computing approach, in which a number of randomly coupled nodes are usually used as a computational resource, and where each node has a statistically uniform role. On the other hand, in our system, due to the intrinsic body structure, we can expect that there is a specific role for each body part. Here, we aim to investigate this point in two ways. First, when running the evaluation phase, we take out the readouts from one compartment and analyze the error. Note that, in this analysis, we use the readouts, which are trained with 20 compartments. By iterating this procedure for each compartment, we can investigate how each compartment contributed to the task performance when the readouts were fully connected. We call this *contribution ratio analysis* of the compartments. Second, we perform the entire experiment (i.e., washout, learning and evaluation phase) with only 19 compartments by skipping one compartment, and compare the performance with that obtained using 20 compartments. The difference with the previous contribution ratio analysis is that the readouts are, in the first place, trained to maximize the performance with 19 compartments including the entirely new readout weights. Since the readout

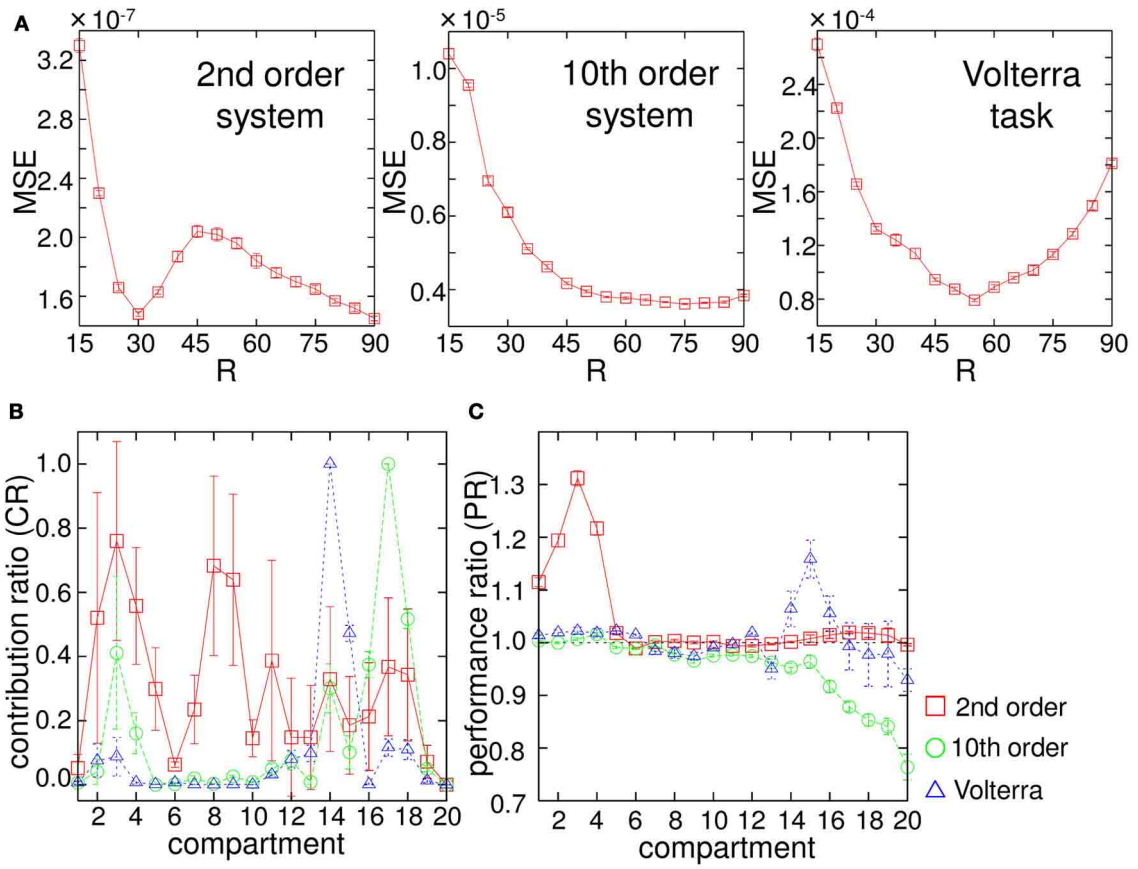

FIGURE 5 | (A) Dependence of the performance of the system output (MSE) on the base rotation range, *R*, for each task. The plots show the averaged values of MSE over 20 trials. The error bars show the standard deviation. The averaged value of MSE of the linear regressor was much higher than that of the system output with respect to each *R* value (usually an order of magnitude higher). **(B)** Results of the contribution ratio analysis for each task. The horizontal axis shows the number of the compartment discarded in the evaluation phase, and the vertical axis shows the contribution ratio (CR). The plots show the averaged CR values over 20 trials, and the error bars show the standard deviations. **(C)** Results of the computational power analysis for each task. The horizontal axis shows the number of the compartment excluded to train the readout weights, and the vertical axis shows the performance ratio (PR). The plots show the averaged PR values over 20 trials, and the error bars show the standard deviations. See text for the details.

weights are optimized without using a specific compartment, we can infer back the overall computational power of each compartment as a deviation from the original 20 compartment case. We call this *computational power analysis* of the compartments. Hereafter, the base rotation range, *R*, is fixed to 60 for the analyses.

In the contribution ratio analysis, the experimental procedure is the same as that explained in section 2.2, except that the evaluation phase is performed by taking out the readouts from a specific compartment (thus, four nodes are excluded). We iterate this procedure for each compartment by using the same input time series and body dynamics in a trial and calculate the MSE for each case. After testing all the compartments, we normalize them with the maximum MSE collected, and obtain *contribution ratio* (CR) for each compartment. If the CR is high for the compartment, then it implies that this compartment was contributing to the task performance largely when the readouts were fully connected. **Figure 5B** shows the result of the contribution ratio analysis for each task over 20 trials. In the case of the 2nd order system, although compartments 2, 3, 4, 8, and 9 seem to have high CRs, the standard deviations for these are also high, while compartments 1, 6, 19, and 20 have low CRs with low standard deviations. This suggests that specific compartments, such as 1, 6, 19, and 20 always contribute less to the task performance, while the computational role for this task is relatively distributed throughout the resting compartments, and among them, there is no specific compartment that consistently has a high contribution. In the case of the 10th order system and the Volterra task, the situation is different. There seems to be key compartments that always show high contributions to the task performance. In the case of the 10th order system, compartments 16, 17, and 18 show high performance, and in the case of the Volterra system, compartments 14 and 15 show high performance. Overall, these results suggest that our system adopts various strategies in the performance of computational abilities, according to the task. One strategy is to distribute the computational role throughout the entire arm, while the other is to always select and rely on the motion of specific body parts.

Next, in the computational power analysis, the experiment is performed both under the default condition (using 20 compartments) and with the exclusion of a specific compartment when training the readout weights. This is done by using the same input time series and body dynamics in a trial for each task. We calculated the MSEs in the evaluation phase for both cases and divided the MSE of the case without the specific compartment by that of the default condition and obtained the performance ratio (PR) for each task in each trial. Thus, if the PR is larger than 1.0, it implies that the task performance is worse than in the default condition, and the value indicates the degree of how the exclusion of the specific compartment affects the overall task performance in terms of ratio. **Figure 5C** shows the result of the computational power analysis for each task over 20 trials. In the 2nd order system task, we can clearly see that there are high PR values around the base of the arm (in compartments 1, 2, 3, and 4) suggesting that these compartments contain significant information for the performance of this task. Similarly, in the Volterra task, there are high PR values in compartments 14, 15, and 16. On the other hand, in the 10th order system task, PR values lower than 1.0 are shown around the tip of the arm (in compartment numbers higher than 15), suggesting that these compartments have a negative influence on the performance of this task. We speculate that this is caused by an overfitting effect produced by the compartments around the tip of the arm. The network is too specialized for the learning data and is not able to generalize to the new (evaluation) data. The reason for this should be explored in more detail in future work. Overall, we showed that there are specific regions in the body parts that contain positive or negative information for the performance of the tasks.

In this section, we first demonstrated that our soft robotic arm can perform the task to emulate non-linear dynamic systems by positively exploiting the non-linearity and memory originates from its body dynamics. We also confirmed that the way the input is applied (in our case, the amplitude range for the arm movement) significantly affects the computational ability, and its body parts show specialized roles due to their intrinsic morphological structure and corresponding diverse body dynamics, unlike the conventional reservoir computing approach. In the next section, we see how these body dynamics can potentially be used to control the arm's motion in a closed-loop manner by embedding non-linear limit cycles.

3.2. TASK 2: CLOSED-LOOP CONTROL—EMBEDDING NON-LINEAR LIMIT CYCLES

In this section, we show the results for Task 2. By following the procedure described in section 2.2.2, we conducted a number of computer simulations to train the readouts with various values of the base rotation range R and the degree of white noise ν. As a result, we heuristically found that the system performance is extremely sensitive to the setting of these parameters [as opposed to the results presented for the simpler and abstract networks used in Hauser et al. (2012)]. (As for R, we have already shown in the previous section that R changes the computational power of the system significantly.) If these parameters were not set appropriately, we often observed that, when the system was switched from the teacher forcing condition to the closed-loop control, the arm gradually approached the resting state or showed unrealistic behaviors due to numerical problems. For the latter case, since we adopt the position control of the base angle, if the output showed much higher values than that of one timestep before (for example, if $|O(t+1) - O(t)| > 10$, then the arm would have to rotate its base extremely quickly, namely, larger than 10^4deg/s, which is unrealistic in the physical platform), then, as a result, the simulator showed numerical problems. We carefully discarded these cases from our experiment. Even if the system has a high computational power as we saw in the previous section, the closed-loop setting requires additional care due to the stability issues. Since the output, which includes the error, is fed back to the system as input, the error may grow larger and larger in each simulation timestep.

Figures 6–8 show the typical results we obtained when the arm does not approach the resting state or the unrealistic behaviors mentioned above, for closed-loop control of the Van der Pol limit cycle, the quadratic limit cycle, and the Lissajous curve,

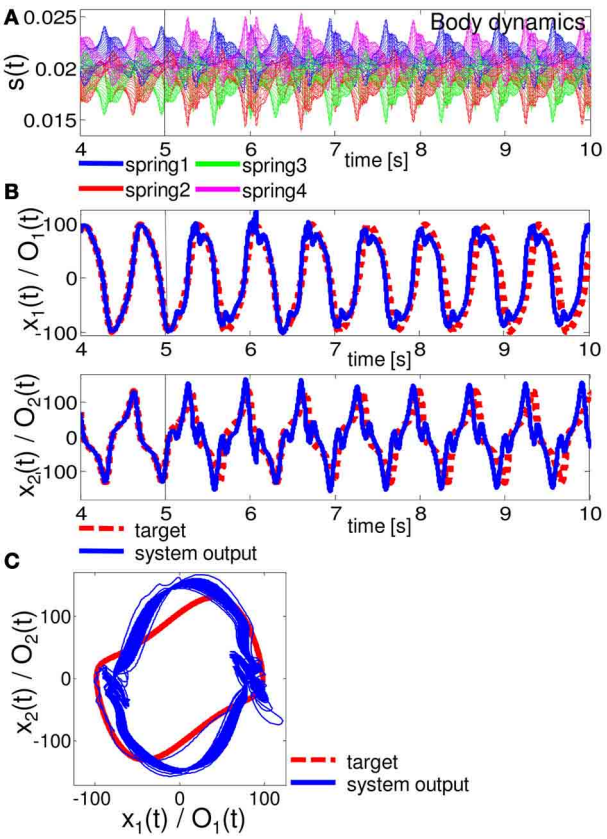

FIGURE 6 | Results for implementing the Van der Pol limit cycle. At timestep 5000, the system is switched from the teacher forcing condition to the closed-loop control (black line). **(A)** The time series of the lengths of springs 1, 2, 3, and 4 for all 20 compartments. **(B)** Comparisons between the system output ($O_1(t)$ and $O_2(t)$ (blue lines)) and the target output ($x_1(t)$ and $x_2(t)$ (red lines)). **(C)** Comparisons between the system output (blue lines) and the target output (red lines) in the $O_1(t)$ - $O_2(t)$ ($x_1(t)$ - $x_2(t)$) plane. respectively. [1]3 For the parameters (R, v), we adopted $(R, v) = (130, 1.5 \times 10^{-6})$, $(90, 1.0 \times 10^{-6})$, and $(10, 1.0 \times 10^{-11})$, for the Van der Pol limit cycle, the quadratic limit cycle, and the Lissajous curve, respectively. For the Van der Pol limit cycle, we can see that the system is not implementing the target trajectory (**Figures 6B,C**), but is rather implementing an irregular one (**Figure 6C**). We also observed that the behavior of this trajectory is not as stable, but rather constantly changes its trajectory for each cycle, and this change remains throughout the trial. However, the results for the quadratic limit cycle and the Lissajous curve show almost a complete fit with the target trajectory (**Figures 7B,C**, and **8B,C**, respectively). We confirmed that these trajectories were stable enough to run for 1,000,000 timesteps without leaving the trajectories of the target limit cycles. These results suggest that the task performance of the closed-loop control is not only restricted to the degree of non-linearity or memory required for the limit cycles but is also dependent on how the arm is driven. These preferences are caused by the intrinsic structure of the body. From now on, by using the system embedding the quadratic limit cycle (**Figure 7**) and the Lissajous curve (**Figure 8**), we move on to analyze the stability of the closed-loop controls and the role of each body part in these limit cycles as we saw in the previous section.

One important aspect to evaluate the embedded closed-loop control is its robustness against external perturbations. To test this, we added white noise, $\delta O_1(t)$ and $\delta O_2(t)$, in the range of ϵ ($\delta O_{1,2}(t) \in [-\epsilon, \epsilon]$) to the two motor outputs of the embedded control, such as $O_1(t) + \delta O_1(t)$ and $O_2(t) + \delta O_2(t)$, during $t = 6000$–7000 timesteps for each as an example. **Figure 9** shows the typical results of the performance of the embedded quadratic limit cycle regarding each noise level ($\epsilon = 10.0, 5.0,$ and 1.0).

[3]Strictly speaking, to prove that the embedded trajectory is really a "limit cycle", we need to analytically show whether the trajectory is an attractor of the system. In our case, this is unrealistic because the equation governing the mechanical system is too complex, and we would have to rely on a heuristic approach. Accordingly, as we see later, we here call the embedded trajectory a "limit cycle" if and only if the trajectory can stay at the target limit cycle for 1,000,000 timesteps and the trajectory has a certain attraction when perturbed externally.

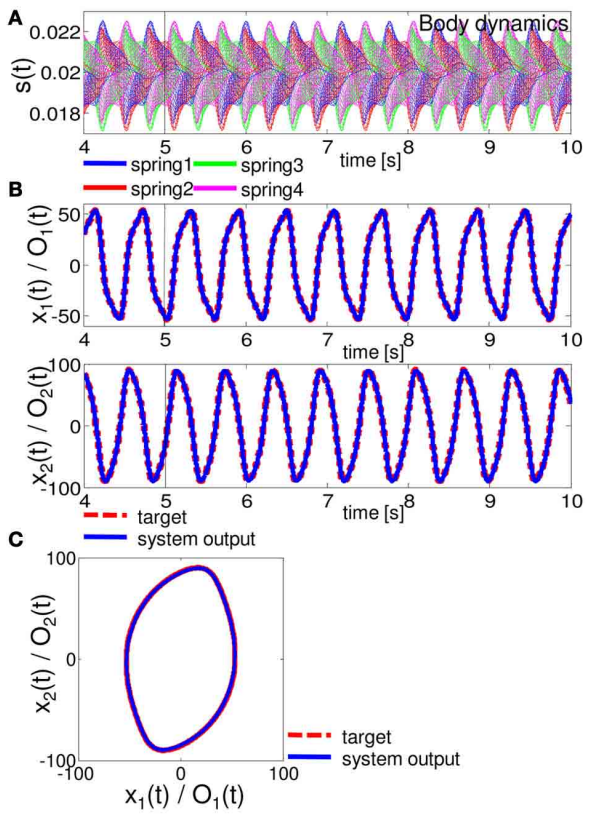

FIGURE 7 | Results for implementing the quadratic limit cycle. FIGURE 9 | Typical examples showing the performance of the embedded quadratic limit cycle with external noise. The white noises, $\delta O_1(t)$ and $\delta O_2(t)$, in the range of ϵ ($\delta O_{1,2}(t) \in [-\epsilon, \epsilon]$) are added to the motor outputs during $t = 6000 - 7000$ timesteps. **(A)** Typical trajectories of $O_1(t)$ and $O_2(t)$ compared with the target time series. The upper, middle, and lower figures show the case with $\epsilon = 10.0$, 5.0, and 1.0, respectively. **(B)** The corresponding plots in the $O_1(t)$ - $O_2(t)$ ($x_1(t)$ - $x_2(t)$) plane. For each noise level, the trajectories are overlaid from 5000 to 30,000 timesteps.

We can clearly see that even if the noise level is relatively large, such as $\epsilon = 10.0$, the trajectories eventually recover to the limit cycle, which suggests that the embedded quadratic limit cycle is robust against external noise. We also confirmed that, even if we elongate the duration of time for the added noise, the system can successfully recover its performance. Note that, although the perturbed trajectories came back toward the limit cycle (**Figure 9B**), the oscillation phase was often shifted (**Figure 9A**). This was mainly caused by the relatively long duration of time for adding noise. We observed that by shortening this duration, this phase shift tendency can be reduced accordingly. Next, let us see the case for the embedded Lissajous curve. Compared to the quadratic limit cycle case, the system is less robust. When ϵ is more than around 0.3, we often observed that the trajectories go out from the limit cycle and never come back. **Figure 10** shows the typical results of the performance of the embedded Lissajous curve for each noise level less than 0.3 ($\epsilon = 0.3$, 0.15, and 0.1). If the noise level was less than around 0.3, we observed the system performance recovered toward the limit cycle as in the quadratic limit cycle case. However, even in this noise range, we sometimes observed an unstable trajectory as shown in **Figure 11**. In addition, similarly to the quadratic limit cycle case, even if the perturbed trajectories came back toward the limit cycle (**Figure 10B**), the oscillation phase was often shifted (**Figure 10A**).

Now, we move on to see the role of each body part (compartments or springs) as we saw in Task 1. Since the motor outputs and the body dynamics are reciprocally coupled through the feedback loop, the scheme we adopted in the Task 1 case, such as skipping one compartment, will cause unrealistic behavior of the arm due to numerical problems, as explained previously, and cannot always be adopted to appropriately evaluate the contributions of the body parts. Accordingly, we aim to investigate the contribution of each body part in terms of robustness against noise. Namely, we evaluate how the noise added to each body part affects the overall system performance. As is obvious from the system construction (Equations 24, 25, and 26) for the closed-loop control, the slight difference in the motor outputs at timestep t can affect the corresponding sensory time series, i.e., the lengths of the

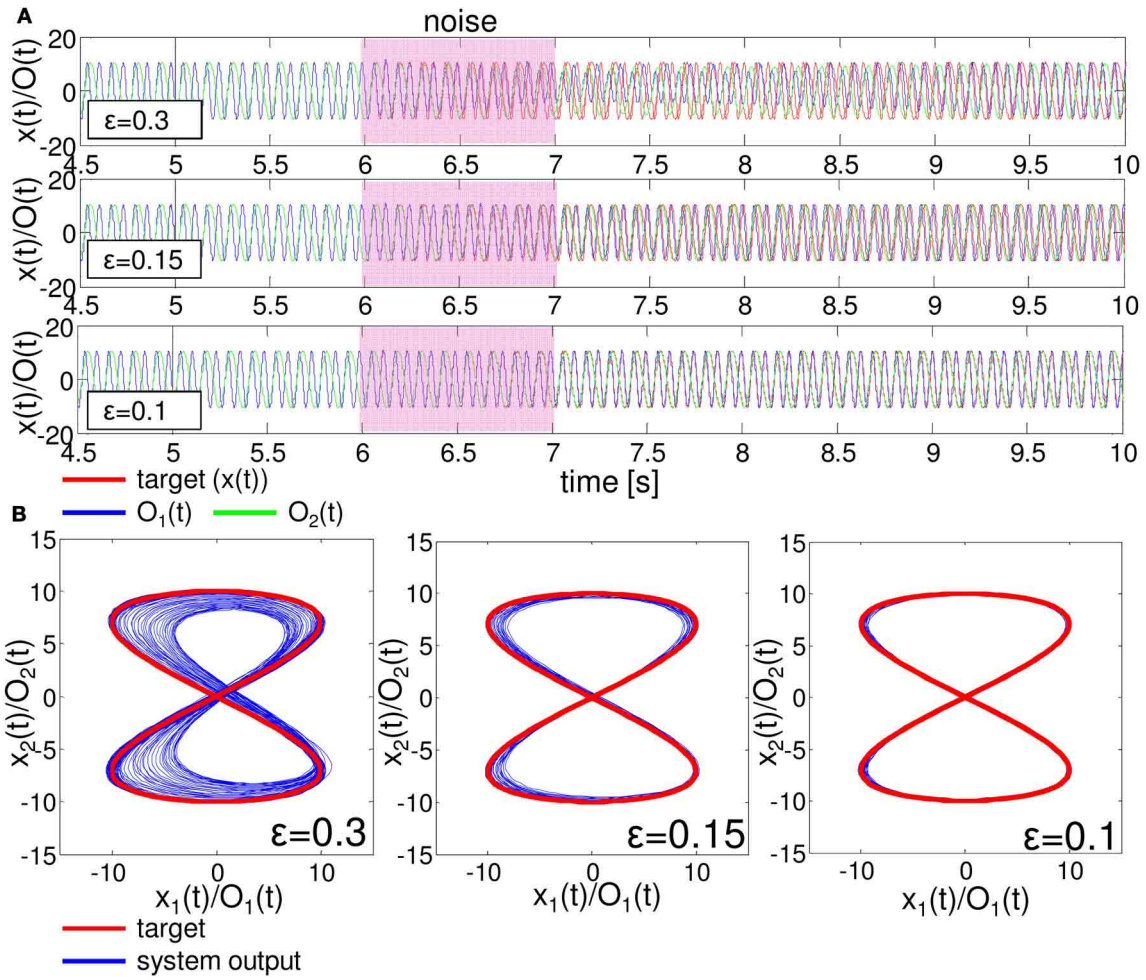

FIGURE 10 | Typical examples showing the performance of the embedded Lissajous curve with external noise. The white noises, $\delta O_1(t)$ and $\delta O_2(t)$, in the range of ϵ ($\delta O_{1,2}(t) \in [-\epsilon, \epsilon]$) are added to the motor outputs during $t = 6000 - 7000$ timesteps. **(A)** Typical trajectories of $O_1(t)$ and $O_2(t)$ compared with the target time series. The upper, middle, and lower figures show the case with $\epsilon = 0.3$, 0.15, and 0.1, respectively. **(B)** The corresponding plots in the $O_1(t)$ - $O_2(t)$ ($x_1(t)$ - $x_2(t)$) plane. For each noise level, the trajectories are overlaid from 5000 to 30,000 timesteps.

springs, and this effect influences the motor outputs at timestep $t + 1$. That is, according to the slight difference in the motor outputs, $\delta O_1(t)$ and $\delta O_2(t)$, the sensory time series, $s_{ij}(t)$, will deviate from the original expressed as $s'_{ij}(t) = s_{ij}(t) + \delta s_{ij}(t)$, where $s'_{ij}(t)$ is the actual spring length at timestep t. Then, from Equation (26), the outputs at timestep $t + 1$ can be simply expressed as:

$$O'(t+1) = \sum_{j=1}^{20}\sum_{i=1}^{4} w_{\text{out}}^{ij} s'_{ij}(t), \tag{30}$$

$$= \sum_{j=1}^{20}\sum_{i=1}^{4} w_{\text{out}}^{ij} \left(s_{ij}(t) + \delta s_{ij}(t)\right), \tag{31}$$

$$= O(t+1) + \sum_{j=1}^{20}\sum_{i=1}^{4} w_{\text{out}}^{ij} \delta s_{ij}(t), \tag{32}$$

$$= O(t+1) + \delta O(t+1), \tag{33}$$

where $O'(t)$ and $O(t)$ are the actual and original motor outputs at timestep t, respectively. Note that for simplicity we dropped the index expressing two outputs. Since the deviation of the motor outputs is expressed as $\delta O(t+1) = \sum_{j=1}^{20}\sum_{i=1}^{4} w_{\text{out}}^{ij} \delta s_{ij}(t)$, we can investigate how the noise applied to a single spring at timestep t can affect the motor outputs at timestep $t + 1$ by fixing the other springs as the original. By investigating how $\delta O(t+1)$ evolves through time, we can also evaluate the effect of the noise against the overall system performance.

Now, let us assume that the noise was applied to the sensory value of the spring i in compartment j at timestep t by fixing the other sensory values as the original. Then, the deviation of the motor output at timestep $t + 1$ can be simply expressed as $\delta O(t+1) = w_{\text{out}}^{ij} \delta s_{ij}(t)$, which straight-forwardly means that the degree of $\delta O(t+1)$ is only linearly dependent on the readout weight of the focused spring. Therefore, we can infer and compare how the noise added to each sensory value affects the

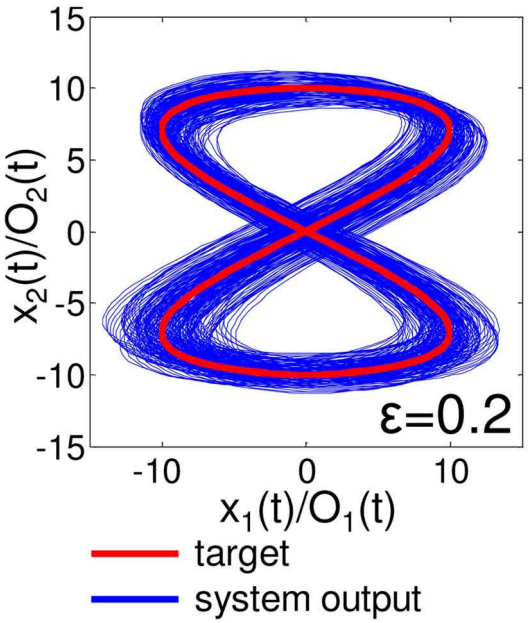

FIGURE 11 | Unstable trajectory of the embedded Lissajous curve with external noise in the range of $\epsilon = 0.2$. The plot is in the $O_1(t)$ - $O_2(t)$ ($x_1(t)$ - $x_2(t)$) plane. The trajectories are overlaid from timestep 5000 to timestep 30,000. The target trajectory is also shown as a reference.

motor output at timestep $t+1$, regarding the fixed noise value, only by checking the weight distributions. Simply saying, if the value of $|w^{ij}_{\text{out}}|$ is large, then the effect of the noise for spring i in compartment j at timestep t on the outputs for timestep $t+1$ is also large, which means this spring makes a big contribution to the transition of the outputs for timestep $t+1$. **Figure 12** shows the readout weight distributions of $w_{\text{out},1}$ and $w_{\text{out},2}$ for the embedded quadratic limit cycle (**Figure 12A**) and Lissajous curve (**Figure 12B**). We can see that the distributions show a characteristic pattern for each limit cycle. For example, in the embedded quadratic limit cycle case, the value of the weights often seems to have a symmetric and corresponding distribution over springs in each compartment (e.g., between spring 1,2 and spring 3,4 in compartment 3–13), and even over $w_{\text{out},1}$ and $w_{\text{out},2}$ (**Figure 12A**). In the embedded Lissajous curve case, this type of symmetric and corresponding distribution can also be found within each weight, but not over $w_{\text{out},1}$ and $w_{\text{out},2}$ (**Figure 12B**). In addition, for the distribution of $w_{\text{out},1}$, the value of the weights is almost zero in compartment 7–20, which means the external noise applied to these compartments at timestep t will not affect the motor outputs at timestep $t+1$ very much.

To systematically proceed with this line of analysis for the overall system performance, we need to confirm whether the large deviation in the sensory value at a specific time also leads to the large deviation of motor outputs over time. Although this seems to be trivial in our system, it is not trivial in general because the transition $\delta O(t) \rightarrow \delta s_{ij}(t)$ depends on the construction of the body (for example, imagine the sensory value that exhibits a saturation)[4]. To evaluate this, we added a small white noise in the degree of ϵ to the motor outputs only at timestep 6000, and investigated how the differences in the motor outputs, $|\delta O(t)|$, and the spring lengths, $|\delta s_{ij}(t)|$, carry on over time according to the degree of ϵ by measuring the mean square errors between the actual and original motor commands, such as $\text{MSE}_{O1} = \frac{1}{T}\sum_{t=1}^{T}(O'_1(t) - O_1(t))^2$, $\text{MSE}_{O2} = \frac{1}{T}\sum_{t=1}^{T}(O'_2(t) - O_2(t))^2$, and between the actual and original sensory time series as $\text{MSE}_{\text{spring}} = \frac{1}{80\times T}\sum_{t=1}^{T}\sum_{j=1}^{20}\sum_{i=1}^{4}(s'_{ij}(t) - s_{ij}(t))^2$, where $T = 500$ throughout this experiment. Note that we consider only a small range of noise around $\epsilon \in [0.005, 0.1]$, since if the noise level is too large, the trajectories often show phase shifts as we saw in the previous analysis (**Figures 9**, **10**), which make the measures miss capturing the intended difference even if the trajectories were in the original limit cycles. **Figure 13A** shows the results of the averaged MSE_{O1}, MSE_{O2}, and $\text{MSE}_{\text{spring}}$ for each embedded limit cycle. We can clearly confirm that according to the increase in the noise level ϵ, the value of each measure also increases, which means that the large deviation of the motor outputs at a specific time also leads to a large deviation in the motor outputs over time. In addition, in the embedded Lissajous curve case, MSE_{O1} is larger than MSE_{O2} for each ϵ value, which suggests that the output $O_1(t)$ is more sensitive than $O_2(t)$ (**Figure 13A** (right)).

Now, we are ready to investigate the role of each body part. According to the results shown in **Figure 13A**, the weights assigned for each spring directly reflect how the noise added to each sensory value affects the overall system performance. To correspond to the results in **Figure 13A**, we first calculated $dw = \sqrt{(w^{ij}_{\text{out},1})^2 + (w^{ij}_{\text{out},2})^2}$ for each spring i in each compartment j, since the size of the noise to the motor output can be expressed as $\delta s_{ij}\sqrt{(w^{ij}_{\text{out},1})^2 + (w^{ij}_{\text{out},2})^2} = \sqrt{\delta O_1(t)^2 + \delta O_2(t)^2} \leq \epsilon$ by scaling the size of δs_{ij} in the appropriate range. Thus, the value of dw directly reflects the contribution of each spring to the overall system performance regarding the fixed noise value. **Figure 13B** shows the value of dw for each spring i according to each compartment for the embedded quadratic limit cycle and Lissajous curve. Interestingly, the value of dw for each spring is almost the same within each compartment for both limit cycles, which means that the contribution of each body part can be expressed at the compartment level. In the case of the quadratic limit cycle, the value of dw shows almost a zig–zag pattern and gradually decreases when the compartment number increases from the base toward the tip [**Figure 13B** (left)]. In the case of the Lissajous curve, only the compartment around the base shows high values for dw [**Figure 13B** (right)]. These results suggest that, according to the limit cycles embedded, the sensitivity and degree to affect the overall system performance against the noise show different tendencies for each body part.

[4]Theoretically, this is to analyze the basin structure surrounding the original trajectory. Due to the number of parameters, instead of analyzing the basin structure according to $\delta O_1(t)$ and $\delta O_2(t)$, we analyzed the basin volume in terms of the error measures introduced later according to $|\delta O(t)|$.

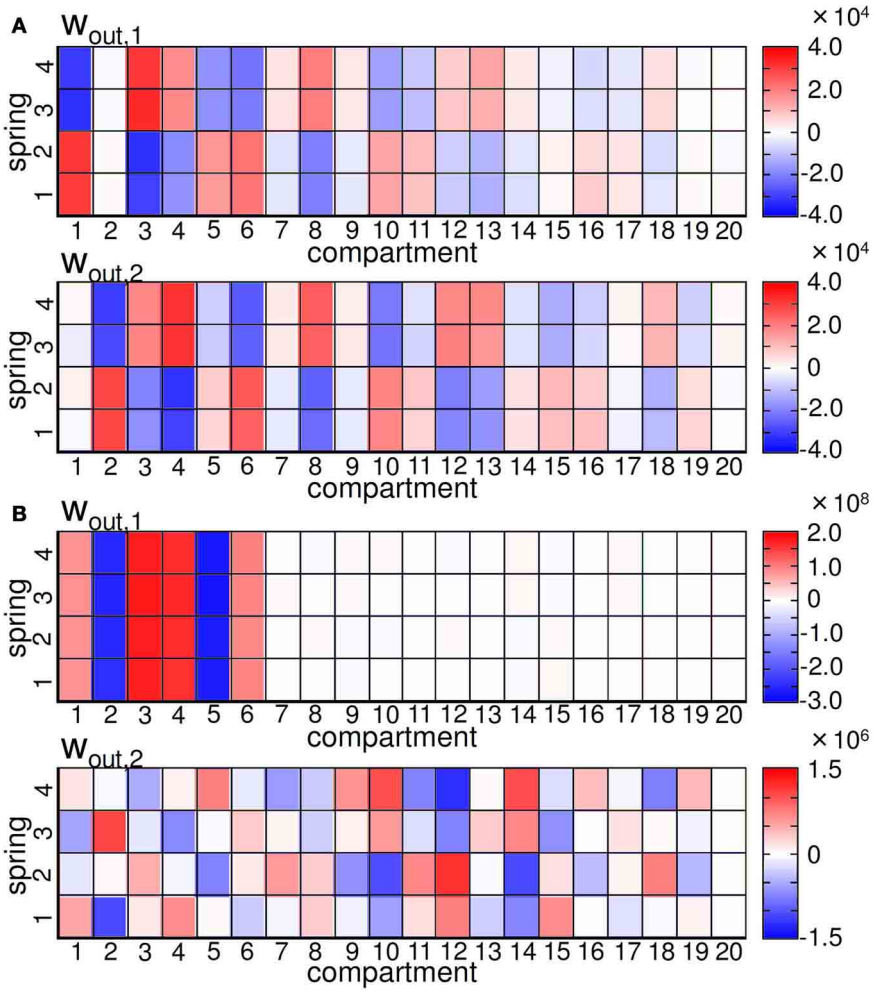

FIGURE 12 | (A) Plots showing the readout weight distribution for the quadratic limit cycle. **(B)** Plots showing the readout weight distribution for the Lissajous curve. For each figure, the upper and lower graphs show $w_{out,1}$ and $w_{out,2}$, respectively.

In this section, we have investigated whether our soft robotic arm can embed limit cycles in a closed-loop manner, and have shown that several properties, such as the system performance, the robustness against external noise, and the role of each body part differ according to which limit cycle to embed. Since we are adjusting only the linear readouts by using the same body, we can speculate that these specific properties corresponding to each limit cycle are caused by the intrinsic body structure.

4. DISCUSSION

In this paper, by using the dynamic simulator of the soft robotic arm inspired by the octopus, we demonstrated that the robot's body dynamics are already capable of emulating non-linear dynamical systems and embedding non-linear limit cycles in a closed-loop manner by only adjusting the fixed linear readouts. The arm we used did not contain any rigid components. Instead, it is soft, including only springs, which are aligned to mimic the muscular structure of the octopus. This resulted in several compartments, each of which had a specific muscular-hydrostat property, which enforced the springs to be coupled in well-defined, but constrained, manner. In addition, the arm was assumed to be immersed in an underwater environment, in which the friction constants were identified via CFD simulations. All these factors, including this intrinsic body structure and its interaction with the environment, generated diverse body dynamics, including rich non-linearity and memory. The technique presented here allowed us to exploit these properties as computational resources. In addition, it is possible to infer the amount of non-linearity and memory that can be potentially exploited for information processing in terms of the task performance. For roboticists, this may open up the way to quantitatively characterize which control is efficient for which body design, as well as outsourcing the control load to the body parts. Although we kept the arm's mechanical structure as bio-inspired as possible throughout the analyses, it would also be meaningful to investigate how the information processing capability would change if the arm's mechanical properties (such as stiffness, damping,

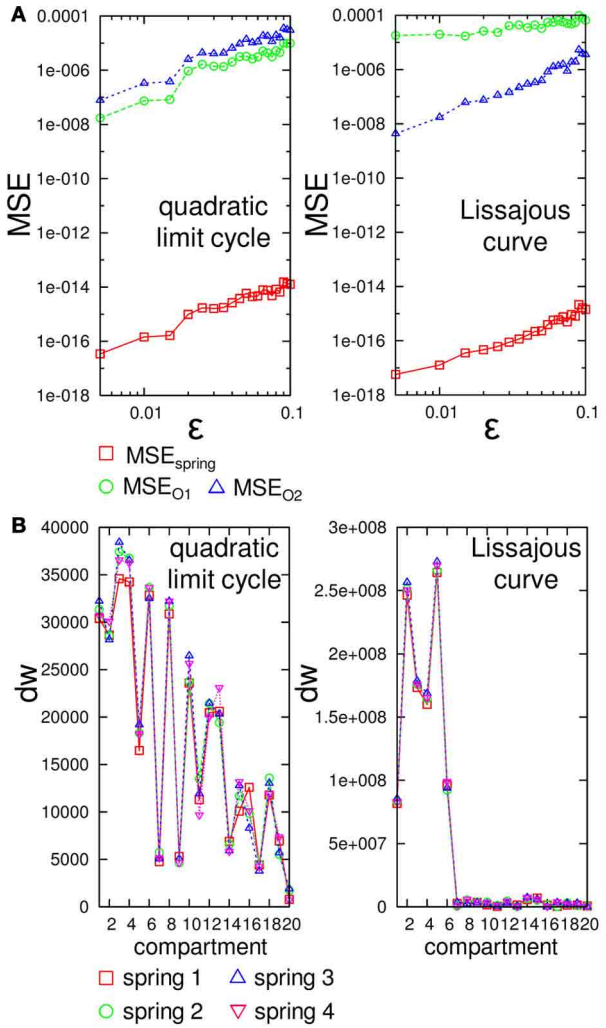

FIGURE 13 | (A) Plots showing the averaged MSE_{spring}, MSE_{O1}, and MSE_{O2} according to each noise level ϵ for the embedded quadratic limit cycle (left) and Lissajous curve (right). Each MSE value is averaged over 15 trials by adding a randomly chosen value from $[-\epsilon, \epsilon]$ to two outputs at timestep 6000. Note that both plots are in log-log plots. **(B)** Plots showing dw calculated by using the weights $w_{\text{out},1}$ and $w_{\text{out},2}$ for each spring i in each compartment for the embedded quadratic limit cycle (left) and Lissajous curve (right). See the text for details.

drag parameters) are altered. This line of experimentation will be included in our future work.

For the emulation tasks of non-linear dynamical systems, in addition to its high computational power, we showed that each body part has a specific role according to the task type. Additionally, for the closed-loop control tasks, we showed that the arm prefers some limit cycles over others (i.e., the quadratic limit cycle and the Lissajous curve were possible to embed, while the Van der Pol limit cycle was not). These obvious and specific coherencies are usually not observed in conventional reservoir computing where the reservoir consists of randomly coupled non-linear computational elements, suggesting that these properties originate from the intrinsic body structure.

From a biological systems point of view, this result seems natural. In nature, animals adapt to their respective ecological niches, where they evolve their body morphology to survive within their environment. The octopus is not an exception; its specific body structure is specialized to permit survival in a complicated underwater environment, enabling it to behave efficiently in particular ways. In this context, it would be interesting to investigate whether the arm could embed more biologically plausible behaviors in future work. For example, as we mentioned earlier, it is well known that the octopus adopts a specific strategy for reaching, called *bend propagation* (Gutfreund et al., 1996; Gutfreund, 1998; Sumbre et al., 2001; Yekutieli et al., 2005a,b). In this specific motion, it is suggested that the CNS only initiates the motion and all the muscle activations are handled at the PNS level (Gutfreund et al., 1996; Gutfreund, 1998; Sumbre et al., 2001). Several researches have investigated this behavior by directly extracting the muscle contraction patterns from the real octopus, and by externally applying these patterns to the octopus arm models (Gutfreund et al., 1996; Gutfreund, 1998; Yekutieli et al., 2005a,b). On this point, our technique presented here may reveal further insights on this overall scheme by including the role of the arm's body dynamics. Considering that the PNS does not have a plasticity (Kandel et al., 2000), it would be worth investigating how the arm's body dynamics, together with the PNS, modeled as a linear and static feedback loop onto the arm, embeds the motor patterns of bend propagation according to the initiation command sent by the CNS. This line of experiment can be investigated in future work.

There exists a growing number of documented cases in nature, which support that certain morphologies found in animals are facilitating a kind of computation. This observation is usually characterized by the term *morphological computation*. For example, the non-linear, non-homogeneous spatial arrangement of the ommatidia in insect eyes are more dense toward the front than on the side in order to compensate for motion parallax, which is non-linear (Franceschini et al., 1992). The morphology counteracts the non-linearity introduced by the parallax; hence, the complexity of the computational tasks to steer through obstacles based on the visual input is reduced. Since the resulting task for the brain is now simpler and not non-linear anymore due to the "clever" morphology, one could argue that part of the computation is conducted by the morphology. While this is a very simple case of a morphological computation, since the given morphology represents only a static, non-linear mapping, the concept does go further, if we consider, for example, soft, compliant bodies. Such bodies exhibit interesting dynamic properties, such as fading memory and non-linearity. Examples of such complex computations outsourced to the physical layer are passive walkers (Collins et al., 2005). Their design pushes the limits of what can be outsourced to the physical body, in so far that no controller (i.e., CPU) is needed at all. The mechanical design inspired by the musculoskeletal structure enabling "preflexes", which can self-stabilize movements through its elastic material properties, also gives such an example (Brown et al., 1995; Blickhan et al., 2007; Proctor and Holmes, 2010). Their morphology (i.e., the mechanical, soft design and the environment) is able to "do" all the computations needed to walk robustly. While such robots are impressive, their

disadvantage is their inflexibility by restricting the computation to a fixed physical body only. In a biological system, a sensible distribution of the computation between the body and the brain is more probable. Despite the number of biological examples and the series of robots, which have been built considering the concept of morphological computation in their design, there are still a few studies characterizing the concept within a quantitative framework (Hauser et al., 2011, 2012; Füchslin et al., 2013). In this context, we believe that the approach presented here would be one of the interesting directions for further study.

FUNDING

This work was supported by the European Commission in the ICT-FET OCTOPUS Integrating Project (EU project FP7-231608), and was partially supported by JSPS Postdoctoral Fellowships for Research Abroad.

ACKNOWLEDGMENTS

We would like to thank Stefan Häusler, Tao Li, and Junichi Kuwabara for fruitful discussions and helpful suggestions.

In this work we research the role of body dynamics in the complexity of kinematic patterns in a quadruped robot with compliant legs. Two gait patterns, lateral sequence walk and trot, along with leg length control patterns of different complexity were implemented in a modular, feed-forward locomotion controller. The controller was tested on a small, quadruped robot with compliant, segmented leg design, and led to self-stable and self-stabilizing robot locomotion. *In-air* stepping and *on-ground* locomotion leg kinematics were recorded, and the number and shapes of motion primitives accounting for 95% of the variance of kinematic leg data were extracted. This revealed that kinematic patterns resulting from feed-forward control had a lower complexity (*in-air* stepping, 2–3 primitives) than kinematic patterns from *on-ground* locomotion (4 primitives), although both experiments applied identical motor patterns. The complexity of *on-ground* kinematic patterns had increased, through ground contact and mechanical entrainment. The complexity of observed kinematic *on-ground* data matches those reported from level-ground locomotion data of legged animals. Results indicate that a very low complexity of modular, rhythmic, feed-forward motor control is sufficient for level-ground locomotion in combination with passive compliant legged hardware.

Keywords: motion primitives, locomotion patterns, central pattern generator, quadruped robot, passive leg compliance, entrainment, principal component analysis, walk and trot

1. INTRODUCTION

The overlapping fields of functional leg anatomy, leg and body compliance, and neuro-control in legged locomotion are intensively researched. Results potentially allow insights into the structure and functionality of the nervous system of animals. Not surprisingly, roboticists have started researching bio-inspired, legged robot systems, both on the functional morphological level, and the controller level. Though intrinsically limited (Webb, 2001), robots are beginning to be used as proof-of-concept platforms (Raibert et al., 1984; Raibert, 1990; Full and Koditschek, 1999; Ijspeert et al., 2007; Umedachi et al., 2010; Zhou and Bi, 2012).

In this experimental work we present results by comparing basic patterns measured from kinematic leg data from *in-air* stepping movements of a suspended legged, compliant robot, and from *on-ground* locomotion of the same robot during lateral sequence walk and trot. We applied as measure the number of significant principal components (PCs) extracted from joint-angle data of the robot's compliant, multi-segment legs. We compared four parameter setups, altering the robot's gait control parameters between walk and trot, its speed, and the modules and complexity of its locomotor drive signals. For the robot hardware, special attention has been paid to the in-series and in-parallel leg compliance. The robot was designed such that its leg's compliance and cable-driven actuation were the medium of *change of kinematic complexity* between feed-forward-sent and observed kinematic joint patterns, through emerging mechanical entrainment during level-ground (flat ground) locomotion. During *in-air* leg movement, leg-joints were not exposed to gravitational or inertial forces acting on the robot body (they were only exposed to those acting on the leg's own light-weight segments). The robot's legs were hanging freely *in-air*, and replayed motion patterns represented the kinematic complexity of the feed-forward locomotor controller. During *on-ground* locomotion, leg-joints were compressed by gravitational forces acting on the robot body, and Newtonian dynamics acting at the robot's body eventually deflecting the robot's compliant limbs. Self-stable and self-stabilizing locomotion only emerged if appropriate feed-forward patterns were sent to the robot. In all other cases, the robot would stumble, fall, or move only very poorly, i.e., very slowly or even backwards.

Physical, biological leg compliance was found to function as energy recoil mechanism, allowing animals to re-use negative work, and reduce metabolic cost of locomotion (Alexander, 1984, 1990, 1991; Biewener and Blickhan, 1988). Sources of compliance were found both in muscles and muscle complexes (Witte et al., 1994; Labeit and Kolmerer, 1995; Wilson et al., 2003), and in tendons and aponeuroses (Alexander, 1977; Witte et al., 1997; Biewener, 1998; Gregersen et al., 1998; Lichtwark et al., 2007). If biological systems rely that strongly on in-series and in-parallel compliant "locomotion hardware," the nervous system producing motor control patterns has to be able to cope with leg compliance, and is required to send the corresponding control signals. Ivanenko et al. (2002) present experiments with walking humans, and *in-air* stepping with varying amounts of gravity, leading to no

or limited sensory feedback through foot contact. They observe that during air-stepping "…motor patterns are transformed in simple harmonic angular motion of the lower limb segments associated with alternating activation of antagonist muscles" (cf. Ivanenko et al., 2002, p. 3087). Although they conclude on the role of peripheral sensory input, we are building in this work on the idea that the complexity of leg kinematics during locomotion can be increased through compliant, and purely mechanical components of the locomotor apparatus and its interactions with the ground. In turn, this could mean that the underlying layers of motor control do not need to send as complex control signals as one might have guessed from kinematic studies, while still achieving a sufficiently complex, adaptive kinematic output.

The spring-loaded inverted pendulum (SLIP) framework describes how an abstracted, energy conservative point-mass system can make use of a compliant, in-series elastic leg design to self-stably run (Blickhan, 1989; Seyfarth et al., 2002). In a SLIP simulation, minimal control effort is required to stabilize locomotion. Control of the leg's angle of attack is necessary, together with monitoring the system's hip apex height. A feed-forward SLIP controller will lead to self-stable locomotion patterns, also under the influence of small perturbations. Full and Koditschek (1999) explain the SLIP model as a "template." A biological or robotic legged system still requires an "anchor," to map the system mechanics to the template.

In this work, central pattern generator (CPG) control signals in feed-forward mode were implemented as high-gain position signals from the robot's RC-servo motors, actuating hip joints and leg length. Interpreting CPG output patterns as position signals presents an abstraction and simplification of animal motor control and actuation. In animals, motor control signals of the nervous system are interpreted by sets of antagonistic muscles and muscle groups to produce joint torques (Inman et al., 1952). Hence, animals can control their limbs in many modes, including "position-control" (muscle lengths leading to joint angles), but also with adjustable joint torques (Winter, 1983; Fischer and Blickhan, 2006).

With the help of a robotic tool like Cheetah-cub robot, this work's intention is to shed light on the interplay between rhythmic, modular feed-forward motor control, and the mechanical entrainment leading to stable gait patterns. Mechanical entrainment was a result from an in-series and in-parallel segmented, robotic, bio-inspired leg design, appropriate actuator control patterns, gravity and body dynamics, and ground contact during locomotion. Though not within the topic of quadruped legged walk and trot locomotion, entrainment in articulated robotic systems has been looked upon earlier; Lungarella and Berthouze (2002) designed a setup with a swinging humanoid robot, showing that physical entrainment led to a larger basin of attraction for the space of control parameters leading to stable swinging motions. Entrainment was also achieved at the presence of non-linear mechanical coupling of the humanoid to its environment (Berthouze and Lungarella, 2004). This is interesting because ground contact of Cheetah-cub robot also presents a non-linear perturbation (alternating leg swing and stance phase).

Here, the simplified case of a position-controlled system with serial compliance allows us to focus on few components, and dismiss the effects of additional control and hardware complexity (e.g., explicit control feedback loops, corresponding controller architecture, or torque control strategies). As mentioned earlier, animals feature components of (simple) in-series leg compliance (Alexander, 1984; Gregersen et al., 1998). This morphological feature works also well for robots. In-series compliance can lead to reduced impact forces, what consequently can reduce the control complexity (Meyer et al., 2006).

In the presented experiments, change of complexity between the directly commanded *in-air* leg kinematics and the *on-ground* locomotion leg kinematics emerged through the robot's compliant leg design and the interactions with the ground. At level-ground locomotion, periodic leg length shortening is caused (a) by signals of the robot's feed-forward controller and (b) by the robot-body's pitch, roll, vertical, and translational body movements (**Figures 2-2–5**). The inertia- and gravity-induced robot body and leg length movements present a major difference between Cheetah-cub robot and the controller applied in this work, and other feedback-controlled and body-stabilized quadruped robots (Raibert et al., 1986; Havoutis et al., 2013). If one would design a similar set of experiments, but sent feed-forward signals to a high-gain position controlled robot with stiff leg design, its kinematic data from *in-air* running would (largely) match that of *on-ground* running experiments. Hardware springs and cable clutches are not the only way to achieve deviating, adaptive joint kinematics. Alternative setups can facilitate low-gain position controlled actuators, or more generally torque or force controllers (Buchli et al., 2009; Valenzuela and Kim, 2012). These setups, however, require explicit feedback control.

Kinematic leg patterns of Cheetah-cub robot were extracted by principal component analysis (PCA; Krzanowski, 1988; Jolliffe, 2002) on the normalized kinematic leg data, for both *in-air* leg movements, and *on-ground* locomotion. Applying PCA on kinematic leg data from recording of locomotion experiments, or corresponding electromyographic data of the participating muscles has become a common tool in biology, and neurobiology. Dominici et al. (2011) present in a comparative study basic patterns derived from electromyographic (EMG) data of stepping human neonates, toddlers, pre-schoolers, and adults. The authors compare these results to data of neonatal rats, and adult quadruped animals such as cats and monkeys. They report that human neonate stepping and neonatal rat stepping can be represented by two basic patterns, and that human toddler locomotion activation patterns along with all adult quadruped animals share a similar pool of four basic patterns. However, toddler and human adult patterns show differences: "…the four patterns [of human adults] were accurately timed around the four critical events of the gait cycle …" (cf. Dominici et al., 2011, p. 998). Basic patterns from toddler locomotion were less time structured. Dominici et al. (2011) conclude that the increase in patterns is caused by continuous learning, until adulthood. The similarity between toddler data, and basic patterns of adult quadrupedal animal locomotion provides a possible explanation as to where gait patterns in vertebrates originate: central pattern generators located in the spinal cord (Delcomyn, 1980; Grillner, 1985; Ijspeert, 2008). Moro et al. (2013a) extracted four basic patterns (kinematic motion primitives, kMPs) from horses, for the three gaits

walk, trot, and gallop (kMPs account for 93% and 97% of the kinematic data). Moro et al. (2013b) found five kMPs accounting for almost all variance of human walking and running kinematics. Ivanenko et al. (2004) reported five basic muscle activation patterns accounting for almost all variance of muscle activation, during human walking. Koditschek et al. (2004) reported observations on retrieving basic patterns from running cockroaches. Despite the animal's very high number of degrees of freedom—a cockroach is six legged and has multi-segment legs—"…a single component represen[ted] over 80% of the variation …" (cf. Koditschek et al., 2004, p. 256), for very fast running. The authors report that almost all variations were captured by three basic components, leading to the conclusion that a very simple neural controller was likely responsible for the motor control of this insect. The above findings from insects and mammals suggest that basic locomotion on level-ground requires three to five basic patterns, and possibly fewer for very fast locomotion. It is intriguing to be able to hypothesize and through robot hardware implementation and experimentation, test the interplay between locomotion controller, robot morphology, and locomotion patterns. Although direct conclusions can only be drawn for the artificial, robotic system, similar designs of both systems and similar results for the task of locomotion can provide insights into animal locomotion control, and how neuro-control is interacting with bio-mechanical components.

We recorded joint-angle leg kinematics of our quadruped robot, for two situations: *in-air* trotting movements, versus robot locomotion *on-ground* (**Figure 1**). With its legs swinging *in-air* and without contacting the floor, the kinematics of the robot's low-inertia leg-joints followed the commanded patterns. Once Cheetah-cub robot is placed *on-ground* to walk or trot, the interplay between ground contact, in-series leg compliance and spring deflection, and body movements alters the complexity of its leg kinematics. In all experiments documented, motor control patterns where sent feed-forward. Hence, the observed changes between *in-air* and *on-ground* leg kinematics were caused by ground contact and mechanical entrainment.

The experiments of this work are intended to inform on the potential interplay of a compliant, legged system, such as found in legged animals or robots, and its motor control. In animals, the interplay of the brain, spinal cord, peripheral nervous system (PNS), morphology, and intrinsic, mechanical properties (springiness, damping, inertial moments, lengths, speed and force properties) plays a key role for its locomotion capabilities. Studies like Ivanenko et al. (2002) or Hägglund et al. (2013) show that understanding the role, structure, and interplay of locomotor components in animals is difficult. With a largely simplified robot "hardware model" we can focus on the interplay of only a few components. Specifically, this robot features only these locomotor components: a feed-forward, oscillatory motor controller (we implemented a central pattern generator, but any other controller with similar features could be applied), and the mechanically compliant, bio-inspired leg structure. Cheetah-cub robot is stripped off any task-level control feedback, the motor control CPG is purely running in feed-forward mode. Self-stable and self-stabilizing locomotion was a product of appropriate motor control patterns (derived through systematic testing, see Spröwitz et al., 2013), the robot's compliant leg design, and the mechanical entrainment of these components, through ground contact during *on-ground* locomotion.

Establishing a reduced experimental setup, without any task-level feedback from the nervous system, is hard to achieve in live, locomoting animals. Possibilities for modulation of PNS pathways include preparations with drugs, lesions (see for example Grillner and Zangger, 1979), or more recently introduced methods like light-evoked activation and deactivation of spinal cord and PNS components (Daou et al., 2013; Hägglund et al., 2013). The vast number of publications in the field shows the complexity of locomotion generation and control in animals. From this perspective, the use of a legged robot with a programmable motor controller and dedicated hardware presents a diametrical, bottom-up approach to analyze the interplay of only its featured, however, much simpler locomotor components.

As our **first hypothesis** (H1-1) we expect four to five basic patterns accounting for 95% of the variance of kinematic leg data, at low-speed and mid-speed robot locomotion, as observed from legged animals (Ivanenko et al., 2004; Dominici et al., 2011; Moro et al., 2013a,b). Further, Koditschek et al. (2004) had reported a decreasing number of motion primitives at high locomotion speed, for a simpler biological legged systems with leg compliance. Hence, we expect a similar trend: a decreasing number of *on-ground* PCs with increasing robot speed (H1-2).

In addition, we looked at the number of *in-air* stepping PCs, versus the number of *on-ground* locomotion PCs. The interaction of ground contact, feed-forward controlled compliant legs, and the naturally emerging pitch and roll body movements produced a self-stable walk or trot gait (Spröwitz et al., 2013). This richer, additional pattern through mechanical entrainment should be visible as a higher number of observed basic principal components for *on-ground* locomotion, compared to non-contact, *in-air* stepping. *In-air* stepping presents virtual locomotion patterns with rigid, non-compliant legs. No ground contact deflects the serial leg springs out of their slack length, and recorded complexity of *in-air* kinematic data represents effectively the complexity of Cheetah-cub's feed-forward controller. As our **second hypothesis** we expect a higher number of basic patterns for *on-ground* locomotion, compared to *in-air* stepping (H2).

This paper is organized as follows: in section 2 we give a short overview of the robot's locomotion controller and hardware. We provide details of data recording and processing, and of the extraction of basic primitives from the recorded kinematic data. In section 3 we present the results from the four proposed experiments for walk and trot locomotion, *in-air* and *on-ground*. In section 4 we discuss results and their implications for biological and robotic systems. Finally, we conclude the paper.

2. MATERIALS AND METHODS

The first part of this section covers a brief description of the robot's hardware. For a more throughout description please refer to (Spröwitz et al., 2013). Next, this section provides information about the experimental tools and setup, and details about the applied principal component analysis. Cheetah-cub robot's gait controller based on a central pattern generator (CPG in feed-forward mode) is explained. Videos of Cheetah-cub robot running can be found at

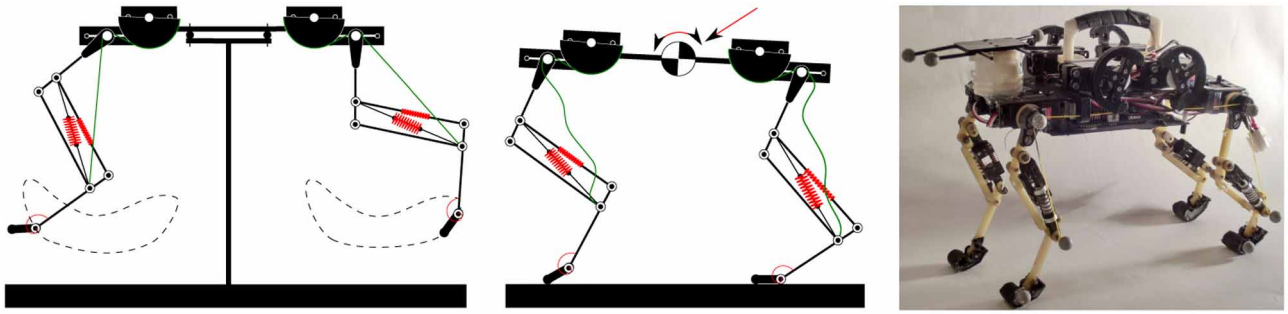

FIGURE 1 | Schematic presentation of the *in-air* experiment (left), the *on-ground* experiment (middle), and a picture of the real robot (right). For the *in-air* experiment, feed-forward locomotion patterns (permutations of trot, lateral sequence walk, locomotion frequencies of 2.5 and 3.5 Hz, two different control pattern types) were sent to the robot, while the robot's body was mounted on a stand, with its legs swinging freely *in-air*. At the *on-ground* experiment, the quadruped robot walked and trotted freely on level-ground, with an average speed between 0.45 and 0.9 ms^{-1}. Identical motor control patterns were sent to both *in-air* and *on-ground* experiments, for each experiment type. In all experiments, resulting kinematic patterns (leg angle and leg length) were recorded. Change of complexity of kinematic primitives between *in-air* and *on-ground* derived from ground contact, and the robot's compliant leg design. Further details of Cheetah-cub robot's leg design and compliance are available in **Figure 2**.

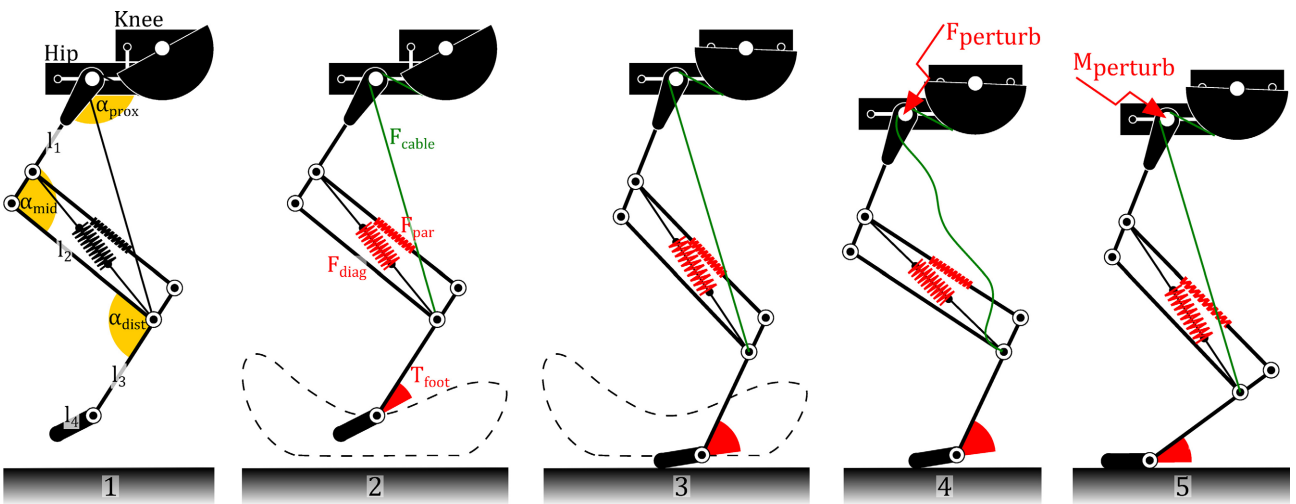

FIGURE 2 | Cheetah-cub leg mechanism, and leg compliance. A single leg is shown abstracted, detailed leg segment ratios are omitted for clarity, robot heading direction is to the left. **(1)** shows the three leg angles α_{prox}, α_{mid}, and α_{dist}. Hip and knee RC servo motors are mounted proximally, the leg length actuation is transmitted by a cable mechanism. The pantograph structure was inspired by the work of Witte et al. (2003) and Fischer and Blickhan (2006). **(2)** The foot segment describes a simplified foot-locus, showing the leg in mid-swing. For ground clearance, the knee motor shortens the leg by pulling on the cable mechanism (green, F_{cable}). F_{diag} is the major, diagonal leg spring. Its force extends the pantograph leg, against gravitational and dynamic forces. **(3)** The leg during mid-stance. **(4)** In case of an external translational perturbation, the leg will be compressed passively. **(5)** If an external perturbation torque applies e.g., through body pitching, the leg linkage will transmit it into a deflection of the parallel spring, not of the diagonal spring.

2.1. QUADRUPED ROBOT HARDWARE

Cheetah-cub robot's leg design is based on a mammalian, animal-inspired pantograph mechanism (Witte et al., 2003; Fischer and Blickhan, 2006). An automatic, cable-based clutch mechanism, proximal actuation, and a compliant foot joint enhanced the original, bio-inspired hardware blueprint (Spröwitz et al., 2013). Each robot-leg was individually controlled by two RC servo motors. The leg length (knee) actuator actively *flexed* the leg via a cable mechanism, antagonistic to the diagonal leg spring (**Figure 2-2**). The cable mechanism also works as an automatic decoupling mechanism. It goes slack if external forces are applied to the leg (**Figure 2-4**). The robot's proximal actuator was directly mounted between body and leg. It protracted and retracted front and hind legs.

The robot's body was implemented as a stiff plate, only legs provided compliance. Three leg springs are acting in this leg design, under different load conditions (**Figure 2**): F_{diag} is the in-parallel spring to the cable actuation, and provides anti-gravity support. F_{par} is the spring replacing one of the struts of the linkage mechanism. Under tension it provides an in-series leg elasticity. The third spring is located in the most distal leg joint. It

is a helical spring and provides serial foot torque. In sum, this presents a very compliant leg design with a very low leg stiffness, in comparison with biological systems. The linearized vertical leg stiffness of two in-parallel Cheetah-cub robot legs is about 0.25 kN/m, for a static measurement with isolated legs. During fast trotting locomotion (Froude number speed of FR = 1.0), a leg stiffness of $F_{\text{vert}}/\Delta l = 0.65$ kN/m was recorded. Leg stiffness for *running*, quadruped animals of this body weight, but at faster speed, are documented to be almost twice as high ($k_{\text{leg}} = M^{0.67} = 1.05$ kN/m, using the convention of treating all ground-contacting legs as one, Farley et al., 1993). Compared to a young cat of equal weight, Cheetah-cub robot exhibits a more crouched leg posture. This is generally associated with a lower overall leg stiffness through bigger effective lever arms.

In all experiments, the robot was tethered to a power supply through a long, light-weight power cable. CPG computation, RC servo motor control signal generation, and wireless communication were controlled from a single board computer, mounted on the robot's body.

2.2. DATASET, EXTRACTION, AND EXPERIMENTAL SETUP

The robot was controlled with four different sets of control parameters (**Figure 4**). The robot ran at two different gait patterns (lateral sequence walk, and trot), a speed range from mid-speed to higher-speed, and two different knee-control strategies. Thus, the robot exploited its body dynamics for different gait patterns, control complexities, and dynamical speed conditions: (a) Lateral sequence walk gait with a locomotion cycle frequency of 2.5 Hz, with double-peak knee deflection (DP, **Figure 3**), at medium robot speed. (b) Trot gait with a locomotion cycle frequency of 3.5 Hz, with DP knee actuation, at high robot speed. (c) Trot gait with a locomotion cycle frequency of 2.5 Hz, with DP knee actuation, at medium robot speed. (d) Trot gait with a locomotion cycle frequency of 3.5 Hz, with a single-peak knee actuator signal (SP), at higher [compared to (a) and (c)] robot speed. Single-peak and double-peak leg length control signals, and hip-joint control signals are plotted for one locomotion cycle in **Figure 3**. All robot runs were repeated 10 times, and between 30 and 60 stride cycles were extracted for each gait. Kinematic robot data was recorded with a motion capture (MOCAP) system, based on infrared reflective markers of 11 mm diameter. Twelve MOCAP cameras (Optitrack s250e, Naturalpoint, Inc., 2011) were mounted at 1.20 m and 2.30 m height, positioned in a large rectangular arena around the locomoting quadruped robot. Cameras observed a volume of 1.5 m width, 4 m length, and 0.5 m height. MOCAP data were captured at $f = 250$ fps. Marker trajectories were processed and cleaned with Arena software (Naturalpoint, Inc., 2011). Unlabeled markers were labeled in *Mokka* (Barré and Armand, 2014). Data was loaded in Matlab (MATLAB, 2009, v. 7.9) with *b-tk* framework (Barré and Armand, 2014). All marker trajectories were low-pass filtered, with an 18 Hz cut-off frequency.

For *in-air* experiments, Cheetah-cub was mounted on a small stand in the center of the arena. Its legs were hanging freely in the air, and MOCAP cameras recorded leg kinematics. For *on-ground* experiments, Cheetah-cub ran the full length of the motion capture arena distance (4 m), without restraints. The robot was powered externally by a power tether. Cheetah-cub's design includes no explicit degree of freedom for changing direction, i.e., adduction or abduction. Before reaching its steady state and before recording was started, the power tether was, in a few cases, used to correct the robot's heading. During recording, the robot would walk or trot while the tether was carefully kept loose. The robot was started from the ground, data was recorded once it reached steady state. This happened typically after less than three locomotion cycles. Markers were attached on the robot's right side of fore and hind limb, on the proximal leg joints, mid-leg joints, and feet (**Figures 1**, **2**). Using leg kinematics, angles of proximal (α_{prox}), middle (α_{mid}), and distal (α_{dist}) joints were calculated (**Figure 2-1**). As the robot leg's parallel spring and foot spring work in-series, deflection of the distal leg segment and the foot segment were combined for simplification into a single angle (α_{distal}). Recorded locomotion stride cycles were synchronized based on $pi/2$ crossing of hip angle of the virtual leg (hip to foot), at mid-swing. The end of each stride cycle was calculated from the inverse stride frequency. Finally, all cycles were divided into 100 samples per cycle, using Piecewise Cubic Hermite Interpolating Polynomial (Fritsch and Carlson, 1980).

2.3. PRINCIPAL COMPONENT ANALYSIS, PCA

Kinematic primitives describing the main components of the kinematic leg dataset can be computed by matrix factorization (Strang, 2003). We applied Principal Component Analysis (Krzanowski, 1988; Jolliffe, 2002) to implement matrix factorization (similar to Fod et al., 2002; Bizzi et al., 2008). The obtained data are represented with $\mathbf{X}_{n_o,n_v}$, with n_o being the number of observations, i.e., the number of samples per cycle, and n_v being the number of variables, i.e., the number of cycles. The dataset was first normalized $\tilde{\mathbf{X}}_{n_o,n_v}$, so each cycle had a zero mean and a standard deviation equal to one. The covariance matrix of the normalized dataset was then calculated, obtaining Σ_{n_v,n_v}:

$$\Sigma = \frac{1}{N-1}\sum_{i=1}^{N}(\tilde{X}_i - \bar{X})^T(\tilde{X}_i - \bar{X}) \tag{1}$$

where $\tilde{X}_i$ is the i-th observation in $\tilde{\mathbf{X}}$, and $\bar{X}$ is the mean observation. Principal components of the covariance matrix were extracted, obtaining the loading vectors $\mathbf{v}_i$, $i = 1..\min(n_o - 1, n_v)$, and the respective eigenvalues λ_i, sorted in descending order. Typically a low number of principal components are sufficient to account for a big part of variance. If the first n_s components account for a percentage variance (e.g., n_s components account for 95% of the variance, for all results in this work), then n_s primitives are obtained by projecting the normalized dataset on the most significant loading vectors $\mathbf{v}_i$, $i = 1..n_s$:

$$\mathbf{p}_i = \tilde{\mathbf{X}}\mathbf{v}_i \tag{2}$$

2.4. LOCOMOTION CONTROL WITH CENTRAL PATTERN GENERATOR

Central pattern generators (CPG) were successfully applied to generate locomotion patterns for legged and other robots (Fukuoka et al., 2003; Ijspeert, 2008; Spröwitz et al., 2008, 2013; Sato et al., 2011). We applied a CPG implemented

as a network of coupled oscillators to rapidly and conveniently encode a feed-forward control signal with explicit, legged locomotion-relevant input parameters such as duty factor, hip amplitude, leg length, and locomotion frequency. Cheetah-cub is a RC-servo motor controlled quadruped robot. The CPG provides for smooth trajectory transition at gait initialization, because of damping terms in the CPG equations. The CPG controller was running feed-forward, i.e., it was streaming a position signal to the RC-servo motors, without incorporating external feedback. Cheetah-cub robot's CPG controller consisted of two modules, a hip controller, commanding the hip motor, and a knee controller, commanding the leg length through a proximally mounted knee motor. Two knee control strategies (single-peak SP, and double-peak DP) were implemented. An example locomotion cycle is provided in **Figure 3**. Top and center plots show a gait applying double peak knee-signals (DP). Top and bottom plots show a gait with a single-peak (SP) knee-signal. The hip signal (top plot) is identical for SP and DP gaits. We used previously derived CPG parameters for trot gait (Spröwitz et al., 2013). The hip-joint-driving CPG consisted of a network of four phase-coupled oscillators, each oscillator controlled one hip joint. The gait was switched from lateral sequence walk (cf. Hildebrand, 1989) to trot by setting the phase shift between hip oscillators accordingly (Righetti and Ijspeert, 2008). Knee oscillators of the corresponding knee were coupled serially to their hip oscillator. The range of speeds obtained for walk and trot is shown in **Figure 4**.

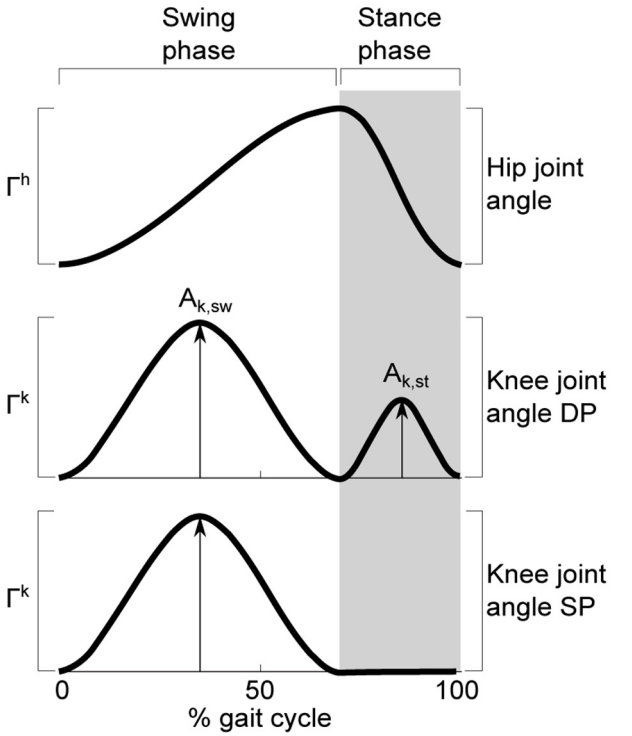

FIGURE 3 | Schematic presentation of the control signals for the two servo motors per robot leg: hip joint-angles (top, Γ_h) and knee joint-angle (center, bottom, Γ_k) for one stride cycle. Swing phase is plotted on the left side (transparent background), stance phase on the right side (gray background). The *double-peak* (DP) knee signal activates the knee motor twice per stride cycle. The leg is flexed stronger during swing phase (larger amplitude), and less flexed during stance phase ($A_{k,st}$). The *single-peak* (SP) knee motor activation signal triggers only during swing phase ($A_{k,sw}$). Leg flexing in SP mode during stance phase emerges through inertia and gravity acting on the robot body, compressing the compliant stance leg at ground contact. For DP knee activation, active actuator leg shortening overlapped with inertia-induced leg shortening (Spröwitz et al., 2013).

3. RESULTS

This section provides the results from four experiments, each for *in-air* stepping and *on-ground* locomotion of the robot. The number and shapes of basic components accounting for at least 95% of the variance of the kinematic leg data are provided.

3.1. DOUBLE-PEAK (DP) KNEE PATTERN, WALK, $F = 2.5$ HZ

Figure 5 shows joint-angle data *in-air* and *on-ground* (**Figures 5A,B**), and the corresponding principal components (**Figures 5C,D**). Average robot speed for this experiment was 0.45 ms^{-1}, around 2.3 body lengths per second. **Figures 5C,D** indicate that more than 97% of the *in-air* patterns can be presented by three principal components, and 96% of the *on-ground* joint-angles kinematics by four principal components. The first PC of *in-air* and *on-ground* represents almost 50% of the kinematic data, for both cases (**Figure 9A**).

3.2. DOUBLE-PEAK KNEE PATTERN, TROT, $F = 3.5$ HZ

Average robot speed for the 3.5 Hz trot gait with double-peak knee actuation was the highest of all four experiment types (0.9 ms^{-1}). Higher average robot speed is possible with higher motor coil voltage, up to 1.42 ms^{-1} (Fr = 1.3, Spröwitz et al., 2013). However, the power consumption becomes so large that motors would break at longer experimentation, caused by coil overheating. A speed of 0.9 ms^{-1} was a compromise between fast robot locomotion, around 4.5 body lengths per second, and a repeatable, robust experimental setup. The results in **Figure 6** show three basic patterns for *in-air* stepping (98%), and four basic patterns for *on-ground* locomotion (97%). **Figure 9B** shows that the first *in-air* PC of this gait accounted for more than 60% of the variance of the kinematic data.

3.3. DOUBLE-PEAK KNEE PATTERN, TROT, $F = 2.5$ HZ

In this experiment the robot trotted at mid-speed level, at $v_{av} = 0.55\ ms^{-1}$. This was little more than the average speed of the robot for walk-gait experiment (0.45 ms^{-1}), at the same gait frequency. Three basic patterns account for 98% of the variance of the *in-air* stepping data (**Figures 7**, **9C**). Four basic components account for 97% of the variance of the *on-ground* locomotion joint-angle data.

3.4. SINGLE-PEAK (SP) KNEE PATTERN, TROT GAIT, $F = 3.5$ HZ

Single-peak (SP) knee actuation based locomotion was only stable above a speed of 0.55 ms^{-1}. The single activation burst of the knee actuator, effectively shortening leg length, is triggered during swing phase. This provides leg ground clearance to freely swing the leg and foot forward. Without leg length actuation during stance phase, leg shortening relies solely on inertia and gravity

forces acting on the robot body compressing (flexing) the leg. This necessary amount of inertial energy explains the minimum required speed for SP experiments. **Figure 8** shows two almost sine-shaped PCs for *in-air* stepping. Both PCs account for 98% of the variance of the kinematic joint-angle data, the first PC accounts for 58% of the variance, the second PC 40% of the variance. *On-ground* locomotion showed four PCs, accounting for 96% of the variance. The number of *in-air* PCs differed, compared to all other experiments (**Figure 9D**). The major change was a switch of the complexity of the knee-control signal, from double-peak to single-peak. This reduction was reflected in the *in-air* PC data, however, *not* in the *on-ground* PC data.

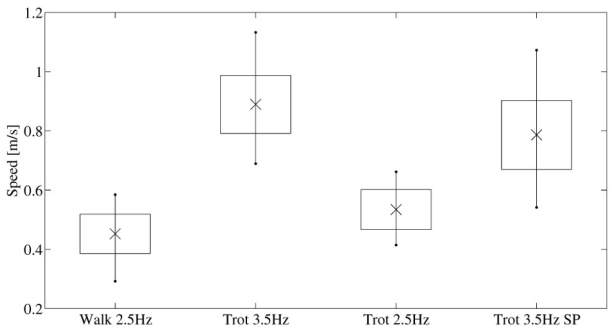

FIGURE 4 | Average speed values of the four experiments, sorted by gait type (walk, trot) and gait frequency (*f* = 2.5, 3.5 *Hz*). The 3.5 Hz trot applied a single-peak knee-trajectory (SP), the three remaining experiments applied double-peak knee-trajectories (DP). For the applied RC servo motor voltage of 12 V, a trot gait speed of 0.9 ms^{-1} (FR = 1) is about the maximum average speed.

3.5. COMBINED DATA

In **Figure 10**, PCs of *in-air* leg movements and *on-ground* locomotion of all four experiments are depicted. This common pool of all collected joint-angle kinematics includes lateral sequence walk and trot gait data. The corresponding joint-angle plot was omitted, it basically covers the entire plot area. Three *in-air* PCs account for 97% of the variance, and four *on-ground* PCs account for 95% of the variance.

4. DISCUSSION

We presented results of locomotion patterns *in-air* and *on-ground*, for the two gait types walk and trot. The robot ran at average forward speeds between $v_{av} = 0.45$ ms^{-1}, more than 2 body lengths per second, and $v_{av} = 0.9$ ms^{-1}, around 4.5 body lengths

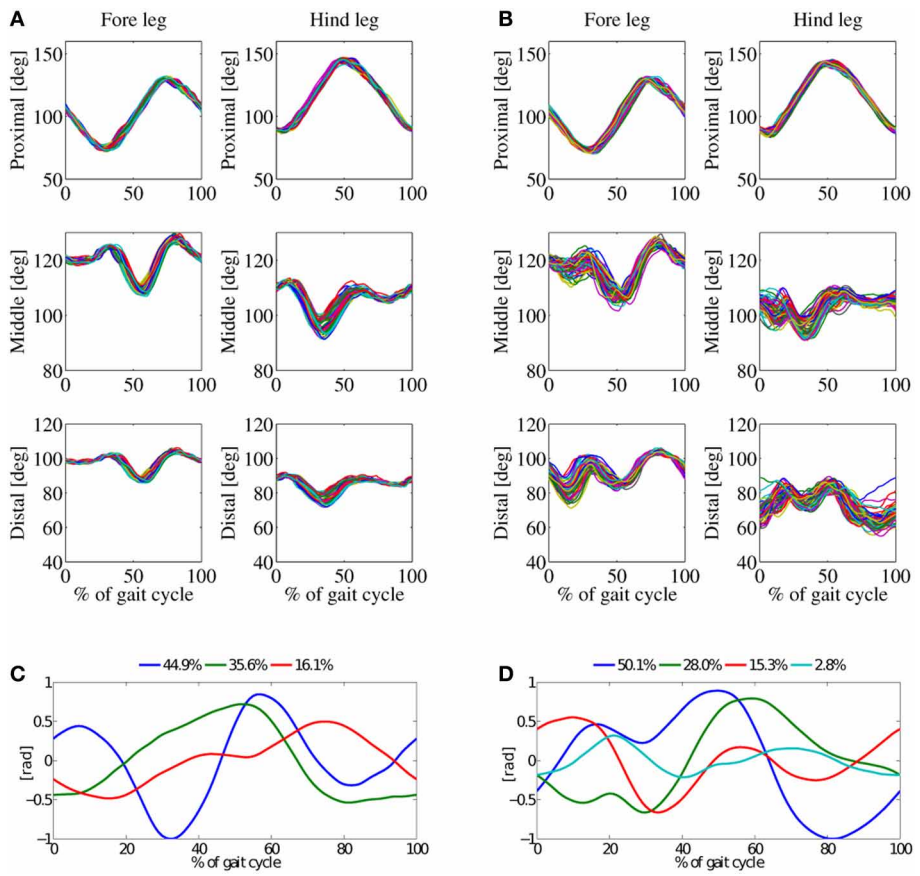

FIGURE 5 | Results from walk-gait experiments, at a locomotion frequency of 2.5 Hz, with double-peak knee activation patterns. (A) Joint angles for *in-air* experiment, and **(B)** joint-angles for *on-ground* experiment. **(C)** Principal components (PC) for the *in-air* experiment, and **(D)** PCs for the *on-ground* experiment. Three basic patterns of the *in-air* experiment sum up to 97%, the four basic pattern of the *on-ground* experiment to 96%.

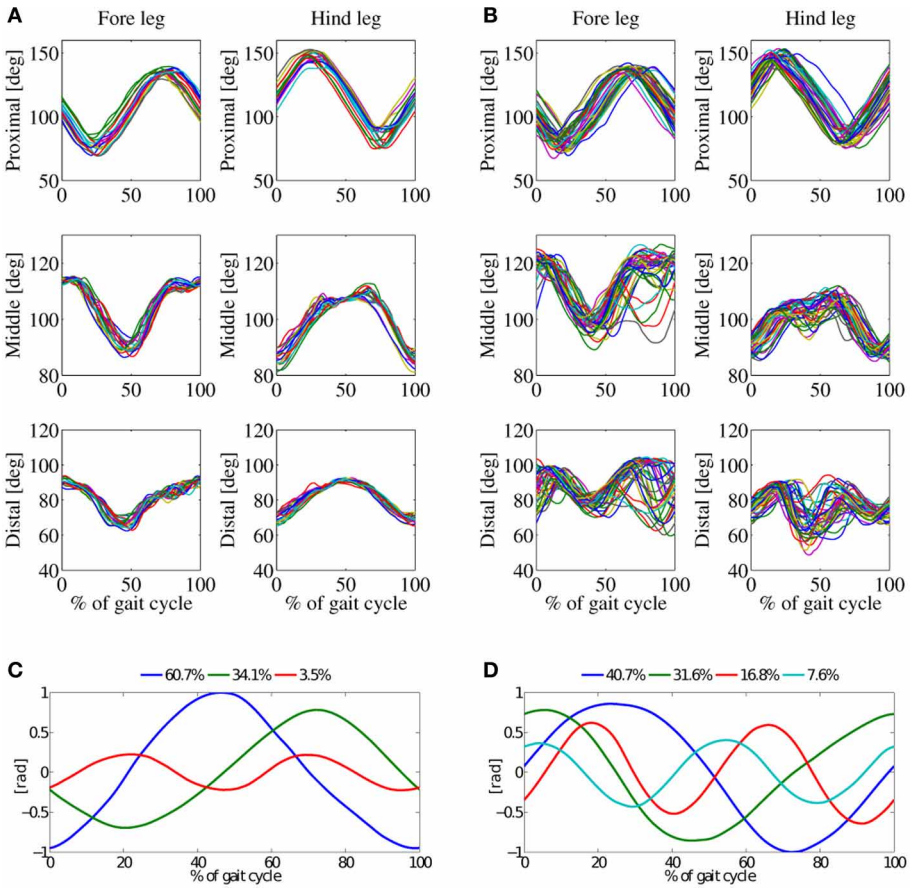

FIGURE 6 | Trot-gait experiments, locomotion frequency 3.5 Hz, average robot speed was 0.9 ms^{-1}, maximum speed was 1.1 ms^{-1}, double-peak knee activation patterns. (A) Joint angles of *in-air*, and **(B)** joint-angles of *on-ground*. **(C)** Principal components for the *in-air* experiment, and **(D)** PCs for the *on-ground* experiment. Three basic patterns of the *in-air* experiment sum up to 98%, the four basic pattern of the *on-ground* experiment to 97%.

per second. All *on-ground* locomotion experiments showed four principal components. *In-air* experiments revealed either two PCs (single-peak knee controller) or three PCs (double-peak knee controller), accounting for at least 95% of the variance of the kinematic leg data.

Stable walk and trot gait pattern were derived by encoding joint control patterns as a set of coupled oscillators (CPG), and manually tuning CPG parameters. For all speeds and gaits, only one type of hip joint pattern was sufficient: a duty-factor distorted sine-wave position signal (**Figure 3**, top plot). For lower speed gaits, double-peak knee signals (**Figure 3**, mid figure) were necessary to produce stable gait patterns. For higher speed, both single-peak (**Figure 3**, bottom plot) and double-peak signals produce stable gait patterns.

4.1. IMPACT OF MECHANICAL ENTRAINMENT

For all experiments mounting the robot on a stand and moving legs *in-air*, gaits with double-peak knee signals (DP-trot and DP-walk) showed three principal components accounting for at least 95% of the variance. All experiments *on-ground*, independent from the robot speed, showed four basic patterns. These results support the first hypothesis (H1-1), derived from observations with animals; level-ground locomotion showed four to five basic components (Ivanenko et al., 2004; Dominici et al., 2011; Moro et al., 2013a,b).

Our *in-air* observations (hypothesis H2) coincide qualitatively with observations from human *in-air* stepping exhibiting simpler, harmonic leg kinematics (Ivanenko et al., 2002), essentially a lower observed kinematic complexity. However, we were unable to find quantitative descriptions of PCs for *in-air* stepping in animals with feed-forward-only motor control. Until otherwise reported, we consider the occurrence of either 2 or 3 PCs for the *in-air* patterns corresponding to 4 *on-ground* PCs as a weak indication for a similar mechanism in animals. Only similarly conducted animal experiments could potentially reveal evidential details on feed-forward motor control mechanisms in animals.

The interaction of the robot with its environment (i.e., ground contact) increased the kinematic complexity by at least one principal component. Qualitatively, this was externally observable through emerging robot body pitch and roll patterns.

For the single-peak knee actuation experiment (SP, 3.5 Hz, trot) Cheetah-cub robot ran at high speed *on-ground*, in average 0.8 ms^{-1}. Replaying the same CPG drive signals

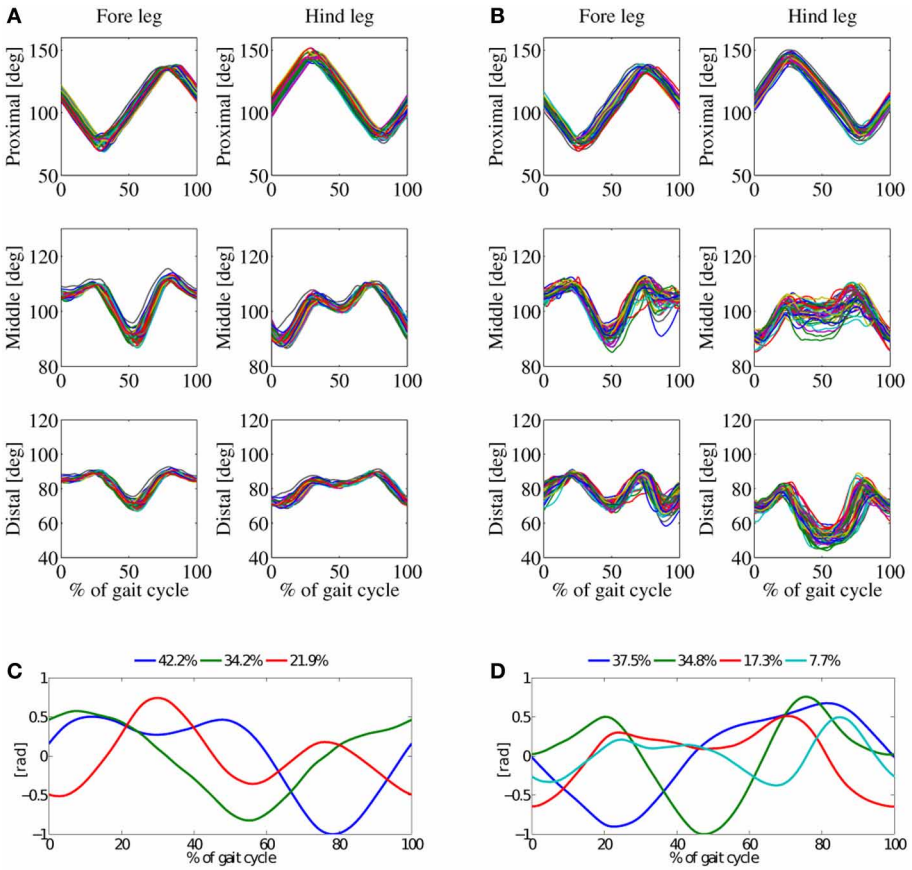

FIGURE 7 | Results from trot-gait experiments at a locomotion frequency 2.5 Hz. Average robot speed was 0.55 ms^{-1}, double-peak knee activation patterns. **(A)** Joint angles for *in-air* experiment, and **(B)** joint-angles for *on-ground* experiment. **(C)** Principal components (PC) for the *in-air* experiment, and **(D)** PCs for the *on-ground* experiment. Three basic patterns of the *in-air* experiment sum up to 98%, the four basic pattern of the *on-ground* experiment to 98%.

in-air showed two basic patterns (98%, **Figure 8C**). We found stable *on-ground* SP-gait patterns only at higher robot speeds, from 0.55 to 1.1 ms^{-1}. From this speed on, the robot's leg springs were sufficiently deflected by inertial forces and gravity, acting on the robot body, and enabled mechanical entrainment. Four basic patterns accounted for at least 95% of the variance of *on-ground* locomotion, for the SP-gait experiment. This result is not in accordance with the second part of hypothesis 1 (H1-2); a decreasing number of *on-ground* PCs was found at higher animal speeds for cockroaches (Koditschek et al., 2004). However, Cheetah-cub robot is unable to perform normalized speeds documented for these insects. The maximum robot speed recorded was 6.9 body lengths per second, or (Froude number of FR = 1.3 Spröwitz et al., 2013). It is possible that Cheetah-cub is not running fast enough to replicate similar results. Above results have potential implications for the general implementation of quadruped robot locomotion controllers: at level-ground running, the resulting patterns *on-ground* require not more than four basic components. This reduces the necessary complexity of the locomotion controller, also for other controller types than CPGs.

4.2. CONTROL DIMENSION REDUCTION AND ROBOTIC GAIT GENERATION

The CPG model used for the control of locomotion included more that 10 open parameters, tuned for each gait. We hypothesize that with a collected dataset of sufficient size, the extracted in-air PCs representing this dataset can be used to reconstruct a new controller. Hence, to generate a new gait, one could tune the in-air primitive-weights for different joints, instead of CPG control parameters. However, many additional experiments are required to prove this claim. If above weight-tuning would apply, one could also encode the extracted primitives into a Dynamical Movement Primitive (Ijspeert et al., 2003, 2013). This would provide smooth modulation of the output signals as well as feedback incorporating capabilities (Ajallooeian et al., 2013). Such a controller would allow for switching between different gaits, by a change of primitive weights.

At present, we found no quantitative data available to compare our results with other legged robotic platforms, to observe the effect of mechanical entrainment of feed-forward controlled, legged robots and their kinematic motion primitives. Platforms other than Cheetah-cub robot exist, locomoting with

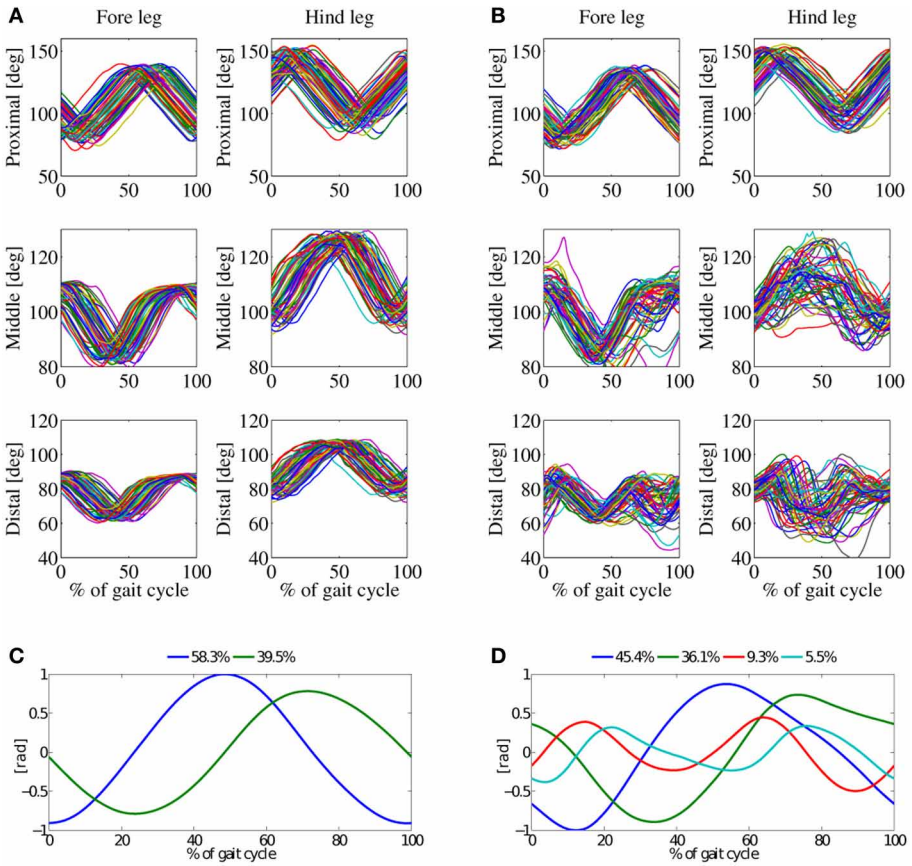

FIGURE 8 | Results from the trot-gait experiments, at a locomotion frequency 3.5 Hz. The average robot speed was 0.8 ms^{-1}, single-peak knee activation patterns. **(A)** Joint angles for *in-air* experiment, and **(B)** joint-angles for *on-ground* experiment. **(C)** Principal components (PC) for the *in-air* experiment, and **(D)** PCs for the *on-ground* experiment. Two basic patterns of the *in-air* experiment sum up to 98%, the four basic pattern of the *on-ground* experiment to 96%.

dynamical, feed-forward controlled, self-stabilizing gaits and similar leg mechanics. Bobcat-robot for example is a small bounding robot and it can reach dynamical, full flight phases in-between touch-downs. It is equipped with a Cheetah-cub-like feed-forward controller, in-series elastic segmented legs, and an actuated spine (Khoramshahi et al., 2013). However, no data on the complexity of its kinematic *on-ground* PCs is available. Typically, motor controller designs for legged robots feature explicit feedback loops (Kimura et al., 2007; Buchli et al., 2009).

Mechanical compliance in legged robotic design has been introduced very early; Raibert's robots featured in-series elasticity (air springs, Raibert et al., 1984). Raibert reported a closed-loop controller with explicit, though simple and linear feedback. We are unaware on how much Raibert's machines could have been controlled in a feed-forward manner. We experienced that sufficiently complex feed-forward CPG signals (two to three PCs, speed dependent), a segmented leg design, and in-series and in-parallel leg compliance were the necessary ingredients for a simple, yet self-stable, dynamically legged quadruped robot system. Cheetah-cub and other robots (Iida and Pfeifer, 2004; Khoramshahi et al., 2013) are indicators that a larger design pool for mechanically entrained, dynamical robots exists.

As for the robot's range of leg compliance; Cheetah-cub features a slightly lower leg stiffness than observed in animals of the same weight and leg length. It would be an interesting future experiment to incrementally alter the leg stiffness, up to a level where the leg has no compliance. This would also require a way to alter the feed-forward control patterns in a systematic way, to ensure comparability between resulting gaits.

4.3. RELEVANCE TO BIOLOGICAL SYSTEMS

Cheetah-cub is a bio-inspired robot designed and motion controlled according to bio-inspired blueprints. Therefore, it presents a strong abstraction. We replicated observed blueprints from functional anatomy (pantograph leg, in-series and in-parallel compliance, clutch mechanism) and control (CPGs and locomotion parameters: duty factor, leg length, leg angle, amplitude, and frequency). The applied feed-forward controller produced position-control motor signals. Swing-leg dynamics are different to that of an animal, because its mechanical spring force cannot be manipulated in an online fashion. The robot's distal compliance acts passively and in-series, whereas quadruped animals are

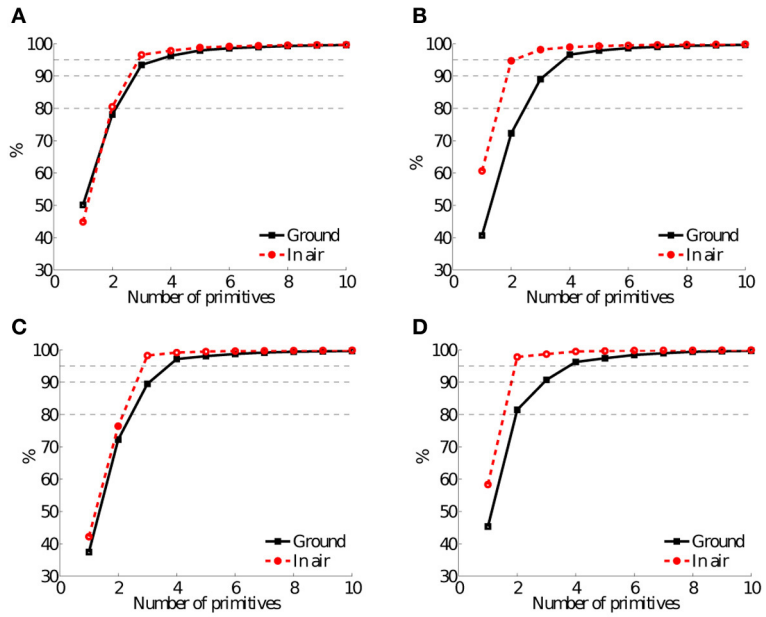

FIGURE 9 | The percent variance accounting for the first 10 primitives, as a function of the number of primitives, for in-air stepping (red, dashed lines) and on-ground (black, solid lines) locomotion patterns. Horizontal, black, dashed lines indicate 80%, 90%, and 95% of the variance. In this article, we used a 95% of the variance interval (top, dashed, black, horizontal line). This results in between 2 and 4 primitives to account for ≥95% of the variance. The single peak (SP) trot gait at 3.5 Hz **(D)** showed the largest change from *in-air* stepping to *on-ground* locomotion: 2 primitives accounted for more than 95% of the variance of *in-air* stepping data, and 4 primitives accounted for the same variance threshold, for *on-ground* locomotion. In the three other **(A–C)** experimental setups 3 primitives accounted for at least 95% of the variance of kinematic *in-air* stepping data, and 4 primitives accounted for the same threshold of *on-ground* locomotion. **(A)** Walk, 2.5 Hz, DP. **(B)** Trot, 3.5 Hz, DP. **(C)** Trot, 2.5 Hz, DP. **(D)** Trot, 3.5 Hz, SP.

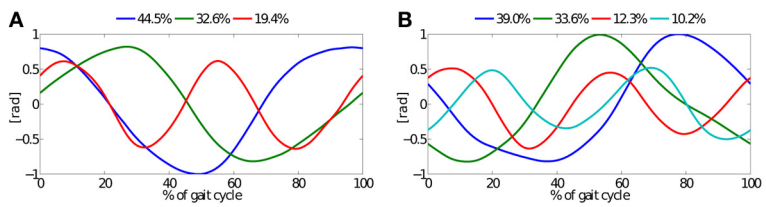

FIGURE 10 | PCs extracted from joint-angle trajectories of all four experiments, i.e., walk and trot, single (SP) and double-peak (DP) knee actuation, and 2.5 and 3.5 Hz locomotion frequency. (A) PCs from *in-air* experiment, and **(B)** PCs from *on-ground* experiment. Three basic patterns account for 97% of the variance during *in-air* stepping, 95% for *on-ground* locomotion.

able to adjust ankle stiffness. Cheetah-cub does not feature an antagonist actuator producing a foot-joint stiffness profile.

Studies on legged locomotion in biology indicate that 4–5 principal components account for a large part of kinematic data variance, both for vertebrates and invertebrates (Ivanenko et al., 2004; Holmes et al., 2006; Dominici et al., 2011; Moro et al., 2013a,b). This is remarkable, considering the range of leg lengths, body sizes and weights, and differences in leg design and actuation strategies. In our study, four PCs accounted for 95% of the variance of all level-ground experimental data, including walk and trot gait data. The corresponding locomotion controller (CPG in feed-forward mode) was programmed with changing complexity. Depending on the range of robot speed either 3 or 2 PCs accounted for the variance of the feed-forward controller data (slower and faster *in-air* patterns, respectively). Perturbation experiments with running birds (guinea fowl) indicate that bipedal running is controlled through a combination of feed-forward control and additional, reflex-based actuator changes (cf. Daley et al., 2006, 2009). For future robotic legged experiments it will become interesting to observe and quantify the effect of explicit, possibly reflex-based feedback. Adult human locomotion patterns showed more pronounced basic gait patterns, compared to those of toddlers (cf. Dominici et al., 2011). These patterns were also phase-locked at important gait events. It is also unclear if and how a faster running robotic system would reduce the number of observable principal components

with increasing robot speed, similar to the findings of Koditschek et al. (2004).

5. CONCLUSION

In this study we reported on the interplay between a modular, feed-forward locomotion controller, and the mechanical entrainment of a quadruped, self-stably walking and trotting compliant legged robot. We measured the complexity of the feed-forward controller, and the complexity of the resulting leg kinematics through the number of basic patterns accounting for a certain variance of kinematic data from *in-air* leg motions and *on-ground* locomotion, respectively. We implemented lateral sequence walk and trot gaits, and applied two different leg length control strategies. We found that the number of basic patterns from *on-ground* locomotion data matched those reported for animals; four basic patterns accounted for $\geq$95% of the variance. Three basic patterns accounted for $\geq$95% of the variance in lateral sequence walk and slower trot *in-air* experimental kinematic data, and two basic patterns accounted for faster trotting. Because patterns were sent in a feed-forward manner, the measured complexity of *in-air* kinematic data represents the complexity of the feed-forward controller. This shows that already a simple, modular rhythm generator is sufficient for level-ground, feed-forward legged quadruped locomotion, for two different gaits walk and trot. It also shows that passive mechanical compliance enables an increase of kinematic complexity, leading to dynamic and self-stabilizing walk and trot locomotion. In the case of our quadruped legged robot, the complexity of the kinematic data increased at ground contact, through mechanical entrainment between the feed-forward controller and compliant, bio-inspired robot hardware. Here, the bio-inspired leg design supported the emergence of additional *on-ground* basic primitives, e.g., through passive leg compliance and leg segmentation. Animals show a much wider range of tools to adapt and modulate dynamic legged locomotion. Similar results between presented robot experiments and experiments with animals at level-ground locomotion indicate that modular, feed-forward, rhythmic pattern-based motor control in combination with compliant hardware are important components of animal neuro-control and bio-mechanics.

In intermittent control, instead of continuously calculating the control signal, the controller occasionally changes this signal at certain sparse points in time. The control law may include feedback, adaptation, optimization, or any other control strategies. When, where, and how does the brain employ intermittency as it controls movement? These are open questions in motor neuroscience. Evidence for intermittency in human motor control has been repeatedly observed in the neural control of movement literature. Moreover, some researchers have provided theoretical models to address intermittency. Even so, the vast majority of current models, and I would dare to say the dogma in most of the current motor neuroscience literature involves continuous control. In this paper, I focus on an area in which intermittent control has not yet been thoroughly considered, the structure of muscle synergies. A synergy in the muscle space is a group of muscles activated together by a single neural command. Under the assumption that the motor control is intermittent, I present the minimum transition hypothesis (MTH) and its predictions with regards to the structure of muscle synergies. The MTH asserts that the purpose of synergies is to minimize the effort of the higher level in the hierarchy by minimizing the number of transitions in an intermittent control signal. The implications of the MTH are not only for the structure of the muscle synergies but also to the intermittent and hierarchical nature of the motor system, with various predictions as to the process of skill learning, and important implications to the design of brain machine interfaces and human robot interaction.

Keywords: muscle synergies, motor control, intermittent control, spinal cord, blind source separation

> Nature sets in motion by signs and watchwords, which are made with little momentum . . . Just as in the army the soldiers are set in motion by one word as if by a given signal and continue to move until they receive another signal to stop, so the muscles move in order and harmony from established custom.
>
> William Harvey (1578–1657)

William Harvey has eloquently described the notion of intermittency in hierarchical neural control of movement, "Nature set in motion by signs and watchwords," Harvey 1627, see Whitteridge (1959) and Meijer (2001). In intermittent control, instead of continuously calculating the control signal, the controller occasionally changes this signal at certain sparse points in time according to the control law, which may or may not include feedback, adaptation, optimization, or other control strategies. When, where, and how does the brain employ intermittency as it controls movement? These are open questions in motor neuroscience (Karniel, 2011).

Evidence for intermittency in human motor control has been repeatedly observed in the neural control of movement literature (Navas and Stark, 1968; Neilson et al., 1988; Hanneton et al., 1997; Welsh and Llinas, 1997; Doeringer and Hogan, 1998; Fishbach et al., 2005; Gawthrop and Wang, 2006; Squeri et al., 2010; Loram et al., 2011). Moreover, some researchers have provided theoretical models to address intermittency (Hanneton et al., 1997; Ben-Itzhak and Karniel, 2008; Bye and Neilson, 2008, 2010; Gawthrop and Wang, 2009). Even so, the vast majority of current models, and I would dare to say the dogma in most of the current motor neuroscience literature involves continuous control (Todorov and Jordan, 2002; Karniel and Mussa-Ivaldi, 2003; Shadmehr and Wise, 2005).

In this paper I present the minimum transition hypothesis (MTH) asserting that the control signal in the high level of the motor system is intermittent and that the system evolved to minimize the transitions in this high level control signal. This hypothesis was first presented in a meeting of the neural control of movement society (Karniel et al., 2002) and has not been thoroughly tested yet.

MUSCLE SYNERGIES

There are various definitions of synergies concentrating on the functional, neural, or muscular levels (Welsh and Llinas, 1997; Tresch et al., 1999; Giszter et al., 2000; Grossberg and Paine, 2000; Saltiel et al., 2001; Domkin et al., 2002; d'Avella et al., 2003; Kang et al., 2004; Mussa-Ivaldi and Solla, 2004; Cheung et al., 2005, 2009; d'Avella and Bizzi, 2005; Sosnik et al., 2007; Kargo and Giszter, 2008; Overduin et al., 2008; Berniker et al., 2009). Here, we define synergy at the muscular level: a group of muscles that can be activated together by a single neural command. Previous studies of such synergies employed recordings

of electromyography (EMG) of multiple muscles and extracted the synergies based on algorithms such as principle component analysis, or non-negative matrix factorization, implicitly assuming that there are only a few synergies which represent most of the variance in the data. After presenting the hypothesis and its predictions, we further discuss more recent theories of synergies, such as the so called time varying synergies and their relation to the MTH.

THE MINIMUM TRANSITION HYPOTHESIS

The MTH asserts that the higher-level motor command is intermittent and sparse, and that the synergies have been developed to minimize the effort of this motor command as measured by the number of transitions. Two assumptions underlie the MTH: (1) There are groups of muscles that are typically activated together at a predefined pattern; we call each group a synergy. (2) The purpose of the synergies is to minimize the effort of the central nervous system (CNS) while controlling movements, i.e., the existence of synergies allows the CNS to send fewer commands than would be needed if each muscle were controlled individually. The minimization is hypothesized to be performed over the entire expected motor behavior of the animal.

More formally, consider a vector of motor commands $\underline{c}(t)$ and a vector of muscle activation $\underline{e}(t)$ which are generated by some spinal cord synergies mathematically denoted by the operator μ, namely $\underline{e} = \mu\{\underline{c}\}$, the MTH asserts that $\mu^* = \arg\min_{\mu} E\left\{\sum_t^T \Delta C(t)\right\}$, where $\Delta C(t)$ is the number of transitions in the control signal vector at time t, and the expectation is over the entire behavior of the animal.

MATHEMATICAL FORMULATION FOR LINEAR TIME INVARIANT SYNERGIES

In order to demonstrate and validate the MTH, we incorporate the following simplifying assumptions, which would definitely be relaxed in future development and validation of the hypothesis: (1) The synergies are static and linear, i.e., there is a linear time-invariant relationship between the activation of the synergies and the activation of each muscle. (2) The activation of the synergies, namely the high level motor command can be well approximated by a sum of step functions of various amplitudes at various time points. The smoothness of the EMG is assumed to be the result of low level filtering.

Suppose that there are K muscles and N synergies, where each synergy is activated by a control command $c_j(t)$. Following the first assumption of linearity, the EMG of each muscle can be written as the following linear combination of the control commands:

$$e_i(t) = \sum_{j=1}^{N} \mu_{i,j} \cdot c_j(t) \quad \forall i \in \{1, 2, \ldots, K\} \tag{1}$$

where μ is a matrix of the weights of the synergies. Following the second assumption (command being pulses and steps), one can count the number of changes in the control signal sent by the CNS as $\Delta C(t) = \sum_{j=1}^{N} \left[c_j(t) \neq c_j(t-1)\right]$ which can be practically relaxed by counting $\left\|c_j(t) - c_j(t-1)\right\| > \varepsilon$. The MTH asserts that the system evolved to minimize the effort of the CNS as measured by the number of transitions in the motor command, therefore, the MTH suggests that the synergies are the result of the following optimization: $\mu^* = \arg\min_{\mu} \sum_{t=1}^{T} \Delta C(t)$, where the changes should be counted over a representative sample of all the possible control signals. **Figure 1** illustrates the main idea of the MTH with a simple toy example.

INTERMITTENCY AND THE HIERARCHICAL NATURE OF THE MOTOR SYSTEM

This paper is opened with a citation from Harvey describing the hierarchical nature of the motor system. The MTH is based on

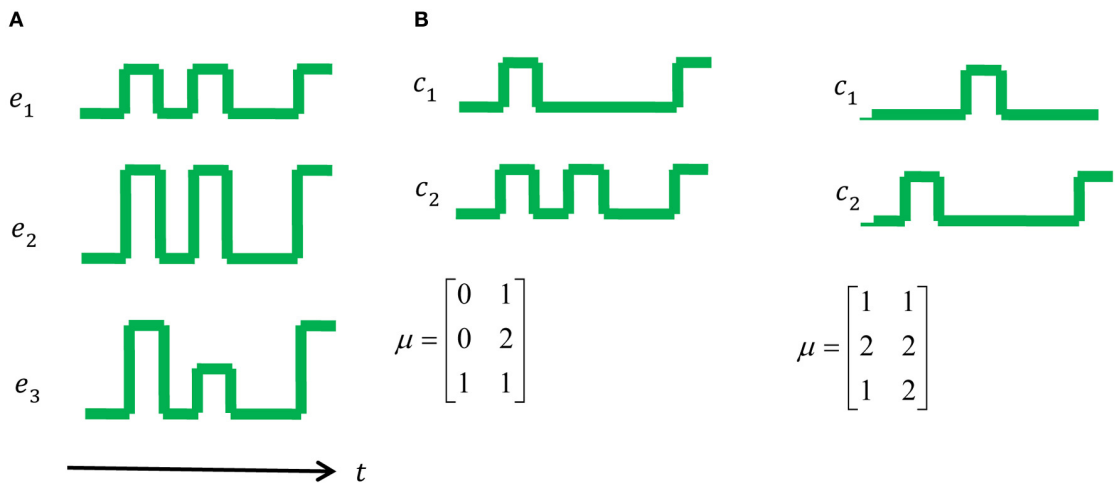

FIGURE 1 | A toy example: muscle activations and control signals with two possible synergies. (A) The set of muscle activations for a specific movement. **(B)** On the left one can see a possible set of two synergies, namely two control signals that can generate the muscle activations in **(A)**, however, one can also generate the same muscle activation using the set of synergies on the right. According to the MTH the option on the right is more plausible since the number of transitions is 5, compared to 8 in the middle and 15 in a trivial synergy, i.e., activation of each muscle separately.

the assumption that the higher level sends intermittent motor commands and that the lower level in the hierarchy evolved to minimize the motor commands sent from the higher level. In this section we consider a simple reaching movement and demonstrate how the MTH may fit into the current view of possible desired trajectories and current models of optimal hierarchical control. **Figure 2** illustrates the motor control hierarchical nature and the location of the MTH within this system. Numerous criteria were proposed to account for the trajectory formation in reaching movements (e.g., Abend et al., 1982; Flash and Hogan, 1985; Uno et al., 1989; Harris and Wolpert, 1998) and several studies have proposed various criterions for the manipulation of mass on a spring (Dingwell et al., 2004; Svinin et al., 2005, 2006; Leib and Karniel, 2012). The desired trajectory is expected to be found at the high level neural activity of the CNS, and in a well-practiced conditions, the actual arm trajectory is expected to be similar to the desired trajectory. Here we discuss intermittent control and in this context the minimum acceleration criterion with constraints [MACC, (Ben-Itzhak and Karniel, 2008; Leib and Karniel, 2012)], which predicts intermittent control signals, is probably the best candidate for the desired trajectory; however, other desired trajectories could be considered. One should note that the MACC predicts a continuous arm trajectory with a bell shaped speed profile, however, the predicted Jerk signal, namely the third time derivative of the path is a piecewise constant function of time and therefore it practically predicts intermittent control signals. It is important to note that some models do not include a desired trajectory, however, even these models typically have some cost function to be minimized or reward to be maximized, and the resultant optimal trajectory can be called "a desired trajectory" in the current formulation. The MTH asserts that synergies evolved to minimize the transition in the control signal issued from the central nervous system to the spinal cord. Learning of a new skill can be also formulated in this framework. First, the high-level controller calculates the desired intermittent trajectory and quickly adapts through feedback error to perform the desired trajectory. Then, at a slower pace, the synergies are adapted to map the motor command to muscle activations to minimize the number of transitions.

Recent measurements in the cerebellum have found clear evidence supporting an intermittent control strategy (Loewenstein et al., 2005; Yartsev et al., 2009). In these studies, it has clearly been shown that the activity of cerebellar Pukinje cells demonstrates bistability—bursting activities separated by pauses.

METHODOLOGICAL TOOLS TO TEST THE MTH

We have developed a few methods to validate the MTH using data from two frogs (one, fs11, performed jump, swim, and kick; and the other, fs17, performed jump, swim, and steps.) The multiple recordings of EMG from a behaving frog provide valuable information that could be used in the attempt to decipher the structure of the synergies. A recent study by d'Avella and colleagues (d'Avella and Bizzi, 2005) suggested a simple method to extract the dominant synergies from the measured EMG signals by means of an iterative minimum nonnegative least squares algorithm (here we refer to these six synergies as SA6) (Saltiel et al., 2001; Karniel et al., 2002; d'Avella et al., 2003; d'Avella and Bizzi, 2005). For detailed description of the animals and the EMG recording and analysis to produce the

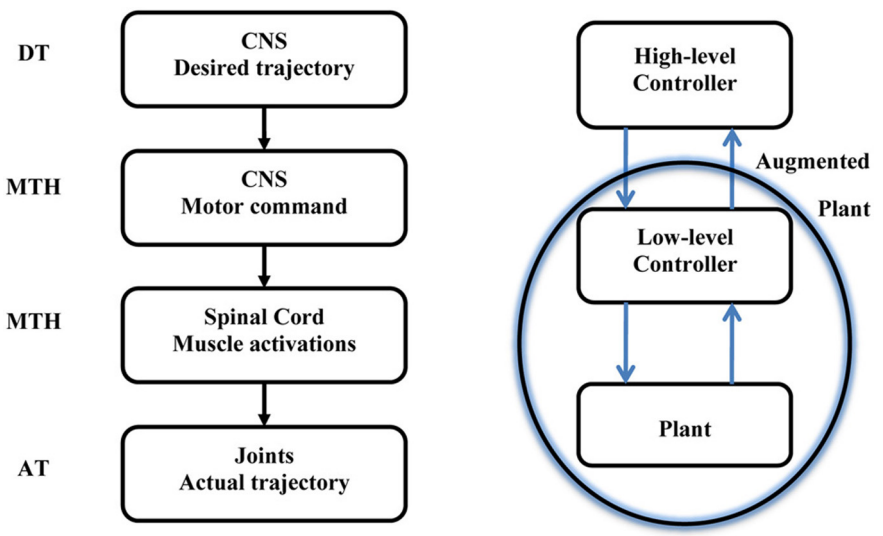

FIGURE 2 | Left: A sketch of the motor system hierarchy and the relation between the Minimum Transition Hypothesis (MTH) the desired and actual trajectories. The MTH asserts that the lower level synergies are organized such that the motor commands form the higher level, CNS, are intermittent and sparse. **Right:** Optimal hierarchical control following Todorov et al. (2005). The optimal feedback control is typically analyzed based on continuous trajectories on both levels. Recently Todorov et al. presented a hierarchical optimal feedback control scheme. Here we assert that the optimization should contain the number of transitions in the cost function in addition to other behavioral error measures and we further hypothesize that in biological neural control systems, provided a set of biologically plausible desired trajectories, the optimal synergies in the low level controller will follow the MTH.

normalized EMG signals and SA6 used here, see d'Avella and Bizzi (2005).

The SA6 convey some information about the tendency to actuate some muscles together, however, it was not clear whether this procedure really extracts the underlying synergies at the spinal cord level. Nevertheless, since we already have a candidate set of synergies, we designed a simple test to check whether they are consistent with the MTH. Similar tests could be later used to other candidate synergies or they could be adapted to extract the optimal MTH based synergies.

Our test was based on counting the number of transitions in the CNS command that is associated with each major transition in the EMG signal. A major transition was defined as a monotonically increasing/decreasing transition during three time-steps to a total change larger than 0.7 in the normalized EMG signal (this is clearly an arbitrary definition, and future sensitivity analysis can be used to validate the results). We then shuffled the EMG data to generate a non-physiological EMG signal, which could be approximated with the exact same synergies, and repeated the same count of transitions in the new signal. The null hypothesis asserts that the SA6 are just a compact mathematical description and they have nothing to do with the structure of the neural control system. Therefore, in particular, we do not expect them to support the MTH. Thus, we expect that any change in the EMG would be described with a change in the contribution of all the "synergies" in SA6. The alternative hypothesis asserts that the specific SA6 coincide with the MTH, namely, the SA6 represent synergies in the nervous system, and these synergies are there to simplify the task of the higher level controller. Therefore, we expect that many changes in the EMG would be a result of a change in the contribution of only few synergies in SA6. The result of this analysis is presented in **Figure 3**. It refutes the null hypothesis and supports the MTH.

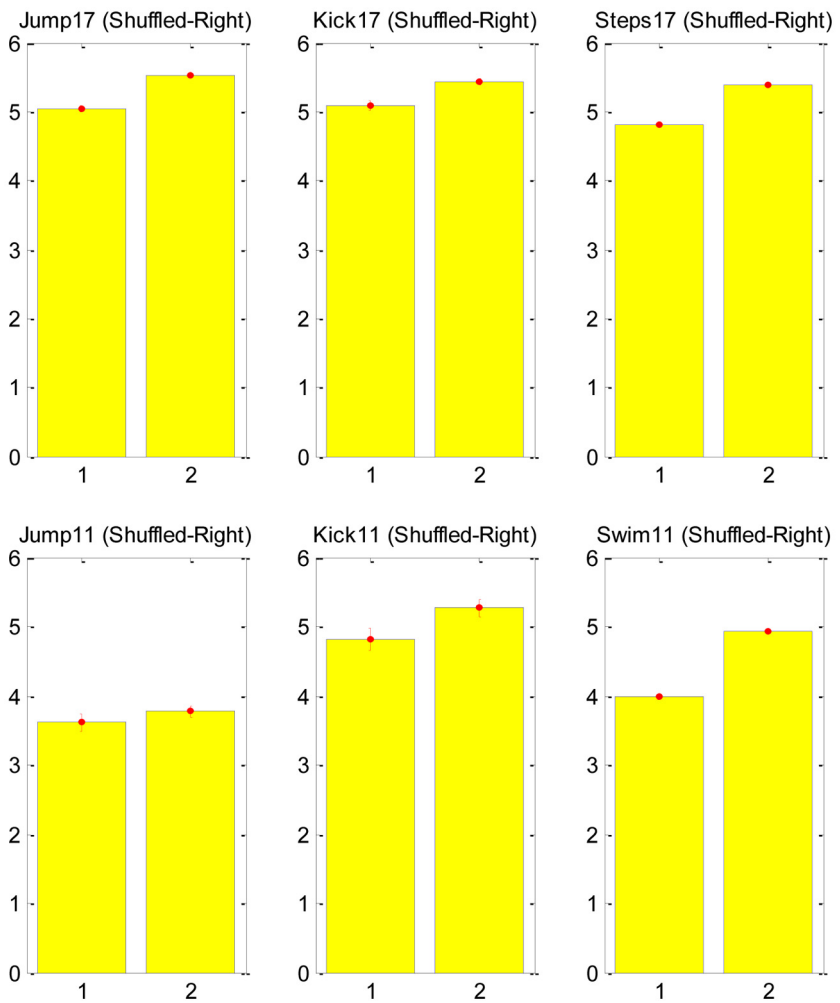

FIGURE 3 | Counts of transitions in the synergies at points of major changes in the EMG signal. The mean number of synergies changes that were required for the original EMG signal (left bar in each subplot) and for the shuffled signal (right bar). The upper raw shows the analysis for frog no. 17 as it jump, kick and step, and the lower raw for frog no. 11 as it jump kick and swim, for both frogs and for all behaviors the number of transitions in the shuffled data was larger than in the natural EMG signal, supporting the MTH. Further details about the ENG signal recording can be find in d'Avella and Bizzi (2005).

To compare a specific synergy (SA6, or simply S) to other possible synergies, we used the S as a seed and generated many random S-equivalents (SE), defined as any set of synergies that can approximate the data with a small residual error. In a matrix notation, we can write Equation 1 as: $E(t) = M \cdot C(t)$. The vector of EMG signals $E(t)$ is given, and we use the S synergies M_S and approximate the CNS signal $C(t)$ such that it would be positive (by means of non-negative least squares): $C(t) = NNLS\{M_S, E(t)\} + \varepsilon$.

To generate the equivalent synergies SE, we generate a random invertible matrix A, and use it to transform S and the control signal as follows:

$$E(t) = M \cdot C(t) = M \cdot A \cdot A^{-1} \cdot C(t) \cong \tilde{M} \cdot \tilde{C}(t);$$
$$\tilde{M} = M \cdot A; \quad \tilde{C}(t) = NNLS\{\tilde{M}, E\} + \tilde{\varepsilon}$$

Note that we used the nonnegative least squared NNLS algorithm instead of calculating $\tilde{C} = A^{-1}C$, since the latter may yield negative control signals.

Figure 4, demonstrates, that most equivalent synergies required more transitions than SA6, suggesting that SA6 is consistent with the MTH.

Additional validation of our predictions can be performed by comparing physiologically plausible synergies from the literature to equivalent synergies by providing predictions about the difference between intact and deafferented preparations (namely, with or without proprioceptive feedback respectively). By simulating continuous and intermittent control signals with physiological noise, we can generate predictions supporting or refuting the MTH, and extract the MTH synergies and compare them to other synergies reported for the same raw data.

As briefly mentioned in this section, we have employed these methods on multiple recordings of EMG from a behaving frog provided by Andrea d'Avella and colleagues at the Bizzi Lab (Saltiel et al., 2001; Karniel et al., 2002; d'Avella et al., 2003; d'Avella and Bizzi, 2005), and the results were consistent with the MTH. However, without probing the higher level system, it is extremely difficult to provide a convincing proof of the MTH, and therefore, further tests are required in animals and in humans. It is also a compelling technological solution for the control of artificial systems facing similar challenges of delay and other conditions facilitating the use of hierarchical control.

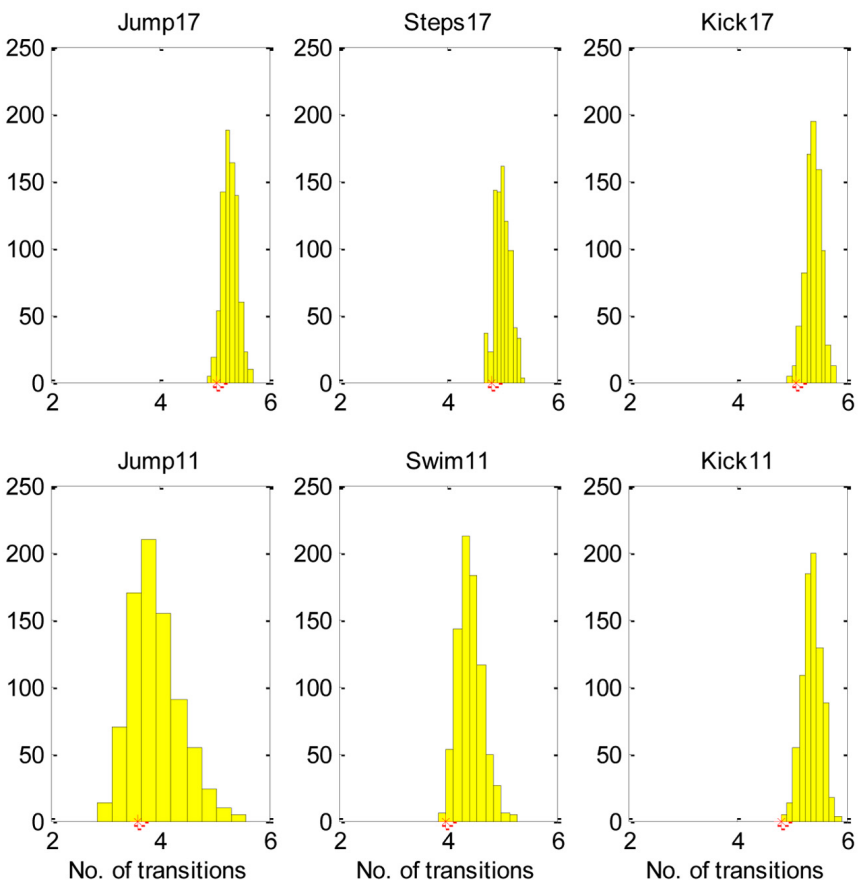

FIGURE 4 | The SA6 compared to other equivalent synergies in terms of the transitions. The histogram describes the mean number of transitions for each of the 800 equivalent synergies and the star describes the mean number of transitions for the SA6. These results indicate that the SA6 synergies extracted by d'Avella and colleagues (d'Avella and Bizzi, 2005) are consistent with the MTH.

GENERALIZATION TO NONLINEAR TIME VARYING SYNERGIES, FEEDBACK, LEARNING, ADAPTATION, AND EVOLUTION

The biological synergies in frogs or in humans are most likely not static linear matrix as we suggested above. On the other hand, with arbitrary complex nonlinear time varying synergies, one can explain any behavior with a single transition in the higher nervous system. The MTH as a biologically plausible hypothesis asserts that there is hierarchical non trivial structure.

One way to relax the assumptions underlying the simple model described above is to allow for dynamic synergies [sometimes referred to as time varying synergies (d'Avella et al., 2003; Cheung et al., 2005)]. This extended model accounts for the possibility that the CNS issues one command, e.g., a step function, and the spinal cord, by means of the synergies, generates complex time varying signals with different delays and temporal structure to each muscle. In formal notation, Equation 1 may be replaced by

$$e_j(t) = \sum_{i=1}^{N} \mu_{i,j}[c_i(t)] \quad \forall j \in \{1, 2, \ldots, K\}$$

In this formulation, $\mu_{i,j}$ is a functional, a general operator on the input signal, and it generates a command to the muscle. The step response of this operator is the time varying signals that are used by d'Avella et al. (2003). Introducing general synergies and general filters in order to validate/refute the MTH in this general case is an overwhelming task, so it is suggested to limit the search to time-invariant filters and consider two special cases (1) delay operator, introducing various delays for each synergy and/or for each muscle and (2) linear filters. In this case, each operator could be represented as a transfer function in the Laplace domain ($\mu_{i,j}(s)$). If one restricts the number of zeros and poles, it is possible to attempt to estimate these parameters. Some other directions for future exploration are: varying the number of synergies, comparing them to synthetic EMG signals with the same frequency content, and comparing synergies between behaviors.

In order to better understand the meaning of this hypothesis it is important to remember that a key property of the motor control system is adaptation in the wide sense, including feedback, adaptation, learning, and evolution, see **Figures 2**, **5** and Karniel (2009, 2011). As illustrated in **Figure 5**, feedback is available to all levels of the control in real time, adaptation can modify the weights of each synergy while skill learning can also modify the number of synergies and generate new synergies, as well as change the motor command accordingly to reduce the number of transitions.

It is also important to note that the hypothesis presented here is only a prototype for the MTH and more details and assumptions are required to provide more specific predictions for specific animal and motor task. For example there is a tradeoff between communication rate and optimal performance that can be included in a more specific MTH, see Nair et al. (2007).

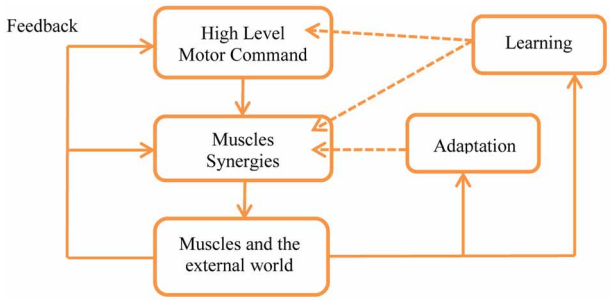

FIGURE 5 | Feedback, adaptation, and learning within the framework of the MTH. Feedback is present at all levels in real time with the limitations of the physiological delays. Adaptation may change the weights used to activate the synergies as well as gradually modify the synergies themselves by changing their parameters. Learning can generate new synergies and facilitate changes in the high level control, optimizing the motor programs according with the minimum transition hypothesis. See Karniel (2009, 2011) for detailed definitions of the distinction between feedback, adaptation, learning, and evolution in the spatiotemporal hierarchy of wide sense adaptation.

PREDICTIONS OF THE MTH

1. Higher level motor command is intermittent and sparse.
2. Well practiced and often-used behavior would require less transitions in the motor commands from the higher level controller than a new motor task or a rarely used task.
3. The MTH combined with the MACC hypothesis predict specific timing of the transitions in the muscles commands occurring during reaching movements and flexible object manipulation (Ben-Itzhak and Karniel, 2008; Leib and Karniel, 2012).
4. During learning of a new task, after prolonged practice, synergies would be generated to reduce the number of transitions required for the performance of the new task.
5. Assuming that the higher level motor command requires attention whereas the lower level is based on reflexes or implicit motor commands, one can conclude that the MTH asserts that a small number of transitions means less attention, namely with practice the attention required is reduced.

In this article we have presented the MTH, demonstrated how it can be tested, and listed its predictions. Our demonstrations cannot be considered statistical proof of the hypothesis and further studies are required to support (or refute) the MTH and to elaborate on the structure of synergies in terms of adaptation and generalization capabilities.

What sources of information and what control strategies the central nervous system (CNS) uses to perform movements that require accurate sensorimotor coordination, such as catching a flying ball, is still debated. Here we analyzed the EMG waveforms recorded from 16 shoulder and elbow muscles in six subjects during catching of balls projected frontally from a distance of 6 m and arriving at two different heights and with three different flight times (550, 650, 750 ms). We found that a large fraction of the variation in the muscle patterns was captured by two time-varying muscle synergies, coordinated recruitment of groups of muscles with specific activation waveforms, modulated in amplitude and shifted in time according to the ball's arrival height and flight duration. One synergy was recruited with a short and fixed delay from launch time. Remarkably, a second synergy was recruited at a fixed time before impact, suggesting that it is timed according to an accurate time-to-contact estimation. These results suggest that the control of interceptive movements relies on a combination of reactive and predictive processes through the intermittent recruitment of time-varying muscle synergies. Knowledge of the dynamic effect of gravity and drag on the ball may be then implicitly incorporated in a direct mapping of visual information into a small number of synergy recruitment parameters.

Keywords: muscle synergies, interception, EMG activity, intermittency, time-to-contact

INTRODUCTION

Catching or hitting a moving object requires high spatiotemporal accuracy in the control of an end-effector in the presence of visuomotor delays. What sources of information and which visuomotor strategies the central nervous system (CNS) employs to achieve accurate control of interception has been extensively investigated and it is still debated (Zago et al., 2009). On one hand, lawful relationships between visual information available in retinal and extraretinal variables and properties of the target motion, such as time-to-contact or motion in depth, might be exploited to bring the effector on the target (Lee, 1998; Tresilian, 1999; Regan and Gray, 2000). On the other hand, prior knowledge of the characteristics of the target motion and their dependence on environmental conditions, such as gravity acceleration, might be necessary to successfully guide interception (McIntyre et al., 2001; Zago et al., 2004, 2008).

While interceptive movements have been studied extensively in terms of global performance measures and kinematic variables, the underlying muscle activation patterns have received considerably less attention. Even so, the analysis of the timing of muscle activation in preparation for interception has provided evidence for an accurate estimate of time-to-contact. The anticipatory electromyographic (EMG) activity recorded in elbow muscles when catching a ball falling on the hand from different heights shows an early component and a late component (Lacquaniti and Maioli, 1989). The early component has a roughly constant latency from the time of ball release. In contrast, the late component has a constant onset time with respect to the time of impact, indicating that the time-to-contact is estimated accurately. As the ball accelerates under gravity during the fall, precise estimation of time-to-contact cannot be obtained from first order derivatives of retinal variables, as the inverse of the rate of dilation of the retinal image or tau variable (Lee et al., 1983), and requires a-priori knowledge of gravity acceleration (Zago et al., 2008). The onset of EMG activity with respect to the time of impact is also constant for catching of balls thrown frontally (Savelsbergh et al., 1992).

However, to date, the muscle synergies underlying the coordination of multi-muscle EMG activity have not been characterized in catching tasks. It has recently been shown that modulation and superposition of a few time-varying muscle synergies, each appropriately scaled in amplitude and duration and shifted in time, capture the variation of the muscle patterns during reaching to stationary targets in different directions, with different speeds, and after a sudden change of the target location (d'Avella et al., 2006, 2008, 2011b). Such synergies are time-varying as they represent a collection of activation waveforms expressing a balance of muscle activation that varies over a few hundred milliseconds of the time-course of the muscle pattern for a single movement but, as a whole, invariant across movement conditions and repetitions. To test whether an accurate estimation of time-to-contact is used to control the execution of the final phase of an naturalistic and unconstrained interceptive movement and, more

generally, to gain insight on the underlying control mechanisms, here we characterized the spatiotemporal organization of muscle patterns during one-handed catching of balls projected from a fixed location and reaching the subject's frontal plane at two different heights (above and below the subject's shoulder height) after three different flight times (550, 650, and 750 ms). This task involves projectile motion as in the previous study by Savelsbergh et al. (1992), but it requires bringing the hand at a point which is not specified in advance, in contrast with the fixed hand position of Savelsbergh et al. (1992). In our conditions, if the effector starts to move well in advance of the latest time at which visual information can affect its trajectory before impact, it is not clear how to detect a signature of an accurate estimate of time-to-contact in the on-going EMG patterns. Here we show that time-varying synergies allow to identify two partially overlapping components in the muscle patterns for intercepting ball with different flight characteristics: one aligned with the ball launch and a second timed to the ball impact.

MATERIALS AND METHODS

SUBJECTS, APPARATUS, AND EXPERIMENTAL PROTOCOL

Six right handed subjects (4 males and 2 females, between 22 and 47 years old) gave their written informed consent to participate in the study, which conformed with the Declaration of Helsinki and had been approved by the Ethical Review Board of the Santa Lucia Foundation. These subjects are a subset of the 14 subjects included in our previous report focusing on task performance and wrist kinematics (Cesqui et al., 2012) for which EMG data was also available. Both the experimental apparatus and protocol have been described in detail previously (Cesqui et al., 2012). Briefly, subjects were asked to catch with the right hand a lightweight (20 g) ball (diameter 7 cm, size similar to that of a cricket or tennis ball) projected in space with different initial velocities by a launching system, built specifically for these experiments (d'Avella et al., 2011a), which allowed to control accurately the mean ball flight time and arrival height at the subject's frontal plane. The ball was projected through a hole in a large screen (4×3 m, width $\times$ height) at 6 m from the subject's right shoulder and flew along a vertical plane passing through the center of the hole and the shoulder. Subjects were instructed to wait for the ball launch standing with their arms beside their body. Before starting the experiment the system was calibrated to deliver the ball with 3 different flight times ($T_1 = 0.55$ s, $T_2 = 0.65$ s, $T_3 = 0.75$ s) at 2 different heights ($Z_1 = 1.3$ m, low launches, and $Z_2 = 1.9$ m, high launches) for a total of six different ball flight conditions. Each subject performed at least 1 block of at least 10 trials for each condition (typically, 3 blocks with 10–15 trials). The order of block execution was selected at random for each subject.

DATA ACQUISITION

The spatial position of the ball (covered with retro-reflective tape, Scotchlite, 3M, Pioltello, Milan, Italy) was measured together with the spatial position of 8 optical retro-reflective markers placed on the subject's trunk and arm close to the following anatomical landmarks: seventh cervical vertebra (C7), clavicle (CL), sternum (SRN), right acromion (RSHO), right epicondylus lateralis (RELB), right forearm (RFRA), right wrist ulnoid styloid (RWRU), right wrist radial styloid (RWRR). Marker positions in space were recorded with a sampling frequency of 100 Hz using a motion capture system (9-camera Vicon-612 system, Vicon, Oxford, UK). A very large tracking volume ($6 \times 3 \times 3\,m^3$) was required for capturing the motion of both the ball and the subject upper limb. The marker reconstruction residual, averaged over the nine cameras, obtained in such volume with the Vicon calibration procedure ranged across subjects between 0.93 and 1.03 mm (mean 0.97 mm). Markers coordinates were referred to a right handed calibration frame placed on the floor at 6 m distance from the launch plane, oriented with the x axis directed along the antero-posterior axis on the horizontal plane pointing toward the screen and with the z axis on the vertical plane pointing upward.

EMG activity was recorded with active bipolar surface electrodes (*DE 2.1*; Delsys, Boston, MA) from the following 16 muscles: biceps brachii, short head (abbreviated as BicShort), biceps brachii, long head (BicLong), brachioradialis (BrRad), triceps brachii, lateral head (TrLat), triceps brachii, long head (TrLong), anterior deltoid (DeltA), middle deltoid (DeltM), posterior deltoid (DeltP), pectoralis major, clavicular portion (PectClav), pectoralis major, sternal portion (PectLow), superior trapezius (TrapSup), middle trapezius (TrapMid), inferior trapezius (TrapInf), latissimum dorsi (LatDors), teres major (TeresMaj), infraspinatus (InfraSp). Each electrode consisted of two parallel silver bars (10 mm spacing) and a differential preamplifier (gain, 10; rms noise, 1.2 μV; common mode rejection ratio, > 80 dB) housed in a compact case ($41 \times 20 \times 5$ mm). Electrodes were taped on the muscle belly and connected to an amplifier (Bagnoli-16, Delsys) where the EMG signal was band-pass filtered (20–450 Hz), amplified (total gain 1000) and digitized at 1 KHz by a A/D board in the Vicon system, synchronized with the kinematic data acquisition. For each muscle, correct electrode placement was tested by asking the subject to perform a number of maneuvers involving both free movements and isometric contractions and monitoring the resulting activation patterns on a computer screen.

DATA ANALYSIS

All analyses were performed with custom software written in Matlab (Mathworks, Natick, MA). We considered trials in which the subjects either intercepted but did not catch the ball or caught the ball thus excluding trials in which the subjects missed the ball (0.9% of the total number of trials on average). Motion capture and EMG data were analyzed between 200 ms before ball launch and 100 ms after the interception. The time of ball launch was obtained by detecting the instant at which the ball passed through the hole on the screen using a photo-sensor (E3T-S112, Omron Electronics S.p.A., Milan, Italy) mounted on the edge of the hole. The time of interception was obtained by computing the instant at which the distance between the ball trajectory (spatial coordinates as a function of time) and the plane passing through the wrist (RWRU, RWRR) and forearm (RFRA) marker positions reached its minimum (Cesqui et al., 2012). The onset time of wrist movement was defined as the time at which the tangential velocity of the averaged position of RWRU and RWRR markers (marker RWRM) crossed a threshold equal to 10% of its maximum.

EMG pre-processing

A notch-filter was used to reduce 50 Hz line noise when present (quality factor 35; Matlab iirnotch function). The EMGs for each trial were digitally full-wave rectified, low pass filtered (20th order FIR filter; 50 Hz cutoff; zero phase distortion; Matlab fir1 and filtfilt functions) and resampled at 200 Hz. Diagnostic screening of EMG signal quality was performed by checking the maximum level of activation, the activation level before the launch time (i.e., with the arm at rest), and the power spectral density of each channel. Eighteen trials (out of a total of 581 trials) that showed high pre-launch activity or abrupt change in signal amplitude, likely resulting from a partial detachment of the electrode from the skin, were excluded. Presence of significant cross-talk was assessed by computing the mean cross-correlation between pairs of channels across trials. Across all subjects, the maximum of the absolute value of the mean cross-correlation was above 0.4 for 11 pairs of muscles (TrLat-TrLong in four subjects, BicShort-BicLong and TeresMaj-InfraSp in three subjects, BicLong-TrLat and PectLow-BrRad in two subjects, TrapInf-TrapMid, DeltA-DeltM, DeltM-TrLat, DeltP-TrLat, PectLow-DeltP, DeltP-BrRad in one subject). Because of the difficulty in distinguishing cross-talk due to volume conduction from synchronous recruitment of motor units in different muscles, we did not remove these muscles from the set used for the main analyses. However, in additional analyses, we verified that the removal of the muscles potentially affected by cross-talk did not change any conclusion drawn from the main analyses. Baseline activity, defined as the mean EMG activity in the 200 ms before launch, was subtracted from each EMG channel. EMGs recorded in each trial were aligned to launch time and averaged across repetitions on each one of the six launch conditions. Finally, the averaged EMG of each channel was normalized to its maximum amplitude across conditions.

Time-varying muscle synergies

We modeled the construction of a muscle pattern by combination of N time-varying muscle synergies as follows (d'Avella et al., 2006):

$$\mathbf{m}(t) = \sum_{i=1}^{N} c_i \mathbf{w}_i (t - t_i) + \epsilon(t)$$

where $\mathbf{m}(t)$ is a vector of real numbers, each component of which represents the activation of a specific muscle at time t; $\mathbf{w}_i(\tau)$ is a vector representing the muscle activation for the i-th synergy at time τ after the synergy onset; t_i is the time of synergy onset; c_i is a non-negative scaling coefficient; $\epsilon(t)$ is the residual. The extraction algorithm was initialized by choosing random values for N synergies of a specific duration, and it proceeded by iterating three steps (d'Avella and Bizzi, 2005; d'Avella et al., 2006): (1) synergy onset time estimation, given the synergies; (2) amplitude coefficient estimation, given the synergies and their onset times; (3) synergy update, given onset times and amplitude coefficients.

We used a convergence criterion of five consecutive iterations in which the decrease in the error was 10^{-4}. To minimize the probability of finding local minima, for each N we repeated the optimization 20 times and selected the solution with the highest goodness of reconstruction. Because the EMG patterns and the residual of the reconstruction of patterns by synergy combination are multivariate time-series, we used the fraction of total variation explained by the model as a measure of the goodness of the reconstruction ($R^2 = 1 - \text{SSE/SST}$, where SSE is the sum of the squared residuals and SST is the sum of the squared residual for the mean activation of each channel).

The number of synergies (N) and the duration of each synergy were selected according to the general features of the time-course of the muscle activation waveforms observed (see **Figures 1**, **2**). In particular, we selected 2 synergies with a duration of 400 ms as the minimum number of synergies with the shortest duration which could fully capture the two distinct bursts of EMG activation. We also verified that the reconstruction R^2 did not increase significantly with synergies longer than 400 ms.

Synergies extracted from individual subjects were compared after grouping them with a hierarchical clustering procedure based on distance between synergy pairs. Distance between two synergies was defined as $1 - s$, where s is the similarity between two synergies defined as the maximum of the scalar product between the two normalized synergies across all possible relative time shifts (d'Avella et al., 2006). A hierarchical tree was constructed from the distances between all pairs (Matlab function linkage) and such tree was used to form clusters (Matlab function cluster; "cutoff" parameter 0.15).

As the highest similarity between synergies in the same cluster was obtained with a non-zero relative time shift, the value of such time shift with respect to the synergies of subject S_1 was subtracted from the timing coefficient (t_i) to compare them across subjects.

To assess the potential effect of catching performance, we compared the synergies extracted from trials in which the ball was caught with those extracted from trials in which the ball was intercepted but not caught.

To analyze synergy amplitude coefficients (c_i), each synergy was normalized to the maximum of the Euclidian norm of synergy vectors ($\mathbf{w}_i(t)$) across time samples and the corresponding coefficient scaled by this norm. Moreover, to compare amplitude coefficient across launch conditions, each coefficient was normalized to its maximum value.

Statistical analysis

To explain the effect on the synergies recruiting parameters of experimental condition (three ball flight times and two ball arrival heights), the synergy amplitude and timing coefficients were submitted to either a Two-Way ANOVA test (3 arrival times × 2 height conditions) or to a multiple linear regression analysis according to the model:

$$y = \alpha + \beta T + \gamma Z_d + \delta(T, Z_d) + \varepsilon$$

where T is the time variable, i.e., the ball flight time, Z_d is a dummy variable for the ball arrival height Z, i.e., $Z_d = 1$ for low launches and $Z_d = 2$ for high launches. Statistical analyses were performed in the R software environment (R Development Core Team, 2011). The level of significance was set at $p < 0.05$.

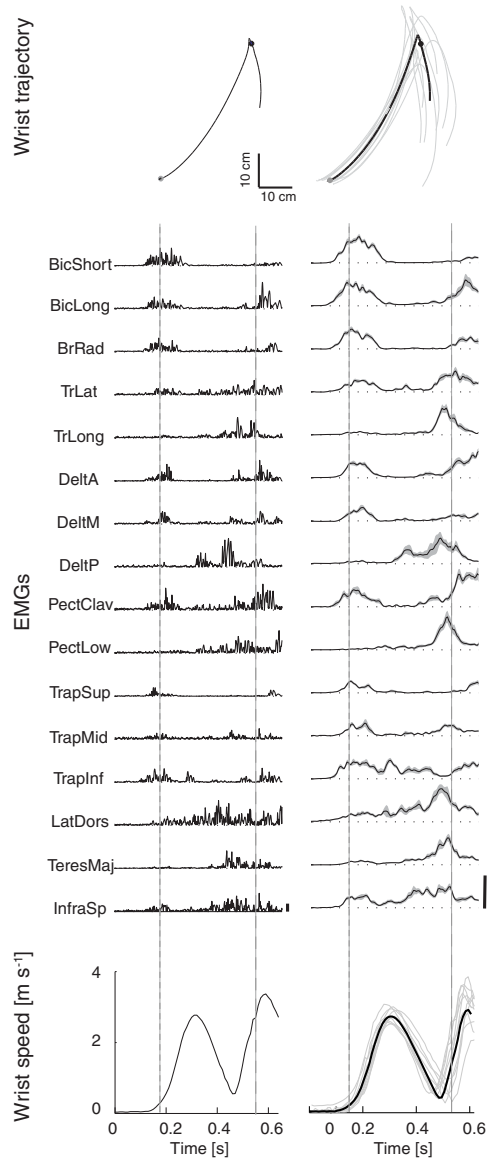

FIGURE 1 | Example of wrist kinematics and EMGs profiles. *First column*: example of wrist path in the sagittal plane **(top)**, rectified EMGs **(middle)**, and wrist speed profile **(bottom)** for one trial of subject S_1 catching a ball with flight duration T_1 and arrival height Z_1. *Second column*: wrist trajectories, filtered EMGs, and wrist speed profiles averaged across multiple trials of subject S_1 in the condition (T_1,Z_1). *Thick black lines* represent averages across trials, *gray areas* represent the standard deviation; EMGs were aligned to the launch time and normalized to the maximum of each channel across all trials and all launch conditions (*vertical bars*). Times of wrist movement onset and of ball impact with the hand are indicated respectively by the *dashed lines* in the EMGs and speed profiles plots and by *gray circular markers* in the wrist trajectory plots.

RESULTS

Subjects, starting with the arm at rest and relaxed along their body, were instructed to catch lightweight balls projected from about 6 m from their shoulder and at 1.66 cm height and arriving at their frontal plane at two different heights and with three different flight times. On average, 67.6 ± 11.8% (mean ± SD, $n = 6$, range 84.6 – 55.0%) of launched balls were successfully caught and 30.8 ± 12.0% (41.7 – 13.5%) were intercepted but not caught. Mean onset time of the wrist movement with respect to ball launch over all trials was 171 ± 15 ms (mean ± SD, $n = 6$, range 149 – 193 ms). Mean movement time was 377 ± 20, 459 ± 21, 538 ± 23 ms (mean ± SD, $n = 6$) for low launches (Z_1) at the three different flight times (T_1, T_2, and T_3) and 370 ± 7, 462 ± 15, and 575 ± 23 ms for high launches (Z_2).

MUSCLE PATTERNS

The EMG activity waveforms recorded during catching of a ball flying along a trajectory with a low arrival height and the shortest flight time (condition Z_1 T_1, **Figure 1**, *first column*, a single trial and, *second column*, average over 10 trials for subject S_1) illustrate the key features of the patterns observed in all conditions and subjects. Muscles were activated mainly in two phases. Elbow flexors (biceps brachii and brachioradialis) and shoulder forward flexors and scapula elevators (anterior and middle fibers of deltoid, upper trapezius) were among the most active muscles in a first phase during which the hand quickly raised from its initial rest position toward the region of interception. Muscles involved in backward flexion, adduction and internal rotation of the humerus (teres major, posterior deltoid, pectoralis major) or in extension and flexion from extended positions of the humerus (latissimus dorsi), together with elbow extensors (triceps brachii) were instead mostly active in a second phase in which the hand impacted the ball.

The general temporal structure of the muscle patterns for catching and their dependence on the flight time can be grasped from the ensemble averages of the EMG waveforms across muscles and trials with the same flight time. Two distinct peaks are clearly visible in the averaged EMG waveforms (**Figure 2**). The first peak has an approximately constant latency with respect to the time of ball launch, independently of flight duration [203 ± 14 ms, mean ± SD, $n = 6$, for T_1; 216 ± 18 ms for T_2; 212 ± 11 ms for T_3; One-Way ANOVA, main effect of T:$F_{(2,\ 17)} = 1.25$, $p = 0.31$]. Instead the second peak has an approximately constant lead with respect to the time of impact, independently of flight duration [−28 ± 16 ms for T_1; −5 ± 19 ms for T_2; −41 ± 26 ms for T_3; One-Way ANOVA, main effect of T:$F_{(2,\ 17)} = 1.73$, $p = 0.21$]. Thus, the general temporal structure suggests that an initial component of the muscle pattern is generated in response to the detection of the ball launch and a second component is precisely timed to the time of interception. This finding confirms previous results obtained for catching a free-falling ball (Lacquaniti and Maioli, 1989), and extends the observation to unconstrained catching of ballistic projectile motion.

TIME-VARYING SYNERGIES

The novel results concern the synergic organization of muscle activity. To characterize the fine spatiotemporal structure of the muscle patterns, we decomposed them as the combination of two time-varying muscle synergies, each one with a condition-specific amplitude and onset time. Each synergy had a duration of 400 ms,

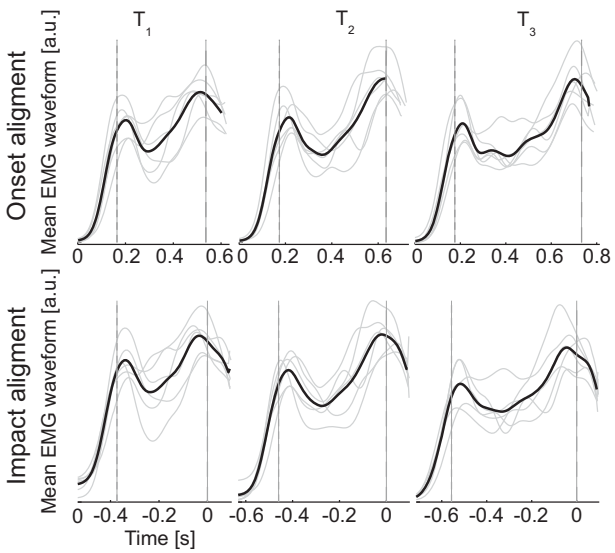

FIGURE 2 | Gross temporal structure of muscle patterns. EMG waveforms averaged across muscles and ball arrival height conditions for individual subjects (*gray thin lines*) and averaged across subjects (*black thick lines*). Dashed lines represent respectively the onset (*small dashes*) and impact (*large dashes*) events. Each channel of the EMG averaged waveforms was normalized to its maximum amplitude across all movement conditions before averaging across channels. In the top panels waveforms are aligned to the onset time, in the bottom panel waveforms are aligned to the impact time. Evidence for rough division of the movement in two phases is provided by the presence of two main peaks in all the averaged waveforms.

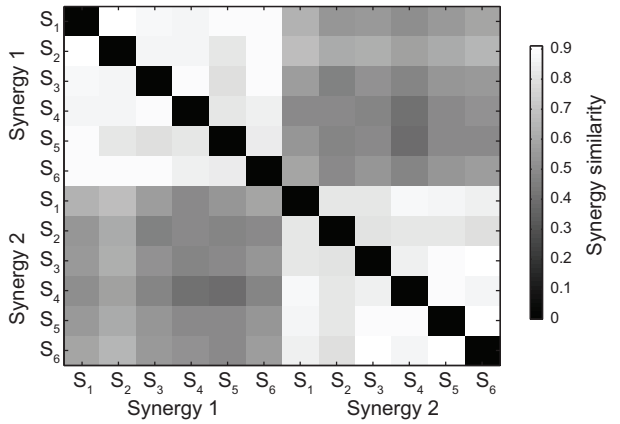

FIGURE 3 | Synergy grouping by hierarchical clustering based on pair similarity. The grayscale matrix shows the similarity between all pairs of time-varying synergies extracted from all subjects (two synergies for each subject) defined as the maximum of the scalar product between the two normalized synergies across all possible relative time shifts. Synergy pairs in the matrix are grouped into two clusters using a hierarchical clustering algorithm (see Materials and Methods).

spanning the duration of both EMG activation phases in all conditions. The reconstruction R^2 was on average 0.73 ± 0.07 (mean $\pm$ SD, $n = 6$, range 0.65 – 0.83) indicating that a decomposition into two time-varying muscle synergies adequately captured the key features of the EMG waveforms.

The set of all pairs of synergies extracted from all subjects could be grouped according to their similarity into two clusters (see Materials and Methods), each contacting only one of the two synergies extracted from each subject (**Figure 3**). The mean similarity between pairs of synergies was 0.86 ± 0.03 (mean $\pm$ SD, $n = 15$, range 0.50 – 0.91) in the first cluster and 0.85 ± 0.04 (mean $\pm$ SD, $n = 15$, range 0.55 – 0.88) in the second cluster. Moreover, the structure of the synergies was not affected by catching performance. The mean similarity between synergies extracted from all trials and synergies extracted only from trials in which the ball was caught was 0.94 ± 0.04 (mean $\pm$ SD, $n = 6$, pairs of synergies in the two conditions for each subject) for the first synergy and 0.92 ± 0.05 for the second synergy.

The synergies in both clusters captured synchronous and asynchronous activations of many muscles. The synergies of the first cluster (**Figure 4**, *first row*) recruited strongly elbow flexors (biceps brachii and brachioradialis), shoulder flexors (anterior deltoid and the clavicular portion of pectoralis) and shoulder elevators (superior trapezius) with a shorter bursts in the elbow flexors than in the other muscles in most cases. The synergies of the second cluster (**Figure 4**, *second row*) showed a higher level of co-activation of the entire set of muscles but also a more complex temporal structure and inter-individual variability than the synergies of the first cluster. Elbow extensors (triceps brachii, long and lateral heads), shoulder extensors and adductors (posterior deltoid, lower portion of pectoralis, latissumus dorsi) were strongly recruited with a burst peaking before the end of the synergy, while other muscles (biceps brachii long head, anterior deltoid) were recruited later and showed a ramped activation.

SYNERGY RECRUITMENT MODULATION ACROSS CONDITIONS

The averaged EMG patterns of subject S_1 for all the launch conditions (**Figure 5**, top, gray shaded area) and their reconstruction as combination of the two synergies (black line) illustrate how the synergy amplitude and timing coefficients (represented respectively by the height and the horizontal position of the rectangles below the EMG waveforms) were modulated across conditions. In all six conditions, the first synergy was aligned with the launch time (first dashed vertical line of **Figure 5**). Across all subjects, a Two-Way ANOVA (3 flight times $\times$ 2 arrival heights conditions) showed that the ball flight time and arrival height did not affect the latency time of the first synergy with respect to the ball launch [main effect of T:$F_{(2,\ 35)} = 2.24$, $p = 0.124$, main effect of Z:$F_{(1,\ 35)} = 1.41$, $p = 0.244$, interaction:$F_{(2,\ 35)} = 0.22$, $p = 0.801$]. Instead, the onset of the second synergy appeared to be aligned with the impact time (second dashed vertical line of **Figure 5**). Across all subjects, there was a significant effect of the ball flight time but no effect of the ball arrival height [main effect of T:$F_{(2,\ 35)} = 3.83$, $p = 0.033$; main effect Z:$F_{(1,\ 35)} = 1.92$, $p = 0.156$; interaction:$F_{(2,\ 35)} = 1.91$, $p = 0.165$] on the onset time of the second synergy with respect of impact time. However the observed effect of the ball flight time could be ascribed to subject S_3 and S_4, who recruited the second synergy closer to the impact event in the T_3Z_2 condition (S_3 and S_4) and in

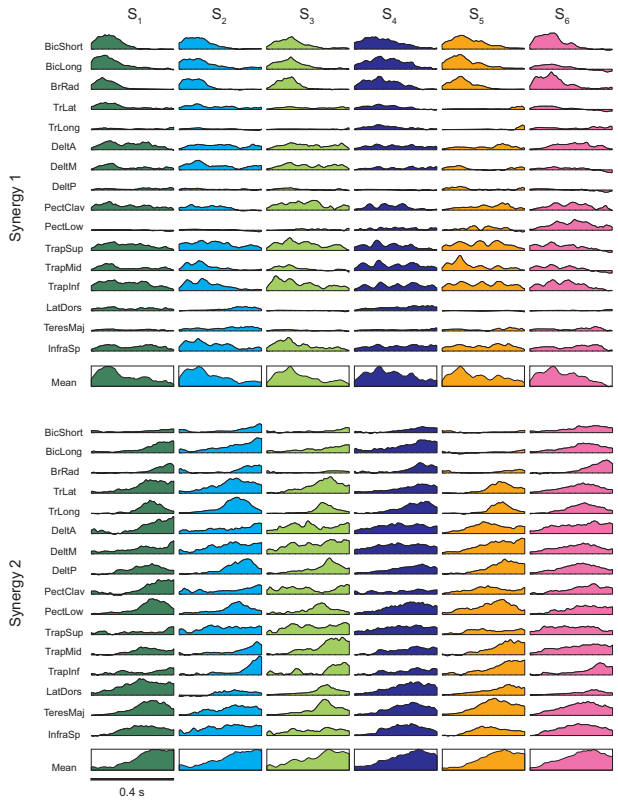

FIGURE 4 | Time-varying muscle synergies. Time varying muscle synergies are shown for all subjects (color coded). The first synergy (**top row**) captured mostly the EMG patterns related to the initial phase of the movement in reaction to the ball launch. The second synergy (**bottom row**) captured mostly the EMG patterns related to the final interceptive phase of the movement. Below the set of muscle waveforms constituting each muscle synergy their mean waveform is illustrated within a box.

the T_2Z_3 condition (S_4). When we excluded those two subjects, we found no statistically significant effect of either flight time or arrival height [Two-Way ANOVA without S_3 and S_4, main effect T:$F_{(2,\ 23)} = 2.14$, $p = 0.14$; main effect Z:$F_{(1,\ 23)} = 0.03$, $p = 0.85$; interaction:$F_{(2,\ 23)} = 1.54$, $p = 0.24$].

We also analyzed the onset of the two synergies as a function of ball flight duration (**Figure 6**) after alignment to the launch time (*top*) and to the impact time (*bottom*) for all subjects (*different colors*) and both low (*circular markers*) and high (*square markers*) launches, as the flight time also depended on the choice of interception point, which varied across conditions and individual. When aligned to launch time, the onset of the first synergy did not depend on ball flight conditions (multiple regression analysis: $p_\beta = 0.14$, $p_\gamma = 0.24$, $p_\delta = 0.29$), while the onset of the second synergy increased linearly with the flight time (multiple regression analysis; $p_\beta < 0.01$ with $\beta = 1.08$, $p_\gamma = 0.149$, $p_\delta = 0.12$). On the contrary, when aligned to impact time, the onset of the first synergy decreased linearly with flight time (multiple regression analysis:$p_\beta < 0.01$ with $\beta = -0.79$, $p_\gamma = 0.25$, $p_\delta = 0.29$) while the timing of the second synergy did not depend on flight time (multiple regression analysis:$p_\beta = 0.55$, $p_\gamma = 0.149$, $p_\delta = 0.12$).

The amplitude coefficients c_i of the synergies were also modulated with respect to the ball arrival height. **Figure 7** shows the coefficients of individual subjects for each arrival height, normalized to the maximum across all conditions and averaged across flight times. The first synergy coefficient increased with arrival height (multiple regression analysis: $p_\beta = 0.44$, $p_\gamma = 0.004$ with $g = 0.75$, $\pi_\delta = 0.0571$). In contrast, the amplitude coefficient for the second synergy was modulated differently with arrival height [multiple regression analysis $p_\beta = 0.02$, $p_\gamma = 0.19$, $p_\delta = 0.034$; Two-Way ANOVA test main effect T:$F_{(2,\ 35)} = 0.75$, $p = 0.482$; main effect Z:$F_{(1,\ 35)} = 40.93$, $p < 0.01$; interaction:$F_{(2,\ 35)} = 1.53$, $p = 0.23$]. For subjects S_1, S_3, S_4, and S_5 the coefficient almost doubled going from Z_1 to Z_2, while for subjects S_2 and S_5 the coefficient showed only a small increase.

DISCUSSION

The synergy decomposition of the muscle activity patterns recorded during one-handed catching of fast balls, projected along spatial trajectories with different flight durations and arrival heights, revealed remarkable spatiotemporal characteristics. A large fraction of the variation of the muscle patterns for catching of balls with different flight parameters was captured by amplitude modulation, onset-time shift, and superposition of two time-varying muscle synergies, each representing the coordinated recruitment of a group of muscles with specific temporal activation profiles. The first synergy was recruited with a fixed latency from the time of ball launch and the second synergy with a fixed anticipation of the time of hand-ball impact. These results indicate that the control of the fast hand movements required to intercept a ball with flight duration below 750 ms relies on a combination of reactive and predictive processes. The initial muscular response, captured by the first synergy, was generated as fast as possible after the detection of the ball launch and allowed the subject's hand to reach the interception zone, always above the position of the hand at the time of launch. The following component of the muscle pattern, captured by the second synergy, guided the hand to the interception point in a fixed time interval, i.e., according to an accurate estimation of the time necessary to reach the interception point.

The fact that we could reconstruct the muscle patterns for catching balls with three different flight times and two different arrival heights by combining two time-varying muscle synergies does not imply that the two identified synergies are basic building blocks sufficient to control all possible interceptive movements. Many recent studies of the muscle patterns for the control of the arm have identified muscle synergies by systematically varying the spatial constraints of the task (Muceli et al., 2010; Cheung et al., 2012; Roh et al., 2012; Delis et al., 2013). In particular, in our previous studies of time-varying muscle synergies for reaching (d'Avella et al., 2006, 2008, 2011b) we systematically varied the direction of the movement. In contrast, in this study we have focused on the effect of changing the temporal constraints inherent in an interception task (flight duration) with only two related spatial constraints (arrival height). A much larger set of flight conditions with a variety of arrival locations should be tested to make

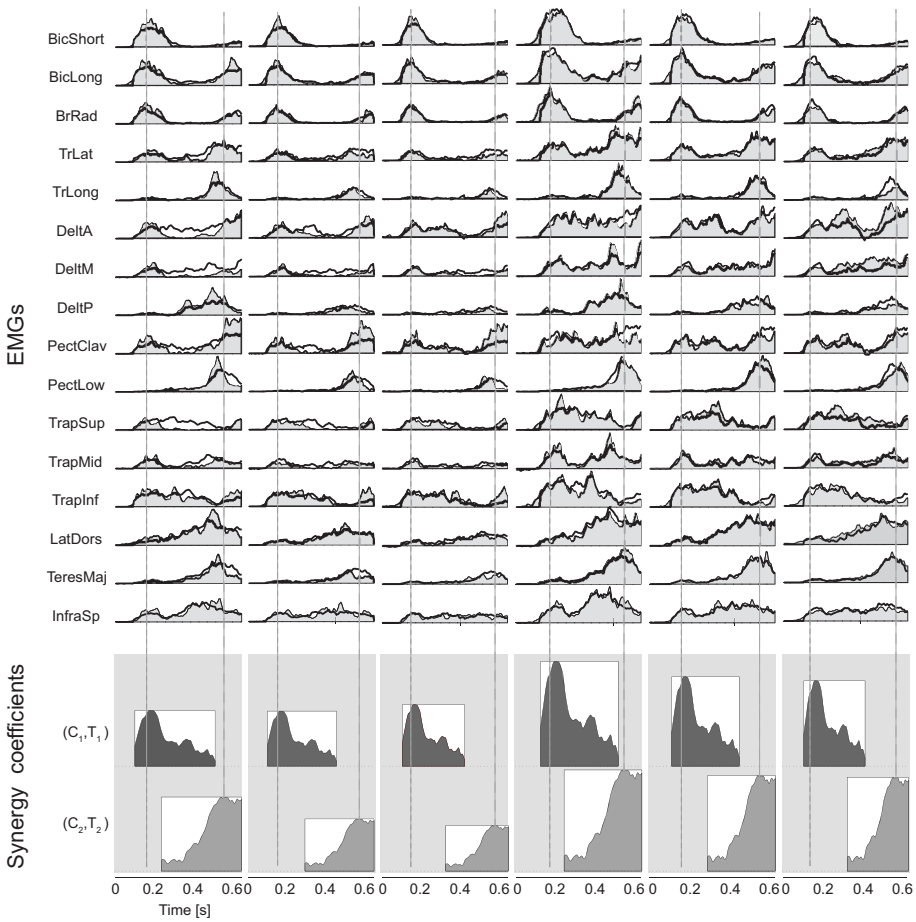

FIGURE 5 | Example of reconstruction of muscle patterns by synergy combination. Recorded muscle activation waveforms (*light gray area*) in all movement conditions for subject S_1 are reconstructed (*thick black line*) by the combination of two synergies (amplitude and timing coefficients represented by the height and the horizontal position of the rectangles with the mean activation waveform at the bottom of each panel). Onset and interception time are represented respectively by the dashed lines. The patterns are aligned to the launch time and normalized to the maximum amplitude for each EMG channel across all the six conditions. For all launch conditions, the first synergy was aligned to the launch time and the second synergy was aligned to the impact time.

the synergies identified by a decomposition algorithm from the muscle patterns representative of basic building blocks underlying the generation all possible catching movements. While we plan to test a more diverse set of experimental conditions in the future, the synergy decomposition approach was used here as a tool to identify spatiotemporal components in the muscle patterns independent of temporal constraints, such as flight duration. Thus, the synergies identified from this dataset might be composed by the combination of a larger number of more fundamental building blocks modulated by the spatial demands of the task, such as ball arrival locations at different medio-lateral coordinates.

Our observation of the modulation of the onset time of the second synergy by the temporal demands of the task, i.e., the duration of the ball flight and of the ball arrival at the interception point, may be contrasted with the timing modulation of the synergies for reaching a stationary target. In our previous investigation of the time-varying synergies for reaching with different movement directions and speeds (d'Avella et al., 2008) we found that a set of phasic and tonic synergies captured the muscle patterns once time-normalized to equal movement duration and that the onset of the synergies most active in each movement direction, expressed as a fraction of movement time, was approximately constant over a broad range of movement speeds. Thus, when reaching a stationary target with a movement which could be planned in advance and whose duration did not depend on an online estimation of the ball arrival time, as with an interceptive movement, the entire muscle pattern was scaled with the movement duration and the onset time of the synergies was then shifted accordingly with respect of the movement end. To directly compare the synergy timing for catching and reaching in similar conditions, we considered a subset of the data we had previously collected (d'Avella et al., 2008), selecting only the trials for reaching upward, and we averaged the muscle patterns over the trials with a movement time within three intervals around the mean movement times of the catching movements for the three ball flight time conditions of this study. We then extracted two

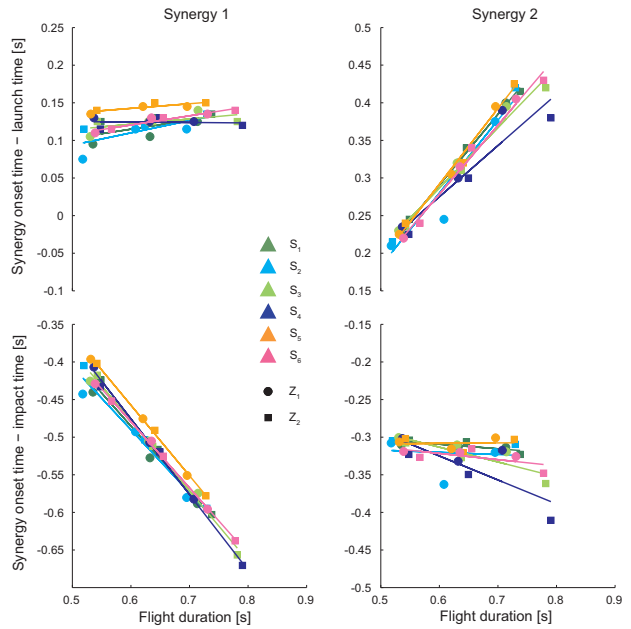

FIGURE 6 | Synergy onset as a function to the flight time. The synergy timing coefficients t_i are shown with respect to the flight time after time alignment of synergies to the launch time (**top**) and to the impact time (**bottom**), for all subject and all launch conditions (circular markers are referred to low launches, square markers are referred to high launches). Results of linear regression performed subject by subject are also shown. For all subject the onset of the first synergy was constant with respect to the launch time and the onset of the second synergy was constant with respect to the impact time, independently of the flight time.

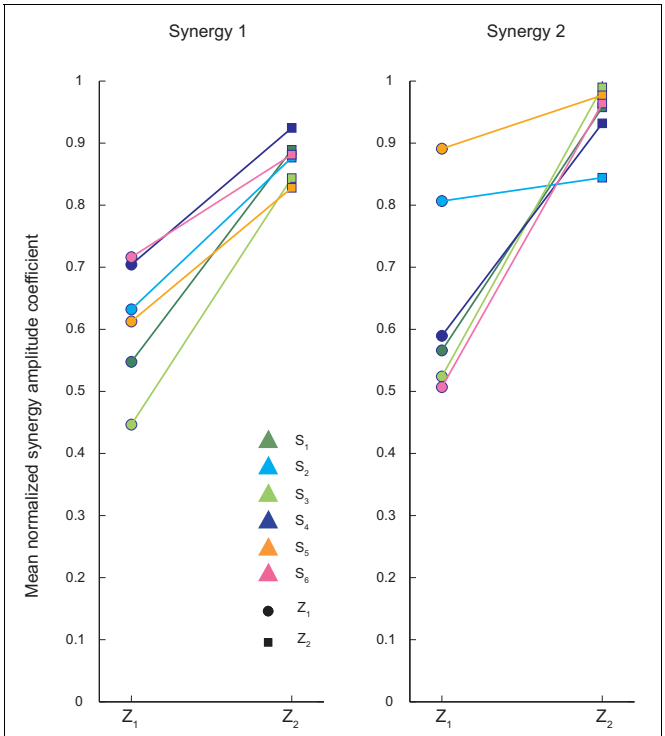

FIGURE 7 | Averaged synergy amplitude coefficients for the two different ball arrival heights. Synergy amplitude coefficients, averaged across flight times for low (Z_1) and high (Z_2) launches, are showed for all subjects. The amplitude coefficients of the first synergy increased similarly with ball arrival height in all subjects. The amplitude coefficients of the second synergy showed instead a weaker modulation with arrival height for subject S_2 and S_5 than the other four subjects.

time-varying muscle synergies from the averaged reaching muscle patterns, aligned to movement onset and time-normalized to equal movement time, as in the original analysis, and with the baseline activity before movement onset subtracted, as in the present analysis. The fraction of data variation explained by two synergies was higher for reaching than for the catching patterns ($R^2 = 0.83 \pm 0.10$, mean $\pm$ SD, $n = 5$, range 0.71 – 0.92) and the onset of the second synergy was not aligned with movement end but it occurred closer to the movement end for faster movements than for slower ones, as expected for muscle patterns scaled in time with movement speed. Thus, the modulation of the recruitment timing of the time-varying muscle synergies indicated that the muscle patterns for catching movements with different duration, differently from those for reaching, were not-scaled in time as a unit but consisted of two distinct temporal components, one aligned to the ball launch and movement onset and a second aligned to the time of ball interception and thus shifted progressively later for longer movement times.

The observation of a fixed temporal relationship between muscle synergies and specific task events, ball launch and ball impact with the hand, is in accordance and extends previous observations made in the context of catching balls falling vertically on the hand (Lacquaniti and Maioli, 1989) and of balls launched frontally onto the hand (Savelsbergh et al., 1992). A fixed relationship was found between the onset of an early component of wrist and elbow muscle activity and the time of ball release and between the onset of a late component and the time of ball impact for when catching balls falling from different heights (Lacquaniti and Maioli, 1989). Moreover, the onset of wrist and finger muscle activity showed a fixed relationship with the time of impact for balls launched frontally with different speeds (Savelsbergh et al., 1992). However, in contrast to those studies, in our catching task the location of the interception was not specified prior to ball launch, as the ball could be intercepted anywhere along the portion of the ball trajectory inside the hand workspace, and subjects had to determine not only the appropriate time of interception but also the appropriate place. Thus, in our unconstrained and naturalistic task subjects had to move their hand to the interception location and simultaneously time the closing of the fingers on the ball. Moreover, as all trials started with the arm relaxed along the body and all ball trajectories crossed the hand workspace above that hand initial location, subjects initiated their movement as soon as they detected the ball launch to bring the hand close to the interception region. Indeed, such reactive component was characterized by a time-varying synergy, recruiting mainly elbow flexors, shoulder flexors, and shoulder elevators. The amplitude coefficient of this synergy was modulated by ball flight arrival height (**Figure 7**), which was known

by the subject after the first trial of each block. When catching balls falling vertically on the hand, a conditions in which is it not necessary to displace the hand, the early anticipatory response in elbow (but not in wrist) muscles, is time-locked to the ball release and modulated in amplitude by release height and it has been interpreted as an alertness reaction (Lacquaniti and Maioli, 1989). More generally, the initial component of the interceptive muscle pattern, captured by the first synergy, may be interpreted as the reactive release of a motor program that brings the hand in an adequate spatial location from which a second motor program can be released once the interception location and time has been determined. As the time-to-contact during the ball flight depends on the final interception position and since the onset of the second synergy occurred at about the same time-to-contact, we can speculate that during the first part of the flight the recruitment parameters, activation amplitude and onset time, of the second synergy are selected to intercept the ball at a specific location and time along its trajectory. The selection of the appropriate synergy recruitment parameters might derive from a combination of visual information and a-priori knowledge of the dynamic behavior of the ball under gravity and viscous drag forces (Zago et al., 2009). Thus, in such synergy-based control scheme, a-priory knowledge of gravity and drag on the ball may be implicitly incorporated in a direct mapping of visual information into a small number of synergy recruitment parameters. Non-invariant parameters involved in this mapping, such as those relative to drag, may be learned quickly from experience if such mapping is intrinsically low-dimensional, as it would be if also the dimensionality of visual input is reduced by the extraction of a few spatiotemporal features.

Whether the control of interceptive movement relies on predictive or prospective control is debated (Bootsma and van Wieringen, 1990; Brenner et al., 1998; Dessing et al., 2002; Tresilian, 2005; Zago et al., 2009). According to prospective control strategies, appropriate processing of the visual information directly drives the hand toward the target, thus continuously updating the motor response according to an extrapolation of the trajectory based on sensory feedback rather than on an explicit representation of the trajectory or a prediction of the interception point and timing (Chapman, 1968; McLeod and Dlenes, 1993; Peper et al., 1994; McBeath et al., 1995; Brenner et al., 1998; Montagne et al., 1999; Dessing et al., 2002). In contrast, according to the simplest form of predictive control strategy, a stereotyped motor response of a fixed duration is preprogramed and triggered when the predicted time-to-contact is equal to the sum of the movement duration and the sensorimotor delay (Tyldesley and Whiting, 1975). However, as movement duration and velocity have been observed to depend on the parameters of the interceptive task (Bootsma and van Wieringen, 1990; Smeets and Brenner, 1995; Tresilian and Plooy, 2006), according to a more flexible predictive control strategy movement time and the criterion for triggering the response may be adjusted (Tresilian, 2005). In general, hybrid control strategies combining predictive and prospective control, with different weights depending on the time available for the interceptive movement, may be adopted by the CNS (Tresilian, 2005; Zago et al., 2009; Katsumata and Russell, 2012). For rapid interceptive actions, as those required in our task, the effectiveness of continuous on-line guidance by visual feedback is limited because of sensorimotor delays and subjects might adopt an intermittent control strategy (Burdet and Milner, 1998; Gawthrop et al., 2011; Loram et al., 2011; Karniel, 2013) based on an overlapping sequence of time-varying muscle synergies (d'Avella et al., 2011b). Each synergy might be triggered at a critical time and modulated according to a combination of visual information and a-priori knowledge. This control scheme is related to the biphasic preprogrammed model proposed to explain biphasic movements observed in a one-dimensional hitting task (Tresilian, 2005). In such model a first slow component is initiated at one critical value of time-to-contact and a second faster component at a smaller value. In our three-dimensional interception task, however, the location of the interception is not fixed and known prior to ball launch and the parameters of the interceptive movement cannot be fully pre-programmed. Thus, rather than a process that simply triggers a command when a visually driven time-to-contact signal reaches a critical value dependent on the duration of the preprogrammed movement component, we envision a process that triggers a muscle synergy at a critical time-to-contact value and simultaneously adjusts the synergy amplitude parameters to ensure that the hands is at the right location after that time interval.

In our previous study of the kinematic characteristics of the interceptive movements in this naturalistic, unconstrained catching task we found that individuals with similar performance level used different movement strategies (Cesqui et al., 2012). Also for the six subjects included in this study, inter-individual differences were particularly clear in terms of wrist trajectory in the sagittal plane and wrist velocity at impact (**Figures 8A,B**). As the second synergy captures mostly the second phase of the movement, we expected differences in the relative recruitment of elbow flexors and extensors. Indeed, it is apparent in **Figure 4** that in the second synergy of subjects S_4 and S_6, who impacted the ball with on average backward velocity (negative x component), both elbow flexors and elbow extensors are highly recruited. In contrast, in the second synergy of subjects S_1, S_2 and S_3, who showed hook-like trajectories and impacted the ball with low horizontal velocity, the elbow extensors are more strongly recruited than the elbow flexors. Finally, in the second synergy of subject S_5, who impacted the ball with a forward directed movement, the elbow flexors were almost completely silent and the elbow extensors were highly recruited. We then quantified these observations by computing, for the second synergy, the ratio between the mean area of the activation waveforms of the elbow flexor muscles (BicLong, BicShort, BrRad) and the mean of the area of the activation waveforms of elbow extensor muscles (TrLat, TrLong) as a function of the horizontal component on the sagittal plane of the wrist velocity (**Figure 8C**). The linear regression between the elbow flexors/extensors ratio and the wrist tangential velocity at impact was significant ($R^2 = 0.76$, $p = 0.02$). Thus, some of the individual characteristics of catching kinematics are reflected in the structure of the synergies. However, despite these inter-individual differences in the structure of the second synergy, the overall spatiotemporal organization of both synergies was remarkably similar across individuals (**Figure 3**). Additional inter-individual characteristics in the synergy organization can be

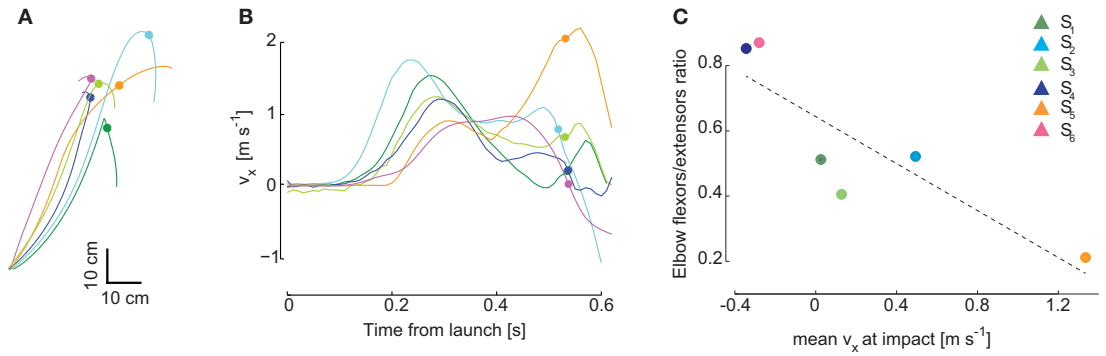

FIGURE 8 | Inter-individual variability in wrist kinematics and in the structure of the second synergy. Individual characteristics in the movement kinematics were observed in the several features such as the wrist paths in the sagittal plane, illustrated in **(A)** for condition (T_1,Z_1), and the horizontal component of the wrist velocity in the sagittal plane (v_x), illustrated in **(B)** for the same condition. Subject color coding as in preceding figures; *circular markers* indicate the time of impact. **(C)** Differences across subjects in the mean activation level of elbow extensors and elbow flexors of the second synergy waveforms are related to differences in the mean horizontal wrist velocity at impact across conditions. Subjects S_4 and S_6 who intercepted the ball with on average negative (backward) velocity showed a high ratio close to 1 between elbow flexors activation and elbow extensors activation areas. For the subjects who impacted the ball with low velocity (S_1, S_2, S_3) the ratio was near 0.4/0.5, while for subject S_5, who impacted the ball with a large forward velocity, the ratio was near zero.

found when more than two synergies are extracted in each subject. We characterized the muscle patterns with two time-varying synergies because their gross temporal organization in all subject was biphasic (**Figure 2**) and because two synergies captured always at least 65% of the data variation. However, while in two subjects (S_1 and S_5) the R^2 value reached a plateau at 2 synergies [assessed by the detection of a "knee" in the R2 curve, see d'Avella et al. (2006)], in the remaining four subjects (S_2, S_3, S_4, S_6) the plateau was at three synergies. In these sets of three synergies, one synergy was always similar to the first synergy of the set of two and it showed the same temporal relationship with ball launch. The other two synergies were related to the second synergy in the set of two but they showed additional subject-specific features. In general, one of the two remaining synergies was aligned to the impact time. The other synergy was recruited mainly for high launches and it was timed differently across subjects, generally in between the other two synergies, but with variable onset alignment. Thus, subtle differences in the muscle patterns captured by sets with more than two synergies might contribute to additional individual kinematic features. However, the similarity of two synergies across subjects suggests that individual kinematic strategies emerge from a rather subtle differentiation of the same basic control scheme.

In conclusion, the decomposition into time-varying muscle synergies of the activation waveforms of a large set of shoulder and elbow muscles underlying unconstrained and naturalistic hand movements for catching fast flying balls reveals an intermittent control strategy based on two phases associated to specific synergies and timed according to two key events, ball launch and ball impact. Such strategy may allow for a fast and efficient selection of the appropriate motor commands by incorporating a priori knowledge of the ball flight dynamics in a low-dimensional mapping of the kinematic features of the ball trajectory, extracted from vision, into synergy amplitude and timing recruitment parameters.

Modular organization in control architecture may underlie the versatility of human motor control; but the nature of the interface relating sensory input through task-selection in the space of performance variables to control actions in the space of the elemental variables is currently unknown. Our central question is whether the control architecture converges to a serial process along a single channel? In discrete reaction time experiments, psychologists have firmly associated a serial single channel hypothesis with refractoriness and response selection [psychological refractory period (PRP)]. Recently, we developed a methodology and evidence identifying refractoriness in sustained control of an external single degree-of-freedom system. We hypothesize that multi-segmental whole-body control also shows refractoriness. Eight participants controlled their whole body to ensure a head marker tracked a target as fast and accurately as possible. Analysis showed enhanced delays in response to stimuli with close temporal proximity to the preceding stimulus. Consistent with our preceding work, this evidence is incompatible with control as a linear time invariant process. This evidence is consistent with a single-channel serial ballistic process within the intermittent control paradigm with an intermittent interval of around 0.5 s. A control architecture reproducing intentional human movement control must reproduce refractoriness. Intermittent control is designed to provide computational time for an online optimization process and is appropriate for flexible adaptive control. For human motor control we suggest that parallel sensory input converges to a serial, single channel process involving planning, selection, and temporal inhibition of alternative responses prior to low dimensional motor output. Such design could aid robots to reproduce the flexibility of human control.

Keywords: modularity, motor control, intermittent control, posture, redundancy

INTRODUCTION

In the everyday acts of standing and movement, humans easily generate complex multi-joint behavior. When performed in conjunction with secondary task requirements (e.g., reaching to grasp an object) the Central Nervous System (CNS) is confronted with an impressive coordination and control problem involving redundancy at many levels (e.g., sensory, biomechanical, and neuromuscular). Despite the numerous possibilities, task performance is characterized by remarkable regularity and low-dimensionality in motor output (Latash et al., 2007). Equally, performance shows "repetition without repetition" (Bernstein, 1967) which means that repetitive solutions are never the same but always vary. Open, exciting questions for researchers studying human motor behavior include: how is this abundant, robust control achieved, and how might it be replicated artificially?

In the example of human standing, multi-elemental motor outputs are defined based on an input specifying what, out of multiple task possibilities, the system has to produce as a whole (cf. Latash, 2010). This input-output coupling is faced with the "problem of selection" that is: how do accumulated task possibilities and sensory information, supplied initially through parallel channels including different modalities and sensory cells within single modalities, converge to parallel motor output? It has been suggested that at the motor level, flexibility, versatility, and adaptability in (parallel) muscle output can be achieved through modularity of the control architecture [e.g., through muscle modes, motor primitives, pattern generators, etc.; for an overview see: Latash et al. (2007), Safavynia and Ting (2012)]. What is unknown, however, is how the many-to-many convergence from parallel sensory input to parallel motor output is organized that is, the interface of sensing and action associated with task selection.

The "problem of selection" has been studied in the context of the multiple degrees of freedom (DOFs) problem (i.e.,

selecting a solution from the range of possible solutions). One approach that of motor synergies, has been defined as a neural organization that ensures a one-to-many mapping between important and inconsequential variables/quantities providing for both stability of important performance variables and flexibility of motor patterns to deal with possible perturbations and/or secondary tasks (Latash et al., 2007). More recently, it was suggested that "all the DOFs at all levels always participate in all the tasks." This hypothesis called the "principle of abundance" (Latash, 2012), predicts both stability and flexibility in performance. According to this principle, the CNS facilitates "families of solutions" each of which is able to solve a multiple DOF problem. These solutions emerge from the interplay between the state of the system "body + environment" and the (task) imposed constraints (cf. Hu and Newell, 2011). This means that at any level of the sensori-motor control system, behavior is defined by the laws of physics (cf. Latash, 2012). However, a fundamental question remains unanswered: what and where is the process by which tasks are selected and by which these families of solutions are reduced to unique actualizations at temporal instances, in other words the process of selection (Stepp and Turvey, 2010; Latash, 2012)?

In tasks such as human standing, the neuro-muscular-skeletal system uses sensory information to regulate its motor output. In control engineering terms this means that the feedback loop between the control system's inputs and outputs is closed. Redundancy implies that the motor system generates parallel possible goal-solutions (which include alternative equivalent motor solutions to the overall task goal) from parallel sensory input (Cisek, 2005) and that this mapping is many to one. Thus, in a full model, the interface between (all) sensory input and modular motor output should hypothetically include the processes of parallel goal-solution generation and convergence to an instantaneously unique goal-solution prior to motor output.

Within the generalized optimal control models of biological control (Li et al., 2004; Todorov, 2004; Todorov et al., 2005; Lockhart and Ting, 2007; Karniel, 2011, 2013; Safavynia and Ting, 2012) the process for solving the redundancy problem lies outside the low level feedback control loop: it lies within a response planner which provides (continuous) settings for the continuous feedback control loop. Thus, a single optimal solution is provided from many possibilities (Rosenbaum et al., 1995; Todorov et al., 2005). Although such a system is not invertible causing a problem for control methods using an inverse model to generate appropriate motor commands from desired movement outcomes, optimal control provides a unique solution to the control of multi-input systems (Goodwin et al., 2001). However, usually this scheme does not provide a full model for the interface between sensory input and modular motor output because: (1) the task level parameters including the goal, the cost function and the mapping between high level and low level variables are usually preselected and, (2) the processes of parallel goal-solution generation and choice-selection is usually omitted. According to the generalized optimal control models (Todorov, 2004; Lockhart and Ting, 2007; Safavynia and Ting, 2012), the CNS monitors a (small) number of task parameters and, using low-level controllers, performs continuous feedback of plant output according to the task goals and optimization constraints set by high-level commands. Although this popular framework transcends the "classic robotics" approach in which trajectories are planned in joint space, and subsequently executed using servo control governing joint torque, even if correct, it begs the question of the process by which the task and optimality criteria are selected.

Recent demonstrations have shown that even for the control of external second order unstable systems[1], continuous feedback control is not necessary, and that intermittent control has inherent advantages for control and adaptability (Loram et al., 2011). Evidence from sustained manual control of an external single degree of freedom system (Loram et al., 2012; van de Kamp et al., 2013) showed that it is unlikely that the entire sensory-motor pipeline is implemented in parallel as a continuous linear time invariant process. Rather the evidence is highly consistent with a limiting serial process along a single channel which is expressed formally in the intermittent control paradigm illustrated in **Figure 1** (Gawthrop and Wang, 2011; Gawthrop et al., 2011; Gawthrop and Gollee, 2012; Loram et al., 2012). The hypothesis of a limiting serial, single channel process is supported by extensive studies in Psychology showing refractoriness in double stimulus experiments. This effect is known as the Psychological Refractory Period (PRP) (Telford, 1931; Pashler et al., 1998). Refractoriness refers to the temporal duration for which control responses cannot be, or are not modified following their initiation (Vince, 1948; Pashler et al., 1998; Gawthrop et al., 2011; Loram et al., 2012; van de Kamp et al., 2013). Extensive experimentation has firmly associated the PRP both with the Single Channel Hypothesis (Smith, 1967) and with response planning/selection in the stages of sensory analysis (SA), response planning/selection (RP/S) and response execution (RE). While SA and response execution operate through parallel channels, only the RP/S converges to a serial process along a single channel in these experimental conditions (Pashler et al., 1998).

In the current study two competing hypotheses will be tested. The multi-channel mapping hypothesis predicts continuous parallel processing which is free from refractoriness. The alternative single channel hypothesis postulates a limiting serial process along a single channel associated with the Psychological Refractory Duration (see **Figure 1**).

Here we aim at connecting two bodies of literature. The first concerns the PRP, the second concerns Modularity in Motor Control. We ask a novel theoretical and experimental question: namely, in the control of whole body movements, is the single channel hypothesis (characterized by a PRP) relevant for the modular organization of the motor control system? In brief, the rationale behind this question is: (1) multi-segmental control is subject to redundancy, thus the process of selection is relevant, (2) for a flexible yet integrated multi-segmental structure, organization of selection should converge along a single or coordinated number of task goals within the main

[1]The external second order unstable system can be thought of as an average standing human behaving as an unstable second order inverted pendulum with a time constant of ∼0.9 s.

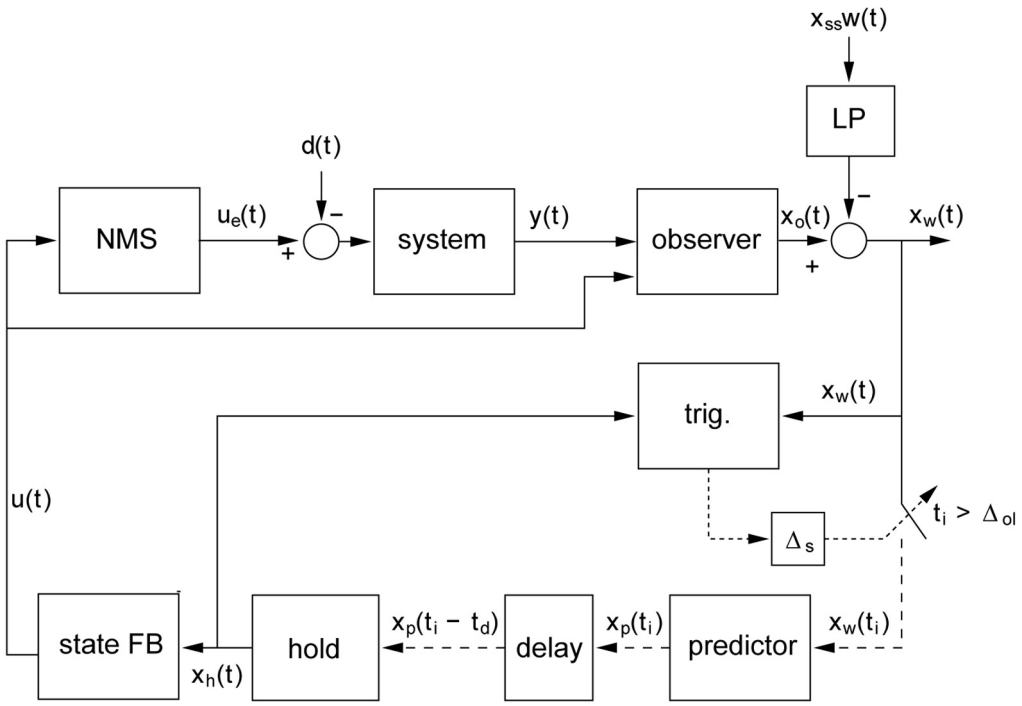

FIGURE 1 | General model of intermittent control. The intermittent predictive controller includes continuous control as a special case, but generally the predicted system state is only used intermittently to update the time varying control signal sent from the generalized "hold" to the actuator. "Trig." detects when the control trajectory is to be updated and this event trigger requires three conditions: (1) a single event must be detected (i.e., all events within the sampling delay (Δs) are considered as one), (2) a minimum open-loop interval (Δ_{OL}) must have elapsed since the previous event and (3) an error signal must exceed a threshold. Scalar signals are represented by solid lines, vector signals are represented by dashed lines. The participant's neuro-muscular dynamics are modeled (linear) in the "NMS" block with input $u(t)$. The linear external controlled system with output $y(t)$ (represented by the "System" block) is driven by signals $u_e(t)$ and $d(t)$ representing the externally observed control signal and the disturbance signal. The state of the composite "NMS" and "System" blocks is estimated $x_o(t)$ by the "observer" block. Sampling is preceded by an anti-aliasing low-pass filter "LP" of the subtracted set point disturbance $w(t)$ and subject to an event delay "Δ_S" between event and sampling. The trigger for the sampling times t_i is provided by the event detector block labeled "trig." Sampling $x_w(t)$ takes place at discrete times t_i. Sampled signals (represented by the dotted lines) are defined only at the sample instants t_i. The future state error $x_p(t_i)$ is provided by the "predictor" block. The various delays in the human controller are accounted for by a pure time delay of t_d represented by the "delay" block. The block labeled "hold" is a system-matched hold that provides the delayed version of the continuous-time signal that is multiplied by the feedback gain vector k (block "State FB") to give the feedback control signal $u(t)$. This figure and its caption are reproduced with permission from Gawthrop et al. (2011).

feedback loop, and (3) response selection and planning is experimentally associated with refractoriness and the single channel hypothesis.

To summarize: We study control of the whole body to move the end effector (head) in accordance with a tracking target. Although the tracking task has one degree of freedom (movement of the head marker in the Anterior-Posterior plane), all the relevant joints, also when locked, have to be controlled appropriately and thus this task involves redundancy. We use our recently developed method to identify refractoriness in sustained control tasks and discriminate intermittent (serial ballistic) from continuous (parallel) control (Loram et al., 2012; van de Kamp et al., 2013). We ask:

- Is refractoriness, consistent with the single channel hypothesis, evident in this task?
- Is refractoriness and the associated serial process along a single channel relevant for modularity in motor control?
- Is there a plausible rationale for why biological control should converge to a single channel?

METHODS

ETHICAL APPROVAL

The experiments reported in this study were approved by the Academic Ethics Committee of the Faculty of Science and Engineering, Manchester Metropolitan University and conform to the Declaration of Helsinki. Participants gave written, informed consent to the experiment.

PROCEDURE, APPARATUS, AND MEASUREMENT

The experimental setup is illustrated in **Figure 2**. Eight healthy subjects (6 male, 2 female), aged between 27 and 59 years received real-time visual feedback about the Anterior-Posterior (AP) position of a of a VICON marker, placed on the participants head whilst pursuing a double stimulus tracking sequence with varying Inter Stimuli Intervals (ISIs: 0.2, 0.3, 0.5, 0.8, 1.4,

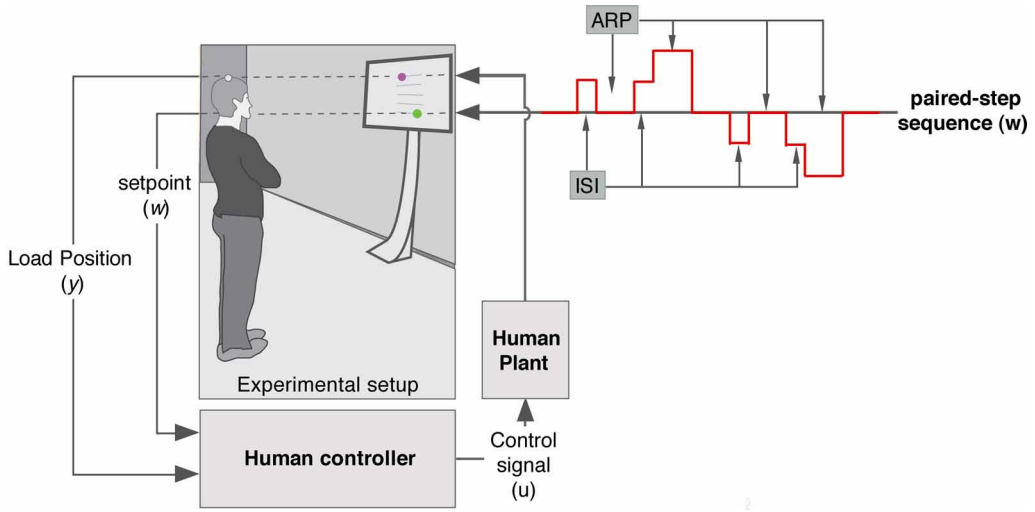

FIGURE 2 | Diagram of the experimental set up and the paired-step sequence. The participant receives visual feed-back information about the Anterior-Posterior head position through a dot presented on a TV screen mounted on a trolley. While stabilizing posture, participants were asked to track the position of a second dot displayed on the screen. The four possible step sequences (uni- and reversed-directional step up or down) of the pursuit target are illustrated by the red line. First and second stimuli are separated by an inter-step interval (ISI).

2.4, and 4 s). Feedback was displayed on a 42″ TV screen that was mounted on a trolley positioned at a 1 m distance in front of the participant. The visual scene contained two (3 cm, green and magenta) spheres (moving up and down alongside the vertical mid line of the screen) and was constructed using the Simulink 3D Animation Toolbox (a 1 cm movement of the VICON marker in the AP direction corresponded to a 2.5 cm movement of the magenta sphere in the superior-inferior direction on the TV screen). Using Vicon's SDK we developed C++ code to stream (UDP protocol) marker data to the Simulink model that was compiled using Real-Time Workshop and executed on a laptop using Real-Time Windows Target within MATLAB v7 (MathWorks) at a sample rate of 1000 samples per second. We informed the participants that every now and then, the green target would jump up or down the screen which should be pursued by controlling the magenta sphere which represented antero-posterior head position. Participants were told to keep their feet in the initial position, to track the green target position by means of swaying their body forward and/or backwards as quickly and accurately as possible, and that, as a measure of performance, we would look at the deviation between target position and head position (i.e., the green and magenta spheres on the screen). In a randomized order, the stimuli with seven different ISIs (see above) were displayed four times. Following (van de Kamp et al., 2013), the tracking target step sequence was designed such that participants were unable to anticipate either the timing, direction, or amplitude of step change in target position (**Figure 2**). Unpredictability of the direction of the double step stimuli was achieved by varying the direction of the 2 cm step in target position (up-down, down-up, up-up-down to center, down-down-up to center). By varying the ISI and recovery time, also the temporal predictability was eliminated. Based on previous experiments (Loram et al., 2012; van de Kamp et al., 2013) we estimated that when stabilizing posture, a random 4–5 s period would be sufficient to recover from a step response (participants kept tracking the target which then was in the neutral/middle position). To serve as an independent base measure, the two longest ISIs were chosen in the vicinity of the recovery period. The remaining five ISI were chosen to span the range from less than to more than the expected refractory duration based on previous published work (Loram et al., 2012; van de Kamp et al., 2013). Participants verified that the delay between marker movement and its presentation on the screen (∼100 ms) was not detectable. After familiarization with the intuitive control tasks and some practice all participants were ready to take part. Trial duration was approximately 4 min.

METHOD OF ANALYSIS

Here we applied our published three-staged method of analysis (Loram et al., 2012) to the set-point (target) and response (AP head position) signals. Details with respect to the method of analysis are stated more fully in previous work (Loram et al., 2012; van de Kamp et al., 2013) and have been restricted here to the minimum necessary.

Stage 1: reconstruction of the set-point

For each first and second step, we estimated the time delay (i.e., RT1 and RT2) between the step in target position and the subsequent whole-body-movement response (see **Figure 3**). This was achieved by modeling the closed loop relationship between the target (step sequence) and response (head position) as a low order, zero delay, autoregressive moving average (ARMA) process (for details see: Loram et al., 2012; van de Kamp et al., 2013). Next, the step sequence was reconstructed by sequentially and individually adjusting the instant of each step. This procedure, optimizing the fit of the ARMA model, was done in two consecutive ways; (1) reconstruction of the step sequence using a single

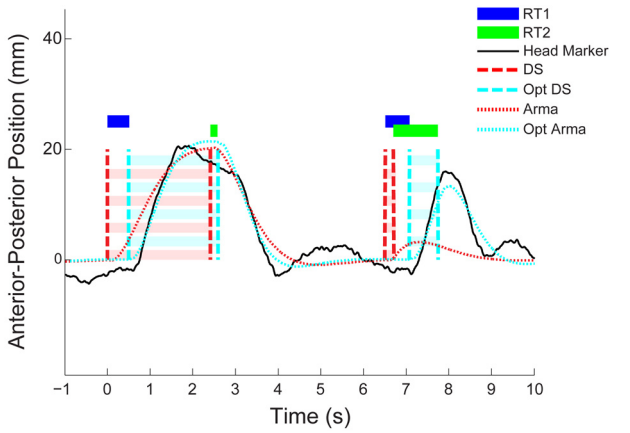

FIGURE 3 | Representative responses; reconstruction of the set-point (stage 1). The figure shows two representative examples of a whole body response to a double-step disturbance over time (black solid lines). The first response is free of interference, the second response shows interference between responses to the second and first stimulus. The dashed line (red) shows the time-invariant optimized ARMA fit corresponding to the original/actual double step stimulus (cyan dashed line). The dotted line (cyan) shows the best fitting ARMA model corresponding to the non-time-invariant optimized step sequence. Estimates of first (RT1 in blue horizontal bar) and second (RT2 in green horizontal bar) delays hover above, and span the interval between the actual and optimized step sequence.

equal adjustments of the instant of all steps -in effect determining the time delay of the ARMA model in **Figure 3** and (2) reconstruction of the step sequence allowing individual adjustment of the instant of each step (i.e., the optimized ARMA in **Figure 3**). By optimizing the delay to each step, this "set-point reconstruction" procedure provides a distribution of response delays to first and second steps (see RT1 and RT2 in **Figure 3**). The statistical analysis of these delays in the second stage enables testing for refractoriness.

Stage 2: statistical analysis of RT1s and RT2s

To compare the distributions of RT1 and RT2 over ISIs (levels 1 through 7) a two factor (Stimulus Number and ISI) repeated measures ANOVA design is used. To evaluate significant main and interaction effects *post-hoc* ANOVAs were run. To maximize statistical power, bi-directional, and unidirectional step-pairs were analysed in one group.

The two stages outlined above allow us to test the following null hypotheses:

(i) Distributions of RT1 and RT2 are equal (i.e., a hypothesis of zero refractoriness would predict equal ranges (5–95th percentile) and means in the distributions of RT1 and RT2).
(ii) There is neither a main effect of ISI nor an interaction effect between Step Number and ISI (i.e., a hypothesis of zero refractoriness would predict that both RT1 and RT2 are independent of ISI).

If these hypotheses are rejected, the following tests provide evidence discriminating against continuous control and quantifying the extent of refractoriness in this whole body movement task.

(iii) Testing within each level of ISI for differences between RT1 and RT2 will reveal the ISI up to which there is interference between RT2 and RT1 and quantifies the duration of refractoriness.
(iv) Using linear regression to fit RT2 vs. ISI for ISIs where RT2 is significantly greater than RT1, will reveal the maximum increase in RT2 (i.e., the regression intercept (ISI = 0) minus average RT1).

Stage 3: model based interpretation of delays

If, in Stage 2, we find evidence of refractoriness which favors the alternative hypothesis that the single channel/IC model does apply to multi segment control of movement, the following tests would reveal its open-loop interval

(v) Repeat the regression method explained in (*iv*), assuming a least mean squares fit with slope constrained to −1 [i.e., if a response is triggered by the first step a slope of −1 is predicted in the relationship between average RT2 and ISI for ISI < open-loop interval (Pashler et al., 1998; Gawthrop et al., 2011)].

RESULTS

REPRESENTATIVE PURSUIT TRACKING RESPONSES TO DOUBLE STEP STIMULI WHILE STABILIZING POSTURE; RECONSTRUCTION OF THE SET-POINT (STAGE 1)

Figure 3 shows the comparison between a response pair without interference followed by a response pair that shows evidence of interference (i.e., the response to the second stimulus is delayed following close temporal proximity of the first stimulus). When the ISI is relatively long (see 2.4 s example **Figure 3**), the response delay to the second steps is not elongated relative to the first response. However, with a small ISI (see 0.2 s example **Figure 3**), RT2 is clearly elongated compared to RT1. This observation is quantified by means of the "set-point reconstructed" ARMA procedure. That is, if in **Figure 3** we overlay the participant's whole body response (in solid black), the ARMA prediction in dotted red, and the "set-point reconstructed" ARMA prediction in dotted cyan we see that reconstructing the set-point results in a better (ARMA) description of the data. If we then compare the delays identified in this first stage of the method of analysis (i.e., the blue and green bars in **Figure 3**, displayed over the interval between the actual and optimized steps) we see that for the small ISI, RT2 is elongated relative to RT1.

STATISTICAL ANALYSIS (STAGE 2): GROUP RESULTS

Figure 4 shows that the average 5–95% range in RT was systematically affected by Step Number. The mean range in RT was significantly higher for step 2 than for step 1 [693 ± 77 ms, 497 ± 75 ms, $F_{(1,\ 7)} = 48.8$, $p < 0.0005$].

The mean RT (see box plots in **Figure 5**) was significantly higher for step 2 compared to step 1 [431 ± 130 ms, 357 ± 95 ms, $F_{(1,\ 7)} = 14.2$, $p < 0.01$]. Combining RT1s and RT2s showed a significant increase in RT with decreasing ISIs [406 ± 93 ms,

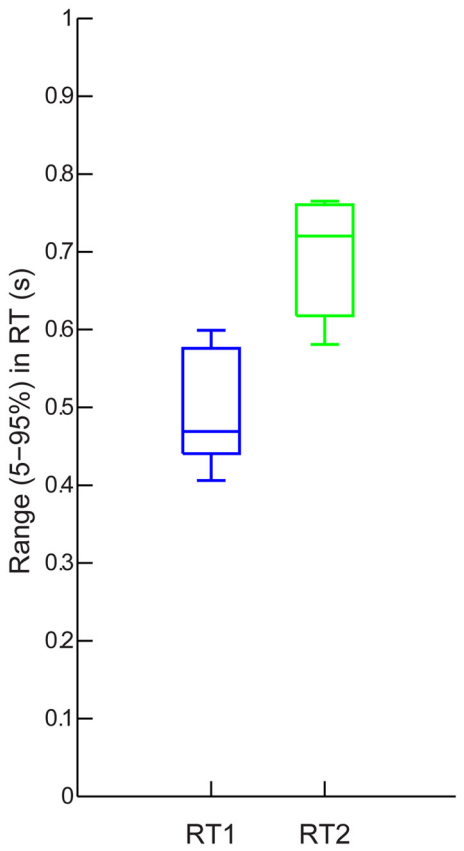

FIGURE 4 | Group results: Ranges (5–95%) of delays in RT1 (blue) and RT2 (green). Each box shows, the median range (central mark), the 25 and 75th percentile range (the edges of the box are), and the most extreme data points not considered outliers (the whiskers) of these ranges combined across the eight participants.

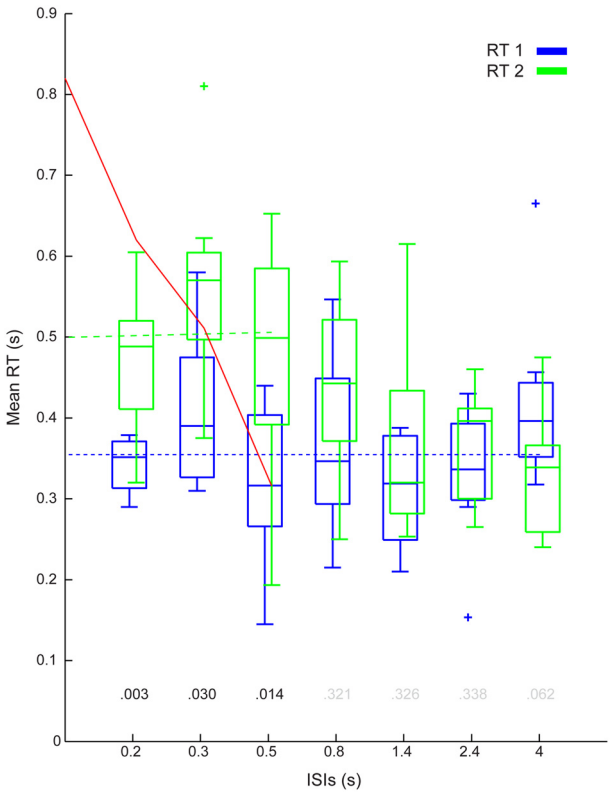

FIGURE 5 | Group results: Mean delays (stage 2). Figure shows the inter participant mean RT1 (blue) and RT2 (green) against ISI combined across the eight participants. The *P*-values of the ANOVA's *post-hoc* test are display above each ISI level (black if <0.05, gray if not). The blue dotted line shows the mean RT1, the dashed green line shows the unconstrained regression linear fit between (interfered) RT2 and ISIs. The red line is a linear interpretation of the single-channel hypotheses (please note that the steps between ISI do not necessary increase linearly).

488 ± 135 ms, 397 ± 149 ms, 403 ± 117 ms, 339 ± 103 ms, 349 ± 79 ms, 375 ± 103 ms, $F_{(6,\ 42)} = 3.83$, $p < 0.05$]. The significant interaction effect between Step Number and ISI, [$F_{(6,\ 42)} = 3.19$, $p < 0.05$] indicates that reducing the ISI had different effects on RT1 compared to RT2. Conducting two separate *post-hoc* tests to break down the interaction, showed a significant effect of ISI on the RT2s, [$F_{(6,\ 42)} = 4.53$, $p < 0.05$], but not on the RT1s.

Refractoriness was quantified in three ways. The first metric, as shown in **Figure 5**, revealed that RT2 was increased relative to RT1 for ISIs up to 500 ms (see **Figure 5** for *p*-values of the planned comparison of Step Number at each ISI). The second metric showed a mean increase in RT2 of 145 ms [subtracting the average RT1 (355 ms) from the intercept (500 ms) of the regression line of mean interfered RT2s over ISIs (cf. **Figure 5**)].

SINGLE CHANNEL INTERPRETATION OF RT INTERFERENCE (STAGE 3)

The red line in **Figure 5** (as discussed in Loram et al., 2012; van de Kamp et al., 2013) represents the mean RT2s in accordance with the Single Channel interpretation for the externally triggered Intermittent Control model in **Figure 6B**. The intercept of the red line (820 ms) in **Figure 5** minus the base line of the refractory duration (i.e., the average RT1 355 ms) provided a third metric (465 ms) for the refractory duration. Like we showed in van de Kamp et al., 2013, this third metric corresponded closely to the first metric (compare 465–500 ms) both transcending the second, unconstrained linear regression, metric (i.e., 145 ms).

DISCUSSION

SUMMARY OF RESULTS

In this study we hypothesized that refractoriness is relevant to the coordination of multi-segmental movement. Eight participants controlled their whole body to ensure a head marker tracked a target as fast and accurately as possible. The following results were shown unambiguously.

- Refractoriness was present in whole body movement. Delays in response to the first step (RT1) were independent of the inter-step interval (ISI). Delays to the second step (RT2) depended on ISI were greater than RT1 for ISI's less than and including 500 ms.

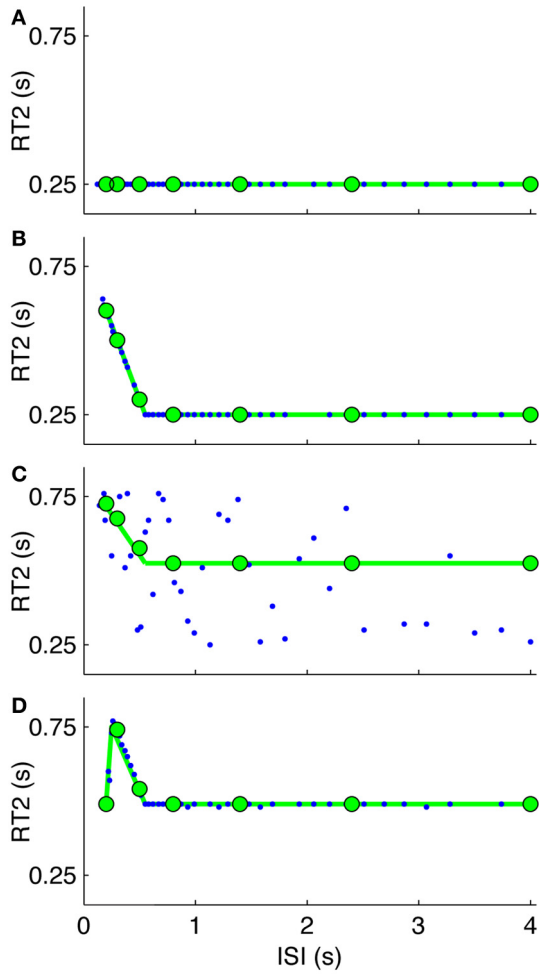

FIGURE 6 | Model based interpretation (stage 3). Parameter variants from the generalized IC model of **Figure 1** showing several possible relationships between RT2 and inter-step interval (ISI) indicative of serial ballistic (intermittent) and continuous control behavior. The simulated system is zero order. The open-loop interval (Δ_{OL}) is 0.55 s and feedback time delay (t_d) is 0.25 s. For four models: **(A)** continuous LTI ($\Delta_{OL} = 0$), **(B)** externally-triggered intermittent control with a prediction error threshold, **(C)** internally-triggered intermittent control (with zero prediction error threshold, triggered to saturation), and **(D)** externally-trigger intermittent control supplemented with a sampling delay of 0.25 s which us associated with the ISI at the maximum delay for RT2. The joined green circles represent the theoretical delays as a function of ISI which are confirmed by the model simulations (blue dots). This figure and its caption are based on van de Kamp et al. (2013).

- The refractory duration was substantial. The ISI up until which there was distinct interference between responses, was 500 ms. The delay to RT2 compared with the mean delay for RT1 was 200 ms at an ISI of 0.3 s
- At the smallest ISI, the relationship between RT2 and ISI departed from the linear relationship between RT2 and ISI predicted by the single channel hypothesis.

This paper concerns evidence for refractoriness, the relevance of refractoriness for modularity in motor control, and the possible rationale for a serial process along a single channel. Following the facts established here and previously (van de Kamp et al., 2013) we discuss the following issues:

(i) Is this evidence of refractoriness consistent with a serial process along a single channel?
(ii) What is the relationship between intermittent control and modularity of motor output?
(iii) Is there a possible rationale for why biological control should converge to a serial process along a single channel?
(iv) Is there any plausible neural substrate for a central, serial, single channel process?
(v) Could the design of autonomous robots benefit from a module including a serial, single channel process?

Is this evidence of refractoriness consistent with a serial process along a single channel?

The evidence for refractoriness in this whole body movement task is clear even with a relatively small sample of trials and participants. This evidence of increased delays for RT2 at low ISI is consistent with sustained manual control of an external, second order, single degree of freedom system (van de Kamp et al., 2013). The similarity includes the evidence that the increased delay for RT2 vs. RT1 is reduced at the smallest ISI. The current results demonstrate refractoriness in sustained movement control of the whole body. This result extends the relevance of refractoriness in sustained control beyond manual tracking where it might be argued that control of the hand is more refined and specialized than control of the postural muscles in the legs and trunk. This result also extends the relevance of refractoriness beyond control of a uniaxial joystick the task in our previous work (Loram et al., 2011, 2012; van de Kamp et al., 2013) because this whole body task requires coordinated control of multiple kinematic segments. Our results appear contradictory to the current prevailing hypotheses of optimal feedback control in which feedback proceeds continuously along low level feedback loops in which the goal and strategy are preset. Thus, the interpretation we have made previously (van de Kamp et al., 2013) applies also to this task of moving the whole body to control head position and the reader is referred to that discussion. The key point is that refractoriness is not compatible with a continuous, time invariant and linear process and that because the system is refractory, redundant, time varying with sensory delay and containing many DOFs, a serial process along a single channel is relevant to the control of such a system. The reader will probably not be surprised that human motor control is non-linear. However, the finding of refractoriness, a systematic time variance in which responses show increased delay when they follow a closely preceding response, points to a modular element or process in the human motor control architecture that authors usually neglect.

Does the evidence of refractoriness imply a serial process along a single channel? If RT2 were linearly related to ISI with a gradient of −1, then as clearly articulated by Pashler and Johnston (1998) that would be consistent with a serial process along a single channel in which a second process cannot start until a first process has completed. Within a control system, this idea is represented

within an intermittent control paradigm in which feedback cannot be applied until a minimum open loop interval has elapsed (**Figure 1**) (Gawthrop and Wang, 2009, 2011; Gawthrop et al., 2011; Gawthrop and Gollee, 2012; Loram et al., 2012). The minimum open loop interval, or intermittent interval as it is called, is an implementation of the single channel PRP as expressed by Craik (Vince, 1948) and Pashler (Pashler et al., 1998). Within this event driven intermittent control paradigm (**Figures 1**, **7**), elapse of the minimum open loop interval is one of the two necessary conditions for triggering a feedback informed control trajectory. This ensures that control proceeds serially as a sequence of control actions that are constrained to be ballistic for at least the minimum open loop interval. This serial process along a single channel, and the associated refractoriness, is not represented by state related switching in which a state dependent error signal crosses a threshold. State related triggering is advocated by some authors (Asai et al., 2009; Suzuki et al., 2012) and is represented in the second triggering condition of our intermittent control paradigm (**Figure 1**).

The purpose of the model simulations in **Figure 6** is to show that: (1) a continuous model does not show refractoriness, (2) a gradient of RT2 vs. ISI shallower than −1 is compatible with the single channel hypothesis, and (3) a reduced RT2 at the lowest ISI (i.e., departure from the red line in **Figure 5**) is compatible with the IC model by using a sampling delay. As illustrated in **Figure 6**, our model simulations show that the largest ISI at which RT2 is significantly larger than RT1 gives the open loop interval and that that the ISI at which the RT2 is largest shows the sampling delay.

Departure from the linear relationship between RT2 and ISI at small ISI or a gradient of −1 does not invalidate the single channel hypothesis (**Figure 6**). For this explicitly single channel model (**Figures 1**, **7**), when one events is triggered for each target step, following the minimum open loop interval, the gradient is −1 (**Figure 6B**). If additional events are subsequently triggered, by an error signal crossing a threshold (e.g., due to increased noise) the slope will be less than −1. Setting the event threshold to zero so events trigger internally at the maximal possible rate will result in a gradient of -0.5 and a range of reaction times equal to the intermittent interval (**Figure 6C**). If applied noise is high enough, the relationship between RT2 and ISI is not defined by the IC model and the slope is zero (Loram et al., 2012). Supplementing the intermittent control model with low pass filtering of the set-point and a sampling delay (i.e., the delay between the event and the sampling instant cf. **Figure 1**) leads to RT2 decreasing as ISI decreases resulting in a peak in RT2 at a ISI which is equal to the sampling delay (**Figure 6D**). This feature reproduces the amplitude transition function (ATF) observed by Barrett and Glencross (1988a,b), in which participants combine their responses to first and second steps stimuli for small ISIs. Depending on parameter settings for noise levels, event thresholds, sampling delays, and low pass filtering; varying relationships between RT2 and ISI can be simulated consistent with the single channel hypothesis. The key evidence supporting a serial process along single channel hypothesis is the evidence of refractoriness. The decrease in RT2 with decreasing ISI at the lowest inter-stimulus-intervals may indicate incomplete convergence to a single channel for those lowest-inter-stimulus intervals (Resulaj et al., 2009).

What is the relationship between intermittent control and modularity of motor output?

The existence and nature of the modules in the control architecture is far from settled. For instance, regularity and low-dimensionality in the motor output are often taken as an indication of modularity but could they simply be a by-product of optimization and task constraints? Moreover, what are the relationships between modules at different levels, such as muscle synergies and basic action concepts?

Our data for this whole body tracking task and for the visuomanual tasks that we have studied (cf. van de Kamp et al., 2013) shows refractoriness compatible with a single channel hypothesis as embodied in our intermittent control model (**Figure 1**). From psychology, refractoriness of this kind has been demonstrated to be associated with response selection according to a single channel hypothesis (Pashler et al., 1998). Biological systems are characterized by redundancy at multiple levels. Many joint configurations can produce the same end effector location, many actuator/muscle activation patterns produce the same joint torque, many control/neural activation patterns and pathways can produce the same actuator/muscle activation. Our data, combined with the evidence from psychology, leads us to propose that a process of selecting one movement alternative from the many possible occurs within the feedback loop that regulates this head tracking task (cf. **Figure 7**).

Selection of task in the space of performance variables and translation to elemental variables seems common to many schemes. To aid discussion of this question, we show in **Figure 7** two main schemes. In the first scheme (see **Figures 7A,B**), the redundancy problem is solved outside the main feedback loop within a planner. The planner provides hierarchically and temporally prior settings to the main feedback loop, which is continuous and parallel in nature. We regard this scheme as broadly representing the prevailing idea of biological control discussed by many authors within the continuous optimal feedback paradigm (e.g., Li et al., 2004; Todorov, 2004; Todorov et al., 2005; Lockhart and Ting, 2007; Karniel, 2011, 2013; Pruszynski and Scott, 2012; Safavynia and Ting, 2012). It has been argued that this scheme is, however, un-biological (Cisek, 2005). In the second, alternative, scheme (see **Figures 1**, **7C,D**) we propose a new hypothesis that the redundancy problem is solved within the feedback loop in a refractory response selector. The refractory response planner continuously observes multiple sensory input and multiple possible task-goal choices. The refractory response selector converges the redundant possibilities into a single output which is communicated intermittently to the response execution process. The response execution process translates the single output synergistically to the multiple muscles according to its current parameter settings. Once these are selected, the underlying control actions in the space of the elemental variables can be achieved by lower order mechanisms such as pattern generators, muscle modes, synergies, or optimal feedback systems. This second scheme generalizes the intermittent control hypothesis presented in **Figure 1**.

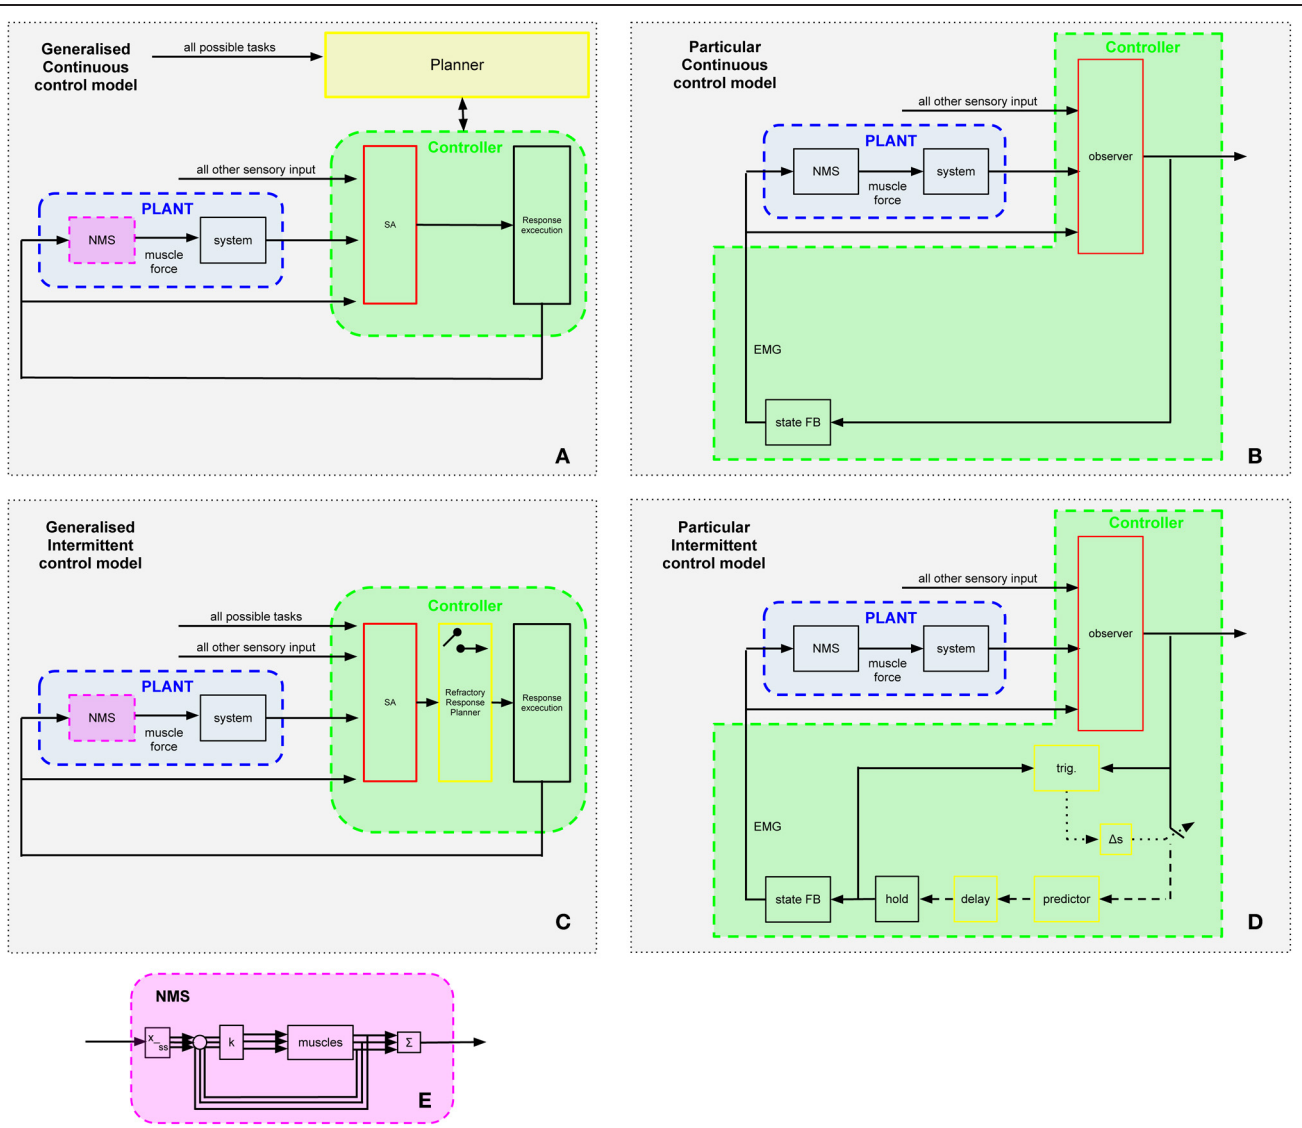

FIGURE 7 | Generalized control schemes. In the Continuous Optimal Feedback scheme (panel **A**), task selection occurs at the "Planner" level ordering the selected strategy to be employed continuously via the low level feedback mechanism. This feedback loop consists of the "Controller" enclosing the continuous stages of sensory analysis (SA) and response execution (RE). Panel **B** shows a particular version of panel **A**: a standard engineering controller with observer and state FB blocks. The command signal serves as a single input to the "Plant" whose neuro-muscular system (NMS; panel **E**) synergistically (e.g., pattern generators, muscle modes, synergies, or optimal feedback systems) translates it to the multiple muscles according to its current parameter settings. Once these are routed, the underlying muscle forces actuate the multi-segmental system in the space of the elemental variables. In the generalized Intermittent Control scheme (panel **C**), the IC model (i.e., the "refractory Response Planner" from **Figure 1**) forms the intermediate stage between sensory analysis (SA) and response execution (RE); an online process of selecting one movement alternative from the many possible which occurs within the feedback loop that regulates the task. Panel **D** shows a particular version of panel **C** based on the authors' implementation of intermittent control in engineering terms (Gawthrop et al., 2011, **Figure 2**). Panel **E** shows a particular hierarchical representation of the NMS block of panels **A**–**D** where k is the feedback gain, Sigma generates a weighted sum of muscle forces and $x_{_ss}$ synergistically allocates the desired forces to each muscle.

Is there a possible rationale for why biological control should converge to a serial process along a single channel?

Exploitation of redundancy is biologically important. Biological systems generally exploit redundancy to improve robustness and flexibility of control (Karniel, 2011). The exploitation of all available DOFs to maximize performance and flexibility is generally a sign of skill and learning (Bernstein, 1967, page 107–108), whereas the elimination of available DOFs is usually a symptom of declining ability through age (Hsu et al., 2012), disease (Oude Nijhuis et al., 2008; Pasman et al., 2011), or fear (Adkin et al., 2002).

Utilization of redundant possibilities requires selecting one possibility from many at any instant. Fundamentally, the process is one of convergence and as stated by Cisek (2005), "the processes of motor planning appear to be inextricably entwined in the processes of decision-making." Important questions are whether

convergence should narrow to a single channel and whether convergence should lie within or outside the main feedback loop. For example choice might be exercised once in selecting one strategy which is employed continuously via low level feedback mechanisms or choice might be exercised online during execution of the task in mechanisms which allow or require choice to be exercised iteratively within the feedback loop between sensory input and motor output. We see two relevant issues, namely compatibility and optimization of coordination, and rate of implementation of selection.

Compatibility and optimization of coordination: Some human tasks are incompatible. We cannot point and make a fist; we cannot flex our knees while at the same time extending them; we cannot walk and stand still simultaneously. Some tasks are partially compatible, for example walking and pointing. To avoid simultaneous engagement in mutually incompatible tasks is obviously essential. More subtly, the selection of compatible routines and the suppression of routines which are partially incompatible or merely inappropriate must underlie skilled and economical task performance. When we perform compatible tasks simultaneously such tasks need to be fully integrated to prevent mutual interference. One way to do this is to select sequentially a compatible family of lower level modules such as pattern generators, muscle modes, and synergies which translate the command to control actions. By using a single channel, only one such compatible family is selected at one time and all others are held off. For this experiment staying upright and tracking a dot might be two independent compatible tasks, two independent incompatible tasks, or one coordinated task. Our reasoning is that optimization of coordination of two tasks (dot tracking and staying upright) by eliminating mutual interference—in effect—becomes the same thing as controlling a single task in the task-space. Hence we offer the rationale that optimization of coordination leads to unification of control into a single synergy requiring a single channel for its selection.

Rate of implementation. We suggest that maintaining the response selection process within the feedback loop, maximizes the rate at which response selection can be translated to motor output as an open loop process. The alternative of placing the response selection process temporally or hierarchically outside the feedback loop reduces the rate of translating response selection to motor output because it imposes the closed loop dynamics of the feedback control loop onto the translation between response selection and motor output (cf. **Figure 7**).

To summarize, until the point of selection, competitive commands could be prepared in parallel as envisaged in models of decision making (Cisek, 2005; Sinha et al., 2006; Carpenter et al., 2009; Noorani et al., 2011). After selection, competitors should be suppressed (Neumann, 1996). The duration of the suppression should be sufficient for the command to be executed without interference. Convergence of parallel input to a sequential, serial process along a single channel seems the ideal solution to maximize optimal, coordinated function. The serial process involves planning, selection and temporary inhibition of competing responses prior to low dimensional motor output. The serial, ballistic nature of the process removes the obligation of closed loop dynamics from response generation. The consequences are intermittent control and refractoriness. Because all input is squeezed through a single channel this is often referred to as a "bottleneck."

Is there a plausible neural substrate for intermittent control and refractoriness?

Some authors support a theory of central IC, with a short planning interval (100 ms), neurologically based in a cerebello-thalamo-cortical loop, and related to a form of physiological tremor ("movement discontinuities" or "bumps") during slow movement (Vallbo and Wessberg, 1993; Neilson and Neilson, 2005; Bye and Neilson, 2008, 2010). However, these high frequency oscillations may simply be an effect of limb resonance (Lakie et al., 2012). Our recent evidence associates IC with longer open loop intervals (250–500 ms) related to the low bandwidth of voluntary control (Craik, 1947; Vince, 1948; Navas and Stark, 1968; Hanneton et al., 1997; Slifkin et al., 2000; Loram and Lakie, 2002; Loram et al., 2005, 2011, 2012; van de Kamp et al., 2013). The "bottleneck" associated with these longer periods of refractoriness does not occur at perceptual or motor stages of information processing, but at some central stage (Pashler and Johnston, 1998; Sigman and Dehaene, 2005). Where is it located? Some brain imaging evidence using dual tasks links have suggested frontal or pre-frontal cortical structures (Jiang and Kanwisher, 2003; Dux et al., 2006). However, Szameitat et al. (2006) have suggested that the increased activity of the prefrontal structures may represent an active task scheduling mechanism (response planning—temporal ordering of the dual tasks) rather than suggesting that this is the site of the bottleneck. It may be that the bottleneck analogy—which suggests a restriction continuously throttling the flow—leads to a search for the wrong type of mechanism. A better metaphor might be that of a conductor, who intermittently engages and suppresses sections of his orchestra. The central limitation is then the rate at which the intermittent adjustments can be made. Where in the brain is an appropriate switching mechanism which involves selective inhibition and facilitation of global motor activity (the central conductor) to be sought?

The basal ganglia are a clear possibility. They are now believed (e.g., Redgrave et al., 1999) to operate as a generic action selection system, receiving input from a broad range of other brain areas, and producing output that selects particular actions to perform. The opposing roles of the two cortical re-entrant loops (direct loop—thalamic facilitation of cortical output via *ansa lenticularis*) and the indirect loop (thalamic inhibition of cortical output via *globus pallidus pars externa*) might provide a plausible mechanism to engage and inhibit cortical outputs. Gurney et al. (2001) have suggested a basal ganglia mechanism whereby *salient* actions are selected and *promiscuous* actions are suppressed, rather like center—surround antagonism in visual processing. There is evidence that the basal ganglia are important to response selection, are associated with refractoriness and are part of the IC loop (Houk et al., 2007). These findings have been used to link the basal ganglia with computational models of IC and with neurological and behavioral deficits in decision making and action selection associated with Parkinson's disease, schizophrenia and

Attention Deficit Disorder (ADD) (Houk et al., 2007). This justifies the possibility that functional deficits in Parkinson's disease including the initiation and selection of new responses, freezing, and postural rigidity might be related to deficits in the IC loop. Clearly, it would be interesting to find physiological and anatomical evidence positively linking IC to the basal ganglia. Do they work as an intermittently adjusted selector switch, and what happens when this switch is damaged by disease?

Could the design of autonomous robots benefit from a module including a serial, single channel process?

Robots, like humans contain redundant possibilities within a multi-segmental structure. The rationale for a serial, single channel process as necessary to optimize task selection and coordination from redundant possibilities applies equally in this case as it does for humans. Intermittent control implements a serial, single channel process as the appropriate engineering solution to control problems in which there is a time consuming online computational process (Ronco et al., 1999). When the actuators, the system being controlled and the external constraints are time invariant, then the control signal can be computed rapidly from measured quantities, the reference signal, and pre-computed parameters such as the gains of a continuous optimal controller. However, when the actuators, system and constraints are time varying then online optimization and computation of the control signal is desirable. Intermittent open loop predictive control uses an intermittently moving time horizon which allows slow optimization to occur concurrently with a fast control action. This approach allows handling of time varying systems and constraints at the expense of increased online computational requirement. Thus, intermittent control provides for a time consuming online optimization process which lies at the heart of flexible predictive control. A serial, single channel process, and its implementation through intermittent control, appears to be a valuable element missing from current schemes.

CONCLUSION

Eight participants controlled their multi-segmental body to ensure their head tracked a stepwise moving target as fast and accurately as possible. This is a one degree of freedom task with control redundancy. Analysis showed enhanced delays in response to target steps with close temporal proximity to the preceding step. This evidence of refractoriness is incompatible with control as a linear time invariant process. This evidence is consistent with a single-channel serial ballistic process within the intermittent control paradigm with a substantial intermittent interval related to the bandwidth of voluntary control. A control architecture reproducing intentional control of human movement must reproduce refractoriness and provide a solution to redundancy. Albeit at this stage not an experimental -deductive conclusion we suggest that best coordination of redundant possibilities provides a rationale for why the biological control architecture might converge parallel sensory input to a serial single channel process involving planning, selection and temporal inhibition of alternative responses prior to low dimensional motor output. Intermittent control, a serial, single channel process, is designed to provide computational time for an online optimization process and is appropriate for flexible adaptive control. Such design has potential to aid robots to reproduce the flexibility of human control.

Along with superior performance, research indicates that expertise is associated with a number of mediating cognitive adaptations. To this extent, extensive practice is associated with the development of general and task-specific mental representations, which play an important role in the organization and control of action. Recently, new experimental methods have been developed, which allow for investigating the organization and structure of these representations, along with the functional structure of the movement kinematics. In the current article, we present a new approach for examining the overlap between skill representations and motor output. In doing so, we first present an architecture model, which addresses links between biomechanical and cognitive levels of motor control. Next, we review the state of the art in assessing memory structures underlying complex action. Following we present a new spatio-temporal decomposition method for illuminating the functional structure of movement kinematics, and finally, we apply these methods to investigate the overlap between the structure of motor representations in memory and their corresponding kinematic structures. Our aim is to understand the extent to which the output at a kinematic level is governed by representations at a cognitive level of motor control.

Keywords: mental representation, basic action concepts, kinematic structure, spatio-temporal kinematic decomposition of movement, structure dimensional analysis—motorics, hierarchical motor control, memory structure

INTRODUCTION

Research on expertise in sports has shown that skilled performance is based not only on physical ability, but equally on task-specific cognitive competences. During extensive practice, relevant mental representations are formed, adapted, and reorganized in such a way that flawless performance is progressively facilitated, based on increasing order formation in the athlete's long-term memory. According to the perceptual-cognitive perspective, actions are planned and performed on the basis of structured cognitive representations of action effects in motor memory (Hommel et al., 2001; Mechsner et al., 2001; Schack and Mechsner, 2006; Hoffmann et al., 2007; Shin et al., 2010). Furthermore, because these representations govern the tuning of motor commands and muscular activity patterns, skillful coordination occurs when appropriate mental representations of the motor task and action goals are constructed (Schack and Ritter, in press). In order to illustrate how these processes can be conceptualized and explored empirically, we will present studies that investigated the organization of task-related cognitive structures, and the way these structures correspond to functional components of skilled motor performance. Additionally, we will present a new empirical approach for linking these mental structures to the structures observed within the movement kinematics. Before we turn to the methodological aspects of these studies, we will first present the underlying theoretical conceptualization of the cognitive architecture of human motor action, beginning with the concept of mental representations, which is fundamental to this approach.

MENTAL REPRESENTATIONS OF HUMAN MOTOR ACTION

The idea that cognitive representations play an important role in motor control is reminiscent of classical ideas in psychology, such as the "ideomotor" approach adopted by Lotze (1852) and James (1890) in the 19th century or the model-theory studies of the construction of movement presented by Bernstein (1947) in the middle of the 20th century. James wrote for instance 1890 in his now seminal work *The Principles of Psychology*: "We may . . .lay it down for certain that every representation of a movement awakens in some degree the actual movement which is its object" (p. 526). Recently, the term mental representation has been widely used in a large variety of disciplines, often with rather diverse content. Gilbert and Wilson (2007) have stated: "the mental representation of a past event is a memory, the mental representation of a present event is a perception, and the mental representation of a future event is a plan." Even though this definition sounds viable, it might not be sufficient for our purposes.

Mental representations were first discussed in the philosophy of language, referring mainly to linguistic representations. Later, the issue was adapted by other disciplines such as philosophy of mind and psychology, and various theories have been formulated to describe the nature of mental representations. From these theoretical perspectives, the functionalistic one seems most relevant in our context, as it states that mental representations predominantly play a functional role for the cognitive system. According to this perspective, the function of mental representations is to make situations and objects cognitively available that are otherwise physically unavailable—in this respect, they are the only way to make non-actual situations and objects available for thinking and acting (Vosgerau, 2009).

Several authors have reflected upon the nature of mental representations of actions (e.g., Rosenbaum et al., 2001), and it has been argued that even mental representations of static objects are dynamic in nature, as they are derived from and based on dynamical action representations, which are evolutionarily more relevant for controlling behavior than representations of static scenes or objects (Freyd, 1987). In the context of the studies presented in the following, we refer to mental representations in terms of states of mind that correspond to experiences, and to the physical reality of objects and movements. Such internal representations arise from exposure to sensory stimuli, are multimodal, and refer to objects or events that we perceive in our environment via the processes of perception and processing in our brain (Barsalou, 2008). Mental representations occur on different levels and, due to the nature of our nervous system, can be independent of the actual presence of the object that they refer to in the world. Our ability to store such representations is the basis of our ability not only to learn, but also to make plans and predictions regarding what will happen in the future. Wilson (2002) points out that our cognitive apparatus can even construct mental representations of situations that we have never experienced, purely on the basis of linguistic input. Mental representations thereby play a central role in the control and organization of actions, serving as "organizers of activity" (Steels, 2003). In cognitive systems, internal representations co-evolve together with corresponding actions and become vehicles for higher mental functions, such as thinking and planning (Steels, 2003). As a consequence, these representations stay closely connected to the actions they serve (Glenberg, 1997), resembling them most crucially in terms of structural similarity (Johnson-Laird, 1989). Mental representations are considered vital for learning complex movements and movement sequences, for refining and adapting learned movements to the requirements of actual situations, and for automatizing movement patterns on an expert level. Expert performance in sports is typically characterized by a high degree of control and a sense of clarity, which can arise based on regularities in the mental representation that allow for relieving cognitive load, or, as Wilson (2002) has put it, for circumventing the "representational bottle neck."

REPRESENTATIONS AS A BASIS FOR ACTION CONTROL

Current perspectives in cognitive psychology suggest that actions are represented in terms of their anticipated perceptual effects (e.g., Prinz, 1997; Hommel et al., 2001; Knuf et al., 2001). Interestingly, these perspectives resonate with the earlier ideas of Bernstein (1996a,b, 1967) regarding the construction and control of movements. Prior to the current perspectives, Bernstein had already pointed toward the large number of degrees of freedom in the human motor system, the need for continuous processing of sensory feedback to control this highly redundant system, and the importance of the anticipation of movement effects for movement organization. Bernstein (1996a,b, 1967) proposed a model of the construction of movements according to which different organizational (and evolutionary) levels interact to generate and control different types of movement. These levels are thought to interact not simply in a fixed hierarchical manner, but their mode of interaction and hierarchical organization depends on the type of movement task and the level of expertise of the performer. Bernstein's model claims that movements are constructed on the basis of five levels described as (1) paleokinetic regulation (regulation of muscular tonus and basic postures, including tonic reflexes), (2) synergies (dynamical stability of movement, rhythmic and cyclic movement patterns), (3) movement in space (spatial orientation and object manipulation), and (4) action (volitional control of movements, object-related action, focus of attention), and (5) symbol coordination (symbolic action control, speech).

Bernstein's model reflects the general idea that movement control is based on representations, which serve intentional movement planning, and that these representations reflect the functional movement structure. Alongside Bernstein's approach to the construction of action, there have been several formulations of the idea that movement control is constructed hierarchically. The model we propose here provides a comprehensive account for the way complex movements are controlled, stemming from the volitional initiation of the action to the lowest level of motor control. Thus, this model acts to provide the relevant framework for a connection between mental representations and motor output. Specifically, the model proposed views the functional construction of actions (Schack, 2004; Schack and Ritter, 2009; Maycock et al., 2010) on the basis of a reciprocal assignment of performance-oriented regulation levels and representational levels (see **Table 1**). These levels differ according to their central tasks on the regulation and

Table 1 | Levels of motor action (modified from Schack, 2004; Schack and Ritter, 2009).

Code	Level	Main function	Subfunction	Tools
IV	Mental control	Regulation	Volitional initiation control strategies	Symbols; strategies
III	Mental representation	Representation	Effect-oriented adjustment	Basic action concepts
II	Sensorimotor representation	Representation	Spatial-temporal adjustment	Perceptual representation Internal models
I	Sensorimotor control	Regulation	Automatization	Motor primitives basic reflexes

representation levels. Each level is assumed to be functionally autonomous.

Both control levels, the *level of sensorimotor control* (I) and the *level of mental control* (IV), serve the main function of regulation, whereas the *level of sensorimotor representation* (II) and *level of mental representation* (III) are representational, and are closely connected to the two regulation levels. Levels I and II could be understood as responsible for the functional manipulation of objects and events, whereas levels III and IV can be assigned a more distal focus on objects and events. All levels are connected and interact with each other, but are functionally autonomous.

The *level of sensorimotor control* (I) is based on movement primitives and directly linked to the environment. It is induced perceptually, built on functional units composed of perceptual effect representations, afferent feedback, and effectors. The essential invariant, or set value, of such functional units is the representation of the movement effect within the framework of the action. The system is broadly autonomous, and automatisms emerge when the level of sensorimotor control possesses sufficient correction mechanisms to ensure the stable attainment of the intended effect. Studies of patients with impaired motility showed that the execution of movements can best be realized via anticipated sensory effects, and that such direct sensory effects are the crucial invariant of movement control (e.g., Van der Weel et al., 1991).

Modality-specific information representing the effects of the particular movement is stored on the *level of sensorimotor representation* (II). The relevant sensory modalities might change as a function of the level of expertise in the learning process and as a function of the task context. Grasping movements, for instance, are associated with kinesthetic, tactile, visual, and (in part) auditory feedback. This involves the representation of perceptual patterns of exteroceptive and proprioceptive effects that result from particular movements and refer back to the action goal. During the first steps of learning a novel complex motor action in sports, visual information is often used to monitor body posture and movement timing. In later stages of the learning process, proprioceptive information gains increased meaning, and aspects related to body position and timing are no longer needed to be monitored consciously. During the learning process, movement automatization is characterized by increasingly adequate correction mechanisms between levels I and II.

The *level of mental representation* (III) predominantly forms a cognitive workbench for the *level of mental control* (IV). The *level of mental representation* is organized conceptually, and is responsible for transforming the anticipated action effects into movement programs that sufficiently bring about desired outcomes. According to Bernstein (1967), an action is a structure subdivided into details, and action organization therefore has to possess a working model of this structure, containing the topology and spatiotemporal effects of the action. Mental representations of movement structures that serve this purpose are located within the *level of mental representation (III)*, and are based on the conceptual building blocks of action Basic Action Concepts (BACs) that will be described in the following section.

The *level of mental control* (IV) is induced intentionally and is relevant for the anticipation of effects. Movements are planned, controlled, and performed with reference to the anticipated effects, or intended goal postures (e.g., Rosenbaum and Jorgensen, 1992; Rosenbaum et al., 1992; Kunde and Weigelt, 2005). Findings from such studies suggest the existence of a mental model of the action, including its outcome, to which all control processes can be related. Level IV comprises functional components of volition or mental control, such as the coding of intended effects into action goals. Specifically in the context of sports, instructions and self-applied strategies for focusing attention and stabilizing performance are important aspects of mental control on this level.

REPRESENTATION UNITS IN MOTOR ACTION

Perceptual-cognitive approaches propose that motor actions are formed by cognitive representations of target objects, movement characteristics, movement goals, and the anticipation of potential disturbances. Movements can be understood as a serial and functional order of goal-related body postures (Rosenbaum et al., 2001) and their transitional states. Furthermore, the link between movements and perceptual effects is bi-directional and based on information that is typically stored in a hierarchical fashion in long-term memory.

Based on Schack's Cognitive Architecture model (see **Table 1**), complex movements can be conceptualized as a network of sensorimotor information. The better the order formation in memory, the more easily information can be accessed and retrieved. This leads to improved motor performance, which reduces the amount of attention and concentration required for successful performance. The nodes within this network contain functional subunits, or building blocks, that relate to motor actions and associated perceptual and semantic content. These building blocks, termed BACs can be understood as representational units in memory that are functionally connected to perceptual events; or as functional units for the control of actions at the level of mental representation, linking goals at the level of mental control to perceptual effects of movements. Such BACs are activated by representations of starting conditions and deactivated by effect representations, both at the perceptual level.

Underlying neurocogntitive theories state that actions are represented in functional terms as a combination of action execution and the intended or observed effect, or movement goal (Prinz, 1997; Hommel et al., 2001; Knuf et al., 2001; Koch et al., 2004). BACs can be regarded as cognitive tools for the execution of actions such as complex movement tasks in sports (see Schack, 2004). Within these tasks, BACs serve the purpose of reducing the cognitive effort necessary for controlling the action. The same applies to actions performed in everyday life, as their successful execution often depends on experience and thereby requires a level of expertise the performer is hardly aware of.

Altogether BACs can be viewed as the mental counterparts of functionally relevant elementary components or transitional states of complex movements. They are characterized by recognizable perceptual features. They can be described verbally as well as pictorially, and can often be labeled with a linguistic marker. "Turning the head" or "bending the knees" might be examples of such BACs in the case of, say, a complex floor exercise. As mentioned above, each individual BAC is characterized by a set of closely interconnected sensory and functional features. For

example, a BAC in tennis like "*whole body stretch motion*" is functionally related to providing energy to the ball, transforming tension into swing, stretching but remaining stable, and the like. Afferent sensory features of the corresponding submovement that allow monitoring of the initial conditions are bended knees, tilted shoulder axis, and body weight on the left foot. Reafferent sensory features that allow monitoring of whether the functional demands of the submovements have been addressed successfully are muscles stretched and under tension, proprioceptive and, finally, perhaps visual perception of the swinging arm and ball in view.

BACs are stored at a basic level of representation and are investigated and defined by experimental methods (like reaction time-measurement) or with the help of biomechanical methods. Altogether the methods are used to learn about the basic body postures of a particular movement and their mental counterparts in memory. The number of BACs that can be assigned to a given movement task depends on the complexity of the task, on the way it has been learned and trained, and on the level of expertise of the addressee. It is hardly possible to define BACs without the extensive feedback and cooperation of persons who master the task with varying levels of expertise, taking into account their different types of knowledge. Consequently, it is important to take the experience of teachers into account, and to also look at the way the task is actively structured during learning and training, as concepts that emerge during training are likely to remain intact as scaffolding in long-term memory. During the experimental procedure, BACs can be represented as pictures or verbal labels that are meaningful to the participants in order to trigger movement-related long-term memory content. Pictures and verbal labels differ slightly in the way they address mental representations. Presenting an action in pictures instead of words commonly allows for a higher temporal resolution, however, dynamical cues cannot be represented in static pictures unless the stimuli are augmented by verbal terms or symbols (e.g., arrows). Furthermore, pictures represent very short time segments that have a clear temporal order within the action, whereas verbal terms can relate to longer-lasting and synchronous partial actions.

MEASURING MENTAL REPRESENTATIONS

In principle, there are two methodological approaches to the experimental study of mental representation structures: to determine them from response behavior or to determine them from reaction times. Whereas the first approach has been used for the study of order formation in LTM, the second approach should be used only to ascertain chunk structures in working memory. Schacks architecture model proposes that not only the LTM structure of mental representations but also the exploitation of working-memory capacity serve a notable function in the organization of movement acts. It assumes that working memory forms a unit that is structurally and functionally distinct from LTM. A particular interesting method to measure structures of mental representation in LTM, the so called Structure Dimensional Analysis (SDA) method has been originally developed by Lander and Lange (1996) in cognitive psychology for ascertaining relational structures in a given set of concepts, and adapted by Schack (2001) for analyzing representations of movements (Structure Dimensional Analysis—Motorics, SDA-M). This experimental approach has been documented in several contributions (Schack, 2004; Schack and Mechsner, 2006; Hodges et al., 2007; Schack and Hackfort, 2007; Schack, 2012). Importantly, the method does not ask the participants to give explicit statements regarding their representational structures, but rather reveals this structure by means of knowledge-based decisions in an experimental setting. Altogether, the SDA-M consists of four steps: First, a special splitting procedure requires one to subjectively differentiate whether or not a given BAC is "functionally close" to another, or not. A randomly selected BAC is presented as the standard unit, or anchor, and all other BACs are displayed below the anchor in a randomly ordered list. One after another, each BAC is subjectively compared for similarity to the anchor. Thereby, the list of BACs is split into two subsets, a positive ("close") and a negative ("not close") set, which are then repeatedly submitted to the same procedure, until every BAC has been compared to every other. Based on the participants' decisions, the program sums the positive and negative subsets separately and delivers an Euclidian distance scaling between the items (BACs). Second in the process, a hierarchical cluster analysis is used to transform the set of items into a dendrogram.

Third, a dimensioning of the cluster solutions is performed through a factor analysis linked to a specific cluster-oriented rotation process, resulting in a factor matrix classified by clusters. Finally, because the cluster solutions can differ both between and within individuals, a within- and between-group comparison of the cluster solutions is performed using a structural invariance measure lambda to determine their structural invariance (Lander, 1991; Schack, 2010). The structural invariance measure is determined based on three defined values: the number of constructed clusters of the pair-wise cluster solutions, the number of items within the constructed clusters, and the average quantities of the constructed clusters. The lambda value is calculated as the square root of the product of two factors; one factor being the weighted arithmetic mean of the relative average quantity of the constructed clusters, the other one being the proportional number of clusters in the compared cluster solutions.

SDA-M can be applied in two alternative modes, a direct and an indirect scaling mode. In the direct scaling mode, participants make direct judgments about the functional equivalence of pairs of BACs (BAC × BAC: pairs of BACs are judged as closely or not closely related to each other). In the indirect scaling mode, decisions concerning the functional relationship of BACs are made on the basis of features (e.g., spatial, temporal or force parameters of a given movement) that are assigned to the BACs, with the BACs serving only as anchors, and features being judged as belonging or not belonging to the anchor in the context action (BAC × features: features are judged as closely or not closely related to anchor BACs). To determine classification probabilities of features in relation to BACs, the initial z-matrix is transformed into a probability matrix (p-matrix), consisting of p-values that indicate the classification probabilities of features to individual BACs belonging to clusters. Both modes of the SDA-M method include a hierarchical cluster analysis that reveals clusters of BACs (step 2); the difference is that in the indirect scaling mode the features are predefined, whereas in the direct scaling

mode the concept dimensions can be accessed via a factor analysis (step 3).

PREVIOUS STUDIES INVESTIGATING MENTAL REPRESENTATION STRUCTURES

In the past, the SDA-M method has been used to study differences between groups who vary in their experience with cognitive or motor tasks. In the following, examples of such studies will be given to demonstrate the broad spectrum of potential applications of the Cognitive Architecture approach.

Schack and Mechsner (2006) applied the SDA-M method to investigate participants' mental representations of the tennis serve by comparing the structures of high-ranking tennis players, low-ranking players, and novices. With the help of tennis experts and coaches, 11 BACs were defined for the tennis serve in relation to the functional movement structure that can be derived on the basis of biomechanical movement parameters. According to this structure, the tennis serve consists of a pre-activation phase that serves to build up tension energy, the strike as the main functional phase during which the energy is conveyed to the ball, and the final swing during which the racket is decelerated and the body is brought back into a stable position. The results of the study showed that the mean group cluster solution of the high-ranking players corresponded to the functional movement structure, reflecting the three functional phases. The low-ranking players' cluster solution combined the strike and the final swing into one cluster that was differentiated from the pre-activation phase. The novices' solution did not contain any clusters, reflecting a lack of functional order formation within this group. Thus, the authors found that the mental representation structure of the experts were well matched to the functional and biomechanical demands of the task, whereas, the low-ranking and novice players' representations were less hierarchically organized and not matched to the biomechanical demands of the task.

Similarly, Bläsing et al. (2009) applied the SDA-M method to compare the mental representations of classical dancers varying in expertise level and dance novices. Mental representations of two well-defined movements from the classical dance repertoire, the *pirouette en dehors* and a small jump called *petit pas assemblé*, were investigated in professional ballet dancers, advanced ballet amateurs, amateur beginners, and sport students without any dance training experience. The results for the *pirouette* revealed that the mean cluster solutions of both groups of professional dancers and advanced amateurs corresponded to the functional phases, with only minor differences. The beginners' cluster solution differed largely from the others and did not show much alignment with the functional phases, and the novices hardly formed any relevant clusters. For the *pas assemblé*, no difference was observed between the two groups of amateurs. Amateurs and novices formed clusters that included all BACs and were similar to the clusters formed by the experts, only the experts' cluster solution reflected the dynamical initiation of the jump, corresponding to the functional phases.

In a follow-up study, the SDA-M method was applied in indirect scaling mode (BAC × feature), in which the BACs appear only as anchors, and features are sorted in relation to these anchors (Bläsing and Schack, 2012). The same movements were used, and the BACs defined for the first study were presented as anchors. Spatial direction labels as features were related to these anchors, and the participants (who had already taken part in the previous study, Bläsing et al., 2009) were instructed to answer positively for spatial directions which they associated with a given BAC within an egocentric reference frame, according to their own motor imagery of the movement. Results showed that for the *pirouette*, only the professional dancers' mean cluster solution contained one cluster that clearly corresponded to the main functional phase and associated this phase with relevant directions. The amateurs' mean cluster solution did not result in any functional clusters, and the novices' did not contain any clusters at all. For the *assemblé*, professionals' and amateurs' cluster solutions associated the main functional phase with relevant spatial directions, whereas in the novices' cluster solution did not correspond to the functional movement parameters.

The SDA-M method has not only been applied to compare task-related cognitive representations of experts to those of novices, but also to monitor differences between developmental stages. In a study on anticipatory motor planning in children, Stöckel et al. (2012), investigated the end-state-comfort (ESC) effect in children aged 7–9 years. Additionally, the children took part in an SDA-M task with pictures of a hand grasping common objects in different ways. Only the 9-years old children produced a cluster solution that separated uncomfortable from comfortable grasps. In combination with the results of the ESC experiment, the study showed that 9-years old children had more distinct representations of comfortable and uncomfortable grasp postures and a better ability to plan movements to end in comfortable postures compared to younger children. Furthermore, both abilities were found to be related, as children who clustered by grasp comfort also showed the ESC effect, whereas children who did not cluster by grasp comfort performed less consistently in the ESC task, suggesting that cognitive representations of grasp postures are crucial for manual posture and action planning.

In the presented studies, the SDA-M method was applied to investigate general differences in cognitive skill representation between participants of varying levels of expertise or developmental stages. For this purpose, mean cluster solutions of groups of participants were compared, with each group representing a defined level of expertise and cluster solutions being understood as typical for this expertise level. The studies did not, however, pay attention to cluster solutions of individual participants within these groups, nor inter-individual differences in cognitive movement representations. This individual approach was taken by Weigelt et al. (2011), who studied the mental representations of a Judo throwing technique (Uchi-mata) in judoka who were competing on the national team level. The individual cluster solutions of two of the eight participants examined in this study were compared *post-hoc* to the mean group cluster solution, which represented the functional movement phases as expected. The individual cluster solutions differed in details from the mean cluster solution and functional reference structure, reflecting individual preferences and technical differences as well as weaknesses in the judokas' performance. The authors point out that such difference, interpreted with accuracy and care, can reveal subtle flaws in the technical skills of the athlete and

can be used by an expert coach to improve and adapt further training.

Comparison between individual cluster solutions and group average cluster solutions has also been used in the context of rehabilitation. Braun et al. (2007) used SDA-M to analyze the mental representations of a common everyday activity, drinking from a cup, in elderly patients recovering from stroke. Sixteen patients 3–26 weeks after their stroke took part in the study as part of their rehabilitation program, along with sixteen matched controls. SDA-M was applied using pictures representing the action sequence, augmented with arrows indicating movement directions if necessary. The results of all participants were regarded individually. The sixteen control subjects produced very similar cluster solutions consisting of two or three clusters corresponding to the functional action phases. The stroke patients' cluster solutions differed largely from those of the control group and from each other and were characterized by a weak functional integration of BACs, ranging from incomplete functional over non-functional clusters to a total absence of clusters. The study showed that SDA-M can be applied as a tool in rehabilitation, even in patients with reduced motor and cognitive capabilities.

Bläsing et al. (2010) used SDA-M to compare individuals with congenitally missing limbs, one of them with congenital phantoms of arms and legs, to different control groups. Instead of BACs, body parts and related activities were used as items in order to evaluate the mental representations of the participants' own bodies. The results revealed that the cluster solution of the individual with congenital phantom limbs, the existence of which had been affirmed in several previous studies using behavioral and neurophysiological methods, differed only slightly from the groups' cluster solutions, showing the same modular structure (Haggard and Wolpert, 2005). In contrast, the result of the individual who had never experienced any phantoms, however, differed largely from this modular structure, but rather reflected the individual's typical use of his body in everyday activities, providing evidence for an action-based influence on the adaptive body representation (Haggard and Wolpert, 2005). The findings from this study suggest that the SDA-M method might provide empirical access to the body schema, which is inextricably linked to the motor system and is constantly involved in the planning and execution of motor actions (de Vignemont, 2010).

The striking differences in representations found between high- and low-level performers support the assumption that motor learning leads to the development of task-specific representations, which play an important role in the control and organization of actions (e.g., Elsner and Hommel, 2001). According to skill acquisition theories (e.g., Fitts and Posner, 1967; Anderson, 1982, 1993, 1995), the cognitive mechanisms governing task performance are refined over the course of learning. To this extent, learning can be viewed as the modification and adaptation of representation structures in long-term memory (Schack, 2004; Schack and Ritter, in press). To directly test this assertion, Frank et al. (2013) investigated the developmental change in mental representation structures over the course of early skill acquisition of a complex motor task. Specifically, the authors employed a longitudinal design in which a group of novices practiced a golf putting task over the course of five training days. Both the change in participants' putting performance as well as the developmental change in the structure of the participants' mental representations were assessed before and after training. Results indicated that along with improved putting proficiency, significant developmental changes emerged within the practice group's mental representation as a result of task practice. These findings support the notion that functional adaptations of mental representations are closely tied to motor learning.

Research in the area of training and feedback has indicated that the type of attentional focus induced by training instructions can significantly impact the quality and rate of skill acquisition. To this extent, instructions that promote an external focus of attention (i.e., attention given to the effects of the movement on the environment) can lead to improved motor learning and retention (e.g., Wulf et al., 1999), reduced working memory demands (e.g., Wulf et al., 2001), reduced susceptibility to performance pressure (e.g., Land and Tenenbaum, 2012), and overall, better outcome performance (e.g., McNevin et al., 2003). Given that the sensory consequences of motor actions are considered an important component within mental representations (e.g., Ford et al., 2007), it appears likely that focusing on the sensory effects of one's movement (i.e., an external focus) during learning may act to facilitate the integration of perceptual effects during the formation of one's mental representation, leading to a more refined representation structure.

To explore this question, Land et al. (submitted) examined the developmental change in participants' representation structures as a function of instruction type. Specifically, novice participants trained on a golf putting task over the course of three training days. For half of the participants, training instructions were given to direct attention to the external effects of their movement (i.e., the roll of the golf ball). For the other half of participants, instructions were given such that attention was directed internally to the execution of the movement (i.e., focus on the swing of the arms). At the conclusion of practice on the third day, results indicated that both training groups displayed improved putting performance along with significant functional changes in their underlying mental representation. However, the performers who were given instructions that directed attention to the sensory consequences of their movement significantly outperformed the group who trained while focusing on skill execution. Additionally, the representation structure of the external learning group was significantly more elaborate and more functionally similar to skilled golfers than those of the internal focus learning group. These findings highlight that the association between movements and their perceptual effects are crucial for learning. To this extent, findings suggest that instructions which emphasize an external focus of attention aid the integration of perceptual effects during the development of mental representations. These findings furthermore give credence to the assertion that sensory consequences of motor actions are an important component within mental representations.

INVESTIGATING THE RELATIONSHIP BETWEEN REPRESENTATIONS AND MOTOR ORGANIZATION

The results of the aforementioned research indicate a clear relationship between mental representations and motor

performance. Specifically, these findings support the hypothesis that voluntary actions are planned, executed, and stored in long-term memory by means of reference structures comprised of BACs. Central to this perspective, mental representations are functionally considered to guide the motor organization during the realization of action goals. In this regard, these representations serve as a cognitive reference for the creation of motor patterns. Given that movements are structured and controlled via these representations, an important theoretical advancement would be to identify direct links between mental representations and movement kinematics in the fulfillment of action goals.

In this direction, Schack (2003) investigated the relationship between mental representations of gymnastic somersaults and the underlying movement kinematics amongst gymnasts of varying skill levels. The results indicated significant correlations regarding the space and time of the movement between kinematic parameters and the structural relationship between BACs within the motor representation. For instance, a significant negative correlation was found between the angular velocity of the somersault and the Euclidean distance between two nodes within the representation structure related specifically to the initiation of the twisting motion.

In a similar investigation, Schütz et al. (2009) were able to show that key biomechanical parameters of a table tennis serve could be modeled based on the mental representation structure of the participants. The movement kinematics and the mental representations of nine table tennis experts revealed that movement duration and ball flight parameters were predictable based on the Euclidean distance between select representation nodes. For example, the movement duration of the table tennis strike could be predicted by the representational distance between the individual BACs "move racket backward" and "move racket downward and forward."

The implications of these two studies indicate that representational structures can be used to predict kinematic parameters of movement for a given task. Specifically, the relationships between local subsets of BACs within a representation structure have been found to be associated with spatial and temporal aspects of movement. However, given that mental representations serve as a reference structure for the unfolding of a movement pattern, it would be important to find a direct link between the structure of the representation and the overall structure of the movement on a more global level. For this to occur, a proper method for decomposing a movement into its structural features must be proposed, which we will do in the following section.

SPATIO-TEMPORAL KINEMATIC DECOMPOSITION OF MOVEMENT

The modern technologies of motion tracking provide researchers with a wealth of kinematic data on the full-body movements of humans, animals, and various robotic platforms. In order to explore this rich data, we have created computationally feasible algorithms for decomposing movements into independent spatio-temporal features directly from the captured kinematic signal. The proposed approach is useful for understanding, interpreting, and modeling complex movements in systems possessing many degrees of freedom, and provides a means for examining the overall structure of a movement.

The following algorithms have been tested on recorded movements from classical ballet and golf, and they allow us to estimate the level of movement expertise, draw the detailed structures of arbitrary complex movements, and automatically classify them into a given repertoire.

From our work on the kinematic analysis of complex full-body movements in classical ballet (see Volchenkov and Bläsing, 2013), we show that a movement tracked by a motion tracking system (MTS) can be understood in terms of a hierarchy of major and minor scales, in which the spatial and temporal components can be separated and studied independently. Based on our Spatio-Temporal Kinematic Decomposition (STKD) method, the major structure of a movement can be assessed. Specifically, the affinity between markers is identified by measuring the distance between them in the largest scale of kinematic signal, and by visualizing the results via a dendrogram. This approach reveals the functional relationship between markers by their geometric proximity. The typical character of movement is featured by the few major scales, while the minor scales determine the individual movement traits and can uniquely disclose the individual level of movement expertise, uneven distribution of the fine motor skills, and the emotional character of an individual (see Volchenkov and Bläsing, 2013 for details). The functional separation of scales can explain why we can perceive movements categorically (for example, as the highly stylized figures of classical ballet).

STKD PROCEDURE

To track ballet movements (as in Volchenkov and Bläsing, 2013), we used a MTS (Vicon Motion Systems, Inc.) based on 12 high-resolution cameras outfitted with IR optical filters and rings of LED strobe lights streaming data at 200 *fps*; the cameras detected the 3-dimensional spatial positions of passive retro-reflective spherical body markers with millimeter accuracy. Markers were attached to key anatomical locations according to the standard Vicon full-body marker placement protocol (Plug-in Gait) (see **Figure 1**).

Scale decomposition of kinematic data

The MTS delivers positional data for N markers, across T time frames ($T >> N$) at the rate of 200 *fps*, in the form of a rectangular $3N \times T$ matrix $\boldsymbol{M} = (x_1, y_1, z_1, \ldots, x_N, y_N, z_N)$, in which the consequent triples of columns, $\boldsymbol{x}_k = (x_{kt1}, \ldots, x_{ktT})^{\mathbf{T}}$, $\boldsymbol{y}_k = (y_{kt1}, \ldots, y_{ktT})^{\mathbf{T}}$, $\boldsymbol{z}_k = (z_{kt1}, \ldots, z_{ktT})^{\mathbf{T}}$, represent the Cartesian coordinates of the markers $k = 1, \ldots, N$, at the sequent time frames $\tau = t_1, \ldots, t_T$. The T sign indicates transposition. The data matrix $\boldsymbol{M}$ is factorized using the *singular value decomposition* (SVD),

$$M = U\Sigma V^{\mathrm{T}} = \sum_{s=1}^{3N} \sigma_s \boldsymbol{u}_s \otimes \boldsymbol{v}_s^{\mathrm{T}}, \qquad (1)$$

where the $\bigotimes$ sign stands for the outer product of vectors, U is a $3N \times 3N$ unitary matrix with the columns $\boldsymbol{u}_s$ representing the left singular vectors of $\boldsymbol{M}$, V is a $T \times 3N$ unitary matrix with the columns $\boldsymbol{v}_s$ representing the right singular vectors of

$\boldsymbol{M}$, and $\sum$ is a $3N \times N$ diagonal matrix of ordered non-negative scale factors (singular values): $\sigma_1 > \sigma_2 \geq \ldots \geq \sigma_{3N} > 0$. A number of smallest singular values can be equal to zero if the MTS suffers from optical occlusion. Moreover, a number of left and right singular vectors can belong to the same singular value if the matrix $\boldsymbol{M}$ enjoys an exact spatio-temporal symmetry. However, while processing the actual motion tracking data, we have never encountered multiple singular values. If all singular values of $\boldsymbol{M}$ are non-degenerate and non-zero, then the factorization (1) is unique, up to simultaneous multiplication of the left and right eigenvectors by the same unit phase factor. The left singular vectors form an orthonormal basis for the spatial arrangement of markers, $(\boldsymbol{u}_s, \boldsymbol{u}_{s'})_{R3N} = \delta_{s,s'}$, with respect to the inner product in ${}_R{}^{3N}$. The right singular vectors are orthonormal with respect to the inner product in ${}_R{}^{T}$, $(\boldsymbol{v}_\tau, \boldsymbol{v}_{\tau'})_{RT} = \delta_{\tau,\tau'}$, forming a basis for the temporal sequences of kinematic data. With the use of (1), the kinematic signal $\boldsymbol{M}$ is decomposed into a weighted, ordered sum of separable matrices $\sigma_s \boldsymbol{u}_s \otimes \boldsymbol{v}_s^{\mathrm{T}}$, in which the information about the spatial arrangement of markers corresponding to the singular value σ_s is represented by the vector $\boldsymbol{u}_s$ separately from the vector $\boldsymbol{v}_s$, giving an account of the temporal evolution. For each non-degenerate singular value, the separable matrix $\sigma_s \boldsymbol{u}_s \otimes \boldsymbol{v}_s^{\mathrm{T}}$ is a rank-one $3N \times T$ matrix describing a *one-dimensional* mapping of spatial locations of markers to the sequent time frames that correspond to the synchronous motion of all markers (although with variable velocity) along straight lines. Namely, the trajectories of markers specified by the consequent triples of columns $\mathbf{r}_k^{(s)}(\tau) = \left(\mathbf{x}_{k,\tau}^{(s)}, \mathbf{y}_{k,\tau}^{(s)}, \mathbf{z}_{k,\tau}^{(s)}\right)$ of the matrix $\sigma_s \boldsymbol{u}_s \otimes \boldsymbol{v}_s^{\mathrm{T}}$ can be described mathematically using a single spatial dimension. Let us denote with $\vec{\rho}_k^{(s)}$ the unit vector, tracing the direction of the linear motion of the kth marker at the scale s_k,

$$\vec{\rho}_k^{(s)} = \frac{(\mathbf{r}_k(\tau+1) - \mathbf{r}_k(\tau))}{\|\mathbf{r}_k(\tau+1) - \mathbf{r}_k(\tau)\|}, \quad \text{for any } \tau = t_1, \ldots t_{T-1}$$

and the amplitude function of the linear motion common for all markers by

$$\gamma_s(\tau) = \frac{\left(\mathbf{r}_k^{(s)}(\tau), \vec{\rho}_k^{(s)}\right)}{\left(\mathbf{r}_k^{(s)}(t_1), \vec{\rho}_k^{(s)}\right)}, \quad \gamma_s(t_1) = 1$$

Then, the trajectory $\mathbf{r}_k(\tau)$ of the kth marker recoded by the MTS can be represented by the ordered sum of linear trajectories,

$$\mathbf{r}_k(\tau) = \sum_{s=1}^{3N} \vec{\rho}_k^{(s)} \cdot \gamma_s(\tau), \quad \tau = t_1, \ldots, t_T. \tag{2}$$

The SVD of trajectories into linear components given by (2) is obvious for the motion of a single marker (see **Figure 2**) along a planar elliptic trajectory segment. In such a simple case, the components $\vec{\rho}^{(1)}$ and $\vec{\rho}^{(2)}$ are nothing but the major and minor axes of the ellipse. It is clear that the amplitude functions for the bigger and smaller scales of motion are $\gamma_1(\tau) = -\sin(\omega_1 \tau)$ and $\gamma_2(\tau) = -\sin(\omega_2 \tau)$, respectively.

Application of SVD in data analysis is similar to the well-known principal component analysis and Fourier analysis (see Jolliffe, 1986). By setting the small singular values to zero, we obtain the minimal set of independent spatio-temporal features, ordered according to the scales of motion, which then approximate the original data with a maximal precision. Namely, for $l < 3N$, the $3N \times T$ matrix $M^{(\ell)} = \sum_{s=1}^{\ell} \sigma_s \boldsymbol{u}_s \otimes \boldsymbol{v}_s^{\mathrm{T}}$ renders the best least square approximation to $\boldsymbol{M}$ of the rank-ℓ, with an error

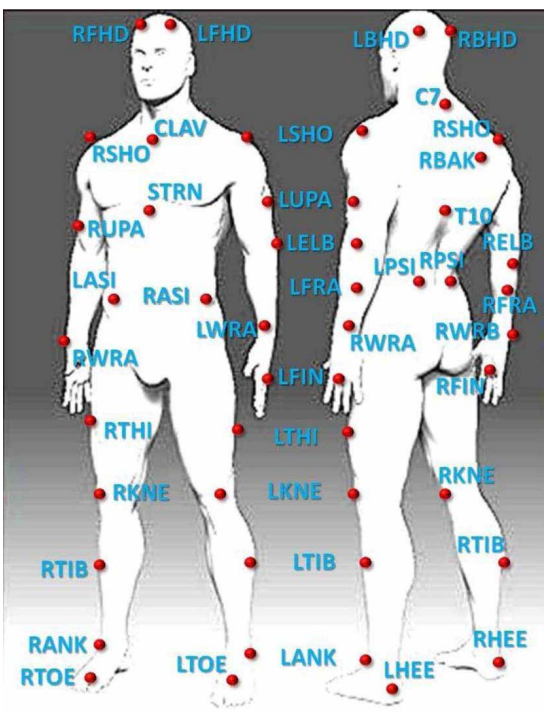

FIGURE 1 | Location of the passive retro-reflective spherical body markers arranged on the dancer's body in relation to the human skeletal system.

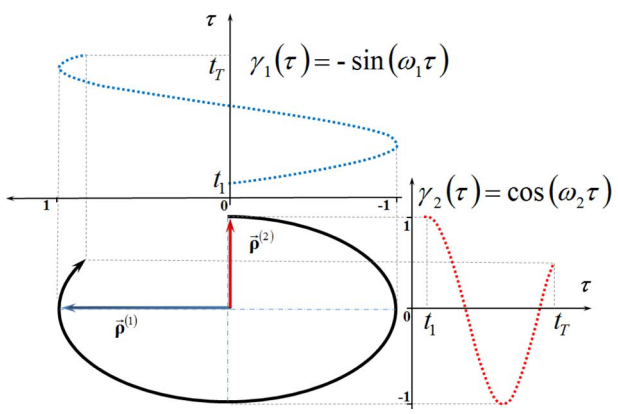

FIGURE 2 | The scale decomposition of a plane elliptic trajectory segment (reproduced with permission from Volchenkov and Bläsing, 2013).

smaller than the first neglected eigenvalue $\sigma_{\ell+1}$. By neglecting the scales $\sigma_{s>\ell}$ in (1) and consequent recombination of the kinematic signal, we can filter out unsolicited scales of motion (e.g., small scale movements of markers fixed on the clothing instead of the skin, movements of skin and tissues relative to the skeletal system, etc.) Despite certain computational similarity, the method of SVD differs essentially from the latent variable models, such as factor analysis, which use regression modeling techniques to test hypotheses producing error terms. The decomposition (1) does not involve any statistical hypotheses, being a purely descriptive technique.

ANALYZING MOVEMENT STRUCTURES

Scale decomposition of tracked movements can be used as a base for the functional alignment of markers. Spatio-temporal relationships between different body parts in evolving movements can be visualized by a dendrogram representing the relative distance between markers on the largest scale of movement through the horizontal branch length. In accordance with (2), a motion can be understood in terms of a hierarchy of scales evolving by $\gamma_s(\tau)$. The lowest level of this hierarchy corresponds to fast, low-scale movements of markers fixed on the clothing relative to the body, whereas the highest levels encode relatively slow, large-scale movements of the skeletal system. Although a detailed analysis of the functions $\gamma_s(\tau)$ lies beyond the scope of the present paper, it is worth mentioning that they typically constitute strongly anharmonic oscillations, indicating that the relationship between force and displacement at each movement scale is strongly non-linear.

Being primarily concerned with the movement on its largest scale, we note that its structure is determined in (2) by the spatial arrangement of vectors $\vec{\rho}_k^{(1)}$ in association with the markers $k = 1, \ldots, N$. For each marker, the magnitude of the vector $\left\|\vec{\rho}_k^{(1)}\right\| \cdot \sum_{\tau=t_1}^{t_T} |\gamma_s(\tau)|$ can be considered as a relative measure of its mobility on the movement scale σ_s. The degree of affinity between a pair of markers, k_1 and k_2, can be attested on the largest scale of the movement by means of the Euclidean distance between the related vectors,

$$d(k_1, k_2) = \left\|\vec{\rho}_{k_1}^{(1)} - \vec{\rho}_{k_2}^{(1)}\right\| \tag{3}$$

It is customary to reproduce the matrices of all-to-all distances in the form of a dendrogram by placing closely-related markers in the same mold. To preserve the structure (3) as much as possible, we use the standard neighbor-joining tree-generating algorithm (Felsenstein, 2004). We search the matrix (3) for the closest markers, and then connect them into a block. Once the markers are connected, they are removed from the distance matrix and replaced by the block connecting them. The neighbor-joining algorithm continues until all N markers are connected in a tree, and each branch acquires a length, with length being interpreted as the estimated number of substitutions required to resolve the block. The functional contingency between blocks of markers on the largest scale of the movement is disclosed by their geometric proximity in the resulting dendrogram. In spite of all participants sharing roughly the same anatomy and performing the same movements, the structures of calculated dendrograms can be substantially different in terms of individual movement features and level of movement expertise (Volchenkov and Bläsing, 2013).

REPRESENTING FUNCTIONAL ALIGNMENT OF MARKERS IN THE PIROUETTE EN DEHORS

In **Figures 3**, **4**, we have shown the neighbor-joining dendrograms representing the functional alignment of markers in the *pirouette en dehors* performed by a professional ballet dancer and a novice, respectively. To visualize spatio-temporal relationships between markers on the major scale of recorded movements, we have used the *TreeView* software, which is freely available on the internet (see Page, 1996). We emphasize that the dendrogram shows the functional alignment of markers in the sequential phases of the movement, irrelevant to the actual durations of these phases (see Volchenkov and Bläsing, 2013 for details). The *pirouette en dehors*, a controlled turn away from the supporting leg, is one of the most difficult of all ballet steps that can be executed with single or multiple rotations. The proper turning technique includes a periodic, rapid rotation of the head that serves to fix the dancer's gaze on a single spot, helping her to maintain control over the body (known as *spotting*). This rotational movement requires highly-defined coordination and constant adjustment of the body axis in order to be performed with the required stability and accuracy (Schack, 2001). The rhythmic structure of the *pirouette en dehors* is described by Tarassow (2005) as four measures in 2–4 time, the first two measures containing the preparation,

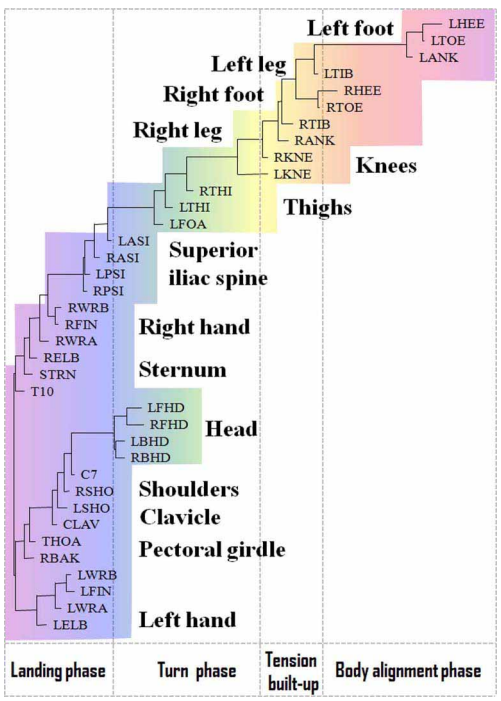

FIGURE 3 | Functional alignment of markers in *pirouette en dehors* performed by a professional ballet dancer. The standard Vicon Plug-in Gait marker notations are used (reproduced with permission from Volchenkov and Bläsing, 2013).

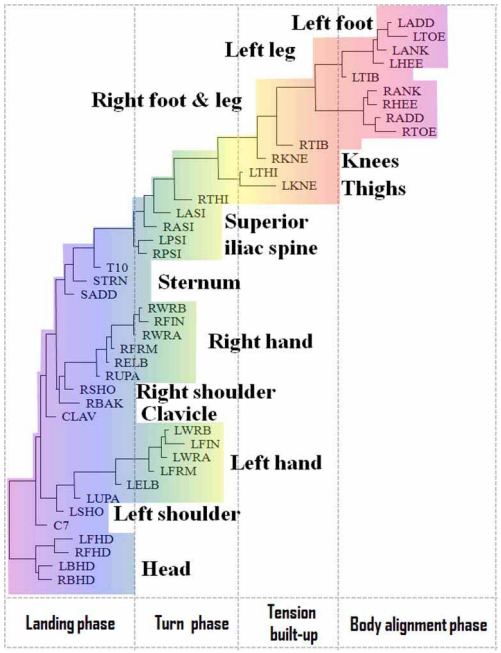

FIGURE 4 | Functional alignment of markers in *pirouette en dehors* performed by a student. The standard Vicon Plug-in Gait marker notations are used (reproduced with permission from Volchenkov and Bläsing, 2013).

and the second two measures containing the turn and conclusion. According to this approach, the *pirouette en dehors* consists of two parts, the preparation and the actual turning movement. Both of these parts can be dissected again; the preparation can be broken down into two rhythmically-separated sections, whereas the turn segment consists of the actual turning movement and the opening to the front that concludes the turn. The dendrogram shown in **Figure 3** discloses the functional structure of the *pirouette en dehors* on the left leg, executed by an expert. On the largest scale of the movement, the pirouette starts (at the upper right corner of the dendrogram) with the function of body alignment by arranging legs in the proper position: the right foot is placed in front of the left foot, both turned outward. The right foot slides to the side (*tendu*, or *dégagé*), which concludes the *body alignment* phase. The spring tension is built up for the turn during the *tension build-up* phase, as the right foot moves back and is placed behind the left one and the knees bend (*plié*). At the beginning of the *turn* phase, both legs push into the ground and the left (supporting) leg adopts *point* or *demi-point* position (on the toes or on the ball of the foot, respectively), while the right knee is bent and the right foot is pulled up to the knee of the supporting leg. During the turn, the head is rapidly whipping around, which helps the dancer to maintain balance. Eventually, in the *landing* phase concluding the turn, the right foot is placed behind the left one, and the knees bend and stretch (*plié*). The arms open, and the arms and torso are used to cease rotation. It is important to mention that each functional phase elicited from the dendrogram shown in **Figure 3** can be ascribed directly to the functional phases of the *pirouette en dehors* as defined in Bläsing et al. (2009) via the BACs, the key points within the functional structure of the movement, which are stored in the long-term memory of a dancer.

In contrast to the movement sequence executed by the professional dancer, the movement of a novice performer inappropriately starts simultaneously in both legs, and turning starts prematurely, while straightening the knees (see **Figure 4**). In the turning phase, the movements are allocated to the superior iliac spine. The head apparently does not play a role until ceasing the movement. Instead, the vigorous hand movements play a major role in maintaining the body's rotation, which is a common mistake among beginners.

LINKING MENTAL AND KINEMATIC STRUCTURES

Given that the STKD procedure identifies the underlying kinematic structure of movements (see **Figure 3**), we are able to examine whether the organization and structures found within the mental representations share common structural features with those found in the movement kinematics. To provide a first glimpse into this overlap, we examined the movement kinematics and mental representations of a golf swing in 9 participants ($M_{age} = 32.3$, $SD_{age} = 10.6$, 6 males) of varying skill levels (0–50 years of golf experience). Specifically, movement kinematics of a golf swing were captured using a 3-dimensional MTS (Vicon Motion Systems, Inc.) in which markers were placed on the anatomical landmarks of the body consistent with the standard Vicon full-body Plug-in Gait marker placement protocol. The subsequent marker trajectories for each trial were subjected to the STKD analysis (presented above) to produce a dendrogram of hierarchical couplings of movement trajectories, indicating the kinematic structure of the movement.

Likewise, the mental representation of the golf swing was procured for each participant through the SDA-M analysis (see Schack, 2004, 2012). The SDA-M identified the structural composition of mental representations by revealing the hierarchical and temporal structure of BACs within long-term memory. In order to assess the underlying mental representation on a level consistent with the kinematic structure revealed by the STKD approach (i.e., coupling between body segments), we utilized verbal labels indicating body parts as the representation units for the splitting task, the first step of the SDA-M. These verbal labels consisted of body parts relating to the tracked body segments in the motion-captured kinematic data[1]. Participants were instructed to assess the similarity between each of the body segments in terms of function and motion with respect to the golf swing. The resulting mental representation signified the functional relationship between body segments involved in the golf swing movement in long-term memory. The use of body parts as part of the SDA-M method has been successfully shown to distinguish between individuals with differing body representations in relation to a particular motor task (e.g., Bläsing et al., 2010).

[1]The body parts used as concepts within the SDA-M procedure, and subsequently tracked via motion capture, consisted of 1) head, 2) chest, 3) left shoulder, 4) left elbow, 5) left hand, 6) right shoulder, 7) right elbow, 8) right hand, 9) hips, 10) left thigh, 11) left knee, 12) left foot, 13) right thigh, 14) right knee, and 15) right foot.

The basis for the comparisons between the representational structure and the kinematic movement structure resides in the Euclidean distance matrices derived from both the STKD and SDA-M analyses. The distance matrix obtained from the SDA-M method is comprised of the Euclidean distances between concepts (body parts) as represented in feature space based on the results of the SDA-M splitting procedure. For the distance matrix obtained from the STKD method, the matrix contains the Euclidean distances between body markers within the major spatio-temporal scale of movement. From these two matrices, the hierarchical structure of the movements were derived, and thusly compared. More specifically, we computed both mean group dendrograms and individual dendrograms for both the mental representation and kinematic data via cluster analysis. Each cluster solution was established by determining an incidental euclidean distance (d_{crit}). Nodes linked together above this critical value were considered unrelated, while BACs linked below this value were considered related. For all cluster analyses conducted, the critical value $d_{crit} = 5.64$ was chosen, which reflects an alpha-level of $\alpha = 0.001$.[2] Next, the invariance measure λ was calculated to determine the degree of similarity between two cluster solutions. According to Schack (2012), two cluster solutions are invariant (i.e., not significantly different) for $\lambda > 0.68$, while two cluster solutions are significantly variant for $\lambda < 0.68$. Additionally, the correlation between the distance matrices was examined as a measure of overall relatedness of structural couplings of body parts on a mental and physical level.

Results of our analyses indicated a high degree of consistency and similarity between the structure of mental representations and movement kinematics. Examination of group mean dendrograms for both the mental representation structure and the major movement kinematic structure revealed a significant similarity between the two structures ($\lambda = 0.71$; $\lambda_{crit} = 0.68$; for more details, see Schack, 2012). That is to say that the structure revealed in the memory representation was statistically equivalent to the movement structure revealed by the STKD procedure (see **Figure 5**). Specifically, both the representation structure and kinematic structure displayed two distinct clusters representing the upper and lower body ($p < 0.001$). However, one difference emerged between the two structures in regard to the body segment "hips," such that in the mental representation, the hips were coupled with the functional relevance of the upper body, whereas the kinematic structure indicated that the hips were more closely coupled to the movement of the lower body. In this case, a mismatch exists between the group mental and group kinematic structure. Additionally, a comparison of the mental and kinematic structures on an individual level[3] revealed that 5 out of 9 individuals displayed significantly similar structures ($M_\lambda = 0.63$, $SD = 0.09$; $\lambda_{crit} = 0.68$, $n = 9$). **Figure 6** displays the similarity in the mental and kinematic structures for a single participant whose structures are statistically invariant ($\lambda = 0.71$; $\lambda_{crit} = 0.68$). Interestingly, the degree of task experience was not related to the degree of similarity between representation and kinematic structure in our current sample ($r = -0.385$, $p = 0.31$). However, future research is needed to determine why some individuals display stronger connections between mental and kinematic structures. To this extent, examination of differences between intact groups of novices and experts may provide further clarity into this connection.

In addition to the structural invariance measures based on the cluster solutions, significant correlations were evident between the mental and kinematic distance matrices. These correlations represent the degree of similarity between the coupling of body segments in feature space, as defined by the SDA-M and STKD procedures. Specifically, the group mean mental

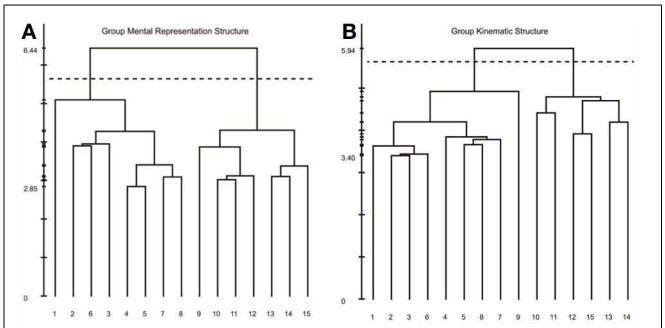

FIGURE 5 | Mean dendrograms for the mental representation (A) and swing kinematics (B). The numbers on the horizontal axis relate to the concept number, the numbers on the vertical axis display Euclidean distances. The lower the link between related concepts, the lower is the Euclidean distance between the corresponding concepts in feature space. The horizontal dotted line marks d_{crit} value for a given α-level ($d_{crit} = 5.64$; $\alpha = 0.001$): links below this line are considered statistically relevant. Concepts: (1) head, (2) chest, (3) left shoulder, (4) left elbow, (5) left hand, (6) right shoulder, (7) right elbow, (8) right hand, (9) hips, (10) left thigh, (11) left knee, (12) left foot, (13) right thigh, (14) right knee, (15) right foot.

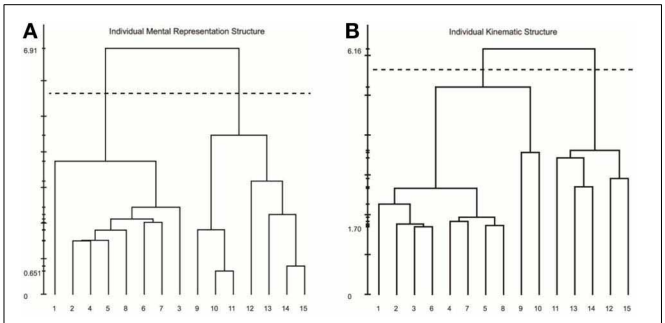

FIGURE 6 | Individual dendrograms from one participant for the mental representation (A) and swing kinematics (B). The numbers on the horizontal axis relate to the concept number, the numbers on the vertical axis display Euclidean distances. The lower the link between related concepts, the lower is the Euclidean distance between the corresponding concepts in feature space. The horizontal dotted line marks d_{crit} value for a given α-level ($d_{crit} = 5.64$; $\alpha = 0.001$): links below this line are considered statistically relevant. Concepts: (1) head, (2) chest, (3) left shoulder, (4) left elbow, (5) left hand, (6) right shoulder, (7) right elbow, (8) right hand, (9) hips, (10) left thigh, (11) left knee, (12) left foot, (13) right thigh, (14) right knee, (15) right foot.

[2]For more details on the SDA-M analysis, please see Schack (2012).

[3]For the individual comparisons, we utilized the SDA-M results and the STKD results from a single kinematic trial.

and kinematic distance matrices indicated a strong and positive correlation ($r = 0.629$, $p < 0.001$). As such, there is a close relationship between the relative body segments in both memory and physical execution. Likewise, significant correlations were evident on an individual level. For all participants, the correlation between the mental and kinematic distance matrices indicated significant positive correlations with values ranging from $r = 0.242$ to $r = 0.712$. Noteworthy, the correlations between mental and physical distance matrices remained remarkably stable over repeated trials within each individual, with an average correlation standard deviation of 0.02 across all participants.

Examining the scatter plot of the relationship between the mental and kinematic distance matrices also provides important insights into the link between representation and movement. Specifically, examination of outliers can be used as a diagnostic procedure to identify mismatches between an individual's movement representation and the physical execution of the movement. For instance, **Figure 7** displays the relationship between the mental and kinematic distance matrices for one participant. As can be seen, the points largely lay along the trend line, representing a strong relationship; however, point A represents a strong deviation from the predicted relationship. Examination of point A reveals that the left knee and left thigh were not similarly coupled in the execution of the movement like they were in the mental representation. This difference corresponds with the differences observed in the structural analyses as seen in **Figure 6** from the same participant. Such differences may suggest areas for targeted skill interventions by coaches, trainers, or physical therapists. Future research is needed to determine the qualitative impact on motor performance where such mismatches between mental and kinematic structure exist.

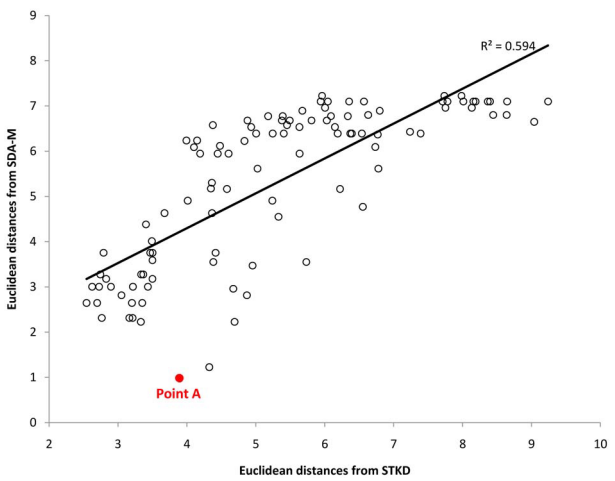

FIGURE 7 | Scatter plot representing the relation between the distance matrices derived from the SDA-M and STKD procedures for one participant. Point A represents an outlier and corresponds to the relationship between the left thigh and hip movement, thus indicating a mismatch between cognitive representation and the major kinematic feature of movement.

DISCUSSION OF FINDINGS

The above findings further confirm the close link between mental representations and the execution of motor actions. These results build on previous findings that have found functional links between representational chunks and specific biomechanical parameters within a given movement (e.g., Schack, 2003; Schütz et al., 2009). Specifically, our findings suggest that mental representations not only play a key role in guiding key biomechanical parameters of a movement, but also guide the overall structure of the action. To this end, we observed a close relationship between the overall structure of both the mental representation and movement kinematics on both a group and individual level.

The close link between representation and kinematic structure is consistent with the Cognitive Architecture model proposed by Schack (2004), which suggests that motor skills are organized within hierarchical memory structures comprised of elementary components or transitional states of complex movements. These memory structures act as a cognitive reference for the unfolding of action, such that they serve to govern the tuning of motor commands and muscular activity patterns. As such, a tight correlation is predicted to exist between the structure of mental representation and the structure of movement.

As we show, the structures observed within the movement kinematics are reflected within the mental representations of the participants. Interestingly, the degree of association or invariance between the mental representation and the movement structure did not appear to be dependent on the level of skill of the individual. Although our sample consisted of relatively few participants, thus likely making any relationship difficult to observe, the lack of a moderating effect of skill level is not entirely baseless. While research has shown that experts have more elaborate and hierarchically-organized mental representations (e.g., Bläsing et al., 2009), the overall function of the representation is to guide the unfolding of motor patterns. As such, regardless of the quality of the representation, the movement unfolds in a manner that is consistent with the representation structure, and thus movements and representations would be clearly correlated across all skill levels. However, this assumption warrants future research to confirm or reject the influence of skill level and other factors on the degree of association between movement and representation structure.

Examining the structural relatedness between mental representations and movements has a number of practical applications. As has been demonstrated, investigating the mismatch between memory structures and kinematic synergies may be useful for diagnosing movement disorders or guiding training strategies. To this extent, investigation of mental representations via the SDA-M method has successfully been shown to identify representational problems within stroke patients who display movement deficiencies (Braun et al., 2007). Similarly, incongruence between mental and kinematic structures may be a key factor in determining how deficient mental representations are manifested within the overall motor production. Additionally, the degree of invariance between mental and kinematic structures may act as a useful benchmark for examining the efficacy of artificial cognitive systems within modern robotics. As robotic platforms make qualitative leaps in the areas of perceptual, cognitive, and motor capabilities, cognitive architectures designed to effectively integrate these functions

become essential. The field of cognitive robotics is increasingly turning to biological models of action organization to guide the development of efficient and natural cognitive control systems (e.g., Schack and Ritter, 2009, in press; Maycock et al., 2010). In this direction, first steps have already been taken in modeling higher level cognitive representations derived from human data into robotic grasping applications (Maycock et al., 2010). The extent to which artificial cognitive systems efficiently represent and guide complex actions may be distinguishable based upon our proposed method, which would indicate a level of cognitive sophistication similar to that of its biological counterparts.

SUMMARY

The present article reviewed the substantial work on mental representations underlying complex action in humans. In doing so, we proposed a new experimental approach to capture the relationship between mental representation and the kinematic structure of movement. The STKD method presented in this paper allows for the segmentation of any recorded movement into a minimal number of independent spatial-temporal features. This method has been found to effectively elicit the hierarchically-organized key kinematic elements of a movement in different spatio-temporal scales. Based on these analyses, we presented a first step toward linking the memory structure of a complex motor task to the unfolding movement dynamics. Results from our analyses indicated a clear structural relationship between the motor representation in long-term memory and the functional structure of movement kinematics. These findings support the theoretical perspective that complex actions are planned and performed with the help of structured cognitive representations in long-term memory that act to guide the biomechanical organization of movements (Hommel et al., 2001; Mechsner et al., 2001; Schack and Mechsner, 2006; Hoffmann et al., 2007). Implications of these findings are important for a number of movement related domains, including physical therapy, sports training, and artificial cognitive systems. While the present paper presents an important first step in the direction of linking cognitive and biomechanical structures, much work remains to extend the current findings to new task domains while also exploring the variables that moderate this relationship.

Advantages of publishing in Frontiers

OPEN ACCESS
Articles are free to read, for greatest visibility

COLLABORATIVE PEER-REVIEW
Designed to be rigorous – yet also collaborative, fair and constructive

FAST PUBLICATION
Average 85 days from submission to publication (across all journals)

COPYRIGHT TO AUTHORS
No limit to article distribution and re-use

TRANSPARENT
Editors and reviewers acknowledged by name on published articles

SUPPORT
By our Swiss-based editorial team

IMPACT METRICS
Advanced metrics track your article's impact

GLOBAL SPREAD
5'100'000+ monthly article views and downloads

LOOP RESEARCH NETWORK
Our network increases readership for your article
