activation in pericytes enhances glucose uptake by increasing the expression of GLUT-1 and GLUT-4 and ATP production through glucose utilization (Carlsson et al., 2018). This could enhance glucose utilization beyond the minimum required and, therefore, could reduce ability of pericytes to survive OGD for a longer period of time. Activation of AMPK was detrimental to neurons during ischemia-reperfusion, while AMPK inhibition was neuroprotective (Ronnett et al., 2009). VEGF can also activate AMPK (Baufeld et al., 2017; Zibrova et al., 2017) and pericytes express VEGF receptor 1 (Eilken et al., 2017). Thus, it is likely that the detrimental effects of simultaneous application of VEGF and EPO on pericytes during OGD could be due to enhanced AMPK activation, which in turn enhances glycolysis, and depletes available energy substrate (i.e., glycogen) more rapidly, while increasing lactate production. An increase in lactate inhibits Na^+/Ca^{2+} exchangers (Yamanishi et al., 2006), which triggers Ca^{++} overload and apoptosis.

The presence of rrAng1 in the medium, though it significantly reduced the number of dead cells (**Figure 2C**), exerted only marginal and insignificant increase in viability of pericytes during 24 h OGD. On the other hand, presence of rrEPO, $rrVEGF_{A1-165}$, and rrAng1 in the cell culture medium exerted protective effects on pericytes during 24 h OGD. It is not clear why this protective effect was so different, when compared to the effects observed in the presence of rrEPO alone, rrAng1 alone or rrEPO and rrVEGF. One of the explanations could be that pericytes secrete Ang1 during hypoxia, but in the absence of oxygen pericytes cannot continue to produce Ang1 for a longer period of time (**Figure 2D**); thus, the protective effect appeared only when rrAng1 was added to the medium. Ang1 exerts its effects by binding to the Tie2 receptor tyrosine kinase (Augustin et al., 2009; Reiss et al., 2015), which is primarily expressed in endothelial cells (Sato et al., 1995), but this study (**Figure 2E**) confirmed previous findings that it was also expressed in pericytes (Teichert et al., 2017). The only common intracellular mechanism that is activated by EpoR, VEGFR, and Tie2 is the phosphatidylinositol 3-kinase pathway (PI3K, EC 2.7.1.137). Subsequent stimulation of 3-phosphoinositide-dependent kinase 1, activates RAC-alpha serine/threonine-protein kinase (AKT1). The resulting phosphorylation suppresses apoptosis by inhibiting the Bcl-2-associated death promoter through the p53 protein. It has been shown that a well-known β-adrenergic receptor agonist that exerts protective effects on retinal pericytes in diabetes patients is mediated *via* Akt activation (Yun et al., 2018). Thus, we can assume that simultaneous activation of the PI3K pathway by the three cytokines, mentions above, reduces apoptosis of pericytes during OGD, similar to earlier findings that have shown PI3K/Akt dependent apoptosis reduction in retinal pericytes (Haribalaganesh et al., 2009).

Do Pericytes Contract During OGD?

In this study, we have video-imaged pericytes, exposed them to OGD of various durations and then video-imaged the same cells again in normal conditions, which partially mimicked conditions that occur during the reperfusion *in vivo*.

Addition of ET-1 to primary cultures caused changes in SCMM and D_f that corresponded to cell contractions, which confirms that the vast majority of pericytes in primary cultures, regardless of their heterogeneity, possess the necessary cellular apparatus to contract. OGD protocols that lasted for 20 min and for 1 h caused changes in pericytes' morphology similar to changes caused by addition of ET-1. However, they did not persist after 3 and 6 h, though the latter data was not conclusive, since changes in D_f were consistent with contraction of processes. We observed that 20 min OGD protocol caused a significant reduction in cell mobility. This was even more pronounced after 1 h OGD protocol. These effects disappeared after 3 and 6 h OGD, which suggests that the mobility of the cells was transiently impaired by OGD. The A/PR increased after 20 min and 6 h OGD, indicating rounder cells with fewer processes. Interestingly, since 1 and 3 h long exposure to OGD had no apparent effects on process formation, it appears likely that two independent molecular mechanisms may control the membrane shape. Overall, it appears that brain pericytes do contract after 20 min and possibly 1 h OGD protocols, but not after 3 h and also most likely after 6 h OGD protocols.

LIMITATIONS AND CONCLUSIONS

Our results revealed that OGD transiently affected cell mobility and cell shape, which was followed by cell apoptosis in cultured pericytes. Angiopoietin-1 may have a potentiality for preventing from the OGD-induced apoptosis. However, further analysis is required to clarify the relationship between cell contraction and cell apoptosis during OGD. The main limitation of this study was that it was an *in vitro* study, hence these findings should be applied to *in vivo* conditions with caution. Also, SCMM has not been determined in the presence of Ang1, VEGF, and/or EPO. If the time pattern of pericytes' survival and contraction *in vivo* is the same as revealed in our *in vitro* study, for which we have no evidence so far, then it is unlikely that rapid death and contraction of pericytes are the cause of no-reflow in the brain.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

The details of the experimental protocol were approved by the Animal Ethics Committee, HSC.

AUTHOR CONTRIBUTIONS

MH performed the study of pericytes' viability and apoptosis during OGD and analyzed these data. LA-A performed the study of pericytes' motility and contractility after OGD and analyzed these data. AH developed the software to

analyse motility and contractility data, supervised data analysis, and partially wrote the manuscript together with ZR. ZS participated in all cell culture work and performed NG2/SMA/PDGFRb staining. SM performed staining for Tie2 receptor in pericytes and BECs. ZR designed and supervised the study, provided funding, supervised data analysis, directed other contributors, and drafted the manuscript together with AH.

FUNDING

This study was generously supported by Kuwait University College of Graduate Studies and Kuwait University Research Sector General Facility Grant No. SRUL02/13.

ACKNOWLEDGMENTS

We acknowledge Mrs. Mini Verkey and Mrs. Deepa Varghese for their excellent technical assistance. We acknowledge the help of Dr. Suleiman Al-Sabah and Miss. Sofija Redzic in improving language, style, and clarity of the manuscript.

Chen S-Y, Lin Y-S, Cheng Y-F, Wang H, Niu X-T and Zhang W-L (2019) Mean Platelet Volume-To-Lymphocyte Ratio Predicts Poor Functional Outcomes Among Ischemic Stroke Patients Treated With Intravenous Thrombolysis. Front. Neurol. 10:1274. doi: 10.3389/fneur.2019.01274

Background and Purpose: According to previous studies, the mean platelet volume-to-lymphocyte ratio (MPVLR) represents a novel marker of a poor short-term prognosis in patients with a myocardial infarction who underwent primary percutaneous coronary intervention. We aimed to evaluate the association between MPVLR and clinical outcomes of patients with acute ischemic stroke who were treated with intravenous thrombolysis.

Methods: Two hundred forty-one patients with ischemic stroke receiving intravenous thrombolysis were prospectively enrolled in this study. Blood samples for MPVLR were obtained at admission and at 18–24 h after treatment with intravenous thrombolysis. A poor functional outcome was defined as a modified Rankin scale score of 3–6 at 3 months after stroke.

Results: At admission, the area under the curve of MPVLR to predict poor functional outcomes at 3 months was 0.613 [95% confidence interval (CI), 0.541–0.686; $P = 0.003$), and the best predictive MPVLR value was 5.8. Patients with an MPVLR $\geq$5.8 had a 3.141-fold increased risk of a poor outcome at 3 months (95% CI, 1.491–6.615; $P = 0.003$) compared to patients with an MPVLR <5.8. At 18–24 h after treatment with intravenous thrombolysis, the area under the curve of MPVLR to predict a poor outcome at 3 months was 0.697 (95% CI, 0.630–0.765, $P < 0.001$), and the best predictive MPVLR value was 6.9. The inclusion of MPVLR as a continuous (odds ratio, 1.145; 95% CI, 1.044–1.256, $P = 0.004$) and categorical variable (odds ratio, 6.555; 95% CI, 2.986–14.393, $P < 0.001$) was independently associated with poor outcomes at 3 months.

Conclusions: Both the values of MPVLR at admission and 18–24 h after intravenous thrombolysis were independently associated with poor functional outcomes. MPVLR may serve as an activity marker for a poor prognosis in patients with acute ischemic stroke receiving intravenous thrombolysis.

Keywords: ischemic stroke, mean platelet volume, MPVLR, thrombolysis, outcomes

INTRODUCTION

Intravenous administration of recombinant tissue plasminogen activator (rt-PA) is recommended as the primary treatment for patients with acute ischemic stroke within 4.5 h from symptom onset (1, 2). However, approximately half of the participants were not independent or died at 3 months, despite the administration of intravenous thrombolytic therapy (3). Since the factors related to the functional outcomes of patients with ischemic stroke who are treated with intravenous alteplase have not been well identified (3, 4), the detection of new risk factors is always important.

Hemocyte variables have been reported to predict the risk and prognosis of ischemic stroke, particularly in patients treated with intravenous thrombolysis (5–8). Platelets play an important role in inducing inflammation and contributing to thrombus formation in cardiovascular disease (9, 10). The mean platelet volume (MPV) is an indicator of platelet function, reflecting platelet size, and activity (11). According to Greisenegger et al. an increased MPV is associated with poor functional outcomes in patients with acute ischemic stroke (12). However, the association between MPV and stroke outcomes remains controversial (13, 14). The pathophysiological pathways induced by cerebral ischemia mainly include the immune response, neuroinflammation, and the accumulation of leukocytes, such as lymphocytes, monocytes, and neutrophils (4, 15). Lower lymphocyte counts are independently associated with an increased probability of a poor functional outcome (7). Recently, the MPV-to-lymphocyte ratio (MPVLR) was considered a novel marker of a poor short-term prognosis in patients with myocardial infarction who underwent a primary percutaneous coronary intervention (16). Based on this information, we were prompted to explore the prognostic value of MPVLR in acute ischemic stroke. Therefore, the objective of our study was to explore whether MPVLR was associated with the functional outcomes of patients with acute ischemic stroke who were treated with intravenous thrombolysis.

MATERIALS AND METHODS

Study Population

We performed a prospective, hospital-based observational study. The study consecutively enrolled patients with ischemic stroke who were treated with intravenous thrombolysis from March 2013 to Oct 2017 in the First Affiliated Hospital of Wenzhou Medical University. Each patient received intravenous alteplase at a dose of 0.9 mg/kg. Notably, 10% of the total dosage was administered as a bolus within 4.5 h of stroke onset, followed by a continuous intravenous infusion of the remaining dose over a period of 1 h. The inclusion criteria for intravenous thrombolysis were as follows: (1) older than 18 years, (2) a diagnosis of acute ischemic stroke by neurologists according to the recommendations from World Health Organization (17), and (3) an onset-to-treatment time within 4.5 h. The exclusion criteria were defined according to the 2013 American Heart Association/American Stroke Association Guidelines (18). The present study was approved by the Ethics Committee of the First Affiliated Hospital of Wenzhou Medical University. All patients or their relatives provided written informed consent and agreed to participate in the study.

Clinical Protocol and Laboratory Tests

The severity of neurological impairment was assessed using the National Institutes of Health Stroke Scale (NIHSS) at admission and at 24 h after intravenous thrombolysis. Baseline information about age, sex, onset-to-treatment time, systolic, and diastolic blood pressure, medical history, including potential stroke risk factors and ongoing antiplatelet therapy, and electrocardiographs were obtained at admission and in the inpatient department. We collected the following poststroke infection parameters within 48 h: pneumonia, tracheobronchitis, urinary tract infections, and other defined infections. In addition, the blood glucose level was measured in the emergency room at admission. All patients were subjected to a routinely performed computed tomographic scan at admission and a follow-up scan at 24 h after thrombolysis, or any other time when the patient's neurological deterioration was noted. We also collected information about the symptomatic intracerebral hemorrhage according to the Safe Implementation of Thrombolysis in Stroke-Monitoring Study definition: a local or remote type 2 parenchymal hemorrhage on imaging 24 h after thrombolysis or earlier if the computed tomographic scan was performed due to neurological deterioration combined with an increase in the NIHSS score of 4 points from baseline or a stroke resulting in death within 24 h (19).

Data were obtained from blood tests performed at admission and at 18–24 h after treatment with intravenous thrombolysis. A complete blood count was determined using the automated hematology analyzer (XE-2100, Sysmex Company, Japan) within 60 min after blood sample collection. The MPVLR was calculated as the ratio of MPV to lymphocytes, the unit of MPVLR is $fl/10^9/L$. The platelet-to-lymphocyte ratio (PLR) was calculated as the platelet count divided by the lymphocyte count.

Outcome Measures

The main outcomes of all patients were evaluated based on the modified Rankin scale (mRS) score recorded in the outpatient department or via a telephone follow-up interview conducted by a trained neurologist. A poor functional outcome was defined as a mRS score of 3–6 at 3 months after stroke. The second endpoint was early neurological improvement (ENI). ENI was defined as a reduction in the NIHSS score $\geq$8 from baseline or an NIHSS score that decreased to 0 or 1 at 24 h after treatment (20).

Statistical Analyses

Statistical analyses were performed with the SPSS 22.0 package for Windows (SPSS Inc., Chicago, USA, RRID:SCR_002865). A $P < 0.05$ was considered statistically significant. Continuous variables are reported as the means with standard deviations or medians with interquartile ranges. Categorical variables are reported as percentages. Statistical analyses were performed using Student's *t*-tests and the Kruskal–Wallis test for continuous data or the chi-square test or Fisher's exact test for categorical data.

Receiver operating characteristic (ROC) curves were constructed to assess the predictive value of MPV, lymphocyte, PLR, and MPVLR for poor outcomes at 3 months. The method of an optimal cutoff was applied to transform the MPVLR into a categorical variable. We divided the participants into two groups according to the MPVLR cutoff at admission and compared the differences in baseline characteristics between these groups. We also compared the differences in characteristics between the poor and good outcome group. We employed different multivariate logistic regression models to evaluate the associations between MPV, lymphocyte counts, PLR, MPVLR, and poor functional outcomes at 3 months.

RESULTS

Among the 266 patients, 12 patients with missing data for the complete blood count at 18–24 h after rt-PA were excluded. Among the remaining patients, four patients with no data on hematological parameters at admission and nine patients who were lost to follow-up were also excluded. Finally, we enrolled 241 patients in this study (**Figure 1**). A detailed description of the baseline clinical characteristics of the study population is provided in **Table 1**. The mean age of all patients was 66.5 ± 12.0 years, and 163 patients (67.6%) were male. The median NIHSS score at admission was 9 points. The mean value of the MPVLR for the entire population of participants was 6.7 ± 3.6 $fl/10^9/L$ at admission and 8.8 ± 4.7 $fl/10^9/L$ at 18–24 h after rt-PA. Among the 241 patients, 25 (10.4%) died, 29 (12.0%) presented ENI, and 105 (43.6%) presented poor functional outcomes at 3 months.

An ROC curve analysis was performed to assess the predictive values of MPV, lymphocyte counts, PLR, and MPVLR for poor outcomes at 3 months (**Table 2**). At admission, the area under the curve (AUC) of MPVLR was 0.613 [95% confidence interval (CI), 0.541–0.686; $P = 0.003$), and the best predictive MPVLR value was 5.8. Furthermore, the predictive value of MPVLR for functional outcomes was better than PLR. Accordingly, at 18–24 h after rt-PA infusion, the AUC of MPVLR to predict a poor outcome at 3 months was 0.697 (95% CI, 0.630–0.765, $P < 0.001$), and the best predictive MPVLR value was 6.9.

The baseline and clinical characteristics of the study cohort stratified according to MPVLR cutoff at admission are listed in **Table 3**. Patients presenting with an MPVLR ≥5.8 were older, had a higher NIHSS score at 24 h after intravenous thrombolysis, and longer onset to treatment time than patients with an MPVLR <5.8. Otherwise, ENI and hyperlipidemia were more prevalent in patients with an MPVLR <5.8. Patients with an MPVLR ≥5.8 more frequently presented with a history of previous stroke/transient ischemic attack (TIA) and atrial fibrillation than patients with an MPVLR <5.8.

The distribution of functional outcomes at 3 months stratified according to the MPVLR cutoff value is shown in **Figures 2**, **3**. Regardless of whether outcomes were measured at admission or at 18–24 h after rt-PA infusion, a poor functional outcome was more common in the higher MPVLR group stratified by cutoff value. However, ENI was less common in the higher MPVLR group stratified by cutoff value (**Table 4**). The blood tests and the baseline characteristics were compared between patients with poor and good functional outcomes, and the results are shown in **Table 1**. Patients with poor functional outcomes at 3 months after stroke were older, had higher NIHSS scores, and

NIHSS, National Institute of Health Stroke Scale; TIA, transient ischemic attack; BP, blood pressure; rt-PA, recombinant tissue plasminogen activator; SICH, symptomatic intracerebral hemorrhage; WBC, white blood cell; MPV, mean platelet volume; PLT, platelet; MPVLR, mean platelet volume-to-lymphocyte ratio; PLR, platelet-to-lymphocyte ratio; SD, standard deviation; IQR, interquartile range.

more frequently suffered from atrial fibrillation and hemorrhagic transformation than patients with good functional outcomes. Before the rt-PA treatment, patients in the poor functional outcome group at admission had lower lymphocyte and platelet counts but higher MPVLR levels than patients in the good functional outcome group. At 18–24 h after rt-PA infusion, white blood cell counts, MPVLR, and PLR were significantly higher in patients with poor functional outcomes than in patients with good functional outcomes. In addition, lower lymphocyte and platelet counts were observed in the poor than in the good functional outcome group.

Table 5 shows the results of the binary logistic regression analysis of MPV, lymphocyte counts, PLR, MPVLR, and poor outcomes. At admission, the inclusion of the MPVLR level as a dichotomous variable was independently associated with a higher risk of poor outcomes at 3 months, with an adjusted odds ratio (OR) of 2.600 (95% CI, 1.396–4.843; $P = 0.003$) after adjustment for age, sex, and baseline NIHSS score (model 1) and 3.141 (95% CI, 1.491–6.615, $P = 0.003$) after further adjustment for the variables included in model 1 plus variables such as hypertension, coronary artery disease, previous stroke/TIA, atrial fibrillation, onset-to-treatment time, diabetes, hyperlipidemia, poststroke infection, and symptomatic intracerebral hemorrhage that were identified as having $P < 0.2$ in **Tables 1**, **3** (model 2), respectively. The predictive value of MPVLR as a continuous variable at admission for poor outcomes tended to become significant, regardless of whether it was included in model 1 or 2. At 18–24 h after rt-PA infusion, regardless of whether model 1 or

2 was used, an increased MPVLR level maintained its predictive accuracy as either continuous or categorical variable.

DISCUSSION

To our knowledge, this study is the first to investigate the prognostic value of the MPVLR in patients with ischemic stroke who were treated with intravenous thrombolysis. When analyzed either pre- or postthrombolysis, the MPVLR was independently associated with increased risks of poor functional outcomes at 3 months. The prethrombolysis value of the MPVLR exhibited a better prediction ability than the PLR. In addition, the best discriminating values of the MPVLR for predicting poor outcomes were determined in this study.

Platelet activation plays an important role in thrombosis and inflammation (21). The size of platelets represents their activity, and larger-sized platelets are functionally more active (22). The MPV is a readily available marker due to the automatic analysis when blood tests were performed. A study including 776 patients with acute ischemic stroke or TIA revealed an adverse effect of a higher MPV son clinical outcome (12). Another study examining patients with ischemic stroke who were receiving intravenous thrombolysis suggested that the MPV was an independent predictor of a poor functional outcome (23), which contradicts the findings from our study. Our study did not observe an association between the MPV and functional outcome. This discrepancy may be due to the use of different designs and outcome measures compared to our study. Furthermore, Ntaios et al. reported that the MPV measured within 24 h after onset was not associated with functional outcomes in patients with ischemic stroke (3).

The inflammatory response after stroke plays an important role in ischemic brain pathobiology (4). The effect of lymphocyte activation on the prognosis of ischemic stroke remains unclear (24). According to the results of some animal experiments, lymphocytes exert a deleterious effect on infarcted brain tissues (5). Another study observed a protective role for regulatory T lymphocytes after experimental brain ischemia (6). Our clinical evidence indicated that lower lymphocyte counts were associated with poor functional outcomes in patients with acute cerebral infarction after rt-PA treatment, consistent with the results reported by Kim et al. (7). Lower lymphocyte counts may be attributed to an increase in inflammation-related lymphocyte apoptosis that predisposes an individual to ischemic stroke.

The PLR predicts clinical outcomes in patients with acute ischemic stroke undergoing thrombectomy (16). However, the

platelet size reflects function and activation more accurately than the platelet count (8). In addition, an increased MPVLR has been introduced as a predictor of no-reflow and a poor prognosis in patients with acute myocardial infarction (8, 16). In the present study, an elevated MPVLR was associated with less ENI and worse functional outcomes in patients with ischemic stroke who were treated with intravenous alteplase, suggesting that increased platelet activity and inflammation may be associated with a poor prognosis. The rate of poststroke infection was up to 30%, and the infection might influence hematological parameters, including the lymphocyte count and MPV. We adjusted for poststroke infection in the multivariate regression models, which did not attenuate the risk of poor outcomes associated with MPVLR (25). We also confirmed that the dynamic monitoring of MPVLR at admission and 18–24 h after rt-PA infusion was prospectively associated with poor functional outcomes. In particular, the MPVLR proved to exhibit a better predictive value for poor functional outcomes than the PLR in ROC analyses. The adjusted OR value of MPVLR was also larger than the PLR. We presume that MPVLR may synthetically reflect the degree of thrombosis and inflammation. A potential mechanism is proposed in which an elevated MPVLR may activate platelets by releasing platelet activators from ischemic/necrotic tissue, leading to increased thrombosis (16). However, the present study is not able to confirm a causative role of the MPVLR in the pathophysiology of ischemic stroke. Prospective studies are needed to explore the exact mechanism of this phenomenon.

The current study has certain limitations. First, the MPVLR level and follow-up data were not acquired from 25 patients included in this study. However, no significant differences in the baseline characteristics were observed between the excluded and included patients. Second, the study was only performed at a single center, and thus, the results may not be generalizable to all other patients with ischemic stroke. In addition, the best discriminating values must be further verified in other studies and populations. Furthermore, other platelet markers and inflammatory markers were not evaluated in the study.

CONCLUSIONS

Despite the limitations mentioned above, we report the first study focusing on the predictive value of MPVLR in patients with

TABLE 4 | Comparison of outcomes between subgroups stratified according to the MPVLR cutoff.

stroke after intravenous thrombolysis. Moreover, we assessed the MPVLR at admission and at 18–24 h after intravenous thrombolysis, and both values were independently associated with poor functional outcomes. The MPVLR is easy to monitor and therefore might serve as an activity marker for an unfavorable prognosis in patients with acute ischemic stroke receiving intravenous thrombolysis.

Front. Neurol. 10:1402. doi: 10.3389/fneur.2019.01402

Background: After a Stroke, there is an autonomic nervous system (ANS) changes. Transcranial Direct Current Stimulation (tDCS) can promote the reorganization of the affected circuits.

Objective: To evaluate the effects of tDCS applied before a session of physical activity on the treadmill, in the modulation of the autonomic nervous system of post-stroke patients.

Methodology: Cross-over study, were randomized 12 adult hemiparetic subjects in 2 groups, Group 1 (active tDCS before exercise on the treadmill) and Group 2 (sham tDCS before exercise on the treadmill). Stimulation times were 20 min; treadmill time was 20 min. The heart rate variability (HRV) and Variability of Systolic Blood Pressure (VSBP) were evaluated for 15 min, in 3 periods (pre and post tDCS and during exercise recovery on the treadmill).

Results: There was no difference in the VSBP and the HRV between the groups, compared with the baseline data; however, in the intragroup analysis, the parasympathetic modulation after active tDCS increased by 18% over baseline by the RMSSD with IC 95% (−7.85 to −0.34). In group 1, the post-tDCS active and post-exercise periods presented a value of variance above baseline, indicating a better prognosis. In group 2, there was a significant reduction of 38% of Variance values ($p = 0.003$) after tDCS sham.

Conclusion: tDCS does not generate immediate effects on HRV and VSBP, except for intragroup comparison, which has greater participation in parasympathetic modulation in the group receiving active tDCS.

INTRODUCTION

One of the most serious causes of stroke reoccurrence is the alteration in the Autonomic Nervous System (ANS) function that leads to a reduction of heart rate variability (HRV). This was due to the disbalance to the homeostasis of the autonomic control, based on cardiac interbeat intervals analyzed by the physiological information, which can lead to myocardial infarction and sudden death (1–3).

Damages to ANS can also affect the control of blood pressure (BP). McLaren et al. (4) conducted a case-control cross-study in which compared the autonomic function of patients that had a stroke, not-treated, with resident controls in the Community and observed that the blood pressure alteration was maintained several months after the stroke.

Although the mechanisms of this cardiovascular autonomic dysregulation have not been fully understood, several studies (3, 5–7) suggest an anatomical-functional asymmetry between the right and left cerebral hemispheres in ANS modulation activity. Dutsch et al. (8) observed that stroke survivors whose infarction occurred on the right side had increased sympathetic cardiac modulation and parasympathetic cardiac deficit. The changes after the stroke in autonomic nervous system showed that favor increased tonus sympathetic and reduced parasympathetic appear to be independent to the both hemisphere injury (1). Macey et al. (7) and Al-Qudah et al. (3) reported that an important area in autonomic control is the insular cortex, with the right lobe insular cortex related to sympathetic modulation and the insular cortex of left lobe responsible for parasympathetic modulation. The insular cortex is located topographically in the neocortex region below the parietal, temporal and frontal cortex (5).

Upon the importance of the ANS in cardiovascular control, some studies have researched the effects of Transcranial Direct Current Stimulation (tDCS) over the left temporal cortex in the ANS modulation. One of them is the study from Montenegro et al. (6) that applied the tDCS in healthy athlete and none athlete individuals. They observed a reduction in the improved HRV in rest and quicker recovery from the exercise for athlete individuals. Another study is from Okano et al. (9) that observed a better parasympathetic action and decrease in the effort sensation and fatigue of healthy individuals during the exercise with cycle ergometer. Cogiamanian et al. (10) observed that the modulation of cortical excitability by tDCS might be used as a possible tool for human artery hypertension treatment.

The use of tDCS in individuals with stroke is safe and may be used during the rehabilitation to promote the reorganization of circuits affected by the lesion (11). However, its effects were not researched in the modulation of ANS by the temporal area in these individuals.

With the increase in surviving patients from stroke events, it is important to expand the comprehension of the lesions' chronic effects and that interferences in this sense, when positive, will enable better prognosis of cardiac autonomic function, reducing the possibility of a stroke relapse and sudden death and providing also better quality of daily living.

Therefore, the main objective of the study was to evaluate the HRV and the Variability of Systolic Blood Pressure (VSBP) in hemiparetic patients due to stroke in basal conditions (rest), immediately after the application of active tDCS and sham (pre-exercise) and during the exercise recovery on the treadmill. As a secondary outcome, the performance of the exercise, and perception of stress was evaluated, with the cardiac parameters (cardiac rate, modified Borg for dyspnea and fatigue, distance traveled).

METHODOLOGY

This study consists of an original cross-sectional, randomized, controlled, double-blind trial study of 12 adult hemiparetic stroke patients. The study followed the norms set by the Consort.

Survey participants included those with stroke hemiparesis for more than 6 months (12); from 21 to 74 years old; with mild or moderate lower limb motor impairment [between 20 and 31 points on the Fugl-Meyer lower limb scale (13)]; which presented comfortable walking speed between 0.3 and 1.15 m/s (14); walk at least 50 meters (15) without difficulty; agreeing to sign a consent and informed form.

Those with cognitive impairment (Mini-Mental State Examination-MMSE) with a score below 24 points (16) were excluded so that they could understand the study protocol; visual alteration that would prevent the execution of the protocol; severe heart problems (congestive heart failure, angina, peripheral vascular disease). Use of pacemaker; contraindications to the use of tDCS (brain metal clip implant near the region to be stimulated, history of recurrent seizure, recurrent epilepsy, brain tumors, brain pacemaker, and opening in the skullcap); women who had an irregular menstrual cycle or who were in the menstrual cycle during the evaluation; without medical clearance for treadmill exercise testing.

This study was performed at University Nove de Julho at unit Vergueiro and approved by Ethics Committee of University Nove de Julho (protocol CAAE: 57314716.7.0000.5511), São Paulo, Brazil and registered in Clinical Trial (NCT02956096) https://clinicaltrials.gov/ct2/show/NCT02956096.

INTERVENTION

The patients were submitted to two intervention protocols crossover (active tDCS and sham tDCS) (**Figure 1**):

1- Evaluation of basal HRV (15 min), followed by active direct current transcranial stimulation (tDCS) (20 min). Immediately at tDCS, 15 min of HRV assessment followed by 20 min of treadmill walking, and finally another 15 min of HRV during exercise recovery.
2- Evaluation of basal HRV (15 min), followed by sham direct current transcranial stimulation (tDCS) (20 min). Immediately at tDCS, 15 min of HRV assessment followed by 20 min of treadmill walking, and finally another 15 min of HRV during exercise recovery.

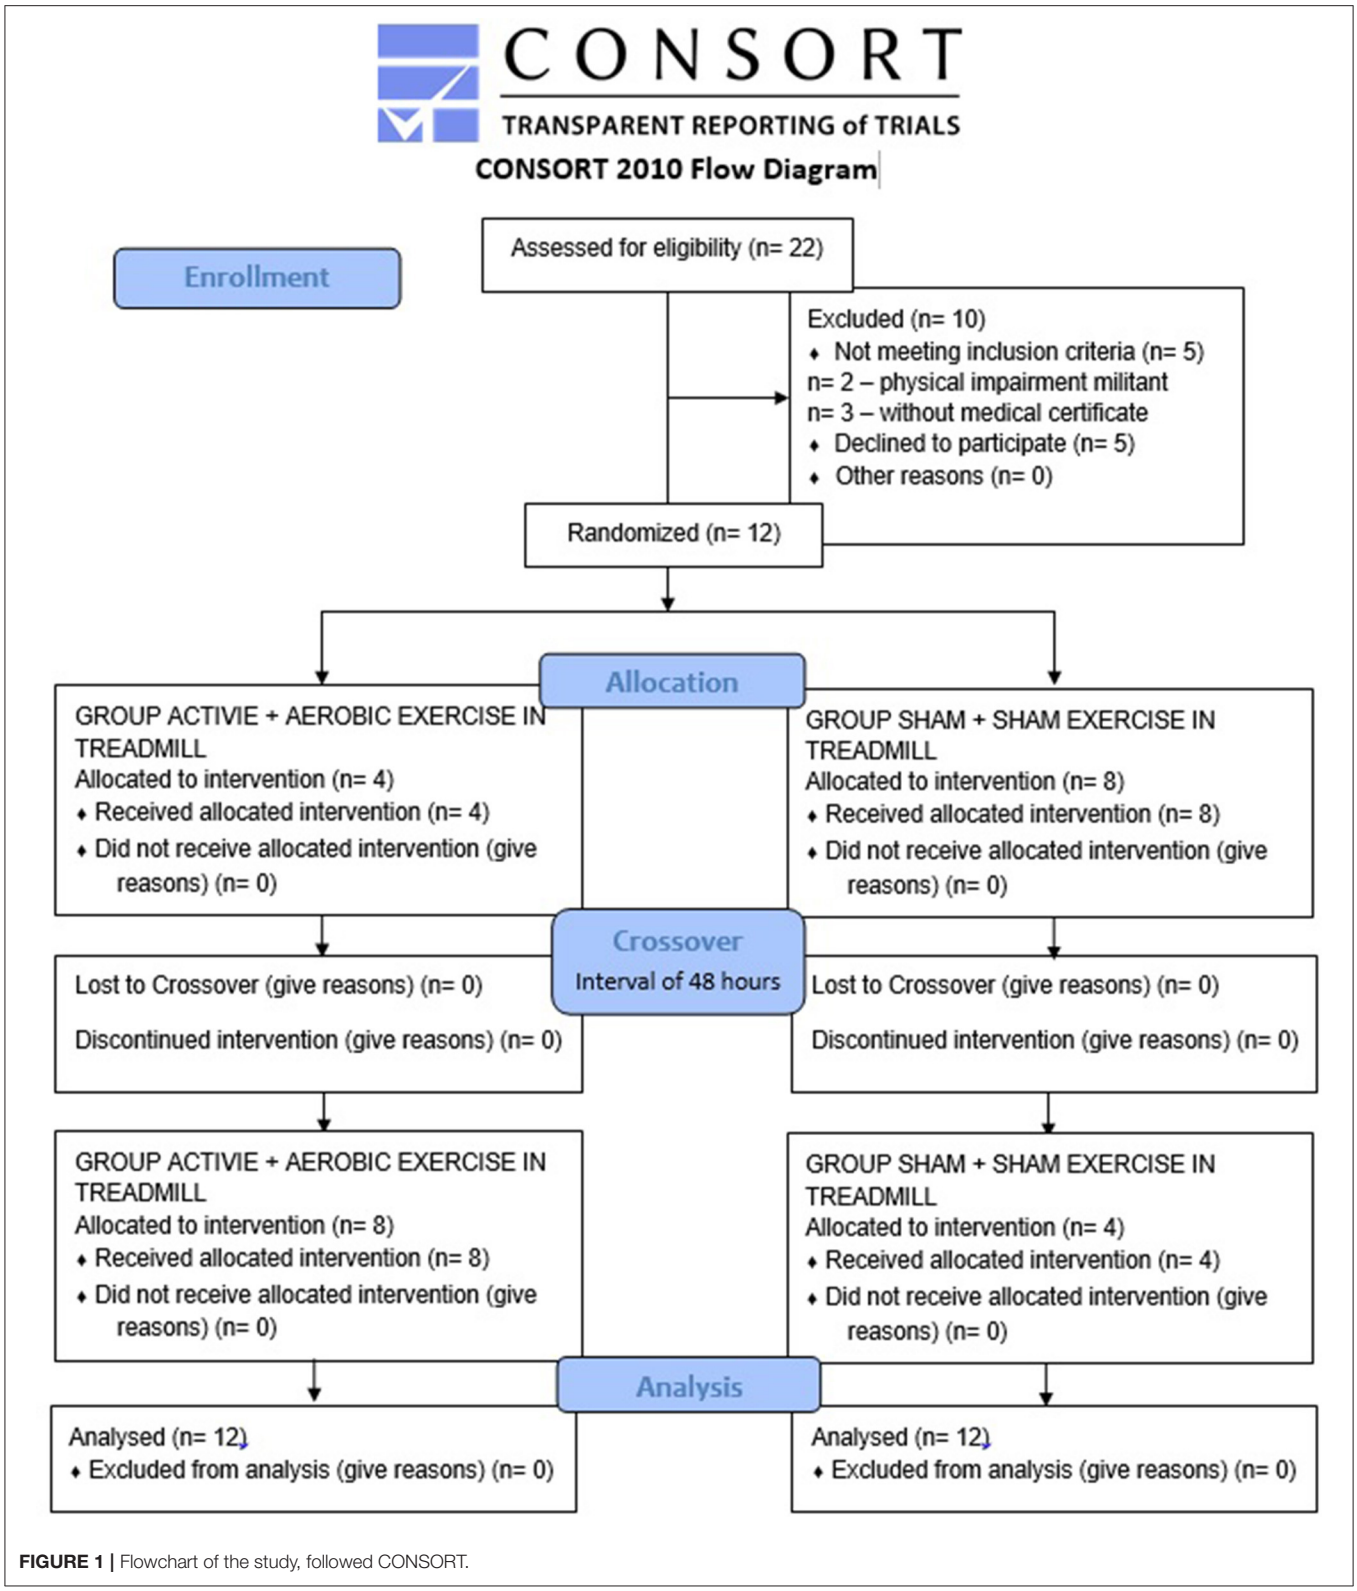

FIGURE 1 | Flowchart of the study, followed CONSORT.

Protocols (active tDCS or sham tDCS) were randomized to the first day of treatment only. On the second day (after 48 h) (17), the crossover was performed to be different from the first day.

Randomization was performed by lottery with brown, sealed envelopes to ensure reliability. The contents of each envelope determined which protocol the patient would initiate.

TRANSCRANIAL DIRECT CURRENT STIMULATION (tDCS)

The investigators responsible for the evaluation procedures and the patients were blinded to the treatment being applied (active tDCS or sham tDCS).

The patient was seated to receive the stimulus. Stimulation was performed with the NeuroConn tDCS DC-Stimulator Plus device using two 5 × 5 cm^2 (non-metallic) surface electrodes, wrapped in a moist saline sponge with a 2 mA current for 20 min before exercise in running machine.

The anode electrode was positioned over the left temporal cortex (T3) and the cathode electrode over the middle deltoid muscle contralateral to the anode. In placebo stimulation, all lead positioning procedures were performed equally to the active tDCS procedure, but the stimulator was maintained on for 30 seconds (according to the fake device program). The patient was informed that he would feel a slight initial tingling, but would reduce, disappear or stay for 20 min after application. Thus, the patients had the initial feeling, but did not receive any stimulus in the remaining time. This procedure is a valid form of control in transcranial direct current stimulation studies (18).

ACUTE AEROBIC EXERCISE ON THE TREADMILL

After 20 min of tDCS in a sitting position, the patients were positioned standing on the treadmill. To avoid possible falls, at least two physical therapists followed the exercise next to the patient. Cardiorespiratory parameters were monitored, such as heart rate, blood pressure, and oxygen saturation. Should these parameters be changed that put them at risk or if they expressed an interest in withdrawing from intervention, this would be immediately discontinued.

The velocity and inclination of each individual were determined by a previous exercise stress test using the modified Harbor protocol (14). Speed was kept constant and comfortable as determined by the individual and the treadmill inclination was increased by 2.5% every 2 min (19) until the patient reached 60–70% of the reserve heart rate (20). The inclination, therefore, was calculated to 60–80% of the maximum obtained in the ergometric test.

The electrocardiographic trace was acquired by (CPX Ultima, MedGraphics); heart rate (HR), oxygen saturation (SpO_2) and blood pressure (BPA) were continuously recorded every 2 min of exercise. Dyspnea scores and perception of lower limb fatigue were measured at rest and immediately after an exercise session by the modified Borg scale (21).

EVALUATION OF HEART RATE VARIABILITY (HRV) AND VARIABILITY OF SYSTOLIC BLOOD PRESSURE (VSBP), OBTAINED BY FINOMETER EQUIPMENT

HRV and VSBP were collected in three moments (basal, immediately after the tDCS and after the exercise on the treadmill, during the exercise recovery). The data HRV were evaluated immediately after exercise for 15 min (during the exercise recovery). For this, the patient was positioned in seated and told not to move or speak.

For this, a Finometer hemodynamic meter (Finomiter® Pro/Finapres Medical Systems incorporates Modelflow technology) was used. It consists of equipment used to continuously monitor non-invasive cardiac pressure, which uses the technique of digital infrared photoplethysmography. For this procedure, an inflatable cuff is used around the middle finger phalanx.

Hemodynamic variables such as systolic (SBP), diastolic (DBP), mean (MBP), blood pressure (BP), cardiac output (CD) and total peripheral resistance (RPF) were assessed by beating and recorded in BeatScope software., based on values derived from the blood pressure curve and information on age, gender, weight, and height.

The data collection of blood pressure and its derivations such as the intervals R-R, observing the waves of high frequency (HF), low frequency (LF), and the low frequency interrelation with high frequency (HF/LF), were collected continuously in the basal periods and during the recovery from acute exercise for 15 min.

Data Analysis of HRV and VSBP

The HRV analysis followed the Task Force's short-term spectral analysis in the time and frequency domain (22).

The cardiac modulation evaluation was performed by the register of interval R-R (ms) with the software *BeatScope*. The data were converted and stored in *Excel* files, used posteriorly for spectral analysis. A verification by visual inspection was performed by software *CardioSeries*, to identify and/or correct some premature or affected ectopic beats, using the linear interpolation to remove undesirable transients that alter the signal stationarity. The variations of Pulse Interval (PI) were evaluated in the time domain and the frequency domain by the linear method.

The linear methods were analyzed in the time domain and the frequency domain. Therefore, each RR interval was measured during a determined time interval, as described in the heart rate variability, calculating the floating transducer indexes of cardiac cycles.

RR intervals were collected in three periods: pretreatment (basal condition) for 15 min, immediately after tDCS application was completed (for 15 min) and during recovery from treadmill exercise (15 min).

In all three periods, the patient remained seated, without speaking or moving. Only 5 min of each patient's data were used for visual inspection by CardioSeries software to identify and/or correct some premature ectopic beats or artifacts, using linear interpolation to remove unwanted transients that could alter the signal stationarity of these patients analyzes in each period.

The indexes obtained by the determination of RR intervals by the time domain were the average of pulse interval RR through the absolute Variance and RMSSD that is the square root of the squared mean of the difference between the adjacent normal RR interval, in a time interval expressed in ms^2 and is better correlated with the vagal modulation. But by the frequency

domain, data were analyzed were through the high band (0.15 and 0.4 Hz), and low frequency (0.04 and 0.15 Hz) in its absolute values, and the sympathetic vagal balance.

STATISTICAL ANALYSIS

The data were analyzed in the statistic program, *SPSSR* version 17.0 according to the distributed nature of variables, the central tendency measures, and the dispersion to be used as the averages and standard-deviation (parametric) or median and interquartile interval (non-parametric). HRV and BPV data are presented as mean ± SD or median and interquartile interval. For comparison between the applications, parametric tests (ANOVA of two repeated measure ways) and for the none-parametric tests were used (Friedman followed by the post-test Wilcoxon). $P < 0.05$ was considered statistically significant.

OUTCOMES

Twenty-two patients were selected, 10 were excluded (two due to physical impairment that prevented them from performing the exercise, three for not having medical authorization for exercise testing and five for dropout (this dropout was reported for different reasons, such as disliking the exercise test (two patients), disliking having to stand still and not talking during HRV analysis (two patients), and unable to return to another assessment (Crossover) (one patient), thus constituting a sample of 12 patients.

To describe the demographic data of the patients, data were collected on age (years and months), topographic diagnosis of stroke, time of injury, classification (hemorrhagic or ischemic), affected hemisphere, weight (kg), height (cm), body mass index (BMI–kg/m²), blood pressure (BP), motor classification according to Fulg Meyer (mild, moderate, striking and severe).

All patients were instructed to appear always at 2:00 p.m. on assessment days, to avoid the influence of the circadian cycle. The prior recommendations were: continue with the use of medications on the respective hours, eat light diet on the test days, abstain from caffeine and ingestion of alcoholic beverages and/or smoking, avoid moderate or excessive effort on the previous day and the test day. The study procedures were performed in 6 moments.

The sample size was calculated using the mean of the three periods (baseline, post tDCS, and exercise recovery) of five individuals from the active tDCS group and five individuals from the tDCS sham group (crossover) from the pilot study.

To make the total average of the standard deviation, the sum of all deviations was calculated and divided by 6, which represents the total number of periods of the two groups.

To calculate the effect size (0.2453323), these values were entered in the G * Power 3.1.9.2 program and applied *F* tests, with a repeated-measures ANOVA statistical test between two factors with an $\alpha = 0.05$, $\beta = 0.80$, and sample correlation of 0.5 giving an $n = 90$.

The clinic-demographic characteristics of patients are presented in **Table 1**.

TABLE 1 | Descriptive characteristics of the sample.

Variables	*N* = 12
Age (year)	59 ± 7.00
Gender (F/M)	12 (4/8)
Injury in right hemisphere	5 (41.7%)
Injury in left hemisphere	7 (58.3%)
Injury time (months)	65.45 ± 54.86
Ischemic stroke	9 (75%)
Hemorrhagic stroke	3 (25%)
Use of blockers	6 (50%)
Use of diuretics	2 (17%)
Use of calcium channel blockers	3 (25%)
Use of ECA inhibitors	2 (17%)
Use of angiotensin receiver blockers	6 (50%)
Use of type 2 diabetes medication	3 (25%)
Use of medication for cholesterol	3 (25%)
Use of medication for arthrosis	1 (8%)
Use of medication for spasticity	1 (8%)

Height (cm)	165 ± 9.92
HR basal (bpm)	71.42 ± 10.70
SBP basal (mmHg)	130 ± 8.42
DBP basal (mmHg)	76 ± 9.30
Comorbidities:	17
Diabetes	3
Hypertension	10
Positive HIV	1
Cholesterol	3

Data expressed in average ± DP and frequency and percentage (%);F, Female; M, Male; MEEM, Mini exam of mental state, BMI, Body mass index; HR, Heart Rate; SBP, Systolic Blood Pressure; DBP, Diastolic Blood Pressure.

Table 1 presents the demographic data for patients evaluated. The average body mass index (BMI) was 26.52 ± 3.47 kg/m² with the average weight 72.25 ± 11.03 kg and an average height of 165 ± 9.92 cm, showing that the patients of the sample were overweight.

The heart rate average in rest was in (71 ± 10.70 bpm) within the normality and the SBP (130 ± 8.42 mmHg) and DBP (76 ± 9.30 mmHg) indicating stage 1 hypertension. All hypertense patients (83%) took medication for arterial hypertension, showing, therefore, a resistance hypertension degree.

Metabolic deficits such as diabetes or thyroid dysfunction were also not exclusion criteria, and of the 12 subjects participating in the study, three had drug-controlled type two diabetes.

TABLE 3 | Values of VSBP of hemiparetic patients, in time and frequency domain, in the period's basal, post-tDCS, and post-exercise, of Groups 1 and 2.

Groups (1 or 2)	Variance (mmHg)	LF ($mmHg^2$)	α-LF
Group 1 basal	30.10 (19.82–45.96)	5.12 (2.82–10.66)	1.74 (0.94–2.20)
Group 2 basal	26.04 (19.75–42.58)	5.61 (3.18–9.73)	1.73 (1.39–2.86)
Group 1 post-tDCS	33.07 (18.63–48.83)	9.81 (2.91–12.43)	1.54 (0.99–2.65)
Group 2 post-tDCS	35.86 (26.70–43.82)	8.82 (4.04–12.95)	1.94 (1.09–2.48)
Group 1 post-exercise	30.71 (25.75–41.70)	5.76 (4.27–10.71)	1.18 (0.63–1.88)
Group 2 post-exercise	31.25 (19.12–45.78)	5.76 (4.27–10.71)	1.45 (0.70–1.66)
P (Group 1)	0.78	0.78	0.74
P (Group 2)	0.53	0.37	0.53
Z	–	–	–

Variance, Total variability; LF, Low frequency band; $mmHg^2$, Millimeters of mercury to square; α-LF, Low frequency alpha index; Median (minimum-maximum).

All patients in the sample were overweight, as can be seen in **Table 1**, but after analyzing the baseline data between the groups, no differences were observed between the means as shown in **Table 2**.

Table 2 presents the results of Heart Rate Variability (HRV) and Variability of Systolic Blood Pressure (VSBP) in basal conditions (pre active tDCS and sham tDCS) of hemiparetic patients due to stroke.

The result presented in **Table 2** demonstrates that there was no difference in HRV and VSBP of patients due to stroke, in the basal condition of the two protocols. These data demonstrates that the patients found themselves in the same pre-test conditions.

In **Table 3** are presented the resulted of VSBP in time and frequency domain in the periods basal, pos-tDCS and during the exercise recovery in the treadmill of Group 1 and 2.

The results of **Table 3** show that there was no difference between the active groups and sham (1 and 2) in VSBP, in both the time domain and frequency domain in all periods analyzed.

Table 4 is presented the results of HRV in time and frequency domain in periods basal, pos-tDCS, and during the recovery from acute aerobic exercise post-exercise of Group 1 and 2.

The results of HRV in **Table 4** demonstrate that there was no difference between the active tDCS groups and sham in the following variables: Total variability (Variance), Square root of the square mean of the difference between adjacent normal RR intervals (RMSSD); Low frequency band absolute (LF abs) High frequency band absolute (HF abs).

In the period's post, tDCS and post-exercise in the linear analysis of time-domain of HRV intra-Group were observed that the variance value in the period post active tDCS increased in respect to the basal values, but did not maintain this increase in the post-exercise period. However, in the analysis intra-Group in the period post tDCS sham is also observed an increase in the variance value in respect to the basal values; however, in the period post-exercise of the group sham, there was a significant reduction in respect to the basal values.

Moreover, in the analysis intra-Groups, it was observed that RMSSD after active tDCS increased significantly and reduced after the exercise recovery period, but not significantly. In tDCS sham Groups, there was no significant difference in RMSSD.

In the frequency domain, it was observed an increase of Low-frequency band after the application of tDCS active and a reduction of the low-frequency band in the period post-exercise. However, in Group tDCS sham is observed the same Standard of high and low-frequency bands of active Group.

The effect size of active tDCS on intragroup HRV between post-tDCS periods compared to baseline HRV was calculated. As a result, an average effect size of ($d = 0.44$) was observed. There was no effect of active tDCS on HRV during the recovery period compared to baseline HRV.

In **Table 5** are presented the short term analysis (1 min) for RMSSD for post-exercise recovery.

Table 5 demonstrate that there was no difference between the active tDCS and sham groups. Intra-group post-exercise period, short-term linear analysis (1 min) for RMSSD demonstrated reduction of RMMSD in active and sham tDCS groups.

An analysis of the effects of tDCS by subgroups of left hemispheric lesions vs. right were generated (**Table 6**) and shows that both the active tDCS and sham tDCS group did not show differences in HRV between the injured hemisphere, regardless of the three periods (baseline, post-tDCS and exercise recovery).

TABLE 4 | Values of HRV in time and frequency domain between pre and post-tDCS periods and post-exercise, of Groups 1 and 2 (active and sham).

Table 7 presents the results after active and sham tDCS of treadmill exercise time performance in minutes (min), distance covered in kilometers (Km) and degree of effort of lower limb fatigue and respiratory exhaustion by the modified BORG.

Observed in **Table 7** that the active Group presented a significant increase of 90 m in the distance traveled in comparison with Group sham and the permanency time on the treadmill was greater in active Group (1 min), but not significant.

No difference was observed between the active Groups and sham in the perception of effort.

DISCUSSION

Considering the increase in patients surviving stroke events, it is important to increase knowledge regarding the mechanisms involved in the progression of lesions, as well as possible strategies for the management of this population, reducing the possibility of relapse and sudden death and providing a better quality of daily life. In this study, we evaluated the effects of a single exercise session, associated or not with prior tDCS stimulation, on BPPV and HRV in stroke survivors. Our results demonstrated that: there was no difference in VSBP and HRV between groups compared to baseline data; there was a reduction in time domain RMSSD band exercise recovery (short period linear analysis) in the groups with and without tDCS; however, in intragroup analysis, parasympathetic modulation after active tDCS increased the RMSSD by 18% from baseline, and the post-tDCS active and post-exercise periods had a variation value above baseline and, finally, and Importantly, there was better physical

performance, as assessed by the increased distance covered in the active tDCS group, suggesting a better prognosis.

The research was composed of patients of both sexes (**Table 1**), with 83% of the sample presenting drug-controlled hypertension, but not yet classified as stage 1 hypertension (23). Hypertension is an important risk factor for stroke patients and is aggravated by the aging of this population (24). As a characteristic, patients were also overweight, which increases cardiovascular risk due to aortic stiffness (23).

The results in **Table 2** showed that baseline HRV and VSBP values between the active groups and time domain and frequency domain simulation showed no differences, which demonstrates that the patients were in the same baseline conditions. Therefore, we show that the 48-h interval period was sufficient to avoid the effect of therapy addition (active or farce tDCS), corroborating with Nitsche and Paulus (25), who report that a 48-h interval between single session protocols is sufficient. to avoid possible effects additions.

The values of band LF absolute, in basal condition, suggested that the sympathetic system is already increased, what is already mentioned in the literature by Constantinescu et al. (26), Sander and Klingelhöfer (27), and Orlandi et al. (28), that describes that an acute ischemic stroke causes an autonomic unbalance capable of increasing the sympathetic cardiac activity, reduce HRV, and increase the risks of cardiac arrhythmia. It is important to remind the limitation about LF band of HRV and LF/HF ratio, sympatho-vagal balance, to provide indexes of the sympathetic activity. In these sense, there are evidences that LF band of HRV is modulated by the sympathetic and the parasympathetic nervous systems, thus LF band does not an index of sympathetic activity and the rationale for use LF/HF ratio, despite used as a cardiac sympatho-vagal balance, can be questioned (29).

In **Table 3**, the results of VSBP shows that the band of LF absolute of SBP was reduced in the basal condition, presenting an approximate value of 5 $mmHg^2$. The normal values, of healthy individuals, present a mean LF band value of SBP around 17 $mmHg^2$. This data suggests an exacerbated reduction of vascular sympathetic modulation, characteristic of sympathetic hyperactivity situations (30).

In respect to the results of VSBP after active tDCS and tDCS sham, no differences were found between the Groups and in the evaluation moments. However, we believe that the vascular sympathetic modulation may be reestablished, at least in part, post active tDCS. That was observed by the value of LF (of SBP) that increased ∼48% (despite not significant) in respect to the basal values. These results corroborate with the studies of immediate effects of anodic tDCS described by Cogiamania et al. (10) and Piccirillo et al. (31) about the autonomic modulation. However, this was demonstrated in healthy individuals, reporting that the techniques no invasive of brain stimulation that effectively modulate the human cortical function may influence the blood pressure.

Piccirillo et al. (31) observed an improvement of temporal dispersion of myocardium, reduction in sympathetic sinus control, and increased vagal modulation in healthy elderly, after the single application of tDCS for 15 min, intensity 2 mA, over the left temporal area (T3) associated to breathing exercises. This differentiation of results observed in our study may have occurred for being a different population, and that already presents an autonomic modulation alteration, as described by Dutsch et al. (8) that report that independent of the ischemia side, the patient's post sever stroke present a parasympathetic cardiac deficit.

In respect to HRV (**Table 4**), our results demonstrate that there were no differences between the variables analyzed between the Groups active tDCS and sham, both post tDCS as well as during the exercise recovery. But, in the analysis of variables between the moment's basal, post tDCS and exercise recovery of each Group, a significant increase was observed of IP Variance in the time domain, between the moments basal and post tDCS in two Groups. However, only in Group sham, the post-exercise values were significantly reduced, demonstrating a domain of sympathetic activation and reduction of vagal modulation, already expected after an acute physical activity. The fact that there was no significant reduction of variance, that expresses the total variability after active tDCS, leads us to suggest that tDCS could maintain a greater parasympathetic modulation post-acute exercise and, therefore, a possible sympathetic regulation by a parasympathetic activation.

We also observed an increase in the RMSSD variable only in the Group active tDCS, showing a possible parasympathetic modulation by tDCS. These findings corroborate with the findings of de Paula et al. (32) that compare HRV and baroreflex sensitivity to aerobic resistance to acute exercise, on men with autonomic dysfunction, showing an increase of sympathovagal balance and a late standard of recovery of baroreflex sensitivity, what delays an abrupt sympathetic reduction.

In the HVR frequency domain of linear mode, still in **Table 4**, we have shown an increase in LF band in its absolute values only in Group active tDCS after stimulation. Furthermore, after acute exercise, was observed a reduction in both Groups, active tDCS, and sham. This reduction is unexpected, being a normal reaction after acute stress from exercise (33). The absolute HF variable shows a significant reduction after acute exercise in both groups, but only in Group active tDCS, there was an increase of this band after active tDCS, showing a possible action of tDCS in the cardiac parasympathetic modulation.

Another important data observed in this study was a significant increase of the distance traveled on the treadmill after active tDCS when compared to the tDCS sham, results that corroborate with the findings Okano et al. (9) and CICCONE et al. (34) that observed the increase of performance in healthy individuals when compared to Group sham.

The literature has demonstrated that tDCS may modify the autonomic responses in healthy individuals Vandermeeren et al. (35) and Clancy et al. (36), in healthy athletes Montenegro et al. (6) and Okano et al. (9). This is the first study that has as purpose to assess the effects of tDCS over the left temporal lobe, in HRV in individuals with stroke sequel. The region where the electrodes were placed in our study differ from Vandermeeren et al. (35) that stimulate frontal cortex, and the reference electrode was extracephalic. Clancy et al. (36) stimulate the primary motor cortex (M1) of none dominant hemisphere placing anode in C3 or C4 (international system 10/20 of EEG) and the cathode electrode over the supraorbital area contralateral to the anode electrode; Montenegro et al. (6) and Okano et al. (9) stimulate left temporal cortex (T3), and the cathode electrode was placed in the supraorbital area (Fp2) contralateral to anode electrode.

We opted to stimulate T3 to be the area closest to the insular cortex, responsible for autonomic control (37) and used by

Montenegro et al. (6) and Okano et al. (9) with positive results in sympathetic modulation, observed by reduction and stability of heart rate of healthy athletes. These athletes performed better during a maximum incremental test, being 4% more efficient than their control group.

We performed more one analysis to see if the side of the lesion would affect our results (**Table 6**), since tDCS stimulation was only applied to the left temporal cortex, regardless of the side of the lesion, and the results showed no difference between groups, corroborating with Korpelainen et al. (38); Tokgözoglu et al. (39); Harms et al. (40); Constantinescu et al. (26) who report that neurovascular diseases such as ischemic stroke present changes in autonomic modulation with sympathetic hyperactivity, regardless of stroke lateralization.

Regarding the positioning of the reference electrode (cathode) we opted for the extracephalic (deltoid) positioning once according to Noetscher et al. (41) and removing the influence of cathode electrode action on the frontal cortex. Vandermeeren et al. (35), when studying the use of tDCS in the frontal cortex with an extracephalic reference electrode, under continuous cardiorespiratory monitoring and sympathovagal balance of healthy subjects, observed that subjects had a progressive reduction in respiratory rate, a constant increase in blood pressure over time, in which HR remained stable. However, regarding HRV, there was a trend of progressive change in sympathovagal balance, benefiting sympathetic tone, even when there is no significant difference between anode groups and cathode when compared with the tDCS sham, but proving to be a safe fit in healthy humans. Clancy et al. (36) observed autonomic modulation after active tDCS in M1 of healthy individuals.

There were no analyzes of all these data in our study regarding age. However, studies show that age alone is a cardiovascular risk factor (42). Aging promotes the reduction of vagal tone, favoring sympathetic predominance (42, 43).

Bonnemeier et al. (44) evaluated healthy individuals between 27 and 57 years old to verify the relationship of age with all HRV parameters and demonstrated that the parameters with the highest correlation with age were SDNNi, SNN50, and rMSSD; noting a decrease in vagal control as they get older, being more prominent among women.

In addition, systolic and diastolic blood pressure tends to increase with increasing age, especially in women, along with changes in peripheral and central mechanisms that help maintain adequate brain flow (45).

However, it should be considered that in our study we evaluated fewer women than men who would have more influence on age. Moreover, the presence of established hypertension and drug use in all research subjects, besides being stroke survivors, certainly have a greater impact on cardiovascular autonomic modulation than age. However, this can be considered a limiting factor in our study.

FINAL CONSIDERATIONS

This study supplies evidence that a single stimulation with tDCS over the left temporal cortex (T3) of hemiparetic patients due to stroke may improve the cardiac parasympathetic response (RMSSD and HF band of IP). However, significant differences were not observed in the other parameters studied. These results may provide the base for future perspectives of researches about the autonomic modulation after tDCS in stroke.

This study is one of the first studies purposes for evaluating the effects of tDCS over the autonomic modulation in hemiparetic patients due to stroke. Therefore, such opens a path for the betterment of a protocol purpose of verifying the best positioning of electrodes, best stimulation moment, as well as the best aerobic training protocol to be associated to electric stimulation over the cerebral cortex. We consider being important the continuity of the researches in this field for the improvement of knowledge and development of this treatment method considering the advantages listed.

STUDY LIMITATIONS

We consider some topics as limitations of our study:

Difficulty in recruiting patients due to their limited mobility;

Some patients had insecurity to walk on the treadmill. This fear may have influenced the increase in stress and, consequently, a greater parasympathetic action;

Absence of other neurophysiological evaluations such as electroencephalogram or lipid analysis, to better understand the effects of treatment.

Absence of complementary exams for an accurate diagnosis regarding the location and extent of the lesion. Patients with metabolic deficits such as diabetes or thyroid dysfunction were not excluded.

Study data were not analyzed by age. All patients were overweight.

DATA AVAILABILITY STATEMENT

Requests for data can be directed to Glauber Heinz, glauber.heinz@hotmail.com.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the proposed study complies with the principles of the Declaration of Helsinki and the Regulating Norms and Directives for Research Involving Human Subjects formulated by the Brazilian National Health Council established in October 1996. The study received approval from the ethics committee of Universidade Nove de Julho (São Paulo, Brazil) under protocol CAAE: 57314716.7.0000.5511 and is registered with the International Registry of Clinical Trials (ClinicalTrials.gov–NCT02956096). The participating institutions have provided a declaration of participation and will be allowed to abandon the study at any time with no negative repercussions. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

GH and FC conceived and planned the theory and drafted the manuscript. GH and MS carried out the experiment. KD, SD, AV, FD, and JC helped supervise the project. GH, MS, and FC conceived the original idea. GH, MS, AV, and FD developed the theoretical formalism and participated in the design of the study. SD participated the performed the statistical analysis. FC oriented the project and the authors KD and SD coordinated the project. All the authors have made substantive contributions to the manuscript and assume full responsibility for its content, conceived of the study, participated in its design and coordination and helped to draft the manuscript, read and approved the final manuscript. All authors agree to be accountable for the content of the work.

FUNDING

This work was supported by Coordenação de Aperfeiçoamento de Nível Superior (CAPES) support and Nove de Julho University (UNINOVE) scholarship.

ACKNOWLEDGMENTS

The authors are grateful to University Nove de Julho for supporting the present study.

Intracerebral hemorrhage (ICH) remains one of the most debilitating types of stroke and is characterized by a sudden bleeding from a ruptured blood vessel. ICH often results in high mortality and in survivors, permanent disability. Most studies have focused on neuroprotective strategies designed to minimize secondary consequences and prevent further pathology. Lacking is an understanding of how ICH acutely affects cerebrovascular components and their response to therapeutic interventions. We hypothesized that ICH alters cortical vessel complexity in the parenchyma adjacent to site of the initial vascular disruption and that vascular abnormalities would be mitigated by administration of the PDGFR inhibitor, Imatinib mesylate (Gleevec). Briefly, ICH was induced in male adult rats by injection of collagenase into basal ganglia, followed by Gleevec administration (60 mg/kg) 1 h after injury. Rats were then perfused using vessel painting methodology (Salehi et al., 2018b) to stain whole brain vascular networks at 1 day post-ICH. Axial and coronal wide field fluorescence microscopy was performed. Analyses for vascular features were undertaken and fractal analysis for vascular complexity. Data were collected from four groups of rats: Sham + Vehicle; Sham + Gleevec; ICH + Vehicle; ICH + Gleevec. Microscopy revealed that cortical vessels in both ipsi- and contralateral hemispheres exhibited significantly reduced density and branching by 22 and 34%, respectively. Fractal measures confirmed reduced complexity as well. Gleevec treatment further reduced vascular parameters, including reductions in vessel density in tissues adjacent to the ICH. The reductions in brain wide vascular networks after Gleevec in the current study after ICH is contrasted by previous reports of improved behavioral outcomes and decreased ICH lesion volumes Reductions in the vascular network after Gleevec may be involved in long-term repair mechanisms by pruning injured vessels to ultimately promote new vessel growth.

Keywords: cerebrovasculature, vessels, vessel painting, magnetic resonance imaging, edema, fractal

INTRODUCTION

Spontaneous intracerebral hemorrhage (ICH) is defined as a sudden bleeding from ruptured cerebral blood vessels. It accounts for about 10–20% of all strokes (Feigin et al., 2009) and is associated with higher mortality and morbidity leading often to worse outcomes compared to other strokes (Broderick et al., 1999). ICH occurs primarily when a hematoma rapidly accumulates within brain parenchyma (Aronowski and Zhao, 2011) with a persistent expansion over 6–24 h (Aguilar and Brott, 2011). This leads to further mechanical disruption of the normal parenchymal anatomy (Aronowski and Zhao, 2011) followed by subsequent tissue compression effects and increased intracranial pressure (Qureshi et al., 2009). This expansion of the hematoma is highly predictive of neurological deterioration, poor functional outcome and mortality (Broderick et al., 1993; Kazui et al., 1996, 1997; Leira et al., 2004). The hemorrhagic expansion can be attributed to leakage or rebleeding from secondary mechanical shearing of vessels surrounding hematoma (Fisher, 1971) but other cellular processes are also known to contribute including, but not limited to: (a) initiation by thrombin of the coagulation cascade leading to activated microglia (Wagner et al., 2002; Nakamura et al., 2005; Nakamura et al., 2006; Xi et al., 2006), (b) hematoma breakdown-products such as hemoglobin (Mracsko and Veltkamp, 2014), and (c) a robust inflammatory response (Wang and Dore, 2007; Yang et al., 2016). These secondary outcomes lead to a disrupted BBB resulting in significant brain edema (Hua et al., 2007) that are strongly predictive of functional outcomes (Gebel et al., 2002). While neuroinflammation and other secondary injury cascades in the context of ICH have been well studied previously (Yang et al., 2016), little has been reported on the how ICH modifies cerebrovascular integrity and morphology. We have previously reported that ICH results in a modified cerebral vascular smooth muscle phenotype (Pearce et al., 2016). However, the morphological features of the injured cerebrovasculature including integrity of the neurovascular unit are critical features that are poorly understood. Clinically, the microvascular integrity has been cited as a potential key factor in hematoma expansion in one third of ICH patients (Chen et al., 2017). Thus, a more complete understanding of how the vasculature is altered following ICH is warranted.

To our knowledge, there are no comprehensive studies examining the vascular morphology of parenchymal vessels following ICH nor the vasoprotective effects Gleevec. Thus, we set out to investigate the microvascular morphological changes adjacent to perihematomal parenchyma and in cortical regions remote from the site of the ICH lesion. To examine whole brain vessel morphology, we applied our novel vessel painting technique as we have reported in other models of acquired brain injury (Obenaus et al., 2017; Salehi et al., 2018b). This approach allows whole brain staining of the vasculature and is amenable to confocal microscopy for derivation of vascular morphological details. In the present study we first investigated how ICH modifies vascular morphological features followed by assessment of how Gleevec treatment could maintain vascular morphology acutely after ICH. We examined the vascular plexus in cortex and basal ganglia closely and analyzed their features in both hemispheres.

Gleevec or Imatinib Mesylate was developed to treat chronic myelogenous leukemia (CML) and is known to have multiple roles (Soverini et al., 2018). Gleevec has been shown to minimize stroke damage by its actions on the vasculature (Su et al., 2008). More recently we and others have identified that Gleevec antagonism of the platelet-derived growth factor receptor-β (PDGFR-β) on vascular elements. We reported that vascular smooth muscle phenotype is modified after ICH and that Gleevec mitigates this phenotypic switch (Pearce et al., 2016; Yang et al., 2016). Others have also shown that PDGF and its family play an important role in vascular protection using the retina as a model system (He et al., 2014). We investigated the role of Gleevec (Imatinib), a PDGFR-β antagonist, on vessels and how it influenced vascular measures acutely (1 day) after ICH. Thus, this study reports that ICH induces vascular loss, locally at the site of ICH and in regions distant from the injury. Moreover, acute assessment of Gleevec treatment found no significant protection of the cerebrovasculature during the acute assessment period.

MATERIALS AND METHODS

Animals

All animal experiments and care were in compliance with federal regulations and approved by the Loma Linda University Institutional Animal Care and Use Committee. Thirty male Sprague Dawley rats weighing 250–300 g (2–5 months old) were housed in a temperature controlled animal facility on a 12 h light-dark cycle and were allowed free access to food and water. Animals were randomly assigned to experimental groups. Aseptic techniques were used for all surgeries. No rats died or were excluded from the study due adverse outcomes from intracerebral hemorrhage injury (ICH).

Experimental Groups

All drug administration was performed by within 1 h following ICH induction, where vehicle (PBS and 0.1% DMSO) or 60 mg/kg Gleevec were injected intraperitoneally. Rats were subdivided randomly into four groups (n = 6/group): (a) Sham + vehicle, (b) sham + Gleevec, (c) ICH + vehicle, (d) ICH + Gleevec. Neurological function and behavior were assessed 24 h after ICH induction.

Intracerebral Hemorrhage Injury (ICH) Model

ICH was induced using the Bacterial Collagenase injection model as previously described (Pearce et al., 2016). Rats underwent isoflurane anesthesia (4% induction with 2% maintenance in 70% medical air and 30% O_2) and then were secured prone onto a stereotactic frame (David Kopf Instruments, Tujunga, CA, United States). Body temperature was maintained at 37.0°C ± 0.5°C using a thermostat-controlled heating blanket throughout the entire surgical procedure. The following stereotactic coordinates were used to localize the right basal

ganglia: 0.2 mm anterior, 5.6 mm ventral, and 2.9 mm lateral to the bregma. An incision was then made over the scalp and a posterior cranial burr hole (1 mm) was drilled over the right cerebral hemisphere into which a 27-gauge needle was inserted at a rate of 1 mm/min. A micro infusion pump (Harvard Apparatus, Holliston, MA, United States) infused the bacterial collagenase Type VII-S (0.2 U/μL; Sigma-Aldrich, St. Louis, MO, United States) through a Hamilton syringe at a rate of 0.2 μL/min. The needle remained in place for 10 min to prevent back-leakage before being slowly withdrawn (1 mm/min). The borehole was then sealed with bone wax, the incision sutured closed and the animals were monitored during the recovery period. Sham animals received the identical manipulations but instead of collagenase injection they received vehicle infusion. Food, water, and post-operative supportive care were provided, as is routinely done. Animals were euthanized 24 h after surgery for assessment of vascular morphology.

Vessel Painting and Tissue Fixation

Animals were sacrificed via transcranial perfusion 24 h after ICH for vessel painting and for tissue fixation (Salehi et al., 2018b). Briefly, rats were anesthetized by intraperitoneal injection of ketamine (90 mg/kg) and xylazine (10 mg/kg), then perfused for vessel painting and finally tissue fixation. Our vessel painting protocol stains the vascular network using DiI (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate) (Life Technologies, Carlsbad, CA, United States) which has been commonly used for labeling cell membranes (Schlessinger et al., 1977) and neuronal tissues (Honig and Hume, 1986; Godement et al., 1987). The lipophilic properties of DiI allow direct vascular staining. The perfusion device consisted of a 25- gauge butterfly needle and syringes for phosphate-buffered saline (PBS), DiI solution and Paraformaldehyde (PFA). After exposure of the heart a butterfly needle was inserted into the left ventricle. Heparin (0.02 mg/g, Sagent Pharmaceuticals) and sodium nitroprusside (0.075 mg/gm, Sigma-Aldrich, St. Louis, MO, United States) were injected followed by serial injections of 150 ml of PBS, 50 ml of DiI (13ug/ml) in diluent solution and 200 ml of 4% PFA. Care was taken to ensure that no air was trapped within the perfusion system. Brains were extracted from the cranium, rinsed in PFA and post-fixed for 24 h. Thereafter, vessel painted brains were stored in PBS until MRI or wide-field microscopy were undertaken. Individual photographs of vessel-stained brains were acquired to document the labeling efficacy. In this study, vessel painting was successful in 71% of animals wherein vascular staining was uniform (**Figure 1**).

Magnetic Resonance Imaging Acquisition and Analysis

High resolution MRI was undertaken using an 11.7T Bruker Avance instrument (Bruker Biospin, Billerica, MA, United States) running with the Paravision software (version 5.1, Bruker Biospin) to assess brain injury volumes. T2-weighted images [T2WI; repetition time (TR)/echo time (TE): 2395 ms/10 ms, 20 × 1 mm slices] were acquired and collected on a 256 × 256 matrix with a 2 cm field of view to quantitate edema and extravascular blood.

Volumetric analysis of hematoma size and quantification of surrounding edema was performed on T2WI coronal slices using Cheshire image processing software (Hayden Image/Processing Group, Waltham, MA, United States, version 4.3). Investigators who were blind to treatment groups manually defined the region of interest (ROI) on each slice that included whole brain, hematoma (hypointensity), and edema (hyperintensity). Hematoma and edema area on each slice affected by the ICH injury were delineated based on the differentiation of hyper-/hypo- intensive regions of injury relative to surrounding normative tissue conditions. Any blood or edema on or below the corpus callosum was classified as subcortical injury, whereas any injury above the corpus callosum was classified as cortical injury. Whole brain analysis started where the olfactory bulb begins to merge with the cortex and spanned the entire cerebrum. To obtain edema volumes the hematoma volume was subtracted as the edematous region typically encased the hematoma. Cortical injury was analyzed separately and also combined with subcortical injury for total ICH injury volumes. All data were organized and summarized in Microsoft Excel.

Vessel Painting Image Acquisition and Analyses

Vessel painted brains were imaged using Keyence BZ-9000 fluorescent microscope (Keyence BZ-X700; Keyence Corp., Osaka, Japan). Whole brains were gently positioned between 2 glass slides and lightly compressed to eliminate bubbles and improve visibility. Whole brain axial views were imaged at 2X with z-stacks using 60 μm steps with 50 slices resulting in 3 mm slab. After axial views were collected, the brains were bisected into 2 coronal segments with an anterior and posterior face at the level of the ICH lesion using MRI data as a guide. Coronal images were then scanned at the same resolution by gently fixing the anterior half of the brain on a single glass slide, examined at 2X, z-stacked at 60 μm with 30 slices resulting in 1.8 mm sections. Z-stacks for both axial and coronal were merged into full focus images using the BZ-II analyzer software (Keyence Corp., Version 1.2.0.1.). Finally, the software haze reduction feature (Blur/Brightness/Reduction: 10/10/1) was applied on the resultant images to remove any background and enhance the vascular network.

Classical vascular analysis was undertaken using the Image J plugin, Angiotool (RRID:SCR_016393) (Zudaire et al., 2011). Originally developed to assess spatial features of the angiogenic vasculature in the retina we have adapted this software for use in evaluating whole brain cortical vessels after traumatic brain injury (Obenaus et al., 2017; Salehi et al., 2018b). Angiotool features used in the current study were structural parameters such as vessel density and length, branch points and lacunarity (space without vessels).

Similar to our previous studies (Obenaus et al., 2017; Salehi et al., 2018b), we utilized fractal analysis to determine vascular complexity. Fractals have been widely used to describe structural

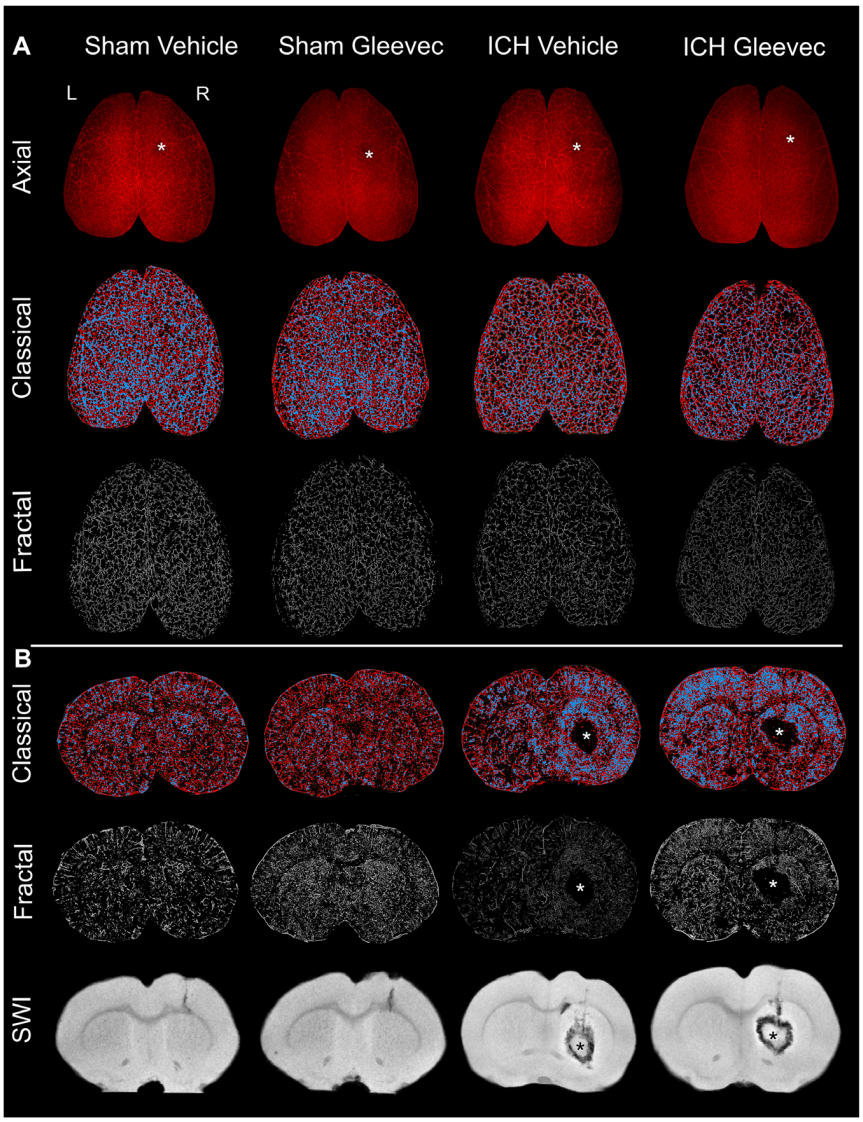

FIGURE 1 | Intracerebral hemorrhage (ICH) results in cerebral vascular decrements at 24 h after injury or treatment. **(A)** Axial: The top row illustrates representative axial vessel painted whole brains in ICH animals with and without Gleevec treatment (* = injection site). The middle row are sample classical vascular analysis maps where red denotes vessels and blue demarcates vessel junctions. The third row displays fractal maps utilized for analysis of vascular complexity. **(B)** Coronal: Classical vascular analysis of coronal sections from all experimental groups wherein the ICH lesion in the striatum can be visualized in the injured rats (*). Middle row are the corresponding fractal analysis maps. The last row of coronal images are from susceptibility weighted magnetic resonance imaging (SWI MRI) which was utilized to monitor the extent of the hematoma and edema after ICH induction. Sham animals exhibited minimal vascular alterations from needle insertion whereas ICH animals have prominent and extensive areas of vessel disruption at the site of the ICH. All images in each column are from the same animal.

complexity of various tissues, including the microvasculature of retina (Cheung et al., 2012), pituitary (Di Ieva et al., 2007), microglial complexity (Karperien et al., 2013) and cortical vessels (Obenaus et al., 2017). The ramified and irregular pattern of vessels after injury has made their evaluation by standard tools inaccurate and difficult. As we have done previously, we utilized the Fraclac ImageJ plugin (RRID:SCR_003070) to optimize quantification of vessels in cortex and basal ganglia (Schneider et al., 2012; Karperien et al., 2013). Briefly, binary images were analyzed by measuring the total number of pixels locally connected in a box of increasing size ε using the slope of the log regression line for pixel mass against scale (Karperien et al., 2013). The Local connected Fractal Dimension (DLC) is extracted and is calculated similar to the mass Fractal Dimension:

$$D_{Bmass} = \lim_{\varepsilon \to 0} \left\lceil {\ln(\mu_\varepsilon)}/{\ln(\varepsilon)} \right\rceil$$

Where με is the mean pixels per box at some size ε. The pixel mass is calculated from concentrically placed sampling units using a connected set at each pixel to produce a distribution

of local variation in complexity in data as previously described (Obenaus et al., 2017).

We used ImageJ analysis software to convert vessel painted images into binary images. First, we outlined our area of interest on each image then we ran Fraclac DLC analysis for each brain and saved the results. The distribution of DLC (also denoted as local fractal dimension, LFD) for each brain was then further processed for kurtosis, skewness, peak fractal frequency and local fractal dimension (LFD) for group comparisons. The LFD represents patterns at different scales and is often used to represent complexity of the subject. Skewness and kurtosis of the fractal histograms offer additional measures on how uniformly the fractal dimensions were distributed and how (peaked) the fractal distribution appears, respectively. Analyzed images were colorized based on fractal dimension using a default LUT color coding.

Laser Confocal Microscopy

Whole vessel painted brains and their coronal sections were imaged on the laser scanning confocal microscope Zeiss LSM 710 (Jena, Germany) to evaluate at high resolution vascular structures. Images were obtained (10X objective lens, excitation wavelength Abs: 549 nm, Ems: 565 nm) of the ipsilateral ICH hemisphere. Zeiss software (Zen) was used to process the z-stacks (28.4 μm steps) for resultant maximum intensity projections.

Statistics

All data was tested for normal distribution and comparisons were made using *t*-test (unpaired). If samples did not have normal distributions data were evaluated using a Mann–Whitney test. All graphical and statistical analysis used GraphPad Prism 7 software (GraphPad Prism, San Diego, CA, United States; RRID: SCR_002798). All calculations were achieved without knowledge of group. All data are presented as mean ± SEM with statistical significance reported at $p < 0.05$.

RESULTS

The results are comprised of two components: (a) first we report the novel findings of how ICH impacts the cortical and basal ganglia vasculature following ICH, and (b) we then describe the results of how Gleevec treatment after ICH may modify the cortical and basal ganglia vessels. Representative axial and coronal vessel painted brains and the classical and fractal vessel analysis maps as well as magnetic resonance imaging (MRI) are illustrated in **Figure 1**. It is readily apparent that ICH results in vascular modifications.

Vascular Modifications in the Cortex and Basal Ganglia 24 h After ICH

Visual examination of the wide field axial microscopic images of Sham + Vehicle ($n = 9$) and ICH + Vehicle ($n = 9$) vessel painted brains revealed a lack of overt gross cortical vascular changes (**Figure 1A**). Mild vascular disruptions at the injection sites on the cortex were visible in both Sham and ICH vessel painted brains (**Figure 1A** – denoted by *). However, in coronal images for classical vascular analysis maps, there was a visible apparent increase in junctional density after ICH, often adjacent to the hematoma (*) (**Figure 1B**, blue dots). Quantitative analysis was undertaken to evaluate the effects of ICH on cortical and basal ganglia vessels. Multiple vascular morphological parameters were quantified including: (1) vessel density (% vessel/total area), (2) branching index (branch points or junctions/unit area), (3) total vessel length, and (4) lacunarity, which describe areas that do not have vascular elements.

Axial Cortex Analysis

The morphological features of cortical vessels were derived from the whole axial cortical surface cortex, the ipsilateral (injection side) and contralateral (intact) cortex. Whole brain cortical (both hemispheres) vessel density of Sham + Vehicle animals was 26.94 ± 0.98 compared to 21.09 ± 0.85 in ICH + Vehicle rats (**Figure 2A**). This reduction in vessel density was significantly decreased by 21.7% ($p < 0.01$) in ICH + Vehicle compared to Sham + Vehicle rats. Similarly, vessel density of ipsilateral axial cortex in ICH + Vehicle rats was significantly decreased by 19.4% ($p < 0.01$) compared to Sham + Vehicle, with Sham + Vehicle having a vessel density of 27.30 ± 1.21 compared to 21.99 ± 0.87 in the ICH + Vehicle animals. Interestingly, contralateral axial cortical vessel density was also significantly decreased by 17.4% ($p < 0.01$) in ICH + Vehicle, where Sham + Vehicle animals had a vessel density of 27.47 ± 0.92 in the contralateral axial cortex compared to 22.69 ± 1.17 in ICH + Vehicle animals.

However, cortical vascular branching (branching index; junctions/mm^2) followed a similar pattern where ICH + Vehicle animals exhibited significant decreases of 34.2% ($p < 0.01$), 32.8% ($p < 0.03$), 31.6% ($p < 0.01$), respectively across the whole brain, in the ipsilateral hemisphere and in contralateral hemisphere (**Figure 2B**). As would be expected, lacunarity features were also increased with decreasing vessel density (**Figure 2C**). In the whole cortex and in the ipsilateral cortex, lacunarity was significantly increased in ICH + Vehicle animals by 21% ($p < 0.05$) and by 23% ($p < 0.01$) compared to Sham + Vehicle rats, respectively. Unexpectedly, the contralateral axial cortex of ICH + Vehicle rats did not exhibit increased lacunarity compared to Sham + Vehicle animals, despite reductions in vessel density and branching indices. Quantitative measurement of the total vessel length of the whole, ipsilateral and contralateral axial cortical vessels revealed no significant differences between the ICH vehicle and sham vehicle groups (data not shown).

Coronal Cortex and Basal Ganglia Analysis

Following axial cortical data collection, the brains were cut through the ICH lesion resulting in an anterior and posterior portion of the brain. Wide field fluorescent microscopic images were acquired from the anterior face of the vessel painted brains (**Figure 1B**). Ipsilateral coronal hemispheric analysis excluded the hematoma. The rationale for these coronal analyses was that it could reveal parenchymal vascular alterations in regions that encompassed cortical and deep gray matter structures such as the basal ganglia.

Coronal vessel density measures of the whole coronal slab in ICH + Vehicle rats was significantly decreased by 38.7%

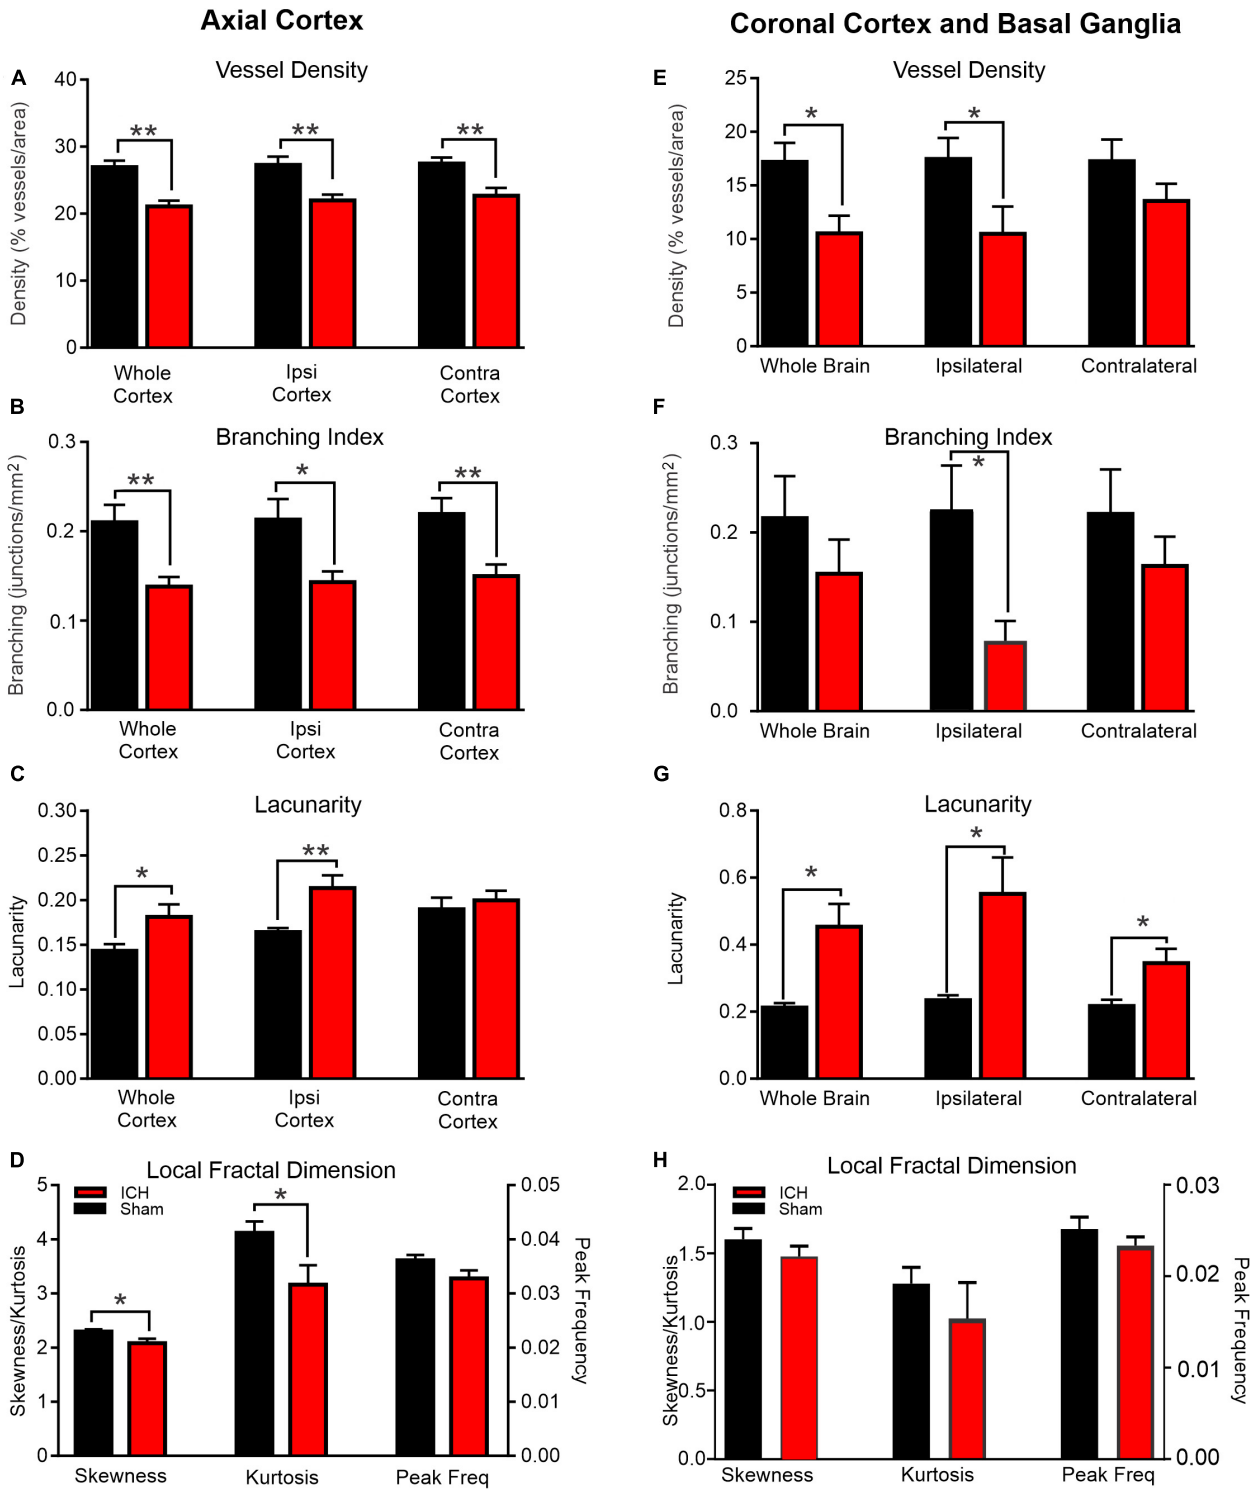

FIGURE 2 | ICH induces modification of vascular features at 24 h post-injury. Axial Cortex: Classical vascular analysis of the entire axial cortex, ipsilateral (Ipsi) and contralateral (Contra) cortical hemispheres resulted in significant reductions in vessel density **(A)** and branching index **(B)** after ICH compared to shams. There was a concomitant increase in lacunarity **(C)** but not in the contralateral hemisphere. Fractal derived vascular complexity of the ipsilateral cortex using local fractal dimension histograms (LFD) **(D)** exhibited significant decrements in skewness and kurtosis between shams and ICH animals. Coronal Cortex and Basal Ganglia: Classical vascular analysis of coronal vessel painted sections at the level of the ICH lesion revealed significant reductions in vessel density **(E)** and reduced branching indices **(F)**. There was a dramatic increase in lacunarity **(G)**. Quantitative analysis of the LFD histograms from the ipsilateral cortex and basal ganglia exhibited no significant changes in skewness, kurtosis or peak frequency **(H)** in ICH vehicle compared to sham vehicle animals (*t*-test $^{**}p < 0.03$, $^{*}p < 0.05$).

($p < 0.03$) compared to Sham + Vehicle rats (**Figure 2E**). The vessel density was 17.20 ± 1.78 in Sham + Vehicle rats compared to 10.53 ± 1.65 in the ICH + Vehicle animals. Similarly, vessel density in the ipsilateral coronal hemisphere of ICH + Vehicle animals were significantly decreased by 39.8% ($p < 0.05$) compared to Sham + Vehicle animals. Sham + Vehicle animals had a vessel density of 17.46 ± 1.97 compared to 10.50 ± 2.53 in the ICH + Vehicle animals. The vessel density of contralateral coronal sections had a 21.4% reduction in ICH + Vehicle compared to Sham + Vehicle animals but was not significantly different ($p = 0.17$).

The branching indices showed considerable variance in the coronal sections which is not overly surprising given differences in the vascular networks between cortical and basal ganglia brain regions (**Figure 2F**). Only the ipsilateral coronal section exhibited a significant ($p < 0.03$) reduction in vascular branching in ICH + Vehicle compared to Sham + Vehicle animals. Coronal total vessel length measures were not significantly different between ICH + Vehicle and Sham + Vehicle animals, similar to axial total vessel lengths (data not shown).

Lacunarity measures from coronal brain slices were significantly increased by 53.2% ($p < 0.03$), 57.4% ($p < 0.03$) and 37.2% ($p < 0.03$) in whole brain, ipsilateral, coronal and contralateral sections respectively (**Figure 2G**). In whole brain slices, lacunarity in ICH + Vehicle animals was 0.45 ± 0.09 compared to 0.21 ± 0.014 in sham vehicle rats. The lacunarity of ipsilateral coronal sections of ICH + Vehicle rats were reduced compared to Sham + Vehicle animals at 0.55 ± 0.11 and 0.23 ± 0.015, respectively. Even the lacunarity of contralateral coronal sections were reduced in ICH + Vehicle animals compared to Sham + Vehicle animals (ICH: 0.35 ± 0.04; Sham: 0.22 ± 0.02).

Fractal Analysis

Global measures of axial vascular complexity also revealed reductions similar to and validating our classical angiographic measures (**Figures 1**, **2D**). Analysis of the ipsilateral axial cortex found that skewness and kurtosis of ICH + Vehicle animals were significantly ($p < 0.05$) reduced by 9.37 and 23.2% respectively compared to Sham + Vehicle animals. Peak frequency of the local frequency dimension (LFD) histograms which is a measure of the number of vessels was also reduced by 10% in ICH + Vehicle compared to Sham + Vehicle animals but did not reach significance ($p = 0.09$).

Skewness, kurtosis and peak frequency of the LFD histograms of the ipsilateral coronal basal ganglia and cortex showed no significant differences (**Figure 2H**). ICH resulted in reduced kurtosis and peak frequency of the LFD histograms of ipsilateral coronal basal ganglia and cortex by 46.9% ($p = 0.42$) and 8.2% ($p = 0.28$) respectively in ICH + Vehicle compared to Sham + Vehicle animals. In the automated fractal analyses we were unable to exclude the hematoma from the analysis and likely contributed to the non-significant findings.

In summary, vascular features of the cortex were predominately reduced with the induction of ICH compared to Sham + Vehicle animals. Both axial and coronal assessments yielded similar reductions, further validating our analyses. Interestingly, ICH in many measures also resulted in reductions in contralateral vessel parameters at 24 h after injury. Acutely, other studies of acquired neurological injury have reported similar contralateral effects on the cerebrovasculature.

Effects of Gleevec on the Vasculature

Axial Cortex Analysis

Gleevec (Imantinib) has been reported to be anti-inflammatory and alter the structure of the vasculature following ICH (Soverini et al., 2018; Su et al., 2008). We undertook a more direct measure of the vasculature after Gleevec treatment on vascular features for the ipsilateral hemisphere. For these analyses our comparisons were made between Sham + Vehicle, Sham + Gleevec, ICH + Vehicle and ICH + Gleevec.

The density of the axial cerebrovasculature was significantly reduced in ICH + Vehicle and ICH + Gleevec rats compared to Sham + Vehicle (ANOVA, $p = 0.002$, *post hoc* multiple comparisons $p < 0.01$) (**Figure 3A**). The reduction between Sham + Vehicle compared to ICH + Gleevc was 28.2%. Identical reductions were observed in the branching index (ANOVA, $p = 0.005$, *post hoc* multiple comparisons $p < 0.01$) with a 35.6% reduction in junctions between Sham + Vehicle and ICH + Gleevec groups (**Figure 3B**). As would be expected with reduced vessel density, lacunarity was significantly increased in Sham + Gleevec, ICH + Vehicle and ICH + Gleevec compared to Sham + Vehicle rats (ANOVA, $p = 0.002$, *post hoc* multiple comparisons $p < 0.01$) (**Figure 3C**). Lacunarity was significantly increased in Sham + Gleevec by 49.2% ($p < 0.01$) compared to Sham + Vehicle animals. Thus, classical vascular measures of the axial cortex did not show improvement in Gleevec treated ICH animals with treatment at 24 h after ICH induction.

Alternatively, we also undertook a less conservative statistical analysis of just Sham + Vehicle and Sham + Gleevec groups and their vessel characteristics (**Supplementary Figure S1**) and found that lacunarity was increased significantly ($p < 0.001$) in Sham + Gleevec rats compared to Sham + Vehicle (**Supplementary Figure S1C**). No significant differences were observed in ICH rats between ICH + Vehicle and ICH + Gleevec groups. Fractal measures were significantly decreased in Sham + Vehicle and Sham + Gleevec rats (**Supplementary Figure S1D**) but no differences were observed between ICH + Vehicle and ICH + Gleevec groups.

Coronal Cortex and Basal Ganglia Analysis

We further investigated whether Gleevec had any effect on parenchymal vascular parameters in coronal brain samples (**Figure 1B**). Specifically, we examined vessels in the ipsilateral hemisphere (injured) that included the basal ganglia (peri-hematoma, but excluding the hematoma) and adjacent cortex.

Similar to our axial cortical findings (**Figure 3A**) we observed a significant reduction in vessel density (ANOVA, $p = 0.002$, Tukey's *post hoc* multiple comparisons $p < 0.05$) (**Figure 3E**). In ICH + Vehicle and ICH + Gleevec rats there were significant reductions compared to Sham + Vehicle rats, 39.8 and 57.3%, respectively. Total vessel length was unchanged with no differences between groups (data not shown). Branching index trended toward a reduction, like vessel density (ANOVA,

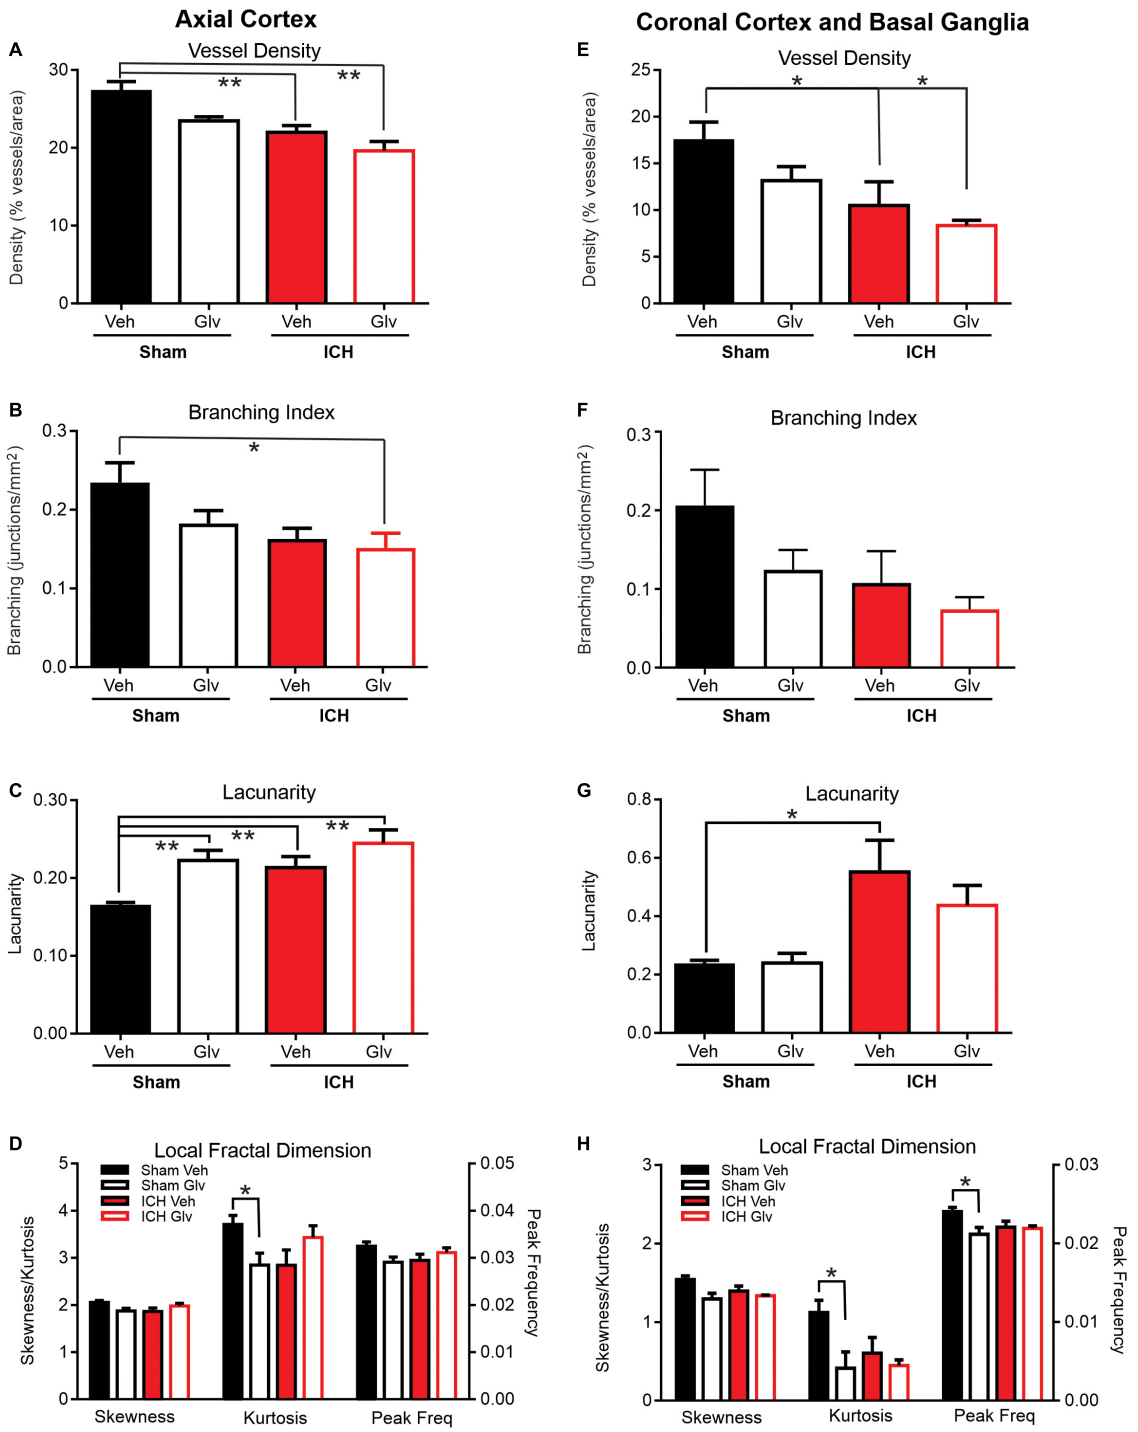

FIGURE 3 | Gleevec treatment does not improve ICH parenchymal vascular measures. Axial Cortex: Ipsilateral cortical vascular analysis revealed no significant changes in vessel density **(A)** or branching index **(B)** between Vehicle nor ICH Gleevec treated rats. However, significant reductions in vessel density were observed between sham vehicle and ICH + Vehicle and ICH + Gleevec rats. Vascular branching was significantly reduced between Sham + Vehicle and ICH + Gleevec rats. Lacunarity **(C)** was only increased in all groups relative to sham vehicle treated rats. Quantitative analysis of the distribution of LFD histograms **(D)** exhibited no significant reductions in skewness, and peak frequency in sham + Gleevec compared to sham + Vehicle animals. Kurtosis was significantly reduced between sham groups. Coronal Cortex and Basal Ganglia: Classical vascular analysis of ipsilateral cortex and basal ganglia revealed a progressively significant decrement in vessel density **(E)** across all groups. *Post-hoc* testing found significant differences between Sham + Vehicle and ICH groups (Vehicle, Gleevec). Branching index **(F)** and lacunarity **(G)** in sham nor ICH animals were not altered, except for a significant increase in lacunarity between sham + Vehicle and ICH + Vehicle rats. The distribution of LFD histograms **(H)** exhibited significant decreases in skewness, kurtosis and peak frequency across groups ($p < 0.05$) but *post-hoc* testing observed significant decreases only in sham groups. (one way Anova with Tukey's multiple comparisons, $^{**}p < 0.03$, $^{*}p < 0.05$).

p = 0.08) (**Figure 3F**). Again, the largest reductions were in the ICH + Gleevec rats. Lacunarity was increased in ICH animals where a significant increase in lacunarity was observed in ICH + Vehicle rats compared to Sham + Vehicle (ANOVA, p = 0.02, Tukey's *post hoc* multiple comparisons $p < 0.05$) (**Figure 3G**). Coronal analyses further substantiated a lack of Gleevec in mitigating the acute vascular consequences of ICH on basal ganglia and cortical vessels.

A similar less conservative statistical approach was applied to the coronal cortex and basal ganglia vascular measures (**Supplementary Figure S2**). No significant differences between Sham + Vehicle and Sham + Gleevec nor ICH + Vehicle and ICH + Gleevec groups were reported for classical vessel features. However, we found fractal measures were significantly decreased in Sham + Vehicle and Sham + Gleevec rats (**Supplementary Figure S2D**) with no differences observed between ICH + Vehicle and ICH + Gleevec groups. Again, the ANOVA and the *t*-tests for group differences essentially reported similar results.

Fractal Analysis

In the axial hemisphere fractal measures, skewness, kurtosis and peak frequency of the local fractal dimensions, were determined. Analysis of the ipsilateral axial cortex found that skewness, kurtosis and peak frequency were significantly reduced ($p < 0.05$) (**Figure 3D**). In the axial cortex Gleevec caused significant reductions ($p < 0.03$) in both skewness and kurtosis of the LFD histograms by 8.6 and 23.1% respectively in Sham + Gleevec compared to Sham + Vehicle animals (**Figure 3D**). Peak frequency of the local frequency dimension (LFD) histograms, which is a measure of the number of vessels, was also reduced by 10.3% in ICH + Vehicle compared to Sham + Vehicle animals but did not reach significance (p = 0.09). Gleevec resulted in no significant differences in fractal measures between the ICH groups (ICH + Vehicle vs. ICH + Gleevec).

Analysis of skewness, kurtosis and peak frequency of the LFD histograms of the ipsilateral coronal basal ganglia and cortex found significant differences when compared across all groups (**Figure 3H**) ($p < 0.05$). *Post hoc* analysis of ipsilateral coronal basal ganglia and cortical regions showed that Gleevec resulted in significant reductions ($p < 0.03$; *t*-test) in skewness, kurtosis and peak frequency of the LFD histograms by 15.9, 63.2, and 12.0% respectively in Sham + Gleevec compared to Sham + Vehicle animals. Gleevec resulted in no differences in fractal measures between the ICH groups (ICH + Vehicle vs. ICH + Gleevec), although post-hoc analyses observed significant changes between the sham groups ($^*p < 0.05$). These findings match those of the ipsilateral axial cortex (**Figure 3D**).

The Gleevec fractal results suggest possible alterations in ipsilateral vascular complexity compared to otherwise intact animals (Shams) at 24 h after ICH. These reductions in vascular complexity could play a role in the reported cerebral edema caused by Gleevec in patients with CML4 (Soverini et al., 2018).

Confocal Vascular Features

The effects of Gleevec on the cerebral vasculature were assessed from axial and coronal confocal images derived from vessel painted brains (**Figure 4**). All confocal images were acquired adjacent to the site of injection. As can be readily appreciated by visual inspection, Gleevec resulted in reductions in vascular density in ICH rats compared to ICH + Vehicle treated rats (**Figures 4A,B**). Vessel density was significantly reduced (p = 0.05) in ICH + Gleevec compared to ICH + Vehicle rats in axial cortex (**Figure 5A**). Branching index was also reduced with a trend to significance (p = 0.052) as was mean vessel length (p = 0.06) but lacunarity was significantly increased in

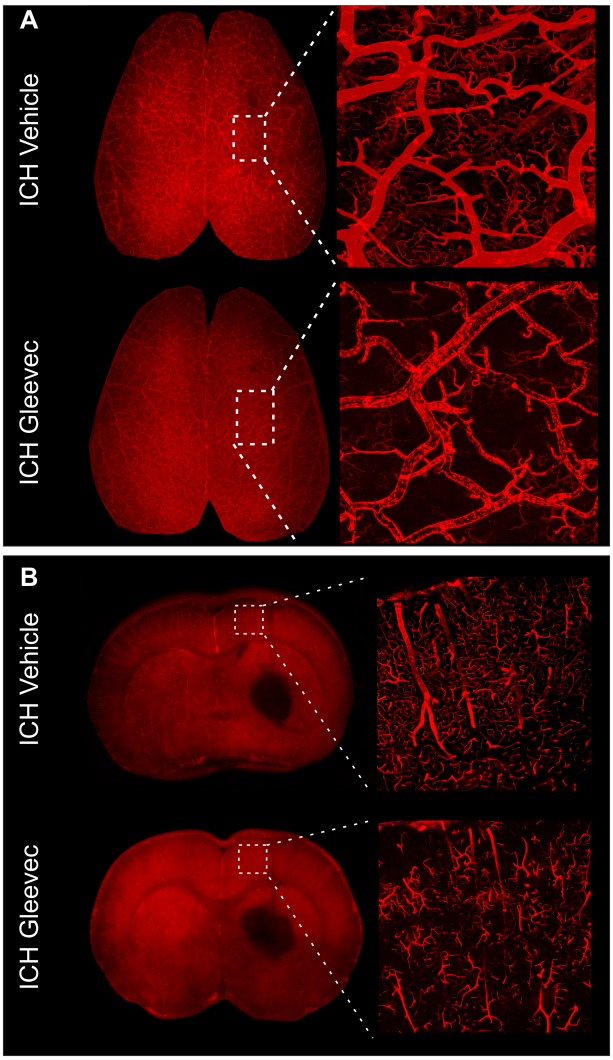

FIGURE 4 | Gleevec treatment does not improve the morphology of the cortical vasculature. **(A)** Vessel painted brains from the axial surface were imaged using confocal microscopy and then subjected to classical vascular analysis. ICH vehicle and ICH Gleevec animals exhibited uniform staining of large, intermediate and small vessels within the cortex. Note the apparent loss of fine branching vessels in the ICH + Gleevec rats. **(B)** In coronal sections from vessel painted brains, the cortical vessels descending into the cortex exhibited a dense plexus of vessels in ICH Vehicle treated rats. In contrast, ICH Gleevec treated rats showed a reduced vascular plexus with fragmented vessels and regions with overt loss of vasculature (see **Figure 5** for quantification).

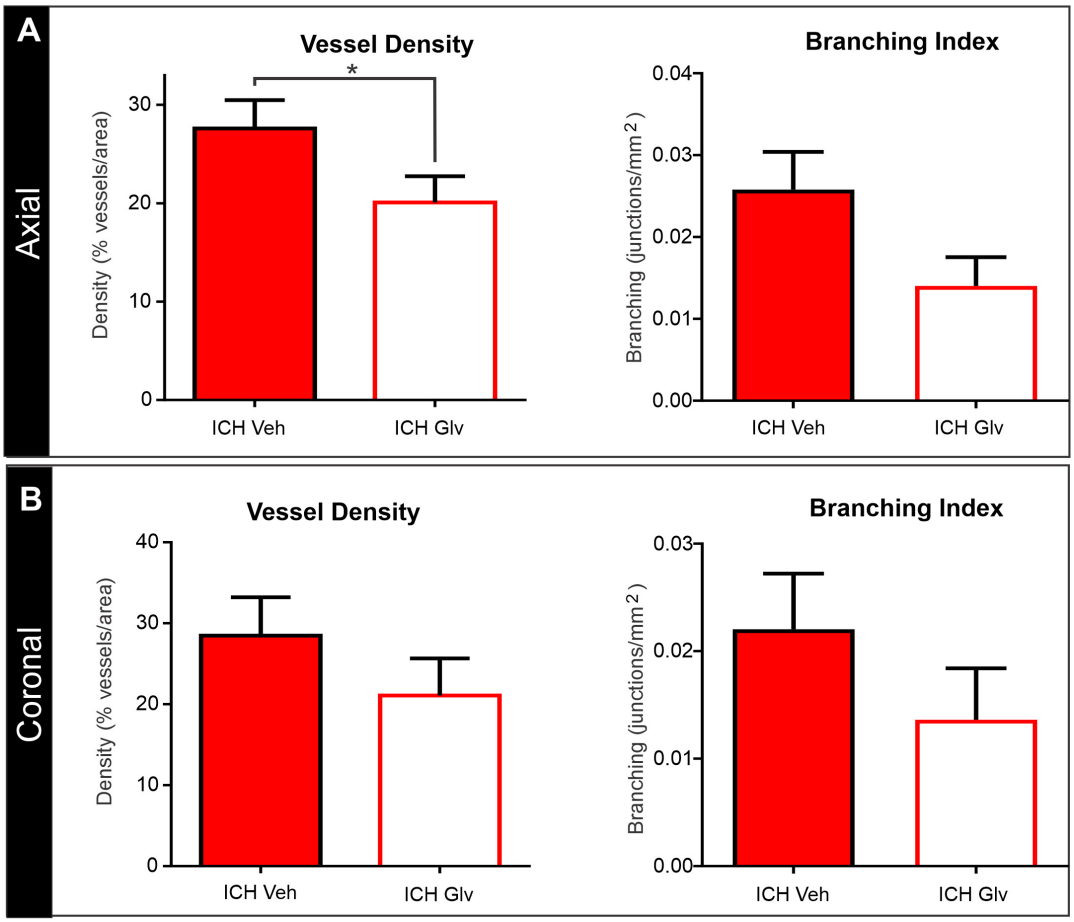

FIGURE 5 | Confocal vascular analysis also demonstrated that Gleevec treatment does not improve vascular density. **(A)** Quantitative assessment of axial cortical vascular features adjacent to the ICH injection site, revealed significant decrements in vascular density and trending decreases in vessel branching after Gleevec treatment. **(B)** Vascular features from cortical sections from coronal tissues also showed decreased vascular density and branching but did not reach significance. Note that both cortical assessments (axial vs. coronal) had similar relative decreases in vascular features (see **Figure 4** for images) (*$p < 0.05$).

ICH + Gleevec treated rats compared to ICH + Vehicle controls ($p = 0.03$). In the coronal cortex, no significant differences in vessel density ($p = 0.14$), branching index ($p = 0.13$), total vessel length ($p = 0.09$) nor lacunarity ($p = 0.06$) were observed, although some features were trending (**Figure 5B**).

We also examined vascular features in the basal ganglia adjacent to the hematoma (**Figure 6**). As can be seen in the confocal microscopy images there was an overt reduction in vessel density in Gleevec treated rats (**Figure 6A**). Quantification demonstrated a significant decrease in vessel density ($p = 0.05$) in ICH + Gleevec compared to ICH + vehicle treated rats (**Figure 6B**). Lacunarity in the ICH + Gleevec rats was also significantly increased ($p = 0.04$) compared to ICH + Vehicle controls. No significant differences were found in branching index ($p = 0.09$) nor total vessel length ($p = 0.70$) (data not shown).

Magnetic Resonance Imaging (MRI)

High resolution *ex vivo* MRI was undertaken to assess hematoma (SWI) and edema (T2WI) volumes (T2WI) (**Figure 7**). Hematoma volumes were outlined from ICH + Vehicle and ICH + Gleevec rats as shown in **Figure 7A** (red dotted line). There were no statistical differences for hematoma volumes between the two groups (**Figure 7B**), where hematoma volumes for ICH + Vehicle rats were 2.30 ± 0.23% of brain volumes and ICH + Gleevec rats had 1.96 ± 0.21% ($p = 0.31$). Similarly, for edema volumes there were no significant differences between groups (**Figure 7C**). Edema volumes corrected for brain volumes were 2.14 ± 0.28% and 2.22 ± 0.38% in ICH + Vehicle and ICH + Gleevec rats, respectively.

To assess relationship between vascular features and MRI lesion (hematoma + edema) volumes, we correlated vascular complexity measures (skewness, kurtosis, peak LFD value, and peak frequency) to total ICH lesion volumes (**Figure 7D**). In ICH + Vehicle treated rats, lesion volume (right hemisphere) was significantly correlated to skewness ($R^2 = 0.6725$, $p = 0.0127$), kurtosis ($R^2 = 0.6665$, $p = 0.0134$), and peak frequency ($R^2 = 0.6290$, $p = 0.0189$), but not for maximum LFD ($R^2 = 0.1194$, $p = 0.4019$) (**Figure 7D**). We

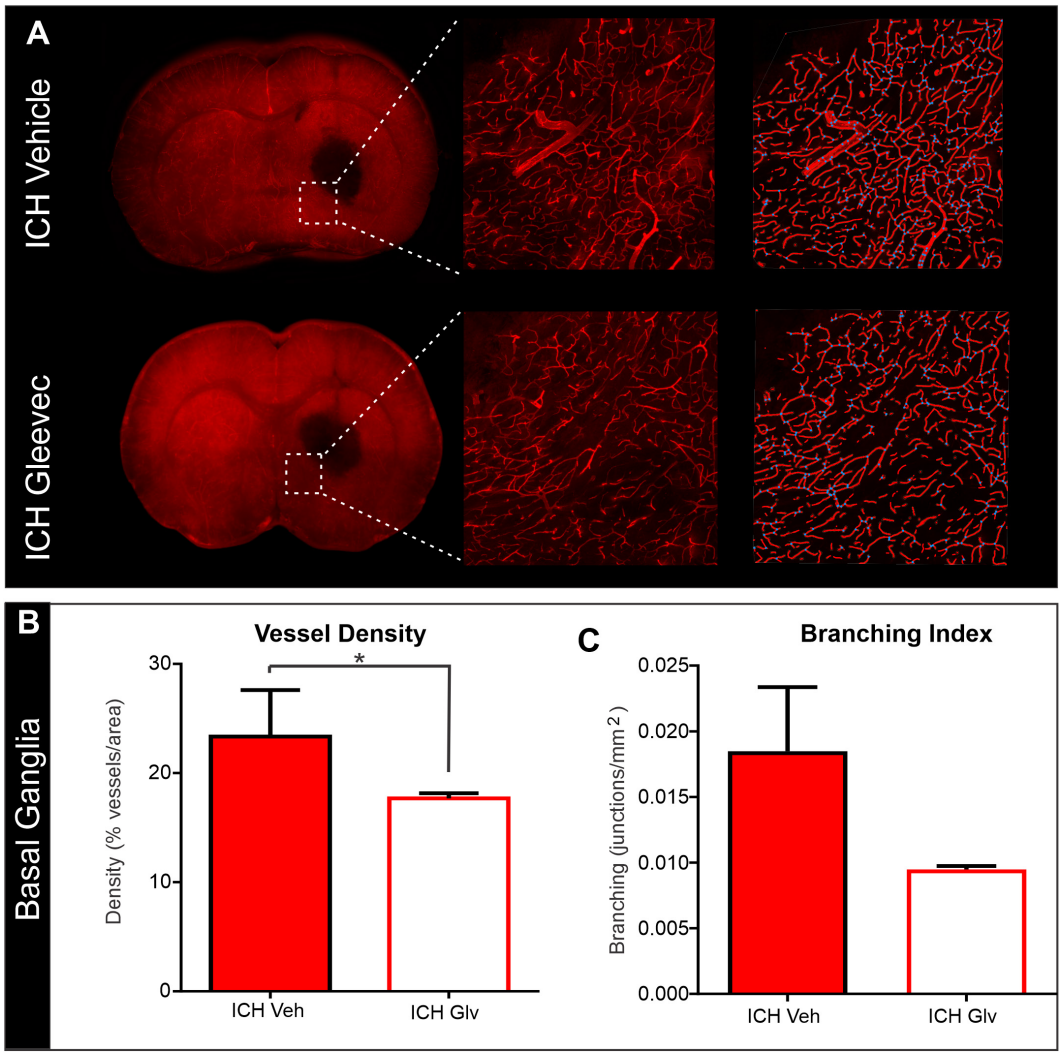

FIGURE 6 | Confocal analysis of the basal ganglia vasculature revealed no improvement with Gleevec treatment. **(A)** The basal ganglia vasculature was assessed for morphological characteristics adjacent to the ICH site. As in the cortex, there was reduced vascular density with loss of fine vascular structures, including branch points. Far right pane illustrates the analysis that derived vessel density (red) and branching (blue dots). **(B)** Quantification of vascular metrics confirmed the visual observations with significantly reduced vascular density ($p = 0.05$) and trending decreases in **(C)** vessel branching ($p = 0.09$) in Gleevec treated compared to Vehicle treated rats.

did not observe any such correlations in ICH + Gleevec treated rats (**Table 1**). **Table 1** outlines a number of additional correlations that were undertaken with respect to whole brain and lesion volumes (cortical vs. subcortical). Interestingly, axial cortical measures of vascular density also did not yield any significant correlations to MRI derived volumes (**Table 1**).

In summary, at 24 h post-ICH there were no significant differences in hematoma, edema nor total lesion volumes as derived from MRI. However, MRI volumes did reflect alterations in vascular complexity but only in ICH vehicle rats. These results further suggest that Gleevec treatment alters vascular phenotype acutely after ICH.

DISCUSSION

A comprehensive examination of the morphological vascular features after ICH is lacking and prior to evaluation of putative neuroprotective compounds a more complete understanding of how ICH modifies the cerebrovasculature is required. Toward filling this knowledge gap, we now report that ICH resulted in decrements of vascular features acutely following ICH. Specifically, the novel findings we report are, (a) the application of our unique vessel painting methodology to the ICH model, (b) significant reductions in classical vessel features including vessel density and branching, (c) these reductions in vascular morphology are present even distant from the ICH lesion (i.e., cortex, contralateral brain tissues), and (d)

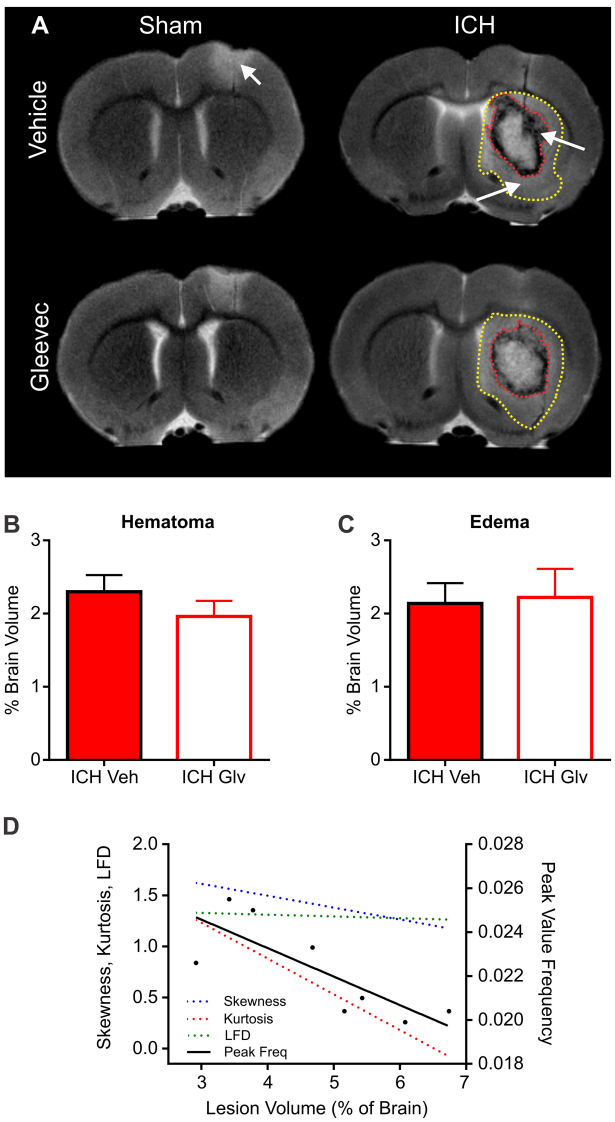

FIGURE 7 | Lesion and hemorrhage volumes were not modified by Gleevec treatment 24 h after ICH. **(A)** Representative MR images from Vehicle and Gleevec treatment rats. Shams exhibited cortical edema (white arrow) at the site of needle insertion. In ICH animals there were hypo- and hyperintense regions visible in the basal ganglia, consistent with blood (red dotted line) and edema (yellow dotted line), respectively (white arrows). **(B)** Subcortical hematoma volumes were not significantly altered between shams and Gleevec treated rats. **(C)** Volume of subcortical edema volumes was not significantly different following Gleevec treatment. **(D)** Correlations of total ICH lesion (blood + edema) volumes compared to ipsilateral fractal properties of ICH vehicle treated rat's revealed significant correlations. The lesion volume was strongly correlated to fractal skewness (R^2 = 0.6725, p = 0.0127), kurtosis (R^2 = 0.6665, p = 0.0134), and peak frequency (R^2 = 0.6290, p = 0.0189), but not for LFD (R^2 = 0.1194, p = 0.4019). See **Table 1** for additional correlations.

measures of vessel complexity using fractal analyses also report decrements. In addition, we used Gleevec to restore or blunt these vessel morphological decrements. Gleevec did not result in improvements but resulted additional vascular reductions in the cortex and in the basal ganglia. Thus, ICH leads to loss of vessels and morphology at 1 day post-injury and Gleevec induces a further exacerbation of vascular density loss.

The effects of ICH on cerebral vessels and blood flow in animal models and in human subjects have been previously described (Zazulia et al., 2001; Xie et al., 2012) and detailed in a recent review (Keep et al., 2014). Most studies investigating the vascular effects of ICH focused on the components of the neurovascular unit (NVU), endothelia, astrocytes and pericytes, with an eye toward blood brain barrier (BBB) breakdown. The disruption of the BBB by ICH leads to numerous downstream (secondary) events including increased bleeding, neuroinflammation and edema formation (Yang et al., 1994; Chen-Roetling et al., 2015; Leclerc et al., 2018; Xu et al., 2019). An 11% reduction in vessel density and volume was reported adjacent to the ICH lesion using high resolution micro-computed tomography (Xie et al., 2012). Functionally, Zazuila and colleagues found a 44% decrease in cerebral blood flow adjacent to the ICH clot within 24 h, consistent with our results that showed a decrease in vascular density and edema at the same time point (Zazulia et al., 2001). Thus, whilst preservation of the BBB is important following ICH, a more thorough understanding of how the morphology of vessels are modified by ICH is clearly warranted prior to studies targeted to improving the vasculature.

We undertook in the present study a quantitative evaluation of the alterations in vessel morphology acutely after ICH. We report a dramatic ∼20% reduction in vessel density in the whole cortex as well as the ipsilateral and contralateral cortices. The observed reduction was distant from the ICH site of injury and in the basal ganglia we observed a 39% decrement in vascular density. Other vascular metrics such as vessel branching were similarly reduced at 24 h post-ICH induction. The marked reduction in vessel density within the basal ganglia would be expected based on the reported mass effects (Brouwers et al., 2014), ferroptosis (Wan et al., 2019) and associated redox activities known to occur after ICH (Chen-Roetling et al., 2015; reviewed in Keep et al., 2014). What was surprising were the global (ipsi- vs. contralateral) cortical reductions in vessel features (density, branching, etc.). In the acute stages of ICH (<24 h) numerous mechanisms could contribute to distant modifications of brain vessels (Aronowski and Zhao, 2011; Ren et al., 2014; Schlunk and Greenberg, 2015). Indeed, we have reported on a yet unidentified diffusible factor after ICH that can alter the structure of vessels distant from the injury site that likely modifies vessel morphology as well as function (Pearce et al., 2016).

We suggest that a combination of factors contribute to the reductions in vessel features we observed following ICH. Firstly, as we and others have reported there is a significant edematous response within the basal ganglia surrounding the perihematomal region (Yang et al., 1994; Belayev et al., 2003; Xu et al., 2019). This robust disruption of the vasculature and subsequent BBB leads to increased vascular permeability and edema formation (see **Figure 7**) in the collagenase model of ICH. Secondly, the deposition of red blood cells and subsequent lysis increase iron and thrombin at the ICH lesion site (Hua et al., 2007; Wan et al., 2019). This results in a neuroinflammatory cascade that certainly further exacerbates existing vessels and might play a significant role in subsequent lesion expansion. A number of

key proteins involved in inflammation, necrosis and apoptosis, have been shown to be upregulated acutely after ICH induction (Ren et al., 2014). Thirdly, a number of endothelial junction proteins and regulatory mechanisms that act synergistically to maintain vascular integrity are known to be impacted by ICH and have been comprehensively reviewed recently (Keep et al., 2018). Thus, a wide range of cellular and molecular mechanisms could directly impact vessel morphology both at the ICH lesion and surrounding tissues and also at distant cortical structures. Further research is needed to clarify the mechanisms that impact the cerebrovascular network after ICH.

A range of interventions have been applied to mitigate the neurobiological effects of ICH and its subsequent poor outcomes (Hatakeyama et al., 2013; Chen-Roetling et al., 2015; Yang et al., 2016; Leclerc et al., 2018; Xu et al., 2019). However, most of the interventions for ICH to date have been neuro-centric, that is, focused on neuroprotection. While protection of cellular elements such as neurons is important, an intact vascular network is critical for neuroprotection with the delivery of nutrients and removal of waste products. There is increasing recognition that platelet-derived growth factor (PDGF; a sub-family of tyrosine kinase receptors) and its various ligands and receptors are critical for the health and stability of endothelial cells and pericytes (Kazlauskas, 2017; Heldin et al., 2018). PDGFs and their isoforms have also provided new treatment options, particularly for manipulating angiogenesis in cancer (Paulsson et al., 2014; Heldin et al., 2018). Foundational studies developed therapeutic interventions targeting tyrosine kinase in vessels to inhibit tumor growth by targeting angiogenic processes, including those associated with PDGFs (Soverini et al., 2018).

As noted above, we and others have targeted PDGF receptors as a therapeutic option for ICH using Gleevec (imatinib mesylate) (Ma et al., 2011; Pearce et al., 2016; Yang et al., 2016). We found that Gleevec treatment following ICH blunts the phenotypic transformation of smooth muscle surrounding arteries (Pearce et al., 2016), reduced BBB disruption leading to improved outcomes (Ma et al., 2011) and mitigated plasmin induced vascular inflammation (Yang et al., 2016). Many of the beneficial effects of Gleevec were found to occur acutely (<24 h) with long term improvements but the direct effects on vascular morphology have not been reported upon.

While arterial smooth muscle phenotypes are rescued by Gleevec, likely through modulation of neuroinflammation, there have been no direct studies examining the vascular morphology after Gleevec treatment. We sought to examine the effectiveness of Gleevec treatment delivered within 1 h after ICH in preventing the vascular alterations observed after lesion induction. Much to our surprise, in general, we found no improvements in cortical vascular morphology after Gleevec treatment 24 h after ICH. ICH + Gleevec rats had significant reductions in vascular measures compared to Sham + Vehicle treated rats, but statistical analyses of group measures found no statistically significant differences between ICH + Gleevec and ICH + Vehicle rats (see **Figure 3**). When comparisons were made for both axial and coronal vessel painted brain sections of the cortex, a modest but significant reduction in vessel density was reported (**Figure 5**). Despite statistically insignificant

reductions in vascular parameters there appeared to be an overall trend for continued decrements following ICH + Gleevec treatment compared to ICH + Vehicle treated rats in both visual assessments and quantitative findings (**Figures 3–5**). The perihematomal region also had statistically significant reductions in vessel density but not vessel junctions (**Figure 6**). Gleevec also did not modify edema nor blood volumes at 24 h after ICH. Overall, Gleevec did not directly improve vascular morphological features at 24 h after treatment. In fact, in some measures there appeared to be a modest further reduction in vascular elements.

Initially, we were surprised by the lack and perhaps enhanced detrimental effects of Gleevec. There are several factors that could be responsible for the lack of therapeutic effectiveness on the vessels. One clear possibility is that we assessed vessel morphology during the early acute phase of the ICH injury, a period during which many molecular processes are being activated (Ren et al., 2014). The prevention of acute changes in vascular smooth muscle we previously reported appeared to be due in part to probable reductions in neuroinflammatory processes (Yang et al., 2016). Further, in CD163−/− mice there was a decreased acute (3 days) inflammatory response to ICH (Leclerc et al., 2018). Similarly, heme oxygenase 1 (HO-1) activation and overexpression in astrocytes improved BBB disruption after ICH, acutely (Chen-Roetling et al., 2015). HO-1 has also been shown to have a vasoprotective effect on vessels in the retina (He et al., 2014). Thus, inflammatory mediators in conjunction with coagulopathic mechanisms that are known to be active during ICH may acutely inhibit vascular remodeling necessary for long-term neurological improvements (Ren et al., 2014; Liu et al., 2018). It is also possible that Gleevec treatment modified vessel staining while using the vessel painting method. However, we do not believe that Gleevec resulted in adverse vessel labeling as we utilized a potent vasodilator, sodium nitroprusside, at the time of perfusion (see methods). Further, several reports have reported a suppression of vascular contractility following Gleevec treatment (Gur et al., 2013; Tang, 2015) including our own findings (Pearce et al., 2016).

PDGF is well known to have angiogenic activities and differential roles for its isoforms have been noted including recruitment of pericytes (Zhang et al., 2009). Tan and colleagues reported increased angiogenesis around the hematoma at 7–14 days after ICH likely via a vascular endothelial growth factor (VEGF) mechanisms (Tang et al., 2007) and confirmed in subsequent reports (Zhou et al., 2012). This vascular repair timeline is very similar to what we have reported in traumatic brain injury, albeit via a Wnt/β-catenin mechanism (Salehi et al., 2018a). In stroke, Gleevec protected the BBB, as well as "normalized" vessels within the brain early (1 h) post-injury (Su et al., 2008). It is likely that in our acute ICH study we did not observe any angiogenic potential due to Gleevec treatment, as this repair mechanism under baseline conditions appears to take several days. In future studies we will evaluate the previously reported spontaneous angiogenesis and whether this might be accelerated by Gleevec treatment.

Gleevec and subsequent generation tyrosine kinase inhibitors are known to act at BCR-ABL and c-KIT sites that can regulate the response of the cerebrovasculature following brain injury (see Rossari et al., 2018, review). However, adverse vascular events have been reported in patients treated with Gleevec or other related tyrosine kinase inhibitors (Pasvolsky et al., 2015). It is intriguing to speculate that the early lack of effect on vascular morphology seen in our study could be related to downstream effects of Gleevec on BCR-ABL on Wnt/β-catenin cascades (Cilloni and Saglio, 2012) which we have previously reported is involved in late vascular remodeling following traumatic brain injury (Salehi et al., 2018a).

Neuroimaging using clinically relevant modalities such as computed tomography and magnetic resonance imaging (MRI) are potent methods for non-invasively assessing the degree of hemorrhage and edema in patients and in preclinical models (Belayev et al., 2003; Goh et al., 2015; Heit et al., 2017). In our present study we also acquired T2 weighted MRI for edema and susceptibility weighted (SWI) MRI for blood content to assess if there was a correlation between vessel features and clinically relevant MRI. No correlations were observed between classical vascular measures (density, etc.) and lesion volumes. However, as noted in **Table 1** and in **Figure 7** there were several strong correlations between total lesion volumes and vessel features derived from fractal measures of vascular complexity in ICH + Vehicle treated rats. We observed that vascular complexity was reduced after ICH but not in ICH + Gleevec rats. For example, as lesion volume (edema + hematoma) increases, vascular complexity was reduced (**Figure 7D**, peak frequency reductions). Similar, reductions in vascular complexity using fractal analysis was observed at 1d post-traumatic brain injury (Obenaus et al., 2017). Interestingly, Gleevec treatment resulted in a loss of significant correlations between lesion characteristics and fractal features of complexity (**Table 1**). While it is difficult to ascertain what the underlying mechanism(s) might be for Gleevec in modulating vascular complexity, it is clear that many of the smaller vessels appear to be lost after treatment (see **Figure 4**). It is possible that the global reduction in vascular complexity due to Gleevec treatment could further disrupt fractal measures leading to loss of correlative measures. Interestingly, fractal analysis of ICH lesions from computed tomography were found to be a good predictor of outcomes (Klis et al., 2018). Thus, MRI-derived hematoma and edema volumes can reflect the relative loss of vascular complexity, but additional research is needed to corroborate these findings.

CONCLUSION

In conclusion, this study for the first-time reports on quantitative measures of the vascular network within 24 h after ICH induction using a novel vessel painting methodology (Salehi et al., 2018b). The acute reductions in vessel density (and other features) after ICH were not reversed by treatment with Gleevec. While previous reports have suggested a restorative effect on vessels with Gleevec treatment, these studies did not directly assess vessel morphology but rather constituents of the BBB and/or artery smooth muscle phenotypes (Pearce et al., 2016; Yang et al., 2016). Inhibition of inflammatory mediators appears to restore the neurovascular unit and

limit BBB disruption but in our hands Gleevec did not appreciably alter the morphology of the vascular network (Wang and Dore, 2007; Mracsko and Veltkamp, 2014). BBB improvements and PDGF modulation of neuroinflammation are likely independent of vessel morphology. Vascular morphology has at least two important components, (a) number of arteries/capillaries and (b) structure of arteries/capillaries. While loosely related modification in one aspect does not necessarily lead to alterations in the other. Smooth muscle can also upregulate and downregulate expression of membrane receptors and ion channels, without any obvious change in structure. From this perspective, our observed changes in vessels are a somewhat crude assessment of vascular response. While it was not examined in the present study, future studies should examine vascular reactivity and perfusion as they are important in understanding the cellular and molecular underpinnings for the vascular morphological changes we observed. Finally, MRI derived hematoma measures related to vascular complexity in ICH + Vehicle but not ICH + Gleevec treated rats. More research is required to better understand the relationship between the vascular network's response to ICH and how putative therapies may enhance vessel structure and function. Thus, vascular morphology is an important outcome measure in assessing future therapies for treatment of ICH.

Agglomerative hierarchical clustering analysis (HCA) is a commonly used unsupervised machine learning approach for identifying informative natural clusters of observations. HCA is performed by calculating a pairwise dissimilarity matrix and then clustering similar observations until all observations are grouped within a cluster. Verifying the empirical clusters produced by HCA is complex and not well studied in biomedical applications. Here, we demonstrate the comparability of a novel HCA technique with one that was used in previous biomedical applications while applying both techniques to plasma angiogenic (FGF, FLT, PIGF, Tie-2, VEGF, VEGF-D) and inflammatory (MMP1, MMP3, MMP9, IL8, TNFα) protein data to identify informative subsets of individuals. Study subjects were diagnosed with mild cognitive impairment due to cerebrovascular disease (MCI-CVD). Through comparison of the two HCA techniques, we were able to identify subsets of individuals, based on differences in VEGF ($p < 0.001$), MMP1 ($p < 0.001$), and IL8 ($p < 0.001$) levels. These profiles provide novel insights into angiogenic and inflammatory pathologies that may contribute to VCID.

Keywords: hierarchical clustering analysis, vascular cognitive impairment and dementia, mild cognitive impairment, VEGF, MMP1, IL8

INTRODUCTION

Vascular cognitive impairment and dementia (VCID) is an active area in dementia research (Murphy et al., 2016) and is described as "encompassing all the cognitive disorders associated with cerebrovascular disease (CVD), from dementia to mild cognitive deficits" (Gorelick et al., 2011). VCID is estimated to occur in roughly 20% of the cases of dementia; however, the exact prevalence in the population is unknown with varying estimates in the literature (Rizzi et al., 2014; Corriveau et al., 2016). Much of the uncertainty in assessing the prevalence of VCID is due to varied diagnostic criteria (Harrison et al., 2016). In addition, there is substantial overlap in cognitive manifestations of cerebrovascular and neurodegenerative pathologies [such as Alzheimer's disease (AD)] that can culminate in clinical dementia (Kapasi and Schneider, 2016), which further complicates our

understanding of VCID. Further, both pathologies commonly co-exist in the same individual, yet some autopsy studies suggest that there is a significant increase in dementia risk due to vascular factors when Alzheimer pathology is low (Abner et al., 2017; Dodge et al., 2017).

Currently, magnetic resonance imaging (MRI) and cerebrospinal fluid (CSF) biomarkers are used to differentiate VCID from AD and monitor the progression of VCID (Cipollini et al., 2019; Wardlaw et al., 2019). Plasma biomarkers are currently being investigated as a lower cost and less invasive alternative approach. The current study is focused on exploring the potential clustering of plasma biomarkers using hierarchical clustering analysis (HCA) in participants with VCID who have mild cognitive impairment (MCI) due to CVD (MCI-CVD) to identify unique plasma profiles of disease (Winblad et al., 2004). Persons with MCI-CVD are of particular interest as they are at an increased risk of developing dementia and already have cognitive decline (Petersen et al., 1999). We evaluated angiogenic (FGF, FLT, PIGF, Tie-2, VEGF, VEGF-D) and inflammatory (MMP1, MMP3, MMP9, IL8, TNFα) protein plasma biomarkers in these participants using the highly sensitive meso-scale discoveries (MSD) platform. Angiogenic and inflammatory markers are of particular interest due to their roles in endothelial dysfunction, which has been shown to play a role in the pathogenesis of CVD (Poggesi et al., 2016; Mahoney et al., 2019). Presently, studies have demonstrated mixed results in the association of angiogenic and inflammatory biomarkers with VCID; however, it is suspected that this is due to the inconsistency in both the patient populations and the analytical measures (Cipollini et al., 2019).

Agglomerative HCA is an unsupervised machine learning technique commonly used to determine similar subsets within a larger population (Xu and Wunsch, 2010). HCA can be used to identify subsets within a variety of different patient populations. The accuracy of this technique is difficult to quantify, as most studies rely on *post hoc* analysis of the clusters produced by HCA to determine their validity. We propose a unique methodology for validating clusters produced by HCA. This method relies on using two unique HCA models on the same dataset and evaluates congruencies between the two models by comparing a novel HCA model to one that is widely used (Wallin et al., 2010; Damian et al., 2013; Nettiksimmons et al., 2014; Racine et al., 2016). Before applying both HCA models to our dataset, we tested the accuracy of each model on various distributions of data and compared them to each other using the adjusted rand index (ARI). After demonstrating the interchangeability of the two HCA models in the simulated data distribution comparable to our dataset, we tested both models on our dataset and compared the underlying components of each cluster produced by the HCA models.

MATERIALS AND METHODS

Participants

Plasma samples were collected from a cohort of adult research volunteers enrolled in a randomized behavioral intervention study for MCI-CVD (N = 80, NCT01924312). Inclusion criteria for the parent study include age older than 55 years, Montreal Cognitive Assessment score < 29, and at least one uncontrolled vascular risk factor. Risk factors included poorly controlled hypertension, poorly controlled cholesterol, cardiomyopathy/CHF, diabetes with a fasting glucose > 110 or HbA1c > 7%, homocysteine > 12, history of transient ischemic attack, tobacco use > 30 pack-years, and BMI > 30. Potential subjects were excluded from this cohort if they had dementia, evidence of a non-CVD cause of cognitive decline, evidence of a non-CVD neurologic disease, or any focal motor, sensory, visual, or auditory deficits. For the current study, participants were also excluded if they had an incomplete panel of markers as measured via MSD assays as described below (n = 7).

Plasma Collection and Quantification

Plasma samples were collected by venous puncture using 10 mL EDTA Vacutainer tubes. Plasma was aliquot into cryo-tubes at 500 mL volumes. Quantification of plasma samples was accomplished using MSD Multi-Spot V-PLEX assays [Angiogenesis Panel 1 (human) and Proinflammatory Panel 1 (human)] and Ultra-Sensitive assays (MMP 2-Plex and MMP 3-Plex). Plasma did not undergo any freeze-thaw cycles after the initial thawing of the aliquot. Assays were performed using plate specific protocols as followed with analysis performed in the MSD Discovery Workbench 4.0 software.

MMP 2-Plex and MMP 3-Plex

MMP plates were brought to room temperature for approximately 30 min and then loaded with 25 μL of diluent, covered (protect from light), and incubated at room temperature for 30 min while shaking at 600 r/min. After incubation, plates were removed from the shaker and 25 μL of calibrator was added to the assigned wells in duplicate with 5 μL of undiluted sample and 20 μL of diluent. Plates were covered and incubated at room temperature while shaking at 600 r/min. After incubation, plates were removed from the shaker and washed three times with 300 μL of wash buffer. Plates were turned upside down and tapped against paper towels to ensure the removal of all wash buffer from the wells. 25 μL of the antibody mix was loaded into each well, covered (protect from light), and incubated at room temperature for 2 h shaking at 600 r/min. After incubation, plates were removed from the shaker and the wash steps were repeated from above; 150 μL of read buffer was loaded into each well and read on the MSD Quickplex SQ 120 machine.

Proinflammatory Panel 1

Proinflammatory plates were brought to room temperature for approximately 30 min and washed three times with 300 μL of wash buffer. Plates were turned upside down and tapped against paper towels to ensure the removal of all wash buffer from the wells; 50 μL of calibrator was added to the assigned wells in duplicate with 50 μL of undiluted sample and covered (protect from light). Plates were incubated at 4°C overnight while shaking at 600 r/min. In the morning, plates were removed from 4°C and incubated at room temperature for 1 h while shaking at 600 r/min. After incubation, plated were removed from the shaker and the wash steps were repeated from above; 25 μL of the antibody mix was added into each well, covered (protect

from light), and incubated at room temperature for 2 h shaking at 600 r/min. After incubation, plates were removed from the shaker and wash steps were repeated from above; 150 μL of read buffer was loaded into each well and read on the MSD Quickplex SQ 120 machine.

Angiogenesis Panel 1

Angiogenesis plates were brought to room temperature for approximately 30 min and then loaded with 150 μL of diluent, covered (protect from light), and incubated at room temperature for 1 h while shaking at 600 r/min. After incubation, plates were removed from the shaker and washed three times with 300 μL of wash buffer. Plates were turned upside down and tapped against paper towels to ensure the removal of all wash buffer from the wells; 50 μL of calibrator was added to the assigned wells in duplicate with 25 μL of undiluted sample and 25 μL of diluent. Plates were covered (protect from light) and incubated at 4°C overnight while shaking at 600 r/min. In the morning, plates were removed from 4°C and incubated at room temperature for one hour while shaking at 600 r/min. After incubation, plates were removed from the shaker and wash steps were repeated from above; 25 μL of the antibody mix was added into each well, covered (protect from light), and incubated at room temperature for 2 h shaking at 600 r/min. After incubation, plates were removed from the shaker and wash steps were repeated from above; 150 μL of read buffer was loaded into each well and read on the MSD Quickplex SQ 120 machine.

Samples were run in duplicate and three pooled control samples were run on each plate to measure inter- and intra-plate variability. MSD quantification was performed on a table stabilizer in order to reduce error in MSD plate readings.

Plasma Sample Analysis

Protein markers measured through MSD assays were subjected to intra- and inter-plate variability tests. Intra-plate variability was assessed through two distinct methods. The first method calculated the percentage of samples for each marker that had a coefficient of variation, as determined by the duplicate runs for each sample, greater than or equal to 0.25. Markers that contained 20% of samples above this threshold were removed from further analysis. The second method ran three pooled control sample twice on the same plate (two samples each run in duplicate) to ensure consistency in final quantifications. The coefficient of variation for each of the three controls measured for each marker was then averaged together. Markers with an average coefficient of variation greater than 0.25 were excluded from the analysis. Markers that passed both criteria were included in the final analysis. Inter-plate variability was accounted for using the three pooled control samples run on each plate. Each plate control value was divided by the control mean and all three of these values for each marker were averaged together to provide a plate-scaling factor. Each value was then divided by this factor to adjust for inter-plate variability. The resulting measures were log-transformed to scale each marker to a common order of magnitude, which is required in clustering algorithms to provide equal weighting of markers. Grubb's test was lastly applied to the data to remove outliers (Grubbs, 1950). Individual samples containing one or more outliers in the measured markers were excluded from further analysis (n = 7) due to their effects on clustering techniques. The final dataset consisted of 66 patient plasma samples, which were quantified for 11 plasma markers (FGF, FLT, PLGF, Tie-2, VEGF, VEGFD, MMP1, MMP3, MMP9, IL8, TNFα).

Hierarchical Clustering Analysis

All HCAs were performed using the Matlab Statistics and Machine Learning Toolbox functions *pdist*, *linkage*, and *cluster*. Previously described HCA models were comprised of three different algorithms, distance, linkage, and clustering (Wallin et al., 2010; Damian et al., 2013; Nettiksimmons et al., 2014; Racine et al., 2016). The conventional HCA model consists of a Euclidean distance algorithm, which calculates the distance between two samples using the Euclidean distance formula (a special case of the generalized Minkowski distance formula), where the distance between observations s and t in a sample with n markers equals d_{st}:

$$d_{st} = \sqrt{\sum_{j=1}^{n} |X_{sj} - X_{tj}|^2}$$

The linkage algorithm used was Ward's Linkage, which calculates the incremental increase in within-cluster sum of squares and links samples one at a time until all samples are combined into a single cluster (Xu and Wunsch, 2010). This method combines similar samples until all samples fall within one cluster (i.e., agglomerative hierarchical clustering). The final algorithm in the conventional HCA model used a standard agglomerative clustering approach (Racine et al., 2016).

The novel proposed HCA model uses consensus clustering as presented by Fred and Jain (2002) to combine HCA models with different distance and clustering algorithms. The distance algorithms used the Minkowski distance formula with p ranging from 0.1 to 2.0 in increments of 0.1. The distance between observations s and t in a sample with n markers equals d_{st}:

$$d_{st} = \sqrt[p]{\sum_{j=1}^{n} |X_{sj} - X_{tj}|^p}$$

Each distance algorithm's data were then used with the weighted average linkage algorithm, which combines samples

TABLE 1 | Means ± standard deviation for age, MMSE, and MoCA for the MCI-CVD cohort population in addition to percent of female participants.

	Mean ± SDev	Range
Age (years)	75.07 ± 8.14	(56.99–89.22)
MMSE	26.86 ± 2.95	(18–30)
MoCA	22.11 ± 3.74	(11–28)
Systolic blood pressure (mmHg)	141.33 ± 15.31	(102–185)
Hemoglobin A1c (%)	6.18 ± 1.31	(4.3–11.8)
LDL cholesterol (mg/dL)	97.44 ± 42.63	(22–299)
Sex	47% Female	

into clusters that have the smallest distance between them and determines that distance using a recursive function which treats the subset of linkages equally (Xu and Wunsch, 2010).

Lastly, data from each linkage algorithm were clustered using an inconsistency clustering algorithm. This algorithm calculates an inconsistency coefficient of a new linkage using the mean and standard deviation of the linkage heights for a specified depth (*dep*) of sub linkages within each new linkage. Clusters were formed when the inconsistency coefficient for each linkage and all sub linkages were less than a specified cutoff (*cut*) value. Each linkage algorithm output was run through multiple iterations of the inconsistency clustering algorithm with values for depth (*dep*) from 2 to 6 in increments of 1, whereas cutoff (*cut*) values were adjusted from 1.0 to 3.0 in increments of 0.1. All iterations of depth and cutoff were evaluated, and if only one cluster was formed, then that iteration was not used in the consensus clustering model. Once each clustering model was established, distances between samples were calculated based on the percentage of models in which two samples shared a cluster. Samples that shared no clusters were given a distance of 1 and, samples that were paired in the same cluster in each model were given a distance of 0. Plots of each clustering model were created using the dimensionality reduction function, t-distributed stochastic neighbor embedding (t-sne), with a random number generation seed of 10 to maintain reproducibility (Maaten, 2008). Clinical data were excluded from the clustering algorithm to avoid clusters based on clinical findings as this study sought to identify clusters of participants based on a differential level of fluid biomarkers.

Simulated Data Generation and Analysis

Simulated data generation was performed using the Matlab Statistics and Machine Learning Toolbox function *mvnrnd*. Each simulated data experiment was run with 35 trials and each trial was initiated with a unique random number generation seed to maintain reproducibility. Generated data contained 11 variables and 100 samples per group, obtained from known distributions with the mean and sigma of each distribution differing depending on the experiment. **Supplementary Tables S1–S3** detail the mean and sigma for each group within each experiment. The ARI was used to evaluate the accuracy of each clustering model by comparing each clustering result to the known cluster assignment. The ARI has a maximum value of 1 indicating that the clustering result matches perfectly to the known cluster assignment. An ARI of 0 indicates that the clustering model assigns observations to the correct cluster assignment with an equal probability as random chance. An ARI below 0 demonstrates that the clustering model is less effective than random chance at assigning observations to the correct cluster assignment (McComb, 2015).

Statistical Analysis

Statistical analysis was performed using the Matlab Statistics and Machine Learning Toolbox and SPSS. A two-sample *t*-test using the Matlab function *ttest2* was conducted to compare the ARI

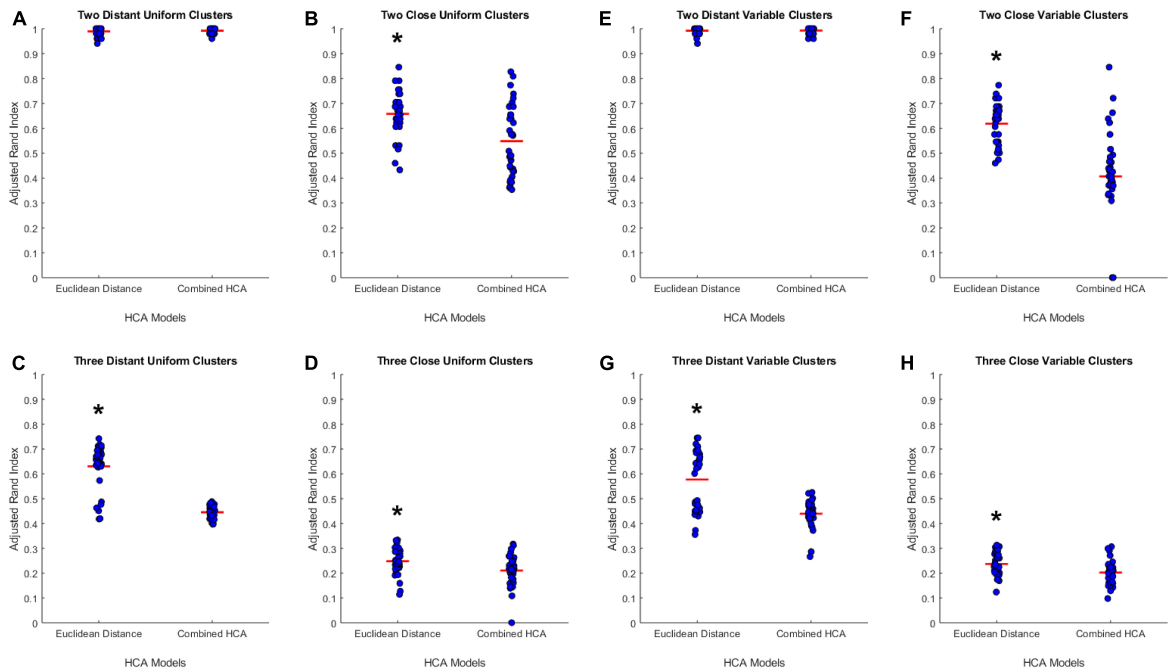

FIGURE 1 | Compares the combined HCA model to the Euclidean distance model in eight different datasets. Each dataset was produced using the *mvnrnd*. The accuracy of each model was assessed using the adjusted rand index (ARI). Datasets used in **A**–**D** have identical means for each variable in each cluster. Datasets used in **E**–**H** have the same means for the first six variables and means of opposite signs for the other five variables. Means and standard deviations for each dataset are shown in **Supplementary Table S1**. Red horizontal lines indicate means for each model. Stars (*) indicate statistical significance between groups using an independent samples *t*-test ($p < 0.05$).

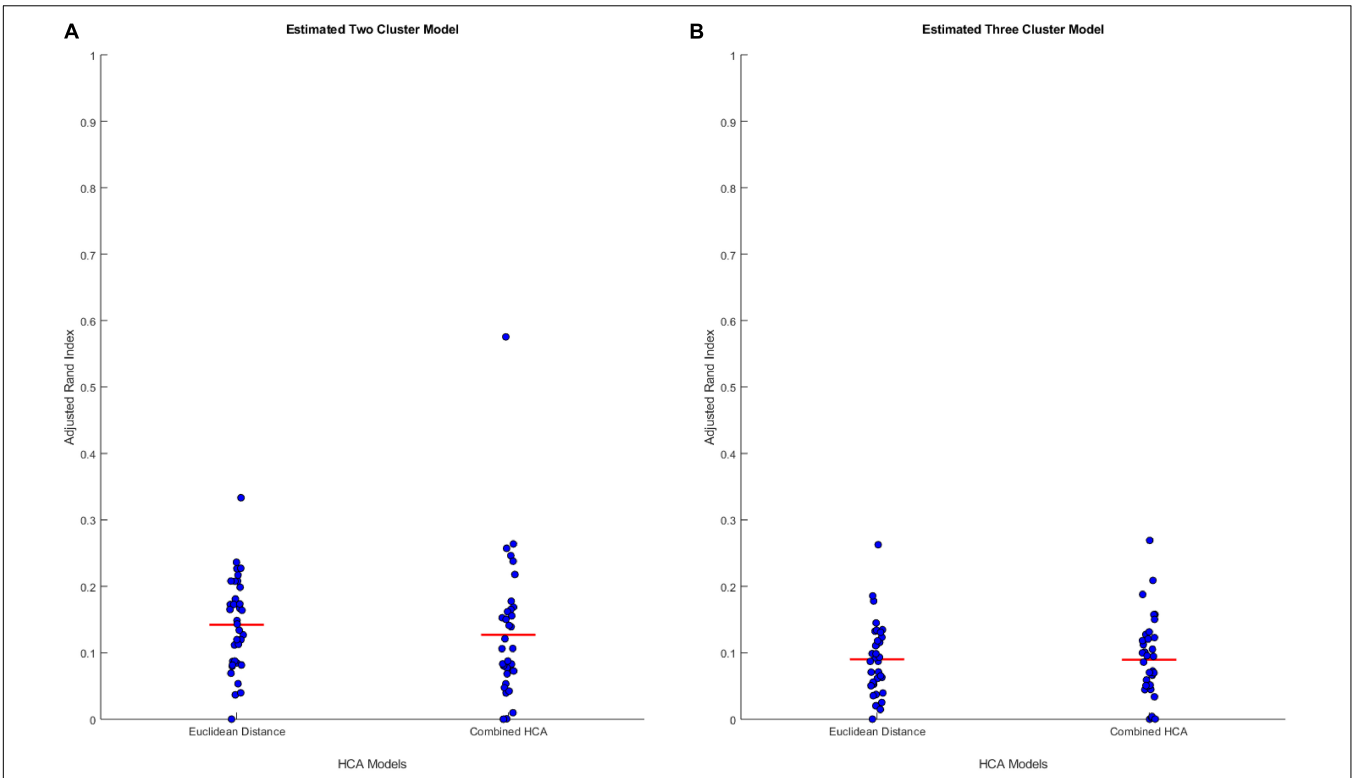

FIGURE 2 | Compares the combined HCA model to the Euclidean distance model in two predicted distributions. Each dataset was produced using *mvnrnd*. The accuracy of each model was assessed using the adjusted rand index (ARI). Means and covariance matrix for each dataset are shown in **Supplementary Tables S2**, **S3**. Red horizontal lines indicate means for each model. Stars (*) indicate statistical significance between groups using an independent samples *t*-test ($p < 0.05$). **(A)** Shows estimated two cluster model, and **(B)** shows estimated three cluster model.

means of the two HCA models for all simulated data experiments. SPSS was used for the remaining statistical tests to determine differences between clusters for each log-transformed protein marker. Levene's test for equality of variances was performed before each two-sample *t*-test, and Satterthwaite's *t*-test was used for any marker found to have significantly different variances. Levene's test for homogeneity of variances based on the mean was also conducted before performing an ANOVA test for each marker and a Welch's test for equality of means was performed for markers with non-homogeneous variances. *Post hoc* analysis was then conducted on markers which had a significant *p*-value for an ANOVA or Welch's test. Tukey's HSD was used for significant ANOVA tests and Dunnett T3 was used for significant Welch's test.

RESULTS

Study Population Description

Demographic and neurocognitive evaluations were obtained in 65/66 participants within our MCI-CVD cohort (**Table 1**). The mean age of the participants was 75.07 ± 8.14 with a female population of 47%. MMSE scores ranged from 18 to 30 with a mean of 26.86 ± 2.95, while MoCA scores ranged from 11 to 28 with a mean of 22.11 ± 3.74. Vascular risk factors including systolic blood pressure, hemoglobin A1C, and LDL cholesterol were also evaluated in our cohort (**Table 1**). Mean systolic blood pressure was found to be 141.33 ± 15.31 mmHg, hemoglobin A1c 6.18 ± 1.31%, and LDL cholesterol 97.44 ± 42.63 mg/dL.

Simulated Data Analysis

To test the applicability of the novel combined HCA model, we tested its accuracy in eight unique simulated datasets (detailed in **Supplementary Table S1**). We tested the novel model against an established HCA model using the ARI to measure the accuracy of each model (**Figure 1**). In our first experiment, we studied the accuracy of both models in a dataset with two distant uniform clusters (**Figure 1A**). The established HCA model using Euclidean distance showed no difference in ARI compared to the novel combined HCA model (Euclidean: 0.9892 ± 0.0029, Novel: 0.9920 ± 0.0019, $p = 0.413$). A similar result was found in a dataset with two distant variable clusters (Euclidean: 0.9920 ± 0.0023, Novel: 0.9926 ± 0.0020, $p = 0.857$) (**Figure 1E**). These results demonstrate that both models were able to assign each distribution to its own cluster. Next, we tested both models on a dataset with three distant uniform clusters (**Figure 1C**) and three distant variable clusters (**Figure 1G**). The established HCA model had a significantly increased ARI over the novel HCA model in both of these experiments (Euclidean: 0.6186 ± 0.0139, Novel: 0.4067 ± 0.0320, $p < 0.001$,

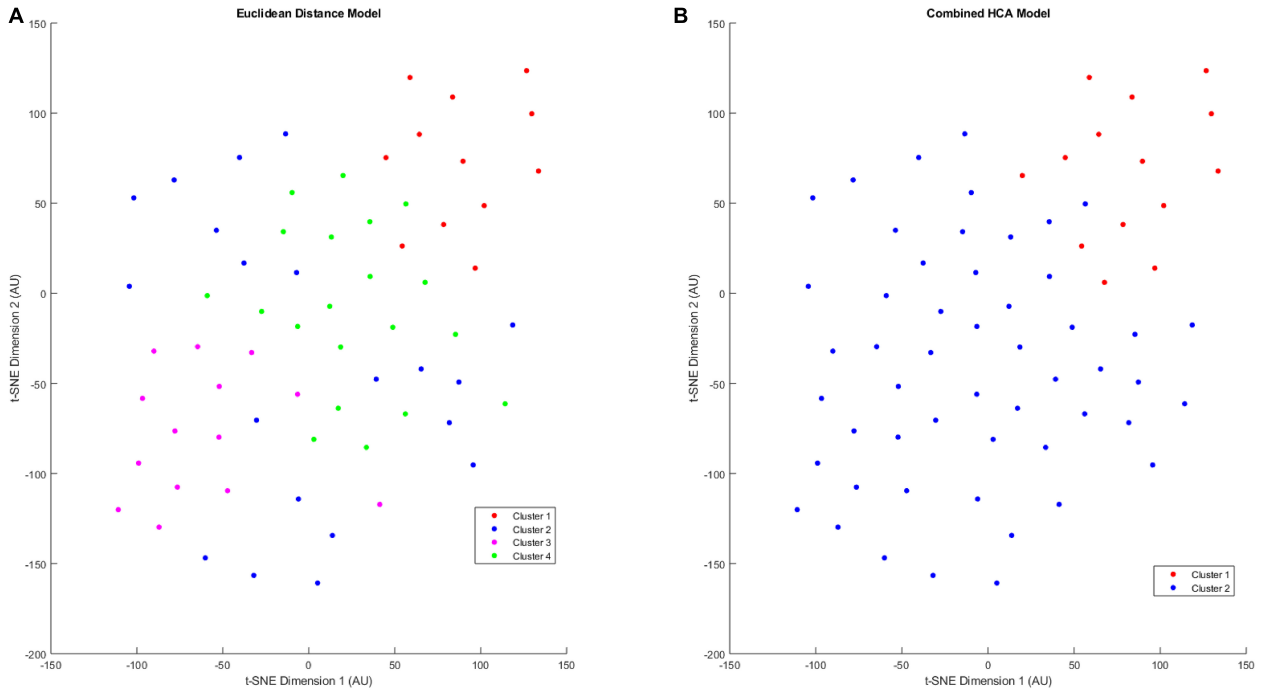

FIGURE 3 | T-SNE dimensionality reduction plot of clustered data. Data were clustered using the Euclidean distance model **(A)** and the Combined HCA model **(B)**. The dataset was produced by measuring 11 inflammatory (MMP1, MMP3, MMP9, IL8, TNFα) and angiogenic proteins of interest (FGF, FLT, PIGF, Tie-2, VEGF, VEGF-D) from 66 participant plasma samples.

*Statistical significance between groups was determined using the log transform of the data shown in **Figure 4** in an independent samples t-test ($p < 0.05$).*

Figure 1C) (Euclidean: 0.5767 ± 0.0200, Novel: 0.4393 ± 0.0092, $p < 0.001$, **Figure 1G**). These results show that the established HCA model has a higher accuracy when separating three distant clusters of normally distributed data. We then tested if the models performed differently on distributions that had more overlapping characteristics. The first experiments of these distributions were with two close uniform clusters (**Figure 1B**) and two close variable clusters (**Figure 1F**). In both experiments, the established HCA model had a higher accuracy compared to the novel HCA model (Euclidean: 0.6579 ± 0.0150, Novel: 0.5482 ± 0.0237, $p < 0.001$, **Figure 1B**) (Euclidean: 0.6186 ± 0.0139, Novel: 0.4067, $p < 0.001$, **Figure 1F**). This difference continued in the final set of experiments which used three close uniform clusters (Euclidean: 0.2477 ± 0.0087, Novel: 0.2103 ± 0.0103, $p < 0.007$, **Figure 1D**) and three distant variable clusters (Euclidean: 0.2370 ± 0.0080, Novel: 0.2023 ± 0.0078, $p < 0.003$, **Figure 1H**). These experiments show that as the distributions progressively overlap the accuracy for both models decrease and the difference between the accuracy of the models decreases as well.

Predicted Distribution Analysis

We hypothesized that clusters, if any, in our empirical dataset would overlap more and thus be more difficult to differentiate than those used in the previous experiments. To test the accuracy of each model in this distribution, we generated simulated data from predicted distributions based on analysis from our collaborators (detailed in **Supplementary Tables S2**, **S3**). The first experiment was based on a two-cluster model within our sample population (**Figure 2A**). This experiment showed no differences between the established Euclidean HCA model and the novel HCA model (Euclidean: 0.1422 ± 0.0118, Novel: 0.1270 ± 0.0181, $p = 0.486$, **Figure 2A**). In addition, we tested a three cluster model for our sample population and found similar results with no differences between the two models in this study (Euclidean: 0.0902 ± 0.0092, Novel: 0.0895 ± 0.0105, $p = 0.962$, **Figure 2B**). The data from these two experiments demonstrate the interchangeability of these two models when studying datasets with extensive overlapping distributions.

Application of Models to Dataset

After validating the novel combined HCA model using predicted distributions, we applied both HCA models to our 66 patient sample (**Figure 3**). When the Euclidean distance HCA model was applied to our dataset, four clusters emerged (**Figure 3A**). Clusters 1, 3, and 4 appear to be more compact in the 2-D t-SNE dimensionality reduction plot, while cluster 2 exists along the periphery of the plot in a more scattered manner. We continued this experiment and applied the novel combined HCA model to the same dataset and uncovered two clusters (**Figure 3B**). Cluster 1 contains 14 samples of which 12 also appear in cluster 1 of the Euclidean distance HCA model. The other 52 samples appear in cluster 2, which is comprised of clusters 2–4 from the Euclidean distance HCA model. The similarity of these two results emphasizes the underlying distributions within this dataset.

Characterizing Cluster Differences

We proceeded to analyze the differences that drive cluster differentiation. First, we examined the clusters produced by

TABLE 3 | Means ± SEM for clusters 1–4 produced by the Euclidean distance model.

Biomarker	*p*-value	Cluster 1 (pg/mL)	Cluster 2 (pg/mL)	Cluster 3 (pg/mL)	Cluster 4 (pg/mL)
FGF	<0.001	24.90 ± 2.78	5.16 ± 0.60	12.70 ± 1.37	20.11 ± 1.97
FLT	0.340	12.77 ± 1.56	13.08 ± 0.82	11.05 ± 1.44	11.42 ± 0.82
PIGF	0.342	3.53 ± 0.45	2.94 ± 0.17	2.79 ± 0.28	3.10 ± 0.16
Tie-2	0.040	512.42 ± 35.98	437.13 ± 25.44	384.29 ± 26.72	405.64 ± 21.72

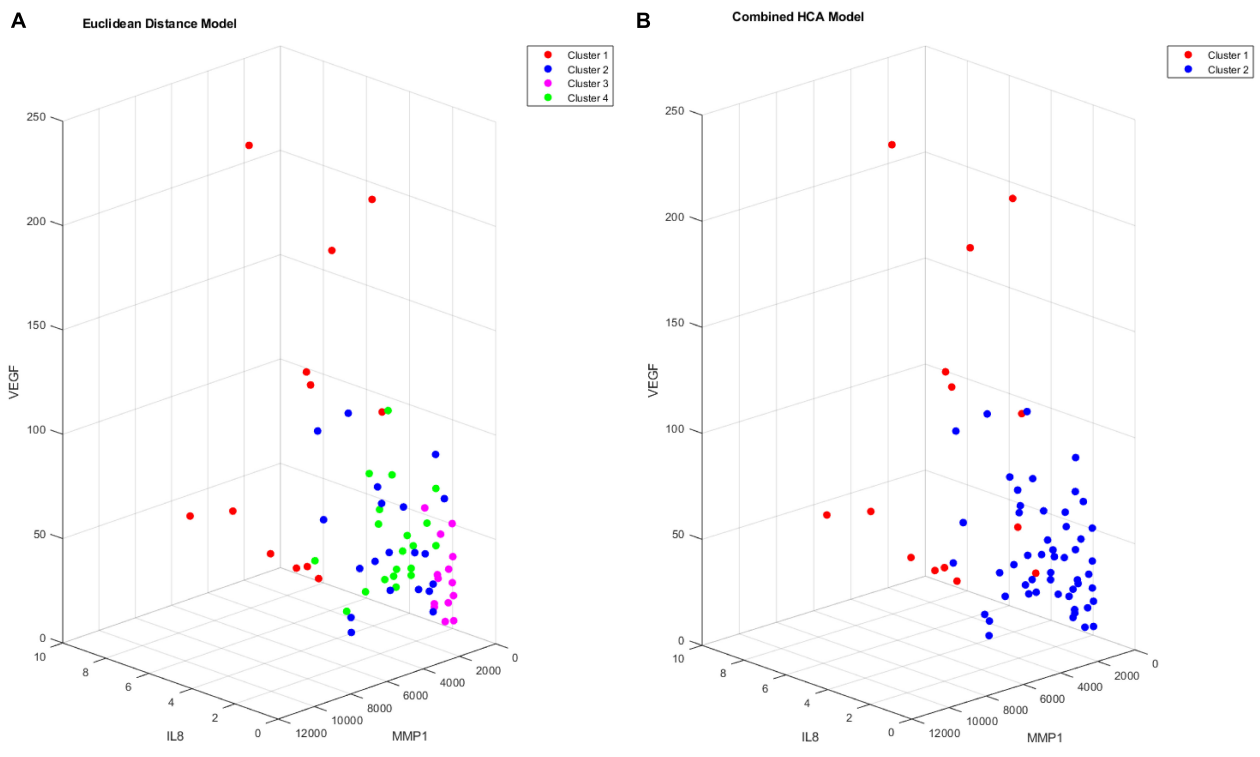

FIGURE 6 | Cluster comparison of VEGF (pg/mL), MMP1 (pg/mL), and IL8 (pg/mL) for data clustered using the Euclidean distance model **(A)** and the combined HCA model **(B)** from 66 participant plasma samples.

the novel HCA model (**Figure 4**), and found that cluster 1 was increased compared to cluster 2 in FGF ($p < 0.001$), Tie-2 ($p = 0.013$), VEGF ($p < 0.001$), MMP1 ($p < 0.001$), MMP3 ($p = 0.005$), MMP9 ($p < 0.001$), and IL8 ($p < 0.001$) (**Table 3**). When the clusters produced from the Euclidean distance HCA model were analyzed (**Figure 5**), we found a similar pattern of clusters. In this model, cluster 1 was increased compared to clusters 2–4 in VEGF ($p = 0.006$, $p < 0.001$, $p = 0.013$), MMP1 ($p = 0.003$, $p < 0.001$, $p = 0.001$), and IL8 ($p < 0.001$, $p < 0.001$, $p < 0.001$), respectively. Cluster 1 was also increased in FGF ($p = 0.004$), Tie-2 ($p = 0.033$), and MMP9 ($p = 0.003$) compared to cluster 3. The elevated level of these proteins in cluster 1 agrees with the characteristics of cluster 1 established previously with both models demonstrating a subset with significant increases in VEGF, MMP1, and IL8 compared to the other subsets (**Figure 6**). However, the Euclidean distance HCA model does show differences between clusters 2 and 4, which were not seen in the novel HCA model. Clusters 2 and 4 were similar in their makeup, both increased over cluster 3 in MMP1 ($p < 0.001$ and $p < 0.001$) and VEGF ($p = 0.032$ and $p = 0.016$), respectively, but different levels of FGF ($p < 0.001$). These differences lead to the possibility of four disease profiles within the MCI-CVD patient population.

DISCUSSION

The results of this study provide evidence supporting the use of the novel combined HCA model in datasets with extensive overlapping distributions. The results of the first set of experiments demonstrate that the Euclidean distance HCA model outperforms the novel combined HCA model in datasets with a moderate amount of overlapping distributions (**Figures 1B–D,F–H**). This difference is reduced as the distributions progressively increase in overlap and eventually disappears entirely in our second set of experiments involving the more complex datasets with predicted distributions (**Figure 2**).

It is important to note that the capacity of the two HCA models to accurately cluster data into their known distributions decreases as the datasets become more complex. In our experiments involving two distant distributions of data, both models were able to separate each distribution with an ARI approximately equal to 1 (**Figures 1A,E**). In experiments using our predicted distributions, the average ARI decreased to approximately 0.13 and 0.09 for the two and three cluster models, respectively (**Figure 2**). These findings demonstrate the limits of reliability in both HCA models and provide a measure to compare additional HCA models to in future experiments. Accounting for this accuracy is crucial when interpreting HCA results because clusters produced by the HCA model may not correspond to any true unique distribution and may simply be a subset within the normal variation of a larger distribution. Therefore, it is important to compare multiple HCA models on an unknown dataset in order to elucidate which clusters are in fact unique distributions within the dataset. Overall, results from our experiments support the interchangeability of HCA models in datasets similar to those shown in **Supplementary Tables S2**, **S3**, which allows for the use of both models in assessing clustering distributions within our dataset.

Both the Euclidean distance HCA model and the novel combined HCA model resulted in similar disease profiles within our cohort of MCI-CVD patients (**Figure 3**). In this study, both models classified participants into a cluster that had elevated levels of VEGF, MMP1, and IL8 compared to the other clusters (**Figures 4**, **5**). We suspect that this disease profile seen in cluster 1 may be involved in a more active VCID process resulting in increased pathology due to the increased level of angiogenic and inflammatory markers. Clusters 2–4 in the Euclidean distance HCA model may also be clinically relevant in terms of disease pathology but require future studies to understand how these profiles may contribute to progression of VCID in a population of individuals with MCI-CVD.

CONCLUSION

The usage of both the novel HCA model and a Euclidean distance HCA model identified a novel subset of patients within the MCI-CVD population. This study provides insight into a potential underlying inflammatory and angiogenic profile of disease in patients with VCID. Defining subsets of patients within this population with different disease profiles continues to be a key research objective. These profiles can provide a more complete understanding of disease progression and allow physicians and researchers to identify patients undergoing different rates of pathologic change in a prospective cohort. In the future, we hope to further clarify these profiles by combining plasma and MRI imaging biomarkers that can also be used in clinical trials as key outcome measures to determine the efficacy of novel therapeutics.

Subarachnoid Hemorrhage Induces Dynamic Immune Cell Reactions in the Choroid Plexus

*Peter Solár[1,2], Ilona Klusáková[1], Radim Jančálek[2], Petr Dubový[1] and Marek Joukal[1]**

Subarachnoid hemorrhage (SAH) is a specific form of hemorrhagic stroke that frequently causes intracranial hypertension. The choroid plexus (CP) of the brain ventricles is responsible for producing cerebrospinal fluid and forms the blood – cerebrospinal fluid barrier. The aim of the current study was to determine whether SAH induces an immune cell reaction in the CP and whether the resulting increase in intracranial pressure (ICP) itself can lead to cellular changes in the CP. SAH was induced by injecting non-heparinized autologous blood to the cisterna magna. Artificial cerebrospinal fluid (ACSF) instead of blood was used to assess influence of increased ICP alone. SAH and ACSF animals were left to survive for 1, 3, and 7 days. SAH induced significantly increased numbers of M1 (ED1+, CCR7+) and M2 (ED2+, CD206+) macrophages as well as MHC-II+ antigen presenting cells (APC) compared to naïve and ACSF animals. Increased numbers of ED1+ macrophages and APC were found in the CP only 3 and 7 days after ACSF injection, while ED2+ macrophage number did not increase. CD3+ T cells were not found in any of the animals. Following SAH, proliferation activity in the CP gradually increased over time while ACSF application induced higher cellular proliferation only 1 and 3 days after injection. Our results show that SAH induces an immune reaction in the CP resulting in an increase in the number of several macrophage types in the epiplexus position. Moreover, we also found that increased ICP due to ACSF application induced both an immune reaction and increased proliferation of epiplexus cells in the CP. These findings indicate that increased ICP, and not just blood, contributes to cellular changes in the CP following SAH.

Solár P, Klusáková I, Jančálek R, Dubový P and Joukal M (2020) Subarachnoid Hemorrhage Induces Dynamic Immune Cell Reactions in the Choroid Plexus. Front. Cell. Neurosci. 14:18. doi: 10.3389/fncel.2020.00018

INTRODUCTION

Subarachnoid hemorrhage (SAH) is a specific form of hemorrhagic stroke that is recorded in up to 10 cases per 100,000 people annually, and has a combined morbidity and mortality of more than 50% (King, 1997; Rincon et al., 2013). More than 80% of these cases are due to the rupture of a cerebral aneurysm with bleeding into the subarachnoid cisterns and fissures (Fisher et al., 1980; van Gijn and Rinkel, 2001). In the first few seconds following aneurysm rupture, intracranial pressure (ICP) rises rapidly and brain tissue gets compressed. This sudden

rise in ICP may reach values up to diastolic blood pressure but later falls to slightly above the baseline (Prunell et al., 2003).

The extent to which ICP rises is correlated with early onset brain injury and mortality (Zoerle et al., 2015). The inflammatory cascade that gets activated within minutes after SAH comprises adhesion molecules, cytokines, migration of leukocytes, and complement activation (Sehba et al., 2011). Early inflammation seems to play an important role in development of delayed cerebral ischemia and affects the outcome after SAH (Sercombe et al., 2002; Miller et al., 2014).

The choroid plexus (CP) of the brain ventricles is responsible for producing almost 60 – 80% cerebrospinal fluid (CSF) by volume. The CP comprises a highly vascularized stroma containing loose connective tissue, fenestrated capillaries and immune cells. The stroma is covered by a layer of cuboidal epithelial cells linked by tight junctions that is one of the fundamental components of the blood–cerebrospinal fluid (B-CSF) barrier. Kolmer cells (KC) of the epiplexus adhere to the ventricular side of these cuboidal epithelial cells and are in direct contact with CSF (Hosoya and Fujita, 1973; Segal and Pollay, 1977; McMenamin et al., 2003; Wolburg and Paulus, 2009).

There is a growing body of evidence that implicates changes in the CP (due to extravasated blood into the CSF following SAH) in hypersecretion of CSF leading to the development of post-hemorrhagic hydrocephalus (Simard et al., 2011; Xiang et al., 2017). It is believed that post-hemorrhagic hydrocephalus results when CSF flow within the ventricular system is impaired or there is a structural blockage of CSF drainage in the arachnoid villi (Yong et al., 2010). It has been suggested that SAH may also lead to hypersecretion of CSF by the CP. Aydin et al. (2014) showed that increased CSF secretion seems to be triggered by the petrous ganglion of the glossopharyngeal nerve and the numerous water-filled vesicles in the early stages of SAH. Similarly, Kanat et al. (2013) observed increased CSF secretion caused by fluid filled vesicles in the CP following SAH and concluded that hypersecretion of CSF contributes to the development of post-hemorrhagic hydrocephalus.

It has been found that SAH increases the number of macrophages in the epiplexus position of the CP (Liszczak et al., 1984). However, the type of macrophages and other immune cells that increase and proliferate after SAH remains a mystery. Further, the dynamics of these cell changes is also unclear. There is very little known about the effect of elevated ICP and inflammation on the SAH-affected CP.

The aim of our study was to investigate and specify cellular changes in the CP following SAH by monitoring the different subpopulations of macrophages, antigen presenting cells (APC), T lymphocytes as well as cellular proliferation over time. A further objective was to clarify whether these changes are caused mainly by blood degradation products or whether increased intracranial pressure after SAH also has an effect. We found that SAH induced increases in the number of several subpopulations of immune cells predominantly in the epiplexus position and enhanced their proliferation in the CP. Moreover, artificial cerebrospinal fluid (ACSF) application also induced similar increases in immune cell numbers in the CP. The results indicate that immune cell changes in the CP can be induced not only by blood and blood degradation products but also by increased ICP.

MATERIALS AND METHODS

Animals and Surgical Procedures

Experiments were performed on 54 adult male rats (Wistar 200 – 250 g; Animal Breeding Facility, Masaryk University, Czechia). All experimental procedures were carried out aseptically and according to protocols approved by the Ethical Committee of Masaryk University, Brno and the Departmental Committee of the Ministry of Education, Youth and Sports, Czechia. The rats were anesthetized with a mixture of 5% ketamine (100 mg/kg) and 2% xylazine (10 mg/kg) administrated intraperitoneally.

Subarachnoid hemorrhage was induced by the application of non-heparinized autologous arterial blood into the cisterna magna following the standardized method originally published by Solomon et al. (1985) and modified by other authors (d'Avella et al., 1996; Matz et al., 1996). Briefly, cannulation of the caudal artery was performed (SAH group) and a midline suboccipital incision was made to expose the arch of the atlas, the occipital bone and the atlanto-occipital membrane. Then, the animal was placed in a stereotaxic apparatus (Kopf Instruments, Tujunga, CA, United States), the atlanto-occipital membrane was cleared of connective tissue, and a syringe with 30G needle was placed on the manipulating arm of the stereotaxic frame tilted at 60° from horizontal plane. Under the high magnification of a surgical microscope the arachnoid was penetrated by the needle and 200 μl of non-heparinized autologous blood taken from the caudal artery was injected within 60 s into the cisterna magna (SAH group).

Two hundred μl of ACSF containing 130 mmol/l NaCl, 3.0 mmol/l KCl, 1.2 mmol/l NaH_2PO_4, 20 mmol/l $NaHCO_3$, 1.3 mmol/l $MgCl_2$, 2.4 mmol/l $CaCl_2$, 10 mmol/l Glucose (Hylden and Wilcox, 1980) instead of blood was injected within 60 s into the cisterna magna to the animals of ACSF group.

The needle was slowly withdrawn 2 min after injection to prevent leakage of blood or ACSF from the cisterna magna and the membrane puncture was closed by gelatin sponge. The muscles and the skin were closed by 4-0 silk suture.

Rats exposed to blood (SAH group) or ACSF (ACSF group) were left to survive for 1, 3, and 7 days (n = 8 SAH; n = 8 ACSF for each time point).

Rats of SAH and ACSF groups as well as a naive group (n = 6) were sacrificed using CO_2, perfused transcardially with 500 ml heparinized (1000 units/500 ml) phosphate–buffered saline (PBS; pH 7.4) followed by 500 ml of Zamboni's fixative (Zamboni and de Martino, 1967).

Then, brains were promptly removed and assessed for successful injection. In the SAH group, brains from animals with expressed SAH (presence of the blood in the subarachnoid cisterns and basal surface of the brain after full blood volume injection) and brains with no SAH from the ACSF group (no blood in the subarachnoid space, full ACSH volume injection) were included. After macroscopic assessment, the brains were immersed in Zamboni's fixative for 3 days, washed in 10%

sucrose and embedded in Tissue-Tek OCT compound (Miles, Elkhart, IN, United States). Coronal cryostat sections were cut (20 μm sections; Leica 1800 cryostat; Leica Microsystem, Wetzlar, Germany) and mounted onto chrome-alum covered microscope slides.

Immunohistochemical Staining

To detect subpopulations of macrophages, the brain sections of naive, SAH and ACSF groups were immunostained under identical conditions with anti-CD68 (activated ED1+ macrophages), anti-CD163 (resident ED2+ macrophages), anti-CCR7 and anti-CD206 antibodies. M1 macrophages are characterized by expression of CD68 (ED1) and CCR7 besides other antigens (Badylak et al., 2008; Ma et al., 2010). The expression of CD163 (ED2) and CD206 antigens marks the M2 macrophage phenotype (Kigerl et al., 2009). APC were detected using an anti-major histocompatibility complex class II (MHC II) antibody (Dijkstra and Damoiseaux, 1993), and T lymphocytes with anti-CD3 antibody (Mason et al., 1989). Proliferation activity was assessed using Ki-67 immunostaining (Gerdes et al., 1984).

Sections were washed with PBS containing 0.3% bovine serum albumin and 0.1% Tween-20, treated with 3% normal serum for 30 min. and then incubated with the primary antibody at room temperature. Primary antibody sources and incubation conditions are listed in **Table 1**. Affinity purified Cy5- or FITC conjugated donkey anti-rabbit or anti-mouse secondary antibodies (Jackson, 1:100) were applied at room temperature for 90 min. Control sections were incubated in parallel omitting the primary antibodies. Positive immunostaining of CD3 antibody was confirmed in sections of the spleen. Immunostained sections were rinsed, stained with Hoechst 33342 (Sigma, St. Louis, MO, United States) to locate cell nuclei, and mounted in Vectashield aqueous mounting medium (Vector Laboratories, Burlingame, CA, United States). Immunofluorescence was observed and analyzed using a Nikon Eclipse NI-E epifluorescence microscope, equipped with a Nikon DS-Ri1 camera (Nikon, Prague, Czechia).

Double Immunohistochemical Staining

Proliferation activity of APC and macrophages in the CP was monitored using double immunostaining for MHC II, ED1 or ED2 and Ki-67. A subset of sections was incubated with rabbit polyclonal anti-Ki-67 antibody and treated with FITC-conjugated donkey anti-rabbit secondary antibody for 90 min. After thorough washing, primary MHC II, ED1 or ED2 antibody was applied overnight followed by Cy5-conjugated secondary antibody. Sections were mounted and analyzed as above.

Image and Statistical Analysis

Images (magnification 200x) were acquired from at least 10 sections cut at 60 μm intervals through the brain ventricles containing the CP for each group of animals. CP area was determined in the images, manually edited when needed, and measured using the NIS-Elements AR Analysis software (version 4.20.00, Nikon, Prague, Czechia). ED1, ED2, CCR7, CD206, MHC II, and CD3 immunopositive cells (ED1+, ED2+, CCR7+, CD206+, MHC II+, and CD3+) were correlated using the positions of cell nuclei and counted manually in the defined CP area. The analysis was performed in a randomized fashion by an investigator who was blinded to the group of animals. The number of positive cells for every 1 mm^2 of CP area was expressed as mean ± standard deviation (SD).

To detect cellular proliferation, double immunostaining (ED1, ED2 or MHC II and Ki67) was analyzed in the colocalization module of NIS Elements software (Nikon, Czechia). The percentage of ED1+/Ki-67+, ED2+/Ki-67+, and MHC II+/Ki-67+ cells (to total Ki-67+ cell number) was expressed as mean ± standard deviation (SD).

The data of naive, ACSF and SAH groups were compared pairwise using the Mann–Whitney *U*-test in STATISTICA 5.5 software (StatSoft, Tulsa, OK, United States).

RESULTS

All animals that underwent application of blood (SAH group; $n = 24$) or ACSF ($n = 24$) survived the experiments and the injection was successful (scored as the presence of blood in the subarachnoid space in the SAH group and no blood in the ACSF group).

Position and Number of Immune Cells in the CP

Activated (ED1+) and resident (ED2+) macrophages as well as CCR7+ and CD206+ cells were found mainly on the ventricular side of the cuboidal epithelial cells in the epiplexus position (**Figures 1–4**).

The number of ED1+ macrophages in the CP of SAH and ACSF animals increased over time in our experiments. One day after SAH, the numbers of ED1+ macrophages in the CP was slightly increased compared to CP of naïve control ($n = 147.2 \pm 36.5/mm^2$). A significant increase, compared to the CP of naïve rats, in the number of ED1+ macrophages was found 3 days ($n = 265 \pm 70/mm^2$; $p < 0.01$) and 7 days ($n = 339.1 \pm 85.9/mm^2$; $p < 0.01$) after SAH as well as 3 days ($n = 215.8 \pm 49.4/mm^2$; $p < 0.05$) and 7 days ($n = 228.2 \pm 51.8/mm^2$; $p < 0.05$) after ACSF injection. The number of ED1 + macrophages after 7 days was significantly higher in the CP of the SAH animals ($n = 339.1 \pm 85.9/mm^2$; $p < 0.05$) compared to the ACSF group ($n = 228.2 \pm 51.8/mm^2$; **Figure 5A**).

Immunoquantification showed a similar significant increase in the number of ED2+ macrophages at 1 ($n = 24.5 \pm 9.3/mm^2$; $p < 0.05$), 3 ($n = 23.3 \pm 1.5/mm^2$; $p < 0.05$) and 7 days ($n = 25.8 \pm 9.6/mm^2$; $p < 0.05$) following SAH compared to naïve rats ($n = 6.8 \pm 4.5/mm^2$). Strikingly, the number of ED2+ macrophages was significantly increased 1, 3, and 7 days following SAH, also when compared to ACSF animals at the same time points ($n = 7.3 \pm 7.9/mm^2$; $n = 8.85 \pm 4.95/mm^2$; $n = 11.5 \pm 2.4/mm^2$, respectively). No significant changes in the number of ED2+ cells were found in the CP of the ACSF animals when compared to naïve controls (**Figure 5B**).

The number of CCR7+ cells was significantly increased, compared to CP of naïve controls, in the CP of animals 1

TABLE 1 | List of primary antibodies used, their dilutions, incubation times and suppliers.

Name	Type of antibody	Dilution	Incubation time	Supplier
ED1	Mouse monoclonal	1:200	240 min	Serotec
ED2	Mouse monoclonal	1:200	16 hrs	Serotec
Ki-67	Rabbit polyclonal	1:500	240 min	Vector Laboratories
MHC II	Mouse monoclonal	1:100	Overnight	Serotec
CCR7	Rabbit polyclonal	1:50	Overnight	Acris
CD206	Rabbit polyclonal	1:50	Overnight	Santa Cruz
CD3	Rabbit monoclonal	1:100	Overnight	Abcam

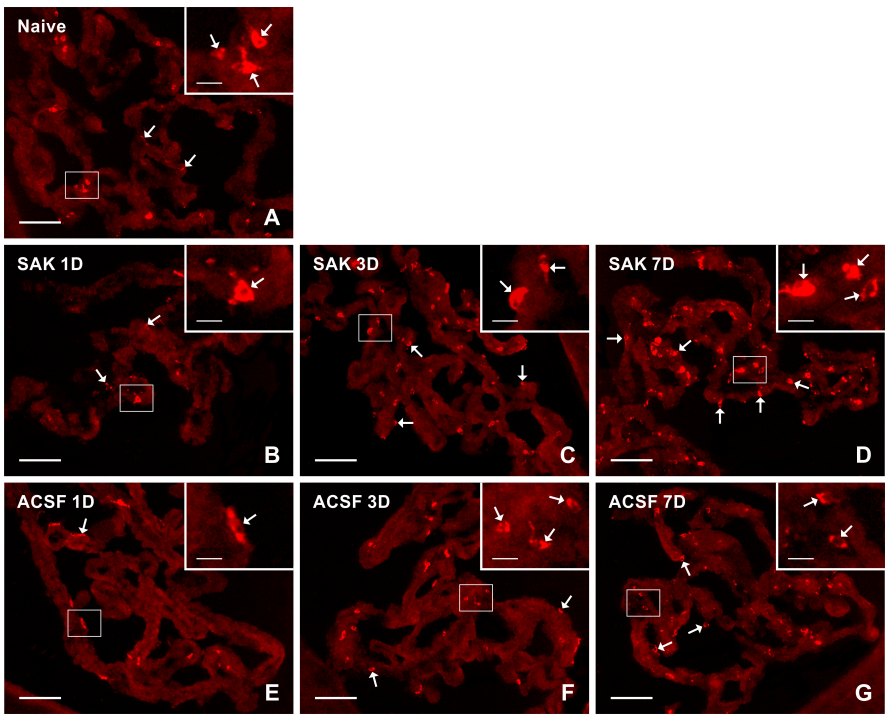

FIGURE 1 | Representative pictures showing results of immunostaining with ED1 antibody in cryostat sections of the CP from naïve **(A)**, SAH **(B–D),** and ACSF **(E–G)** rats at 1, 3 and 7 days (1D, 3D, and 7D) after operation. SAH induced an increase in the number of ED1+ cells 3 and 7 days after operation. Increased numbers of ED1+ cells were also found 3 and 7 days after application of ACSF. Arrows indicate ED1+ cells predominantly in the epiplexus position of the CP. Insets show a higher magnification of regions marked by the boxes. Scale bars = 80 μm (main image); 10 μm (insets).

($n = 45 \pm 8.4/mm^2$; $p < 0.01$) and 3 days ($n = 23.1 \pm 8.1/mm^2$; $p < 0.05$) following SAH ($n = 3.6 \pm 1.8/mm^2$). The number of CCR7+ cells in the CP of the SAH and ACSF group decreased over time and dropped to normal at 7 days. Moreover, the CP of the ACSF group showed a significantly higher CCR7 + cell number ($n = 58.9 \pm 23/mm^2$; $p < 0.05$), compared to CP of naïve rats only after 1 day following ACSF application ($n = 3.6 \pm 1.8/mm^2$; **Figure 5C**).

Immunostaining showed a significantly higher number, compared to naïve controls (n = $21.6 \pm 3.4/mm^2$), of anti-inflammatory CD206+ cells in the CP 1 ($n = 46.4 \pm 8.5/mm^2$; $p < 0.05$), 3 ($n = 90.5 \pm 12.4/mm^2$; $p < 0.001$) and 7 days ($n = 90.4 \pm 11.6/mm^2$; $p < 0.001$) after SAH. However, the number of CD206 + cells in the CP of the ACSF group decreased over time following ACSF injection; it was significantly increased compared to CP of naïve animals ($n = 21.6 \pm 3.4/mm^2$) at 1 ($n = 58.9 \pm 6.1/mm^2$; $p < 0.001$) and 3 days ($n = 40.2 \pm 3.2/mm^2$; $p < 0.01$), but dropped to normal at 7 days. SAH significantly increased the number of CD206+ cells in the CP 3 ($n = 90.5 \pm 12.4/mm^2$; $p < 0.01$) and 7 days ($n = 90.4 \pm 11.6/mm^2$; $p < 0.001$) when compared to ACSF at the same time points ($n = 40.2 \pm 3.1/mm^2$ and $n = 26.7 \pm 3.6/mm^2$, respectively; **Figure 5D**).

MHC II+ APC displayed a range of shapes from oval to ramified and were found in the epiplexus position as well as in the stromal core of the CP (**Figure 6**). The APC population of the CP showed a progressive increase in number following SAH over the duration of our experiment. Significantly increased numbers of APC were found 3 ($n = 647.6 \pm 85.1/mm^2$; $p < 0.01$) and 7 days ($n = 766.2 \pm 111.1/mm^2$; $p < 0.05$) following SAH as well as 3 ($n = 639.5 \pm 77.6/mm^2$; $p < 0.05$) and 7 days ($n = 651 \pm 75.6/mm^2$; $p < 0.05$) following ACSF injection when

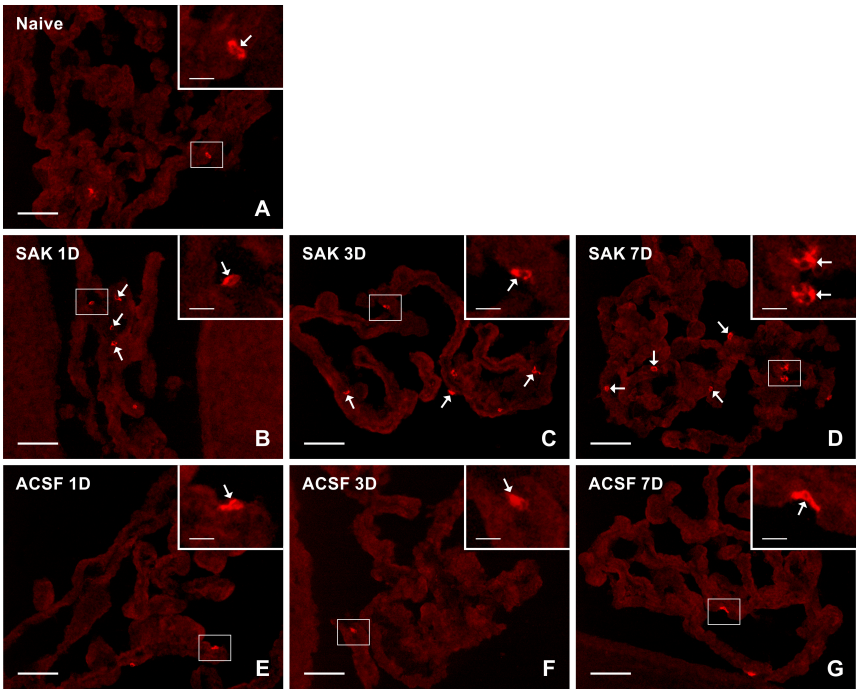

FIGURE 2 | Representative pictures of cryostat sections through the CP showing immunostaining with ED2 antibody from naïve **(A)**, SAH (**B–D**), and ACSF **(E–G)** rats at 1, 3 and 7 days (1D, 3D, and 7D) after operation. SAH led to increased numbers of ED2+ cells at 1, 3, and 7 days after operation. The number of ED2+ cells in CP of ACSF animals did not increase at any time point after ACSF administration. Arrows indicate ED2+ cells in the epiplexus position of the CP. Insets show a higher magnification of regions marked by the boxes. Scale bars = 80 μm (main image); 10 μm (insets).

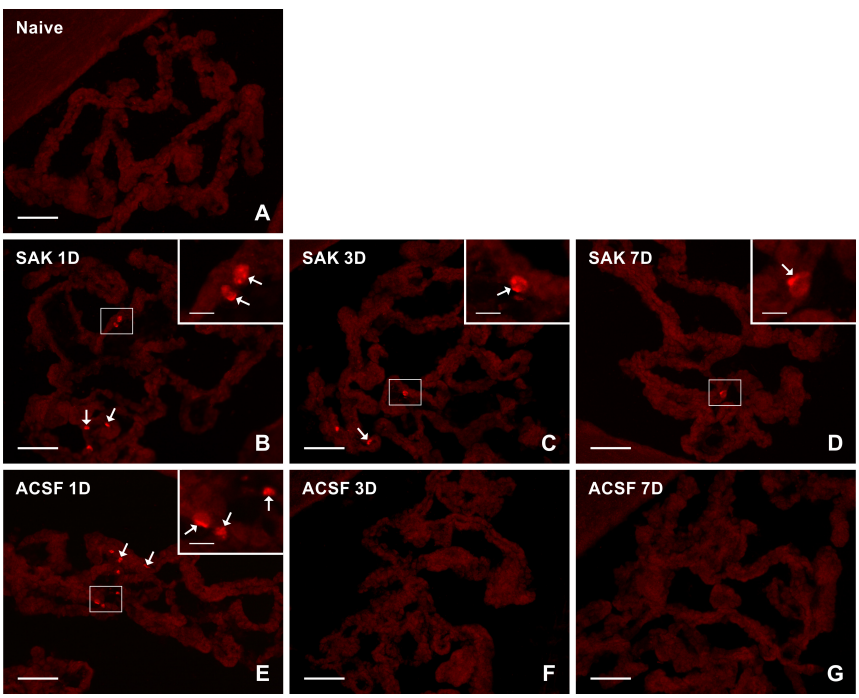

FIGURE 3 | Representative pictures showing results of immunostaining with CCR7 antibody in cryostat sections of the CP from naïve **(A)**, SAH **(B–D)**, and ACSF **(E–G)** rats at 1, 3 and 7 days (1D, 3D, and 7D) after operation. The number of CCR7+ cells was increased 1 and 3 days following induction of SAH and 1 day after ACSF administration. Arrows indicate CCR7+ cells in the epiplexus position of the CP. Insets show a higher magnification of regions marked by the boxes. Scale bars = 80 μm (main image); 10 μm (insets).

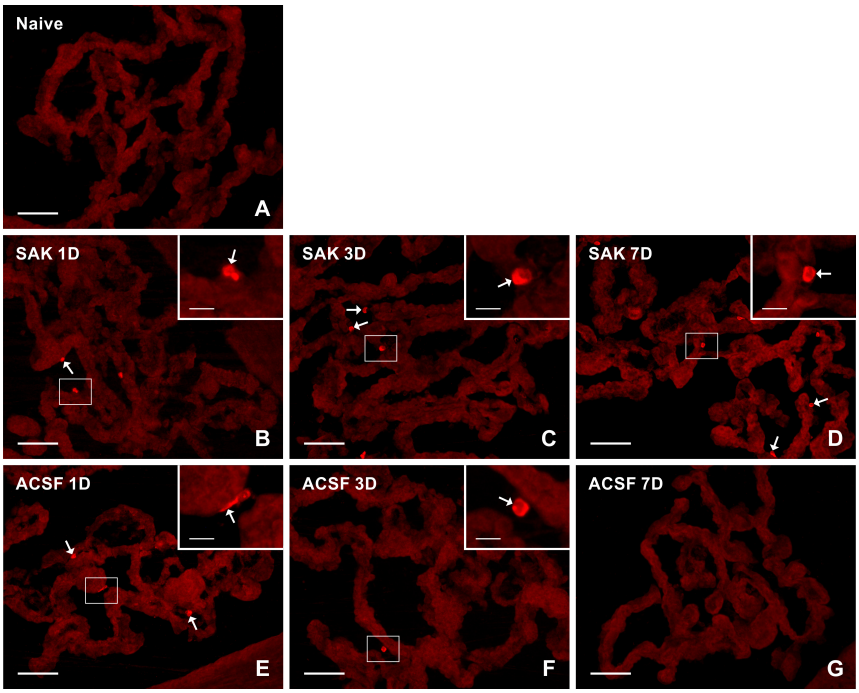

FIGURE 4 | Representative pictures of cryostat sections through the CP showing immunostaining with CD206 antibody from naïve **(A)**, SAH **(B–D),** and ACSF **(E–G)** rats at 1, 3, and 7 days (1D, 3D, and 7D) after operation. Increased numbers of CD206+ cells were found 1, 3, and 7 days following induction of SAH. ACSF application led to an increase in the number of CD206+ cells 1 and 3 days following injection. Arrows indicate CD206+ cells in epiplexus position of the CP. Insets show a higher magnification of regions marked by the boxes. Scale bars = 80 μm (main image); 10 μm (insets).

compared to naïve rats (n = 495.7 ± 98.7/mm^2). The number of MHC II+ APC in the CP was significantly increased 7 days (n = 766 ± 111.1/mm^2; $p < 0.05$) after SAH compared to ACSF animals (n = 651 ± 75.6/mm^2; **Figure 5E**). CD3 immunostaining did not reveal T cells in the CP of any group of the animals (not shown).

Assessment of Proliferation Activity in the CP

Immunostaining for Ki-67 revealed proliferating cells in the epiplexus position (**Figure 7**). Significantly increased proliferation of epiplexus KC was found 1 (n = 63.3 ± 6.8/mm^2; $p < 0.05$), 3 (n = 79.3 ± 12.3/mm^2; $p < 0.01$) and 7 days (n = 86.1 ± 13.8/mm^2; $p < 0.05$) following SAH, compared to the number of Ki-67 positive cells in the CP of naïve animals (n = 37.6 ± 9.4/mm^2). Moreover, the proliferation showed a tendency to increase. Significantly increased proliferation of KC was also found in the CP of the ACSF group 1 (n = 64 ± 12.6/mm^2; $p < 0.05$) and 3 days (n = 58.2 ± 8.3/mm^2; $p < 0.05$) after ACSF injection compared to naïve animals (n = 37.6 ± 9.4/mm^2). KC proliferation activity returned to normal 7 days after ACSF application. The number of Ki-67+ cells was significantly increased 7 days (n = 86.1 ± 13.8/mm^2; $p < 0.01$) after SAH compared to the control group 7 days after ACSF application (n = 19.6 ± 5.2/mm^2) (**Figure 5F**).

Double immunostaining of MHC II+ and Ki67+ cells revealed that all proliferating cells in the CP were APC in all animals (**Figures 8A–C**). Double immunostaining for ED1+ and Ki-67+ (**Figures 8D–F**) cells did not reveal significant changes in the percentage of proliferating activated macrophages in the CP following either SAH or ACSF application (**Figure 8J**). In contrast, double immunostaining for ED2+ and Ki-67+ cells (**Figures 8G–I**) displayed a significantly higher percentage of proliferating ED2+ cells 7 days (n = 38.4 ± 9.4%; $p < 0.05$) following SAH, but at 3 days (n = 17.2 ± 3.5%) the number was lower compared to ACSF animals. Surprisingly, the number of proliferating ED2+ cells in the CP was significantly higher, compared to naïve animals (n = 17.2 ± 3.5%), 3 days (n = 29.6 ± 4.2%; $p < 0.05$) after ACSF application. The proliferation of ED2+ cells was significantly increased 3 days following ACSF application (n = 29.6 ± 4.2/mm^2; $p < 0.01$), when compared to 3 days after SAH induction (n = 17.2 ± 1.2%), whereas it was reversed at 7 days following SAH, being significantly higher (n = 38.4 ± 9.4%; $p < 0.01$) when compared to CP of the ACSF group (n = 15.9 ± 4.1%; **Figure 8K**).

DISCUSSION

Subarachnoid Hemorrhage Induced Inflammatory Reaction in the Choroid Plexus

Subarachnoid hemorrhage from a ruptured intracranial aneurysm results in an initial increase of ICP which together with

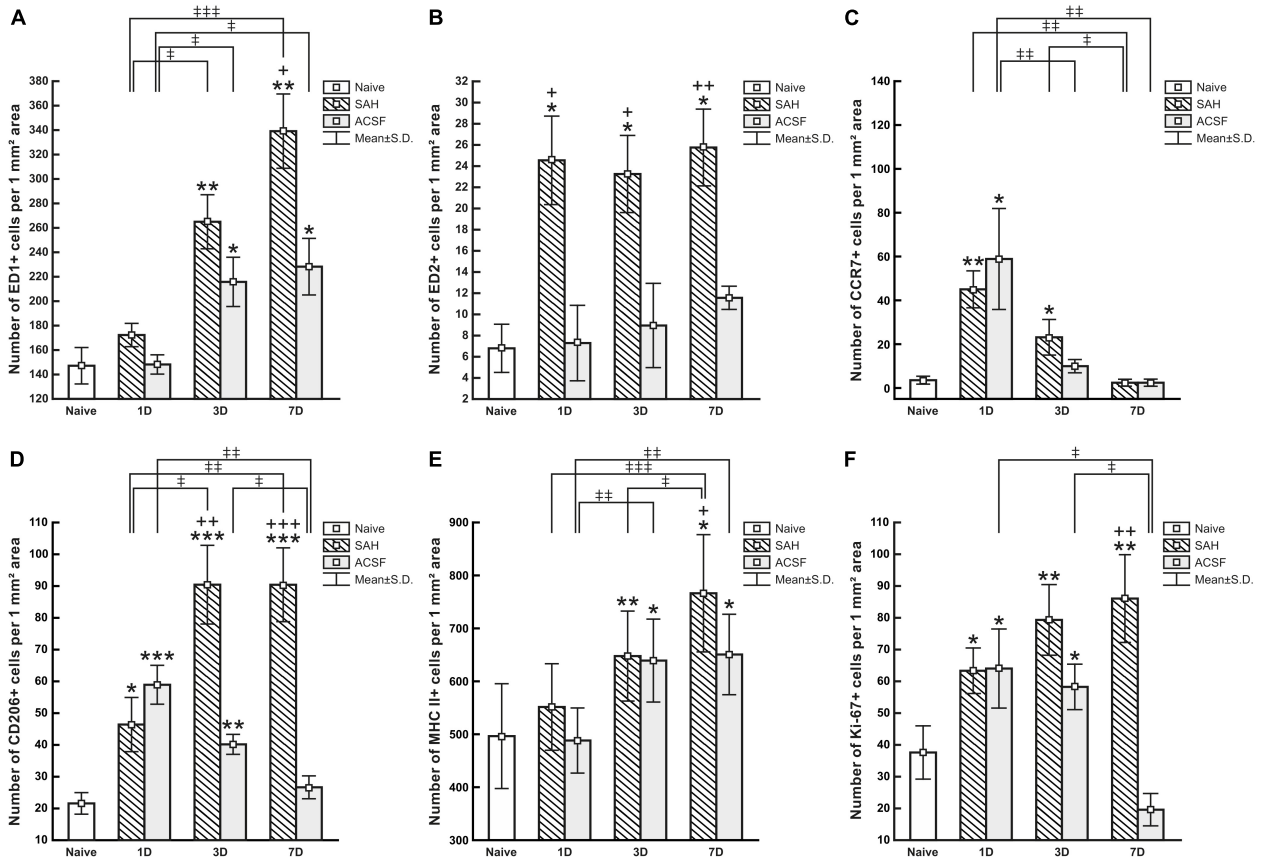

FIGURE 5 | Numbers of ED1+ **(A)**, ED2+ **(B)**, CCR7+ **(C)**, CD206+ **(D)**, MHC II+ **(E)** and Ki67+ **(F)** cells per mm^2 of CP from naive, ACSF and SAH rats at 1, 3, and 7 days after operation. Error bars indicate SD. *Indicates a significant difference when compared to CP from naïve rats (*$p < 0.05$; **$p < 0.01$; ***$p < 0.001$). +Indicates a significant difference when compared to CP from ACSF rats ($^{+}p < 0.05$; $^{++}p < 0.01$; $^{+++}p < 0.001$). ‡Indicates a significant difference between the individual time points of survival ($^{‡}p < 0.05$; $^{‡‡}p < 0.01$; $^{‡‡‡}p < 0.001$).

subsequent blood degradation products produce further clinical complications (Grote and Hassler, 1988; Kamp et al., 2013). The main pathophysiological changes like early brain injury, cerebrovascular inflammation and alteration/disturbance of the blood-brain barrier occur during the first several days after SAH (Germanò et al., 2000; Sercombe et al., 2002; Cahill et al., 2006).

In our experiments, we used the technique of volume infusion, a well-established model of SAH originally published by Solomon et al. (1985) where a constant volume of blood or ACSF is injected into the cisterna magna. Volume infusion is a standardized model with very low mortality in animals (0% in our experiments) and produces a similar change in ICP as well as in cerebral blood flow in all animals. It has been found that application of 200 μl of autologous arterial blood or ACSF into the subarachnoid cistern induced a sudden increase in ICP from 7 ± 1 to 107 ± 5 mmHg (102 ± 7 mmHg, respectively) within 15 s with a drop to near-normal levels within 2.5 min. Moreover, compared to other models, the volume infusion model is more valuable for late SAH changes (Prunell et al., 2002). We injected blood or ACSF within 60 s. It has been found that injection speed plays a crucial role in ICP dynamics, cerebral blood flow and autoregulation. Rapid injection (within 60 s), compared to slow injection (10, 30, or 60 min), produces the highest ICP peaks, autoregulation impairment and neuronal loss resulting in early brain injury (Conzen et al., 2019). In our experiments we did not assess behavioral changes because 7 days is too short a time for evaluating functional outcomes. Nevertheless, it has been found that blood injection into the cisterna magna induces motor impairment compared to saline injection (Germanò et al., 1994).

It is generally accepted that the products of heme catabolism, e.g., free ferrous iron, CO or biliverdin/bilirubin are biologically active substances that may exert profound effects on cellular differentiation, proliferation, physiology and death (Schipper, 2004). Therefore, it is reasonable to assume that the formation and subsequent degradation of a blood clot may lead to the alteration of macrophage numbers and increased cellular proliferation in the CP.

Our experimental study demonstrated that SAH induced an increase in the number of epiplexus macrophages with ED1, ED2, CCR7, CD206 and MHC immunophenotypes and caused their proliferation in the CP. These findings corroborate the findings of Liszczak et al. (1984), where increased KC numbers were seen in the CP 1 week after SAH, but they did not evaluate cellular specification, nor did they monitor earlier time points.

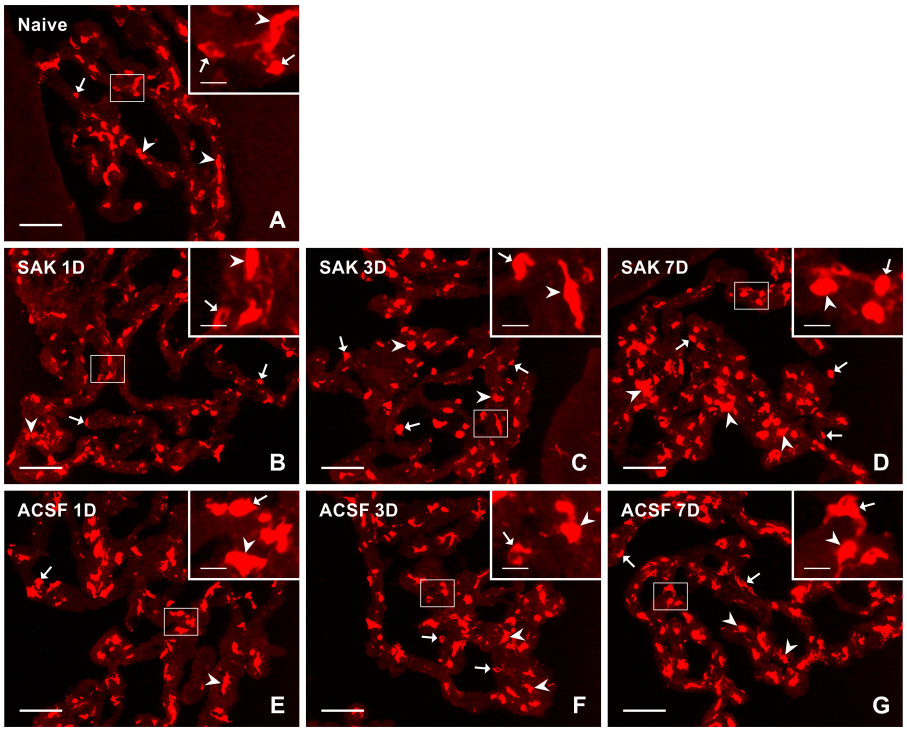

FIGURE 6 | Representative pictures of cryostat sections through the CP showing immunostaining with MHC II antibody from naïve **(A)**, SAH **(B–D),** and ACSF **(E–G)** rats at 1, 3, and 7 days (1D, 3D, and 7D) after operation. Arrows indicate MHC II+ cells in the epiplexus position and arrowheads in the stroma of CP. Insets show a higher magnification of regions marked by the boxes. Scale bars = 80 μm (main image); 10 μm (insets).

Immunostaining revealed higher numbers of activated (ED1+) macrophages and MHC II+ immune cells in the epiplexus position over the period of survival following SAH. This is probably linked to similar cellular specificity of the ED1 antibody and that recognizing MHC II. The ED1 antibody is produced against a 110-kD the lysosomal/endosomal-associated membrane glycoprotein (CD68) highly expressed by monocytes and tissue macrophages. This protein is a member of the scavenger receptor family involved in the clearance of cellular debris and the promotion of phagocytosis in activated macrophages (Juniantito et al., 2010; Zeibig et al., 2019). The ED1 monoclonal antibody of the same clone was specified and used by many other authors as a marker of macrophages with activated phagocytosis (Dijkstra et al., 1985; Hu et al., 2007; Lee and Zhang, 2012). Similarly, MHC-II is strongly expressed in activated and phagocytic macrophages (Lee and Zhang, 2012). Our results are in line with earlier reports showing a high level of MHC-II in epiplexus macrophages (Li and Barres, 2018). There is growing body of recent evidence that inflammation in CP leads to CSF hypersecretion following the intraventricular hemorrhage (Karimy et al., 2017). Moreover, epiplexus cell activation in rat CP characterized by increased number of CD68+ and Iba-1+ cells as well as Iba-1+ cell soma size was associated with the development of hydrocephalus 24 h after SAH induction (Wan et al., 2019). Similarly, inflammation in the CP may lead to hypersecretion of CSF and thus contribute to the development of post-hemorrhagic hydrocephalus.

It has been reported that the recruitment of monocytes after SAH is stimulated by the pro-inflammatory and chemotactic molecules of the CP via activation of toll like receptor 4 (TLR-4; Meeker et al., 2012; Gram et al., 2014). Moreover, upregulation of TLR-4 by heme leads to increased TNF-α expression, inducing alterations in tight junction proteins like zonula occludens-1 (Zeni et al., 2007; Simard et al., 2009, 2011; Aveleira et al., 2010; Lin et al., 2012). Since the percentage of proliferating ED1+ cells was approximately the same in the CP of the SAH, ACSF and naïve groups, it can be assumed that their increased number in the epiplexus position probably arises from recruited monocytes. Moreover, we found a significantly increased percentage of proliferating (Ki-67+) ED2+ macrophages in the epiplexus position 7 days after SAH, but the number of ED2+ macrophages was approximately the same at all time-points. Therefore, activation and proliferation of resident ED2+ macrophages may be another source of increased number of ED1+ activated macrophages 7 days after SAH as has been previously described after nerve injury, focal brain ischemia and traumatic brain injury (Hu and McLachlan, 2003; Hu et al., 2012; Wang et al., 2013). It was demonstrated that circulating monocytes migrate through the fenestrated capillaries into the connective tissue of the CP and pass through epithelial cells by "emperipolesis" to become KC (Ling et al., 1998). Blood circulation in meningeal vessels could be another source of the increased number of epiplexus macrophages (Wilson et al., 2010).

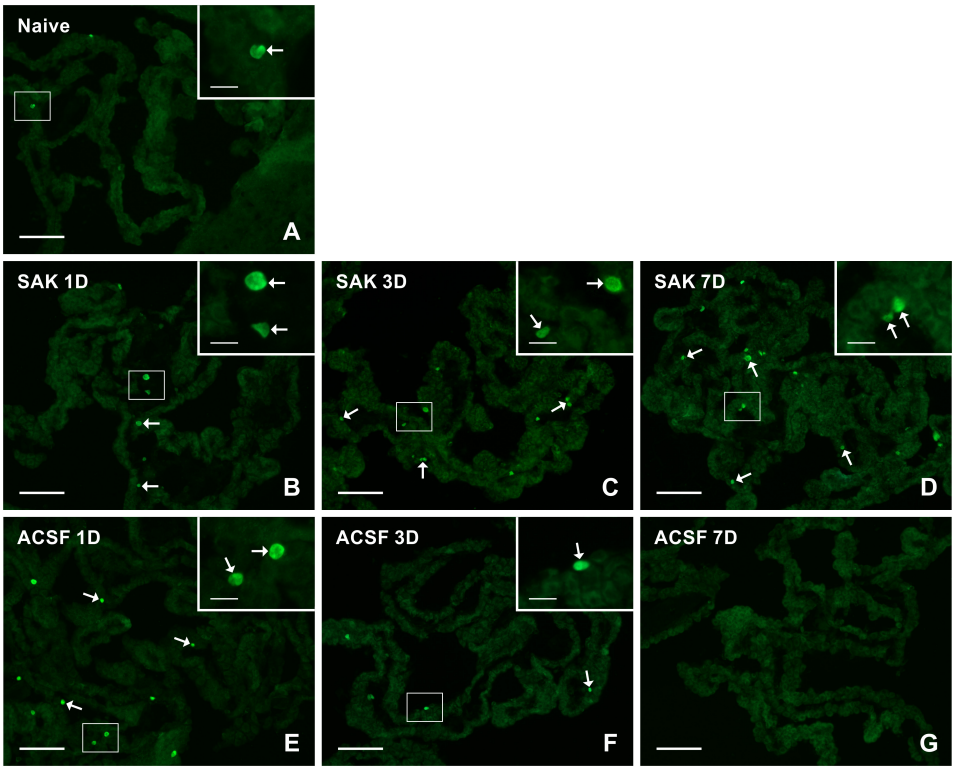

FIGURE 7 | Representative pictures of cryostat sections through the CP showing immunostaining with Ki67 antibody from naïve **(A)**, SAH **(B–D)**, and ACSF **(E–G)** rats at 1, 3, and 7 days (1D, 3D, and 7D) after operation. SAH induced a progressive increase in the number of proliferating cells 1, 3, and 7 days after injection of blood. ACSF application led to an increase in the number of KI67+ cells 1 and 3 days after operation. Arrows indicate Ki67+ cells in the epiplexus position of the CP. Insets show a higher magnification of regions marked by the boxes. Scale bars = 80 μm (main image); 10 μm (insets).

In general, the distinct functional macrophage phenotypes are designated as M1 and M2 (Demeestere et al., 2015). M1 macrophages are characterized by expression of CD68 (ED1) and CCR7 besides other antigens (Badylak et al., 2008; Ma et al., 2010). In contrast, the expression of CD163 (ED2) and CD206 antigens are indicative of the M2 macrophage phenotype (Kigerl et al., 2009). The pro-inflammatory M1 macrophages are associated with the initial phases of acute inflammation, while anti-inflammatory M2 macrophages are associated with tissue repair and regeneration (Chazaud, 2014; Demeestere et al., 2015). It is known that modulation of immune-cell phenotype and function in the CP acts as a "checkpoint" for peripheral immune cells invading into the central nervous system (CNS) in a variety of neurological diseases (Brendecke and Prinz, 2015; Goldmann et al., 2016). Moreover, the CP has been described as the entry point for anti-inflammatory M2 macrophages into the injured spinal cord while the pro-inflammatory M1 macrophages were determined to arise from the adjacent spinal cord leptomeninges (Shechter et al., 2013). However, almost all macrophages in the CP following a cortical ischemic stroke, expressed M1-like markers indicating their pro-inflammatory immunophenotyping (Ge et al., 2017).

In our experiments, we found an increased number of CCR7+ cells (approximately one fourth of all ED1+ cells) in the CP mainly 1 day after SAH, while the cell number dropped back to that of naïve animals 7 days. In contrast, CD206+ cells gradually increased over the period of survival with a peak between 3 and 7 days. This difference in the numbers of CCR7+ and CD206+ cells is probably associated with the acute inflammatory reaction in the CP immediately after and the initiation of regenerative processes in later periods after SAH. This gradual phenotypic shift toward anti-inflammatory and cytoprotective CD206+ cells in later stages after SAH could be mediated by the induction of heme oxygenase-1 (HO-1) stimulated by hemoglobin-degradation products (Abraham and Drummond, 2006; Naito et al., 2014).

Increased Intracranial Pressure Contributes to Immune Cell Changes in the Choroid Plexus

Increased ICP following the application of ACSF mimics aneurysmal subarachnoid hemorrhage (Prunell et al., 2002). ACSF application is widely used as a control for intrathecal drug application and experimental models of inflammatory diseases without any evidence of immunogenicity (Hylden and Wilcox, 1980; Hernangómez et al., 2016). Cellular changes found in the CP after ACSF application are therefore most likely induced by increased ICP. Our quantitative analysis revealed similarly increased numbers of ED1+ and MHC II+

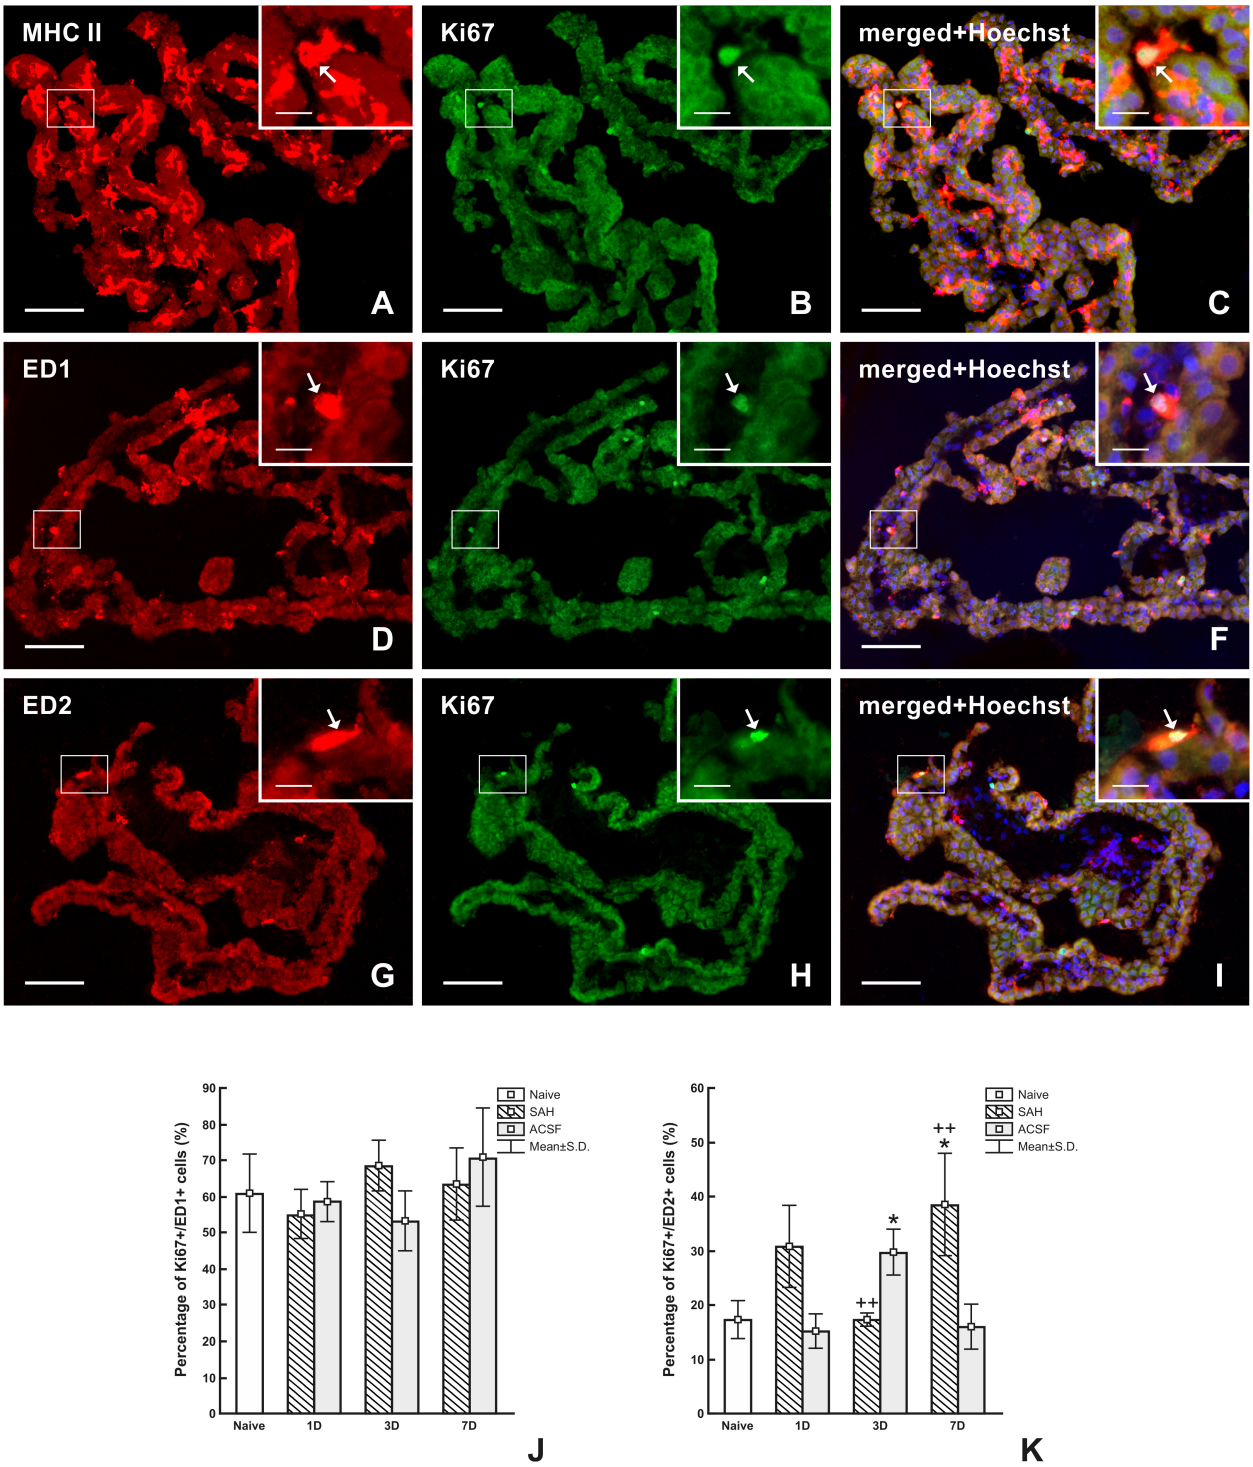

FIGURE 8 | Representative images of double immunostaining to detect MHC II+, ED1+, and ED2+ macrophages as well as Ki67+ cells in the CP 7 days after SAH. Double immunostaining for MHC II and Ki-67 **(A–C)** showed that all proliferating cells are antigen presenting cells *(arrows)*. Simultaneous reaction for ED1 and Ki67 **(D–F)** proved that most proliferating cells are activated macrophages *(arrows)*. Double immunostaining reaction for ED2 and Ki-67 **(G–I)** showed that approximately one-third of proliferating cells are resident macrophages *(arrows)*. Merged figures **(C,F,I)** include a merge with Hoechst-stained nuclei. Scale bars – main images 80 μm; insets 20 μm. Percentage of ED1+/Ki-67+ cells **(J)** and ED2+/Ki67+ cells **(K)** in the CP of naïve, SAH and ACSF rats at 1, 3, and 7 days after operation. *Indicates a significant difference when compared to CP from naïve rats ($p < 0.05$). $^{++}$Indicates a significant difference when compared to CP from control rats ($p < 0.01$).

cells following ACSF application as those seen in SAH animals. On the other hand, the initial increase in CCR7+ and CD206+ cell number followed by a decrease at later time points is probably a reaction to the surgical procedure. These results indicate that the reaction of epiplexus cells after SAH can also be affected by increased intracranial pressure. However, blood application (SAH group) induced a stronger immune reaction as expressed by increased number of ED2+, CD206+ cells and increased proliferation of ED2+ cells. This clearly indicates that blood and/or blood degradation products contributes to strong immune reaction in the later phase (3 and 7 days) following SAH compared to ACSF application. Since anti-inflammatory M2 macrophages (ED2+, CD206+) are associated with tissue repair and regeneration (Chazaud, 2014; Demeestere et al., 2015) we assume that this reaction may contribute to phagocytosis of the blood clot and restoration of brain homeostasis. Moreover, in contrast to the CP of naïve rats, ACSF application into the subarachnoid space elicits significantly increased epiplexus cell proliferation in the initial stages (1 and 3 days after ACSF application), but returns to normal 7 days after injection. We can assume that increased ICP may also affect the number of epiplexus immune cells in the CP by modulating cell proliferation early as an acute reaction. However, based on our results we assume that increased intracranial pressure itself does not have the ability to induce long-lasting changes in the CP.

Interestingly, we did not find CD3+ cells in any animal group even after sensitive CD3 immunofluorescence staining using cryostat sections and image analysis. In addition, positive immunostaining of spleen sections confirmed the function of the anti-CD3 antibody used. Absence of CD3+ cells in our CP samples is consistent with the finding that only a few CD3+ cells are located to the CP of naïve mice (Petito and Adkins, 2005) and indicate no recruitment of CD3+ cells following SAH or ACSF application. In addition, absence of CD3+ cells in CP following SAH might be explained by inhibitory mechanisms of T cell activation and proliferation that get triggered. It is well known that degradation of heme leads to the induction of HO-1 expression in macrophages and dendritic cells. Moreover, overexpression of HO-1 downregulates co-stimulatory molecules of dendritic cells that are necessary for the activation of T lymphocytes (Chauveau et al., 2005; Hull et al., 2014).

CONCLUSION

Our experimental results demonstrate increased numbers of immune cells with diverse immunophenotypes predominantly in the epiplexus position of the CP in response to SAH. Moreover, this increased epiplexus cell number was also found in the CP of the ACSF group, indicating that not only blood, but also increased ICP contributes to cellular changes in the CP. Immune cell changes in the CP may alter the B-CSF barrier with the consequent development of hydrocephalus in response to SAH. On the other hand, SAH triggers the recruitment of epiplexus macrophages that may ingest the blood clot by phagocytosis and may thus contribute to the restoration of brain homeostasis.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

The animal study was reviewed and approved by the Animal Investigation Committee of the Faculty of Medicine, Masaryk University, Brno.

AUTHOR CONTRIBUTIONS

PS and MJ designed the research, performed the experiments, and wrote the manuscript. IK performed the experiments, prepared the samples for immunohistochemistry, and wrote the manuscript. PD and RJ analyzed the data and wrote the manuscript.

FUNDING

This work was supported by the Internal Grant Agency of the Masaryk University (Grant Nos. MUNI/A/1086/2018 and MUNI/A/0908/2017).

Alzheimer's disease (AD) is a neurodegenerative disease with a complex and not fully understood pathogenesis. Besides brain-intrinsic hallmarks such as abnormal deposition of harmful proteins, i.e., amyloid beta in plaques and hyperphosphorylated Tau in neurofibrillary tangles, blood-derived elements, in particular, platelets have been discussed to be involved in AD pathogenesis. The underlying mechanisms, however, are rather unexplored. Here, we investigate a potential role of platelets in an AD transgenic animal model with severe amyloid plaque formation, the APP-PS1 transgenic mice, and analyzed the presence, spatial location and activation status of platelets within the brain. In APP-PS1 mice, a higher number of platelets were located within the brain parenchyma, i.e., outside the cerebral blood vessels compared to WT controls. Such platelets were activated according to the expression of the platelet activation marker CD62P and to morphological hallmarks such as membrane protrusions. In the brain, platelets were in close contact exclusively with astrocytes suggesting an interaction between these two cell types. In the bloodstream, although the percentage of activated platelets did not differ between transgenic and age-matched control animals, APP-PS1 blood-derived platelets showed remarkable ultrastructural peculiarities in platelet-specific organelles such as the open canalicular system (OCS). This work urges for further investigations on platelets and their yet unknown functional roles in the brain, which might go beyond AD pathogenesis and be relevant for various age-related neurodegenerative diseases.

INTRODUCTION

Worldwide, approximately 50 million people live with dementia, a large number that is expected to triplicate by 2050 as the world population grows and the lifespan increases (International Alzheimer's Disease [IAD], 2015). In about 60 to 70% of the patients, dementia is due to Alzheimer's disease (AD), which makes AD not only the most common cause of dementia but also a major economic and social burden (International Alzheimer's Disease [IAD], 2015; Van Cauwenberghe et al., 2015). Nevertheless, and more than a century after its first description, the exact etiology of AD pathology is still not understood (Piaceri et al., 2013). Moreover, there are currently no drugs available that can stop or reverse AD progression, and the approved therapeutics merely ameliorate symptomatology (Frozza et al., 2018).

Drug development in AD over the last decades repeatedly tried to target brain-intrinsic hallmarks of the pathology. These included neuroprotective approaches and attempts to reduce

the load of harmful proteinaceous deposits in the brain, such as amyloid beta (Aβ) in plaques and hyperphosphorylated Tau in neurofibrillary tangles. So far, these approaches failed in the late clinical phases (Michael et al., 2019). Therefore, the amyloid cascade and the tau hypotheses as being causative in AD pathogenesis are increasingly questioned (De Strooper and Karran, 2016). In addition, novel concepts consider that the brain is not an isolated organ but is strongly influenced by systemic factors, which might contribute to brain degeneration or alternatively function as protective and/or self-regenerative mechanisms to compensate CNS damages. Along this line, increasing evidence illustrates that blood components are contributing to brain aging (Villeda et al., 2011; Smith et al., 2018) and that components present in young blood might be developed as therapeutics to treat AD (Middeldorp et al., 2016).

In the context of brain aging and neurodegeneration, blood-derived elements with therapeutic potential are platelets. Platelets have repeatedly been hypothesized to play a role in AD pathology (Li et al., 1998; Evin et al., 2003), in particular, in cerebral amyloid angiopathy (CAA) (Gowert et al., 2014; Jarre et al., 2014; Donner et al., 2016; Kniewallner et al., 2016, 2018). Platelets are small anuclear blood cells, which store a plethora of bioactive factors in specialized cytoplasmic compartments (Rumbaut and Thiagarajan, 2010). Upon activation, these factors are released to the extracellular space, allowing platelets to participate in diverse physiological and pathological processes (Rivera et al., 2016). In AD, vascular abnormalities, such as disrupted microvascular integrity or microbleedings, might trigger platelet activation in an attempt to restore vascular integrity. Once activated, platelets release among other substances Aβ peptides and several inflammatory mediators (e.g., IL-1β, CD40L, Thromboxane A2) (Arman et al., 2015; Canobbio et al., 2015; Heijnen and Korporaal, 2017; Humpel, 2017; Kniewallner et al., 2018). Thus, platelets might contribute to the deposition of Aβ peptides in the wall of cerebral blood vessels as well as to an inflammatory environment, which ultimately translates into vascular degeneration (Kniewallner et al., 2018). Whereas the involvement of platelets in the formation of cerebral amyloid angiopathy deposits has been a matter of extensive study, less is known concerning the general role of platelets in AD (Gowert et al., 2014).

Here, we investigated platelets in APP-PS1 transgenic mice with a severe amyloid plaque formation but no CAA pathology in the brain. We analyzed the spatial location of platelets in the brain with respect to their location within or outside blood vessels. We also studied blood-circulating platelets for their activation status by flow cytometry (FC) and analyzed their ultrastructure using electron microscopy.

MATERIALS AND METHODS

Animals

Female and male APP Swedish PS1 dE9 mice (reviewed in Jankowsky et al., 2001) expressing a chimeric mouse/human mutant amyloid precursor protein (Mo/HuAPP695swe) and a mutant human presenilin 1 (PS1-dE9) both directed to CNS neurons under the prion protein promoter (Jackson Laboratory)[1] were used. Mice were housed at the Paracelsus Medical University Salzburg in groups under standard conditions at a temperature of 22°C and a 12-h light/dark cycle with *ad libitum* access to standard food and water. Animal care, handling, genotyping, and experiments were approved by local ethical committees (BMWFW-66.019/0011-WF/V/3b/2016) and conducted accordingly to the Declaration of Helsinki. For brain histology, FC and transmission electron microscopy (TEM) mice were analyzed at 14 months of age. Age-matched non-transgenic mice derived from the breeding of APP-PS1 were used as control animals (WT).

Tissue Processing

Mice were anesthetized with a solution of ketamine (20.5 mg/mL; Ketamidor; Richter Pharma), xylazine (5.36 mg/mL; Chanazine; Chanelle), and acepromacine (0.27 mg/mL; Vanastress 10 mg/mL; Vana GmbH) in 0.9% sodium chloride. In order to retain blood in the blood vessels, brains were extracted without being perfused and post-fixed with 4% paraformaldehyde in sodium phosphate buffer (0.1 M; pH = 7.4) overnight at 4°C. The brains were cryoprotected and transferred into 30% sucrose in 0.1 M sodium phosphate buffer (pH = 7.4). Sagittal sections of 40 μm were cut on dry ice, using a sliding microtome.

Preparation of Washed Platelets

Upon thoracotomy, blood was collected by cardiac puncture using ethylenediaminetetraacetic acid (EDTA; 0.1 M; Promega) coated syringes. To further prevent coagulation, EDTA (0.1 M) was added to all blood samples. Anticoagulated blood samples were centrifuged at 200 × *g* for 20 min at room temperature (RT) to obtain platelet-rich plasma (PRP). PRP fractions were collected into new tubes, and 1 μM Prostaglandin E1 (Sigma-Aldrich #P55115-1MG) was added to avoid platelet aggregation, before centrifugation at 800 × *g*, for 20 min, RT. The supernatant was discarded and platelet pellets resuspended in Tyrode's buffer (134 mM NaCl, 12 mM $NaHCO_3$, 2.9 mM KCl, 1 mM $MgCl_2$, 0.34 mM Na_2HPO_4, 10 mM Hepes solution). Before use, washed platelets in Tyrode's buffer were allowed to rest for approximately 1 h, to minimize artificial platelet activation.

Immunohistochemistry

Fluorescence immunohistochemistry of mouse tissue was performed on free-floating sections as previously described (Marschallinger et al., 2015; Unger et al., 2016, 2018). Antigen retrieval was performed depending on the used primary antibody by steaming the sections for 15–20 min in citrate buffer (pH = 6.0, Sigma). The following primary antibodies were used: rat anti-CD41 (1:300; Abcam), mouse anti-CD62P (1:300; Abcam), rabbit anti-collagen IV (1:50; Abcam), guinea pig anti-GFAP (1:500; Progen), goat anti-Iba1 (1:500; Abcam), guinea pig anti-NeuN (1:500; Millipore), rabbit anti-Olig2 (1:500; Merck), goat anti-PDGFRβ (1:100; R&D Systems). Incubation with primary antibodies occurred either overnight at RT or for 72 h at 4°C. After incubation with primary antibodies, sections were

[1]http://www.jax.org/strain/005864

extensively washed in PBS and incubated for 3 h at RT in secondary antibodies (all at 1:1,000). The following secondary antibodies were used: donkey anti-goat Alexa Fluor 568, donkey anti-guinea pig Alexa Fluor 647, donkey anti-mouse Alexa Fluor 647, donkey anti-rabbit Alexa Fluor 488 and 568, donkey anti-rat Alexa Fluor 488, goat anti-rat Alexa Fluor 568 (all Invitrogen or Molecular Probes). For amyloid-β plaque staining, Thioflavin S (1 mg/mL; 1:625; Sigma-Aldrich) was added to the secondary antibody solution. Nucleus counterstaining was performed with 4′,6′-diamidino-2-phenylindole dihydrochloride hydrate (DAPI; 1 mg/mL; 1:2,000; Sigma-Aldrich).

Electron Microscopy

Transmission electron microscopy (TEM) was used for morphological characterization of blood isolated platelets from APP-PS1 and WT age-matched controls (n = 3/group). Platelets dissolved in Tyrode's buffer were fixed for 10 min with Cell Fix (BD Biosciences, 1:4). Upon centrifugation at 800 × g, for 20 min, at RT, platelet pellets were post-fixed in 2.5% glutaraldehyde (Agar Scientific), 4% PFA in phosphate buffer solution overnight. Upon centrifugation at 800 × g for 10 min, pelleted platelets were incubated in 1% osmium tetroxide (Electron Microscopy Sciences) in PBS Dulbecco (Merck) for 45 min in the dark. Following centrifugation at 800 × g for 10 min, pellets were washed twice in distilled water for 5 min. Between washes, platelets were centrifuged at 800 × g for 5 min. A third fixation step was carried out for 10 min in uranyl acetate replacement stain (1:10 in water; Electron Microscopy Sciences). Fixative solution was removed by centrifugation at 800 × g for 5 min, and platelets were washed as described previously. Washed pellets were dehydrated in a graded series of ethanol solutions, by incubation in ethanol 25% (5 min), 50% (5 min), 70% (5 min), 96% (5 min), and 100% (10 min). To finally complete dehydration, platelets were transferred to acetone (10 min), before being embedded in DurcupanTM ACM (four-component resin; Sigma-Aldrich). Resin curation was carried out at 37°C overnight and subsequently at 60°C for 72 h. Plastic blocks were trimmed to a trapezoid shape and sectioned using an ultramicrotome (Reichert-Jung Ultracut E, Austria). Semithin sections (0.5 μm) were generated with a glass knife and stained with 1% toluidine blue to confirm specimen exposure. After identification of stained cells, ultrathin sections (approximately 60 nm) were prepared using a diamond knife (Diatome Histo). Sections were flattened with chloroform and subsequently mounted on cooper grids (G75-Cu; Electron Microscopy Science), pre-coated with 0.2% Formvar. Transmission electron micrographs were obtained using a Leo 912 Omega transmission electron microscope (Carl Zeiss, Germany), at an operating voltage of 100 kV and magnification of 20,000×.

Flow Cytometry Analysis

To investigate the basal activation level of circulating platelets in APP-PS1 and WT age-matched mice (n = 7/group), we performed two-color FC analysis in washed platelets. Before staining, a 50 μL aliquot of each sample was incubated with rat anti-mouse BD CD16/CD32 Fc Block TM (1:100; #553142; BD Biosciences) for 5 min at RT in FC buffer [2% bovine serum albumin (Sigma), 2 mM EDTA (Promega) in PBS Dulbecco (Merck)] to block unspecific binding sites. Thereafter, samples were stained with allophycocyanin (APC)-labeled anti-mouse CD41 (1:100; #133913; BioLegend) and fluorescein isothiocyanate (FITC)-labeled rat anti-mouse CD62P (1:100; #553744; BD Pharmingen) antibodies for 30 min in the dark. An aliquot of washed platelets incubated with thrombin from bovine plasma (0.25 U/mL; #1.12374; Sigma-Aldrich) and the respective antibodies, served as positive control for platelet activation. Additionally, isotype IgG staining was performed using FITC-rat IgG1λ isotype control (1:100; #553995; BD Pharmingen). Staining reaction was stopped with FC buffer, and samples were centrifuged at 800 × g for 10 min. Platelet pellets were resuspended in FC buffer and immediately analyzed with BD Accuri TM C6 Plus Flow Cytometer (BD Biosciences).

Platelet population was defined based on their pattern of forward and side scattering on a logarithmic scale and by positive staining for CD41, commonly used as a pan-platelet marker. Cell doublets were discriminated and excluded from the analysis. Per sample, at least 5,000 $CD41^+$ single events were recorded. To determine the activation level of platelets, $CD41^+$ cells were gated for $CD62P^+$ expression. CD62P, also known as P-selectin, is a transmembrane glycoprotein mainly stored in platelet α-granules, which rapidly translocates onto the platelet surface upon activation (Rumbaut and Thiagarajan, 2010; Yun et al., 2016). The percentage of $CD62P^+$ platelets was calculated relatively to the number of $CD41^+$ platelets present in each sample. To compensate for non-specific immunofluorescence, the percentage of positive platelets detected in the isotype control staining for CD62P was subtracted from the percentage of $CD62P^+$ platelets determined in each sample. For data presentation, FC plots were generated with Kaluza Analysis Software (Beckman Coulter).

Microscopy, Visualization, and Image Processing

For qualitative and quantitative microscopic analysis of mouse tissue, confocal laser scanning microscopy was performed using a LSM 710 from Zeiss. Representative images were taken at 20×, 40×, and 63× magnification as confocal z-stack images and imported into the Imaris software (version 9.1.2, Bitplane) for 3D surface rendering and image analysis.

Quantitative and Qualitative Analysis of Immunohistochemical Data

To analyze platelet distribution in the brain, four confocal images from the cortex and hippocampus of each animal (n = 6/group) were used for 3D modeling. Localization of platelets, visualized by CD41 staining, was assessed in relation to cerebral blood vessels, stained for collagen IV. The number of platelets located in the intra- and extraluminal spaces as well as their volume were determined. To study platelet activation *in vivo*, expression of CD62P was investigated in 100 $CD41^+$ platelets present in the brain per animal, regardless of their location in relation to blood vessels (n = 6/group). To evaluate the occurrence of cellular interactions between platelets and

Thioflavin S^+ amyloid plaques (n = 2/group) and other cells of the neurovascular niche (n = 3/group), confocal Z-stacks from randomly selected visual fields of the hippocampus and cortex were employed for 3D surface rendering. Three-dimensional projection models were rotated around different angles in order to seek surface co-localizations. To quantify platelet–astrocyte interactions, four confocal images of the hippocampus were collected per animal (n = 3/group) and processed for 3D imaging in order to determine the number of $CD41^+$ cells co-localizing with $GFAP^+$ cells.

Quantitative Analysis of Electron Microscopy Data

Per genotype, the surface and OCS areas of 90 randomly selected platelets (30 platelets/animal, three animals/genotype) were assessed using the Image J software (version 1.44p). The platelet surface area and OCS area of single platelets were analyzed, and the number of every analyzed platelet per genotype was used for statistical analysis. In order to determine the OCS area, the area of all white vacuole and tubular sections within the cell was measured. Relative OCS area was calculated accordingly to the formula:

$$\text{Relative OCS Area (\%)} = \frac{\text{OCS measured area} \times 100}{\text{Platelet measured area}}$$

Statistical Analysis

Statistical analysis was performed using GraphPad Prism (GraphPad Software, version 6). Data was tested for normality using the Shapiro–Wilk normality test. To compare values between two groups, unpaired Student's t-test was used for normally distributed data and Mann–Whitney test for non-normally distributed data. For multiple comparisons between groups, two-way ANOVA with Tukey's multiple comparison test was used. For statistical analysis of quantitative electron microscopy data, the ROUT method (Q = 1%) was used to identify outliers. Two outliers were identified and removed in the platelet area data set and one in the OCS relative area data set. Values of $p < 0.0001$ (****) were considered most significant, $p < 0.01$ (**) highly significant, and $p < 0.05$ (*) significant. Values were expressed as mean ± standard error of the mean (SEM).

RESULTS

Platelets in APP-PS1 Mice Invade the Brain Parenchyma

First, we investigated platelet localization in the hippocampus and cortex of 14-month-old APP-PS1 transgenic mice and age-matched WT controls by immunohistochemical staining for CD41. We have selected APP-PS1 mice with the age of 14 months, as at this time point the animals present a full spectrum of pathology, showing severe amyloid plaque deposition in the hippocampus and cortex, high levels of microgliosis and astrogliosis, vascular alterations, and cognitive deficits (Jankowsky et al., 2004; Lalonde et al., 2005; Janota et al., 2015; Unger et al., 2016). To discriminate between platelets being completely inside or exposed to the outside of the blood vessels, we modeled the vessel structure in 3D with different levels of transparency, using the Imaris software. This allowed us to visualize platelets located within the vessels. In WT and APP-PS1 mice, $CD41^+$ platelets were mainly located in the intraluminal space of blood vessels, or at least within the blood vessel's basement membrane, which was outlined by collagen IV immunoreactivity (**Figures 1A,B**). Besides that, and more pronounced in APP-PS1 mice, platelets spread through the vessel wall, partially transposing into the extraluminal space (**Figures 1A,B**). Moreover, in APP-PS1 mice, platelets were also found completely outside the blood vessels in the brain parenchyma (**Figures 1A,B**), being in this case mostly located in the vicinity of a blood vessel (**Figure 1B**). Quantitative analysis in hippocampal and cortical brain regions revealed that APP-PS1 mice had a higher total number of platelets per brain section in comparison to WT controls (**Figure 1C**). As similar observations were made in the hippocampus and cortex (**Figure 1C**), we did no further discrimination between these two brain regions in subsequent analyses and pooled the data from both brain regions. A significantly higher percentage of platelets was found outside blood vessels in the extraluminal space in APP-PS1 compared to WT brains (22.18 ± 1.37% vs. 6.81 ± 0.92%), and vice versa; a significantly lower percentage of platelets were inside the vessels in APP-PS1 brains (77.83 ± 1.37% vs. 93.20 ± 0.92%) (**Figure 1D**).

Characterization of Blood Circulating Platelets in APP-PS1 and WT Age-Matched Control Mice

The presence of platelets in brains with an AD amyloid pathology raises various questions such as their molecular profile and identity, their activation status, and their functional role in the brain parenchyma. As a first urging question, we addressed whether platelets are activated once they enter the brain parenchyma or whether they are already activated in the bloodstream. To that, we used FC to analyze the surface expression of CD62P, a widely used marker for platelet activation, as well as TEM for ultrastructural analysis of platelets isolated from the blood of APP-PS1 and WT mice. To assess CD62P expression by FC, we first gated the platelet population based on its pattern for forward and side light scattering and CD41 expression, and further defined the activated platelet population as $CD62P^+/CD41^+$ (**Figures 2A,B**). Up to 70% of $CD41^+$ platelets expressed CD62P when stimulated *ex vivo* with thrombin as a positive control, and only very few $CD62P^+/CD41^+$ platelets were detected under native conditions (**Figure 2B**) indicating that the vast majority of platelets in the blood are not activated. Quantitative analysis revealed only a slight, but not significant, difference between the percentage of activated platelets in the bloodstream of APP-PS1 compared to WT mice (**Figures 2C,D**). TEM ultrastructural analysis (**Figure 2E**) revealed that WT platelets presented a round or discoid shape with smooth plasma membrane, although some WT platelets also showed small elongations and protrusions of the membrane, most likely being pseudopods. In APP-PS1 platelets, the plasma membrane was

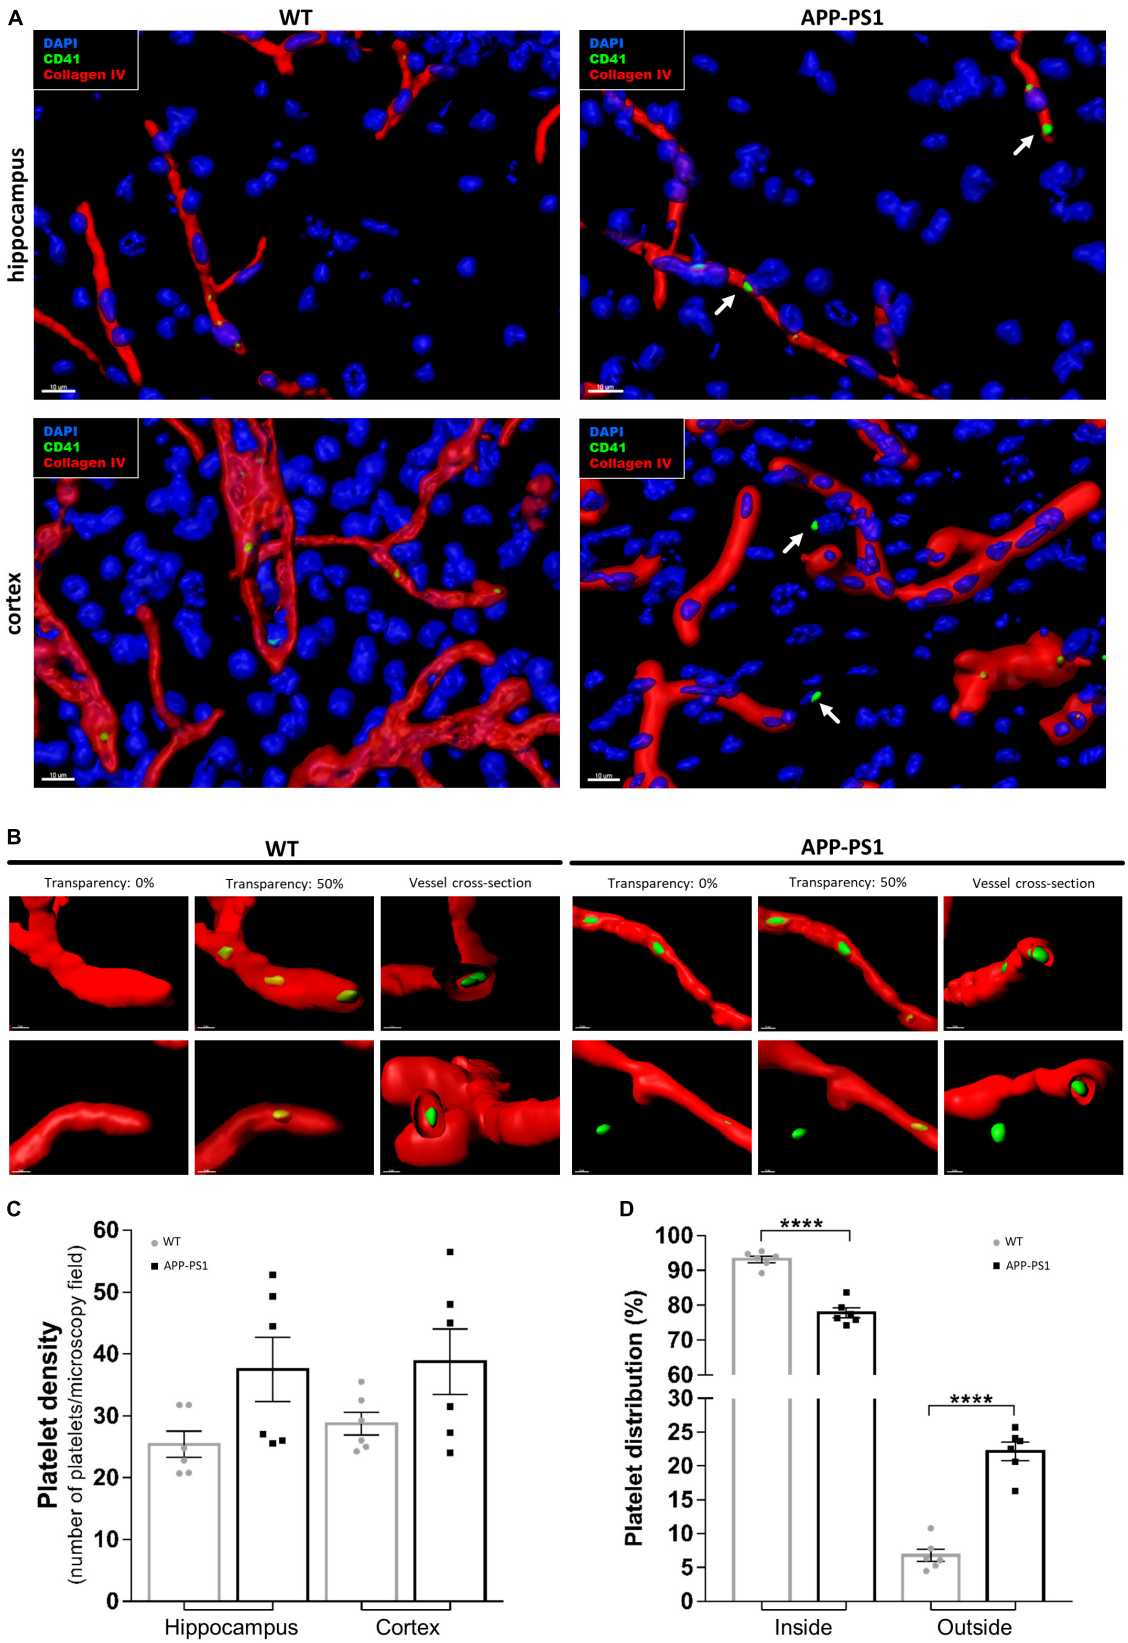

FIGURE 1 | Continued

FIGURE 1 | Immunohistochemical analysis of platelet distribution in the brain of APP-PS1 mice. Brain sections from APP-PS1 mice and age-matched WT controls were stained with collagen IV (red) for blood vessels and CD41 (green) for platelets. 4′,6′-diamidino-2-phenylindole dihydrochloride hydrate (DAPI; blue) was used as nucleus stain. Confocal microscopy images, from randomly selected hippocampal and cortical regions, were processed for 3D imaging. Platelets from WT and APP-PS1 mice were mainly located within the cerebral blood vessels **(A,B)**, whereas platelets from APP-PS1 mice were frequently seen in the brain parenchyma or at the blood vessel wall, suggesting extravasation **(A**—arrows, **B**—right**)**. Overall, APP-PS1 mice seem to have higher platelet densities in the hippocampus and cortex in comparison with WT controls **(C)**. Moreover, quantification of platelets located inside (blood vessel) and outside (parenchyma/vessel wall) cerebral blood vessels revealed that APP-PS1 mice have a significantly higher percentage of platelets outside the blood vessels compared to WT controls **(D)**. Data shown as mean ± SEM. Statistical analysis was performed by two-way ANOVA with Tukey's multiple comparison test (n = 6/group; including WT: six females and APP-PS1: three females and three males); $^{****}p < 0.0001$. Scale: 10 μm **(A)** and 3 μm **(B)**.

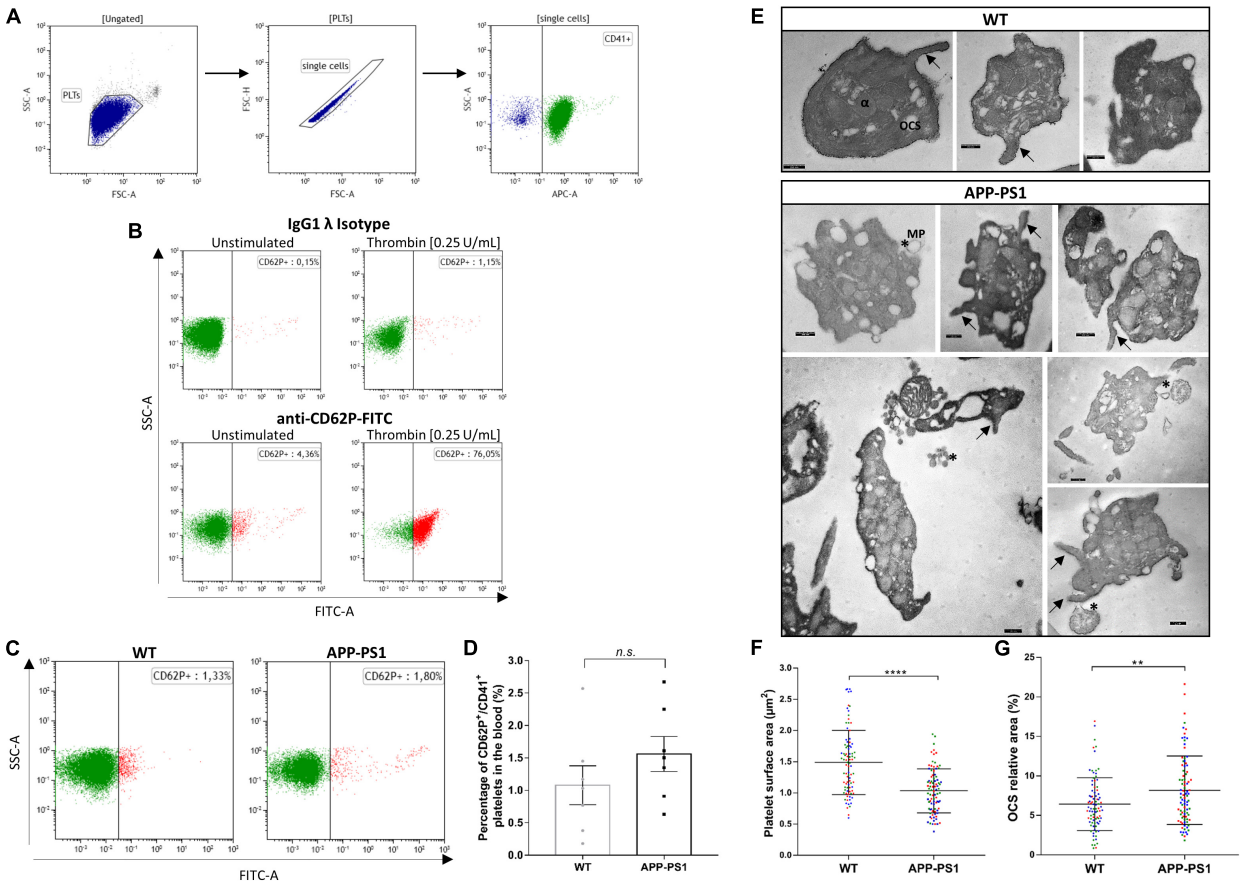

FIGURE 2 | Activation status and ultrastructure analysis of peripheral blood platelets in APP-PS1 mice. Surface expression of CD62P by CD41$^+$ platelets was assessed by flow cytometry to determine the activation status of blood-isolated platelets. Gating strategy for single CD41$^+$ platelets **(A)**. Positive control for platelet activation: Unstimulated or thrombin-stimulated platelets were stained with CD62P or respective IgG isotype control antibody **(B)**. Both APP-PS1 and WT animals showed CD62P$^+$/CD41$^+$ platelets under unstimulated conditions **(C)**, but the percentage of activated platelets in the bloodstream of APP-PS1 and WT were not significantly different **(D)**. However, TEM analysis revealed ultrastructural differences between APP-PS1 and WT blood-isolated platelets. APP-PS1 platelets presented a more irregular cell membrane, with formation of membrane elongations (arrows), and released microparticles (asterisks, *), the last two being signs of platelet activation **(E)**. APP-PS1 platelets also exhibited a significantly smaller surface area **(F)** and an enlarged OCS **(G)** compared with WT platelets. The annotated structures are α-granules (α), open canalicular system (OCS), and microparticule (MP). Scale: 250 nm **(E)**. Graph bars represent mean ± SEM. Statistical analysis was performed by unpaired Student's t test (**B:** n = 7/group; including three females and four males per group) and Mann–Whitney test **(F** and **G:** n = 90 platelets/genotype, including WT: three females and APP-PS1: two females and one male, with the 30 platelets analyzed per animal being color coded**)**. $^{****}p < 0.0001$; $^{**}p < 0.01$.

more irregular, with invaginations and protrusions. Some APP-PS1 platelets presented a microparticle formation (**Figure 2E**, asterisks), showing either microparticles under the process of budding off or already completely located in the extracellular space. Quantification of the platelet area showed that APP-PS1 platelets had an approximately 30% smaller surface in comparison with WT platelets (**Figure 2F**). Moreover, when compared to WT, APP-PS1 platelets presented an enlarged OCS (**Figure 2G**), a specific platelet organelle that appears as cytoplasmic vacuoles and thin tubular structures. In summary, our FC and TEM data suggests that APP-PS1 mice might possess a population of blood-circulating platelets exhibiting classical

signs of activation, with a highly altered cell morphology and increased microparticle formation.

Activated Platelets Are Present in the Brain of APP-PS1 Transgenic Mice

Even though we took special care to avoid platelet activation during the isolation procedure, we cannot exclude the possibility that some of the analyzed activation hallmarks were artificially induced. Therefore, and to investigate the activation status of brain platelets, we stained non-perfused brain sections for CD41, CD62P, and Collagen IV. We further used the IMARIS software to characterize platelets located inside and outside the blood vessels in more detail regarding their CD62P expression. Using 3D models with different levels of transparency, we could allocate platelets inside or outside the blood vessels. By setting the transparency level of the reconstructed vessels at 0%, only platelets exposed to the outside of the vessel can be seen, whereas at 50% transparency, platelets are visible regardless of their location, i.e., inside or outside the vessel. As a result, some of the platelets within APP-PS1 and WT (not shown) cerebral blood vessels were $CD62P^+$ and had cellular protrusions (**Figure 3A**), indicating the presence of activated platelets within the cerebral bloodstream. Similarly, platelets in the process of penetrating the vessel wall, i.e., partially visualized at 0% transparency and fully visible in the 50% transparent situation, expressed CD62P in WT and APP-PS1 mice (**Figure 3A**) indicating activation. At the quantitative level, the percentage of platelets that carry the activation marker CD62P was significantly higher in APP-PS1 compared to WT mice (**Figure 3B**). Taken together, these data suggest that platelets in the brain of APP-PS1 mice are activated.

A crucial hallmark of platelet function, at least in homeostasis, is platelet aggregation. Therefore, we raised the question whether platelets present in the brain parenchyma of APP-PS1 and WT mice might be aggregated. We used the IMARIS software to measure the volume of 3D modeled $CD41^+$ structures. We further categorized these structures as single platelets when the volume was smaller than 10 fL or as platelet aggregates for volumes bigger than 10 fL. This threshold was set accordingly to the current knowledge on platelet size (Everds, 2004). In the brain of APP-PS1 mice, where a higher number of platelets were present, there was a clear shift from single platelets to small aggregates (**Figure 3C**).

Platelets in the Brain Parenchyma Tightly Associate With Astrocytes

In the context of CAA, platelets have been shown to accumulate at cerebrovascular Aβ deposits, where they seem to fuel Aβ deposition (Gowert et al., 2014; Kniewallner et al., 2015, 2016). To assess whether intra-parenchymal platelets might promote similar effects, we analyzed the localization of $CD41^+$ platelets within the brain with respect to Thioflavin S^+ amyloid plaques. However, an association between platelets and amyloid plaques in the brain of APP-PS1 mice was not observed (**Figure 4**). We further investigated the putative cellular interaction partners within the brain, assessing potential interactions with astrocytes, pericytes, microglia, neurons, and oligodendrocytes. In APP-PS1 mice (**Figure 5**), and similarly in WT animals (data not shown), brain-located $CD41^+$ platelets were found in tight association with $GFAP^+$ astrocytes, as revealed by 3D surface rendering and co-localization analysis of GFAP and CD41 signals showing astrocyte processes covering platelet surfaces (**Figure 5A**, magenta showing co-localization, and **Supplementary Videos**). No interactions were detected with $PDGFR\beta^+$ pericytes (**Figure 5B**), $Iba1^+$ microglia (**Figure 5C**), $NeuN^+$ neurons (**Figure 5D**), or $Oligo2^+$ oligodendrocytes (**Figure 5E**). Approximately 60% of the platelets in the brain of APP-PS1 and WT mice were associated with astrocytes, whereas the other 40% did not associate with any other cell type analyzed ($59.91 \pm 5.76\%$ vs. $40.08 \pm 5.76\%$; $p = 0.0352$).

DISCUSSION

The current work reveals the presence of a significantly higher number of platelets in the brain parenchyma of APP-PS1 compared to WT mice. Platelets in the brain were more likely to be activated compared to the blood-circulating platelets, regardless of the genotype. In APP-PS1 mouse brains, the relative amount of activated platelets was significantly higher compared to WT. Platelets presumably invaded the brain and were found in tight association with astrocytes suggesting that these two cell types might interact, and that this interaction might contribute and shape AD pathology.

There is increasing evidence for blood-born elements influencing molecular, cellular, structural, and functional features of the brain in aging and in de- and regeneration in CNS diseases such as AD (Villeda et al., 2011, 2014; Middeldorp et al., 2016; Smith et al., 2018). In this context, blood components of emerging interest are platelets. For example, platelets are actively involved in the onset and development of cerebral amyloid angiopathy (CAA), a vascular pathology common among AD patients, which is characterized by platelet-derived Aβ depositions (Gowert et al., 2014; Jarre et al., 2014; Kniewallner et al., 2016, 2018). Interestingly, injections of platelets isolated from APP-Swedish Dutch Iowa mice, which is an AD transgenic mouse model with CAA pathology, into healthy age-matched control mice caused vessel damage, whereas WT platelet injection failed to do so (Kniewallner et al., 2018). Thus, we hypothesized that platelets in AD are intrinsically altered or dysfunctional, actively contributing to vascular damages (Kniewallner et al., 2018). To determine whether this kind of "aggressive or invasive" phenotype described for APP-Swedish Dutch Iowa mice is a general phenomenon in AD, we investigated platelets in a CAA-independent AD transgenic mouse model, the APP-PS1 (Jankowsky et al., 2001, 2004; Liu et al., 2004).

Here, we show that APP-PS1 mice contained a significantly higher number of platelets in the brain parenchyma compared to age-matched WT controls. Approximately 20% of the platelets present in the APP-PS1 brain invaded the intraparenchymal space, whereas in WT animals, only approximately 6% of the platelets were found within the brain parenchyma. Interestingly, brain intraparenchymal platelets appeared as single platelets as well as small aggregates, with APP-PS1 mice presenting a higher number of aggregated platelets compared to WT animals. Therefore, as the quantitative analysis of platelet

FIGURE 3 | Activation status of platelets located in the brain of APP-PS1 mice. Immunohistochemical analysis revealed that $CD41^+$ platelets (green) expressing the activation marker CD62P (white) circulate within cerebral blood vessels (red) in APP-PS1 mice **(A**, upper row**)**. Similarly, platelets in the process of fenestrating the vessel wall also expressed CD62P **(A**, lower row**)**. Quantitative analysis showed that APP-PS1 mice have a significantly higher percentage of $CD62P^+/CD41^+$ platelets in the brain compared to WT animals **(B)**. Moreover, in APP-PS1 mice, extravascular platelets exhibit a shift from single cells (<10 fL) to aggregates (>10 fL). Graph bars represent mean ± SEM (n = 6/group including WT: six females and APP-PS1: three females and three males). Statistical analysis was performed by unpaired Student's t test **(B)** or two-way ANOVA with Tukey's multiple comparison test **(C)**. *$p < 0.05$; **$p < 0.01$; and ****$p < 0.0001$. Scale: 5 μm **(A)** and 1 μm (**A**—zoom in).

density presented in **Figure 1** did not differentiate between single platelets or platelet aggregates due to methodological limitations, putative aggregates might have been counted as individual platelets leading ultimately to an underestimation of the overall platelet load of APP-PS1 brains. Whether platelets penetrate the brain parenchyma actively or passively is still an ongoing question. We previously demonstrated that penetration of APP-Swedish Dutch Iowa platelets into the brain parenchyma is accompanied by release of platelet-derived matrix metalloproteinases, which promotes blood vessel disruption (Kniewallner et al., 2018). A similar mechanism might mediate the invasion of individual platelets into the brain of animals with subarachnoid hemorrhage (Doczi et al., 1986; Friedrich et al., 2010). In this model, platelets enter the brain parenchyma via "platelet-sized holes" in the basement membrane, possibly originated by platelet-derived proteases such as metalloproteinases-2 and -9 (Friedrich et al., 2010). Alternatively, platelets in AD might invade the brain parenchyma through a disrupted blood–brain barrier (BBB), as at the age of analysis (14 months) APP-PS1 mice present a comprised BBB (Janota et al., 2015).

The Fate and Function of Platelets in the Brain?

Besides the penetration of platelets through the vessel wall, crucial questions are: What is the fate of platelets once they enter the brain parenchyma? What is their functional role in the brain? Are platelets able to home back to the circulation, for example, after discharging their contents? The latter has recently been shown in a mouse model of systemic shock, where platelets entered the brain parenchyma, released pathogenic levels of serotonin, and thereafter returned to the bloodstream (Cloutier et al., 2018). Alternatively, they might become simply eliminated from the brain parenchyma through phagocytosis by, for example, microglia, perivascular-macrophages, or astrocytes. Nevertheless, platelets, as long as they are within the CNS parenchyma, might communicate with certain cell types, modulate their functions, and shape certain pathogenic processes.

Various CNS lesions, e.g., neurotrauma, subarachnoid hemorrhage, demyelination, or experimental autoimmune encephalomyelitis show extravascular platelets in the brain, which are linked to the onset of either beneficial or detrimental responses in the brain (Pluta and Amek, 2008; Friedrich et al., 2010; Hayon et al., 2013; Sotnikov et al., 2013; Au et al., 2014; Kazanis et al., 2015; Rivera et al., 2016). One possible function of platelets in the brain seems to be the impact on neuroinflammation. This has been demonstrated in the context of experimental autoimmune encephalomyelitis (Sotnikov et al., 2013) and chronic hypertension (Bhat et al., 2017), where platelets promote neuroinflammation. In the context of AD, APP-Swedish Dutch Iowa platelets recruit and activate microglia to the penetrated vessels, leading to enhanced levels of tumor-necrosis-factor-alpha and supporting an inflammatory environment (Kniewallner et al., 2018). In the present work, we show that intra-parenchymal platelets are in tight and exclusive association with astrocytes, and this interaction might influence the astrocyte responses in the context of neuroinflammation or plaque load. Platelet–astrocyte interaction was previously reported in experimental autoimmune encephalomyelitis, an established model of neuroinflammation, demyelination, and neurodegeneration (Sotnikov et al., 2013), and in an experimental chronic hypertension rat model (Bhat et al., 2017), the latter being a well-known predisposing factor for vascular dementia and AD (Birkenhäger and Staessen, 2006). In both cases, platelet–astrocyte interactions were associated with enhanced neuroinflammation and neuronal injury (Sotnikov et al., 2013; Bhat et al., 2017). Whether platelet–astrocyte interaction is also promoting neuroinflammation and neurodegeneration in AD remains speculative, and it is a matter of further investigations. Of course, platelet–astrocyte interaction might occur as part of a

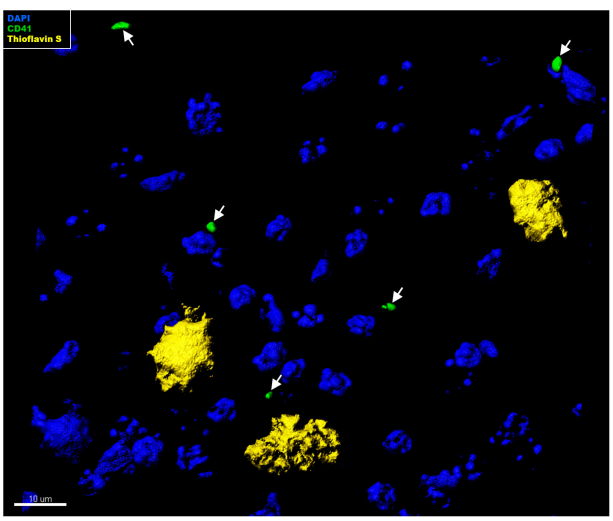

FIGURE 4 | Immunohistochemical analysis of platelet interaction with amyloid plaques in the brain of APP-PS1 mice. Brain sections from APP-PS1 mice (n = 1/gender) were co-stained for platelets (green) and Thioflavin S (yellow). DAPI (blue) was used as nucleus stain. Representative confocal images were 3D modeled for co-localization analysis. In APP-PS1 mice, $CD41^+$ platelets were not associated with Thioflavin S^+ amyloid plaques.

FIGURE 5 | Immunohistochemical analysis of platelet interaction with neurovascular niche cellular components in the brain of APP-PS1 mice. Brain sections from APP-PS1 mice (n = 3, including two females and one male) were co-stained for platelets (CD41), **(A–E**, green**)**, and one of the following cell types: astrocytes (GFAP) **(A**, white**)**; pericytes (PDGFRβ) **(B**, red**)**, microglia (Iba-1) **(C**, red**)**, neurons (NeuN) **(D**, red**)**, or oligodendrocytes (Oligo2) **(E**, red**)**. DAPI (blue) was used as nucleus stain. Representative confocal images were selected for 3D surface projection and co-localization analysis. In APP-PS1 mice, platelets were found in tight association with astrocytes **(A)**. Co-localization of CD41 and GFAP signals is depicted in magenta **(A**, zoom in**)**. No further interactions were observed between $CD41^+$ platelets and other immunolabeled cells **(B)**. Scale: 5 μm **(A,B)**, 2 μm **(B**—zoom in**)**.

clearance strategy, and platelets might simply be phagocytosed by astrocytes. However, the platelet–astrocyte association was not exclusively observed in APP-PS1 mice but also in age-matched WT animals (data not shown). Nevertheless, the load of platelets and the number of activated platelets was higher in the brain of APP-PS1 mice, and therefore, the impact on astrocytes might be different at the quantitative level.

Platelets might not only have detrimental functions in the brain but also beneficial ones. For example, it has recently been demonstrated that the exercise-induced stimulatory effects on adult hippocampal neurogenesis are partially mediated through platelets (Leiter et al., 2019). In the context of stroke and of demyelinating lesions, platelet-derived factors promote neurogenesis and neuroprotection (Hayon et al., 2013; Au et al., 2014; Kazanis et al., 2015). A long-term perspective might be to exploit the beneficial effects and to inhibit the detrimental effects of platelets in a therapeutic context. This could be achieved through pharmacological means, through cell therapies such as infusion of regeneration-promoting platelets, or through the use of platelet-derived factors.

Platelets Are Activated in the Brain of APP-PS1 Mice but Not in the Bloodstream

Increased platelet activation in the blood has been previously reported in AD patients and in animal models of AD (Sevush et al., 1998; Ciabattoni et al., 2007; Stellos et al., 2010; Jarre et al., 2014; Canobbio et al., 2015, 2016). In AD, the activation status of platelets correlates with the rate of cognitive decline (Stellos et al., 2010; Canobbio et al., 2015), indicating that platelet activation might be functionally related to AD pathogenesis. In the APP-PS1 mice, we observed only a slight but not significantly higher platelet activation status in the bloodstream. Nevertheless, at the ultrastructural level, APP-PS1 mouse platelets showed clear signs of activation in cell morphology, i.e., significantly smaller size, membrane protrusions, and microparticle release. As a hypothesis, in AD, platelets might be either primed or even activated in the by bloodstream and become fully activated once entering the brain parenchyma. Regardless, a more detailed understanding of platelet activation as well as their underlying molecular mechanisms, especially in the context of CNS pathologies, is required.

Alterations in the OCS of APP-PS1 Mouse Platelets

Abnormalities in the internal membrane system of platelets in AD have been previously described (Zubenko et al., 1987a,b, Hajimohammadreza et al., 1990; Piletz et al., 1991). In AD patients, 10–25% of platelets are atypical, exhibiting an extensive system of membrane-bounded "trabeculated cisternae" (Zubenko et al., 1987a,b; Hajimohammadreza et al., 1990). In our ultrastructural characterization, we observed that in APP-PS1 mouse platelets, vacuolar and tubular structures occupy a significantly wider area of the cytoplasm in comparison to WT controls. We considered these structures as being part of the platelet OCS, a system of interconnected and tortuous membrane-bound channels that spans through the platelet interior (Rumbaut and Thiagarajan, 2010; White, 2013; Selvadurai and Hamilton, 2018). Further analysis using specific dyes for the OCS, such as ruthenium red (Heijnen and Korporaal, 2017; Selvadurai and Hamilton, 2018), or morphological characterization of platelets using 3D electron microscopy are needed to determine whether the structures we observed are, indeed, part of the platelet OCS. Interestingly, abnormalities in platelet ultrastructure are common to other neurological disorders such as Parkinson's disease, where platelets display an enlarged OCS (Factor et al., 1994), amyotrophic lateral sclerosis (Shrivastava et al., 2011), or major depression (Mendoza-Sotelo et al., 2010). Therefore, it is important to understand whether alterations in the platelet ultrastructure might directly affect the CNS environment and, in particular, to discern whether and how the enlargement of platelet OCS can be related with the pathological processes occurring in AD.

Platelets in the Aging Brain

Even though most of the effects that we observed in the present study were more pronounced in APP-PS1 mice, they were also detected at a lower level in 14-month-old WT mice. Therefore, it will be crucial in future experiments to dissect the aging from the disease-specific effects. It is already well-known that platelet activity and function are altered with advanced age in humans as well as in mice (Zahavi et al., 1980; Kasjanovova and Balaz, 1986; Bastyr et al., 1990; Gleerup and Winther, 1995; Cowman et al., 2015; Jones, 2016). Nevertheless, since aging is the main risk factor for AD and various other neurodegenerative diseases, platelets might be a very promising target for the future development of therapeutic strategies to prevent brain aging and to prevent or treat age-related neurodegenerative diseases.

CONCLUSION

Platelets are an emerging topic in brain aging and neurodegenerative diseases. The functional role of platelets in the brain and the underlying molecular and cellular mechanisms

remain elusive, but platelets might have beneficial as well as detrimental functions in the brain. This requires further investigations, especially since platelets are a very promising and feasible target for cellular and pharmacological interventions, and targeting platelets might be a therapeutic approach to repair, regenerate, or even rejuvenate the aged and diseased brain.

Influence of Age-Related Complications on Clinical Outcome in Patients With Small Ruptured Cerebral Aneurysms

*Jianfeng Zheng, Xiaochuan Sun and Xiaodong Zhang**

Department of Neurosurgery, The First Affiliated Hospital of Chongqing Medical University, Chongqing, China

Background: Small ruptured cerebral aneurysms (≤5 mm) account for the majority of aneurysmal subarachnoid hemorrhages, and its clinical management remains a challenge. The aim of this study was to identify the effect of age-related complications on the outcome of patients with small ruptured aneurysm.

Methods: A retrospective review was performed in patients with small ruptured aneurysms who underwent microsurgical clipping or endovascular coiling from September 2012 to December 2018. According to their ages, the patients were divided into the elderly group and the non-elderly group. Baseline characteristics, clinical complications, and outcome of patients were analyzed between the two groups. A multivariate logistic regression analysis was used to determine the risk factors associated with the poor outcome of the elderly patients.

Results: In the elderly group, 83 patients were treated with clipping and 50 were treated with coiling. In the non-elderly group, 188 patients were treated with clipping and 117 were treated with coiling. The incidence of neurological complications with neurologic deficit in the elderly group was significantly higher compared with that in the non-elderly group ($P = 0.006$). The elderly patients had a longer hospital stay ($P = 0.032$) and a poorer outcome ($P = 0.001$) compared with the non-elderly patients. A multivariate analysis showed that irregular aneurysms ($P = 0.045$) and ischemic events ($P < 0.001$) were independent risk factors associated with poor outcome in the elderly.

Conclusions: Neurological complications with neurologic deficit, especially ischemic complications, were clearly more common in the elderly patients. Irregular small aneurysms or postoperative ischemic events should be paid attention as the higher risk of poor outcome in the elderly.

INTRODUCTION

A growing number of patients with aneurysmal subarachnoid hemorrhage (aSAH) caused by small ruptured cerebral aneurysms have been treated with microsurgical clipping or endovascular coiling (1–3). Compared with the younger patients, the elderly patients may have more underlying comorbidities, poorer physical condition, and higher operation risk (4–6). It is generally agreed

that the outcome of the patients is largely determined by the severity of the initial aSAH and subsequent complications associated with neurologic deficit (7, 8). Old age is reported to be one of the significant risk factors that affect the severity of aSAH (7, 9, 10), and the elderly patients with poor cerebrovascular reserve function are more likely to suffer from severe neurological dysfunction after aSAH. Few previous studies have focused on comparing the clinical outcome of patients with small ruptured aneurysms according to age, and most of these previous studies have focused on the treatment outcome of coiling or clipping for patients with small ruptured aneurysms (3, 11–14). It is unclear whether age itself increases the risk of complications in patients during small cerebral aneurysm treatment. Therefore, this study was a desire to investigate the incidence of complications in elderly patients treated for small ruptured aneurysms and to determine whether age-related complications affected the treatment outcome.

TABLE 1 | Baseline characteristics of patients with small ruptured aneurysms.

	Overall	Non-elderly ($n = 305$)	Elderly ($n = 133$)	*P*-value
Age (year)	53.4 ± 9.8	48.2 ± 6.5	65.3 ± 4.1	<0.001
Sex (female)	310 (70.8%)	210 (68.9%)	100 (75.2%)	0.209
Tobacco smoking	94 (21.5%)	69 (22.6%)	25 (18.8%)	0.448
Alcohol consumption	76 (17.4%)	58 (19.0%)	18 (13.5%)	0.173

Modified Fisher Grade 3 or 4	180 (41.1%)	120 (39.3%)	60 (45.1%)	0.291

Results with P < 0.05 were considered to indicate statistical significance.

METHODS

We retrospectively analyzed the clinical record of 438 patients with small ruptured cerebral aneurysms who were treated with microsurgical clipping or endovascular coiling from September 2012 to December 2018. All of the patients were divided into two groups according to age: the elderly group (those 60 years of age or older) and the non-elderly group (those younger than 60 years). The data of each patient were collected in detail including age, sex, smoking history, drinking history, hypertension, diabetes, cardiopulmonary disease, clinical grade, location, number and shape of aneurysm, treatment modality, clinical complications, and outcomes.

Three-dimensional (3D) rotational angiography was used to examine small aneurysms in all of the patients, and the maximum diameter of the aneurysms as measured by 3D angiography was ≤5 mm. With the use of 3D rotational angiography, the shape and the location of the aneurysms were determined by an experienced neuroradiologist. For patients with multiple small aneurysms, the most likely source of bleeding can be judged by the subarachnoid hemorrhage (SAH) distribution on a CT scan.

Informed consent for the operation was signed after full consideration by the patient or his or her family. The modality of treatment for small aneurysms was determined by the cerebrovascular group composed of experienced neurointerventionists and neurosurgeons. The neurological complications were assessed by two professional neurosurgeons; hemorrhagic event, ischemia event, hydrocephalus, and seizure were recorded. Bleeding events include intraoperative bleeding and postoperative hematoma. Ischemic events include intraoperative thrombosis and postoperative delayed cerebral ischemia. Delayed cerebral ischemia was defined as new or worsening neurological deficits after the exclusion of other possible causes. Hydrocephalus was defined as neurological deterioration accompanied by an enlargement of the temporal horns of more than 2 mm. Cardiopulmonary complications were evaluated by the relevant department physicians, such as arrhythmia, pulmonary infection, and pulmonary embolism. Before discharge, CT angiography or magnetic resonance angiography was performed to evaluate the degree of small aneurysm occlusion and the patency of the parent artery. Each patient's follow-up information was supplemented by imaging reviews and telephone interviews. Based on the Glasgow Outcome Scale (GOS) at the last follow-up, the outcome of each patient was rated and then classified into good outcome (GOS scores of 4 or 5) or poor outcome (GOS scores of 1–3).

Statistical Analysis

All data in this study were analyzed using SPSS V.22 software (IBM Corp., Armonk, New York, USA). Data related to categorical variables are presented as percentages, and Fisher exact test or Pearson χ^2 test was used to compare female, smoking, drinking, hypertension, diabetes, cardiopulmonary diseases, clinical grade, location of aneurysms, irregular and multiple aneurysms, complications, and outcome. Data related to continuous variables are presented as mean ± SD, and Student *t*-test or Mann–Whitney *U*-test was used to compare age and hospital days. All clinical variables with $P < 0.1$ were entered into the multivariate analysis models, and odds ratios (ORs) with 95% confidence intervals (CIs) were calculated.

RESULTS

A total of 133 (30.4%) patients were in the elderly group and 305 (69.6%) were in the non-elderly group, with an average age of 53 years (range, 23–77 years). In the elderly group, the prevalence of hypertension (60.9 vs. 42.3%; $P < 0.001$), diabetes (11.3 vs. 3.9%; $P < 0.001$), and cardiopulmonary disease (12.0 vs. 2.6%; $P < 0.001$) were significantly increased. More Hunt–Hess grade 4 or 5 cases were observed in the elderly group (21.8 vs. 9.8%; $P = 0.001$), but there was no significant difference in the modified Fisher grade 3 or 4. The other baseline characteristics of the two groups are shown in **Table 1**.

TABLE 2 | Location and characteristics of the small ruptured aneurysms.

	Overall	Non-elderly ($n = 305$)	Elderly ($n = 133$)	*P*-value
Aneurysm location				
AcomA	158 (36.1%)	120 (39.3%)	38 (28.6%)	0.031
PcomA	145 (33.1%)	87 (28.5%)	58 (43.6%)	0.003
MCA	55 (12.6%)	35 (11.5%)	20 (15.0%)	0.347
ACA	17 (3.9%)	15 (4.9%)	2 (1.5%)	0.109
ICA	52 (11.9%)	39 (12.8%)	13 (9.8%)	0.424
PC	11 (2.5%)	9 (3.0%)	2 (1.5%)	0.516
Aneurysm characteristics				
Irregular	67 (15.3%)	46 (15.1%)	21 (15.8%)	0.885
Multiple	65 (14.8%)	35 (11.5%)	30 (22.6%)	0.005

AcomA, anterior communicating artery; PcomA, posterior communicating artery; MCA, middle cerebral artery; ACA, anterior cerebral artery; ICA, internal carotid artery; PC, posterior circulation. Results with P < 0.05 were considered to indicate statistical significance.

There were 158 small ruptured aneurysms located in the anterior communicating artery (AcomA), 145 in the posterior communicating artery (PcomA), 55 in the middle cerebral artery (MCA), 17 in the anterior cerebral artery (ACA), 52 in the internal carotid artery (ICA), and 11 in the posterior circulation (PC). The non-elderly patients have more ruptured small aneurysms in the location of the AcomA (39.3 vs. 28.6%; $P = 0.031$), while the elderly patients have more ruptured small aneurysms in the location of the PcomA (43.6 vs. 28.5%; $P = 0.003$). It was observed that the elderly patients had significantly more multiple aneurysms than the non-elderly patients (22.6 vs. 11.5%; $P = 0.005$). The irregularly shaped aneurysms were similar between the two groups (**Table 2**).

Clinical Complications and Outcome

There was no significant difference in treatment modality and intraoperative strategy between the elderly group and the non-elderly group (**Table 3**). Common neurological complications included hemorrhage events in 13 cases (3.0%), ischemic events in 98 cases (22.4%), hydrocephalus in 69 cases (15.8%), and seizure in 15 cases (3.4%). Hemorrhage events included intraoperative rebleeding in six patients (1.4%) and postoperative rebleeding in seven patients (1.6%). The ischemic events included intraoperative thrombosis in three patients (0.7%) and postoperative delayed cerebral ischemia in 95 (21.7%) patients. Temporary clipping was performed in 80 cases (31.1%) and was not associated with hemorrhage events ($P = 0.238$) or ischemic events ($P = 0.963$). Stent-assisted coiling was performed in 113 (25.8%) patients and balloon-assisted coiling was performed in four patients (1.0%). Neither stent-assisted nor balloon-assisted strategy was associated with hemorrhage events ($P = 0.389$ and $P = 1.000$, respectively) or ischemic events ($P = 0.106$ and $P = 0.999$, respectively). Common cardiopulmonary complications included arrhythmia in 30 cases (6.8%), pulmonary infection in 147 cases (33.6%), and pulmonary embolism in five cases (1.1%).

Compared with the non-elderly group, the incidence of ischemic events (28.6 vs. 19.7%; $P = 0.046$), cardiopulmonary complications (44.4 vs. 33.1%; $P = 0.031$), and pulmonary infections (42.9 vs. 29.5%; $P = 0.008$) was significantly higher in the elderly group. The total neurological complications (31.6 vs. 23.3%; $P = 0.075$) and the neurological complications without neurological deficits (15.0 vs. 15.7%; $P = 0.887$) did not vary significantly with the increase of patient age (**Figure 1**). However, compared with the non-elderly patients, the more elderly patients suffered from neurological complications with neurologic deficit (16.5 vs. 7.5%; $P = 0.006$). As a result of complications, the length of stay in the elderly group was significantly longer than that in the non-elderly group (23.2 ± 14.1 vs. 20.3 ± 9.0; $P = 0.032$) (**Table 3**).

After 3–60 months of follow-up (17 months on average), 88.1% of the patients had a good outcome (GOS 4 or 5). Compared with the non-elderly group, poor outcome occurred at a significantly greater rate in the elderly group (20.3 vs. 8.2%; $P = 0.001$). Whether treated by microsurgical clipping or endovascular coiling, the outcome of the patients with small ruptured aneurysms was worse with the increase of age (**Figure 2**). Only the elderly patients were considered, and the risk factors of poor outcome were analyzed. A univariate analysis showed that hypertension ($P = 0.022$), Hunt–Hess grade 4 or 5 ($P < 0.001$), modified Fisher grade 3 or 4 ($P = 0.001$),

TABLE 3 | Complications and outcomes of patients with small ruptured aneurysms.

	Overall	Non-elderly ($n = 305$)	Elderly ($n = 133$)	*P*-value
Clipping	271 (61.9%)	188 (61.6%)	83 (62.4%)	0.915
Coiling	167 (38.1%)	117 (38.4%)	50 (37.6%)

Good outcome (GOS 4 or 5)	386 (88.1%)	280 (91.8%)	106 (79.7%)	0.001
Poor outcome (GOS 1 or 3)[a]	52 (11.9%)	25 (8.2%)	27 (20.3%)	

GOS, Glasgow Outcome Scale. Results with P < 0.05 were considered to indicate statistical significance. [a]After adjustment for smoking, hypertension, cardiopulmonary disease, Hunt–Hess grade, modified Fisher grade, multiple aneurysms, irregular aneurysms, and treatment modality, a multivariate analysis showed that the elderly was independently associated with poor outcome [OR, 2.025 (1.015–4.040); P = 0.045].

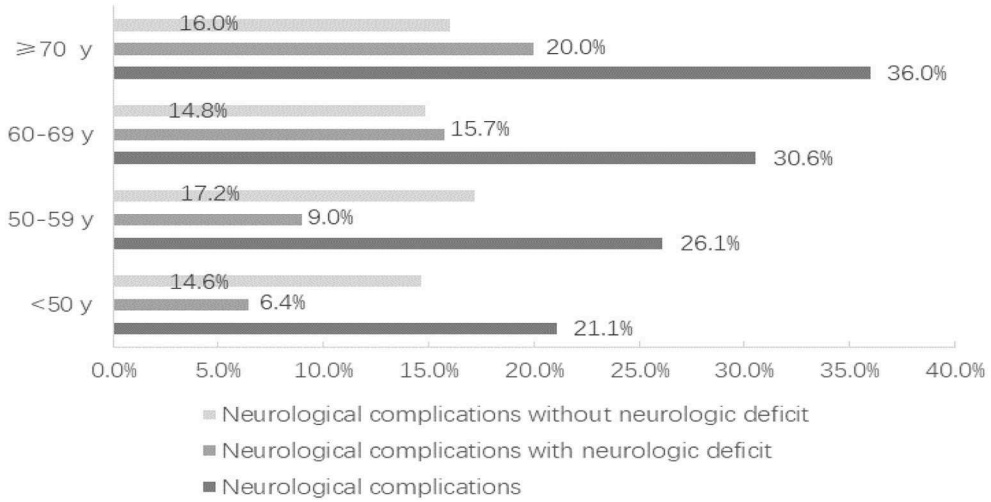

FIGURE 1 | The distribution of neurological complications according to the age of the patients, divided into those with neurologic deficit and those without neurologic deficit.

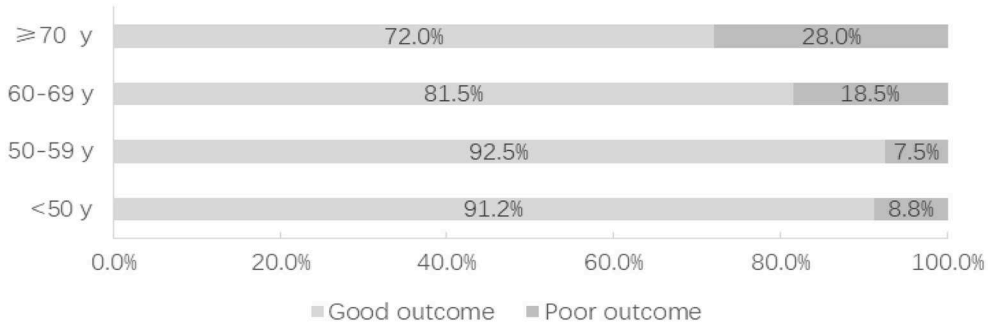

FIGURE 2 | The distribution of functional outcome according to the age of the patients, divided into those with good outcome and poor outcome.

irregular aneurysms ($P < 0.001$), multiple aneurysms ($P = 0.019$), ischemic events ($P < 0.001$), seizure ($P = 0.047$), and cardiopulmonary complications ($P = 0.033$) were significantly associated with the poor outcome of the elderly patients with small ruptured aneurysm. A multivariate analysis showed that irregular aneurysms [OR, 4.465 (1.032–19.310); $P = 0.045$] and ischemic events [OR, 13.532 (4.128–44.364); $P < 0.001$] were independent predictive factors of poor outcome in the elderly patients (**Table 4**).

DISCUSSION

We presented a large number of patients with small ruptured cerebral aneurysms to compare the effect of age-related complications on the functional outcome. The incidence of neurological complications associated with neurological deficit, especially ischemic events, was obviously higher in the elderly patients than in the non-elderly patients. As a result of age-related complications, the outcome of the elderly patients is significantly worse compared with that of the non-elderly patients.

With the advances in medical imaging facilities and techniques, a growing number of small cerebral aneurysms in the world have been detected and treated (1–3, 7, 11, 14). A retrospective study of 223 small unruptured aneurysms by Oishi et al. (11) reported that endovascular treatment is effective with low morbidity and mortality. Feng et al. (14) thought that the coil embolization of small unruptured aneurysms can be performed safely and achieve a low rate of recurrence. Chalouhi et al. (15) reported that patients with small ruptured aneurysms were treated with a pipeline embolization device, and these patients had a good outcome. Although endovascular coiling was technically feasible, smaller aneurysms were reported to be significantly associated with a higher risk of procedural aneurysm rupture (16). Mitchell et al. (17) believed that a small aneurysm size is a significant risk factor for intraoperative rupture in ruptured aneurysms rather than in unruptured aneurysms. In our study of 438 small ruptured cerebral aneurysms, six patients suffer from intraoperative rebleeding. The incidence of intraoperative aneurysm rupture was similar between the elderly and the non-elderly patients, and these did not lead to serious neurological dysfunctions.

TABLE 4 | Risk factors of poor outcome in elderly patients with small ruptured aneurysms.

	Univariate analysis		Multivariable analysis	
	P-value	OR (95% CI)	*P*-value	OR (95% CI)
Hypertension	0.022	3.373 (1.187–9.584)	0.404	–
Hunt–Hess Grade 4 or 5	<0.001	8.214 (3.194–21.126)	0.248	–
Modified Fisher Grade 3 or 4	0.001	4.714 (1.830–12.142)	0.487	–
Irregular aneurysms	<0.001	6.600 (2.412–18.062)	0.045	4.465 (1.032–19.310)
Multiple aneurysms	0.019	2.956 (1.191–7.336)	0.535	–
Ischemic event	<0.001	18.324 (6.443–52.108)	<0.001	13.532 (4.128–44.364)
Seizure	0.047	6.500 (1.029–41.068)	0.848	–
Cardiopulmonary complications	0.033	2.590 (1.082–6.200)	0.637	

Variables with P < 0.1 according to univariate analysis were entered into the multivariate analysis model. OR, odds ratio; CI, confidence interval. Results with P < 0.05 were considered to indicate statistical significance.

However, due to the smaller size and the weaker wall of the aneurysm, and the more difficult operation, the risk of postoperative ischemic complications was significantly increased. Delayed cerebral ischemia is reported to occur in about 30% of patients with aSAH and leads to higher morbidity and mortality (18, 19). Our study on small ruptured aneurysm showed that the incidence of delayed cerebral ischemia was 21.7%, which was obviously higher in the elderly patients than that in the non-elderly patients. Wachter et al. (20) believes that the elderly patients seem to be more vulnerable to aSAH, plus the complications are more problematic. The severe aSAH after rupture together with the subsequent operation on the surrounding anatomical structures such as parent arteries, perforators, brain parenchyma, and veins will cause cerebral vasospasm, which can be further aggravated by the decline of the cerebrovascular regulatory function in the elderly. In our study, although there was no significant difference in the high modified Fisher grade, the high Hunt-Hess grade in the elderly patients was more significant than in the non-elderly patients. This may mean that the elderly patients with poor cerebrovascular reserve capacity are more likely to suffer from severe brain damage after aSAH, even if the aneurysm size is small. The elderly patients have more comorbidities such as hypertension, diabetes, and cardiopulmonary disease, which makes the treatment risk of this special elderly population higher. Differently from our results, another aSAH study (20) reported a lower incidence of delayed cerebral ischemia in the elderly patients than in the non-elderly patients due to arteriosclerosis. The outcome of the study by Lai et al. (21) is consistent with our results that older women are at obviously greater risk of cerebral vasospasm, cerebral infarction, and clinical deterioration. Since the majority (75.2%) of the elderly patients in our study are female, female hormones could play a very important role in the development of ischemic complications in aSAH patients (21).

The total mortality rate of our patients with small ruptured aneurysms was 3.2%, higher than 0.91% of patients with small unruptured aneurysms as reported by Feng et al. (14). It should be noted that a more aggressive treatment performed before the rupture status of small cerebral aneurysms may reduce the mortality, but older age also needs to be considered, which is a very important factor affecting the incidence of complications associated with functional outcome. A study of in-patient samples (22) showed that the mortality rate of patients over 65 years old was obviously higher than that of patients younger than 65 years. Several other studies (23–25) have suggested that the outcome was worse with the increase of age in patients treated with clipping or coiling, but no emphasis has been placed on the influence of age-related complications on functional outcome. Similarly, in our study, the poor outcome occurred at an obviously greater rate in the patients aged 60 years and over compared with the patients under 60 years old, while the outcome of patients over 70 years old was the worst. The neurological complications have a greater impact on the neurological function of the elderly patients.

In the past 10 years of cerebral aneurysm research, the proportion of small ruptured aneurysms has increased to nearly 50% (26–28). Kim et al. believed that a sidewall aneurysm found with multiple aneurysms or an AcomA aneurysm found from a patient with hypertension may be prone to rupture at smaller sizes. In a prospective study in Japan (29), patient age and PcomA were reported to be significant risk factors for rupture in the elderly patients. Similarly, our results show that small ruptured cerebral aneurysms at the location of the PcomA are more common and the proportion of multiple aneurysms is higher in the elderly patients compared with those in the non-elderly patients. A recent survey (30) indicated that 42–76% of surgeons suggested treating the small anterior circulation aneurysms with a SAH history and most of the surgeons stop treating the unruptured aneurysms in patients who are 70–80 years old. Therefore, in order to avoid over-intervention as well as in consideration of the higher aneurysm rupture risk and the age-related complication risk, more preventive treatment is suitable for the younger patients with small unruptured communicating segment (PcomA/AcomA) aneurysms or with multiple aneurysms.

LIMITATIONS

There are several limitations in the current study. The interpretation of these final conclusions needs to take into account our single-center retrospective design. Firstly, since there is no prospective randomized intervention for the small ruptured aneurysms, potential selection bias may affect the efficacy of the treatment. However, the aim of our study was to ascertain the relationship between age-related complications and clinical outcomes rather than simply comparing the outcomes of the different treatment modalities. Secondly, due to the underdevelopment of the economy and the medical level in Western China, fewer patients over the age of 70 received operation and none over the age of 80 received intervention. Thirdly, we define the elderly as patients aged 60 and over, while

other studies have used a different age cutoff, so the overall morbidity and mortality may be different from other research data.

CONCLUSIONS

This study provides some useful data for the clinical management of elderly patients with small ruptured aneurysm. Based on our findings, we conclude that neurological complications associated with neurologic deficit were clearly more common in the elderly patients than in the non-elderly patients. The preoperative irregular small aneurysms or the postoperative ischemic events should be paid attention as the higher risk of poor outcome in elderly patients.

Mild traumatic brain injury (mTBI), or concussion, is reported to interfere with cerebral blood flow and microcirculation in patients, but our current understanding is quite limited and the results are often controversial. Here we used longitudinal *in vivo* two-photon imaging to investigate dynamic changes in cerebral vessels and velocities of red blood cells (RBC) following mTBI. Closed-head mTBI induced using a controlled cortical impact device resulted in a significant reduction of dwell time in a Rotarod test but no significant change in water maze test. Cerebral blood vessels were repeatedly imaged through a thinned skull window at baseline, 0.5, 1, 6 h, and 1 day following mTBI. In both arterioles and capillaries, their diameters and RBC velocities were significantly decreased at 0.5, 1, and 6 h after injury, and recovered in 1 day post-mTBI. In contrast, decreases in the diameter and RBC velocity of venules occurred only in 0.5–1 h after mTBI. We also observed formation and clearance of transient microthrombi in capillaries within 1 h post-mTBI. We concluded that *in vivo* two-photon imaging is useful for studying earlier alteration of vascular dynamics after mTBI and that mTBI induced reduction of cerebral blood flow, vasospasm, and formation of microthrombi in the acute stage following injury. These changes may contribute to early brain functional deficits of mTBI.

Keywords: cerebral cortex, vasculature, blood circulation, mild traumatic brain injury, two-photon imaging

INTRODUCTION

Traumatic brain injury (TBI) is increasingly being recognized as a significant problem of public health. Mild traumatic brain injury (mTBI), or concussion, which accounts for 70–90% of the TBI patient population, often occurs in falls, motor vehicle accidents and sports-related injury (Cassidy et al., 2004; McCrory et al., 2005; Chiu et al., 2007). Although mTBI is known to cause chronic post-concussive syndrome with symptoms such as memory and thinking impairments, headache, anxiety, and sleep disorders that significantly affect the quality of life and long-term outcomes, the injury rarely causes specific neurological deficits or brain structural damages that are detectable in clinical imaging (Levin et al., 1987; Bramlett and Dietrich, 2004; McCrory et al., 2009). This lack

of evidence of brain structural and functional damage represents a major challenge in understanding the mechanism of this disease and finding effective therapeutics (Margulies, 2000; Boake et al., 2005).

The cerebral vasculature consists of a complicated network of arteries, veins and capillaries, and plays an essential role in sustaining energy supply and metabolism of the cortex by delivering glucose and oxygen (Sunwoo et al., 2011; Shih et al., 2012a). Abnormal cerebral circulation is known to occur not only in patients with moderate to severe TBI but also in patients of mTBI during the acute and chronic stages (Bonne et al., 2003; Werner and Engelhard, 2007; Len and Neary, 2011). A strong correlation exists between microvascular dysfunction and TBI outcome, supporting that damage to the microvasculature may be a key contributor to secondary complications, including ischemia and increased intracranial pressure (Golding et al., 1999). Studies in animal models of mTBI found that pathophysiological alterations of cerebral vasculature include increase or decrease in cerebral blood flow, disruption of blood brain barrier, endothelial damage, and loss or altered vascular reactivity to various vasodilators (DeWitt et al., 1986; Wei et al., 2009; Zweckberger et al., 2010; Buckley et al., 2015). However, little information is available about acute dynamic changes in brain vessels and circulation after mTBI, particularly at the microscopic level. Given the critical importance of cerebral perfusion and oxygenation to normal brain function and its role in subsequent secondary injury and recovery, understanding cerebral microcirculation at the acute stage will be fundamental for understanding the mechanism of mTBI and its short- and long-term outcomes.

The recent two-photon imaging technique provides a powerful tool for studying longitudinal changes in cerebral vasculature and blood flow after brain ischemia and brain injuries (Schaffer et al., 2006; Drew et al., 2010a). To better mimic clinical situation of concussion in which most patients have no skull fracture or brain penetration and no positive findings in their neuroimaging examination (Alexander, 1995; McCrory et al., 2009), we used a closed-head mTBI preparation for *in vivo* two-photon longitudinal imaging of the cerebral vasculature and for revealing potential pathological changes in cerebral blood flow. Our results showed that mTBI resulted in decreases in the diameters of cerebral blood vessels as well as the velocities of red blood cells (RBCs), which is attributable to reduced cerebral blood flow and microthrombosis in capillaries.

MATERIALS AND METHODS

Animals

Male C57BL/6J mice or the same background Thy1-YFP transgenic mice were used in this study. For imaging, mice at the ages between 8 and 10 weeks old were divided into a sham group (11 mice) and an mTBI group (15 mice). The animals were kept on a 12 h light/dark cycle with sufficient food and water. The experiment was performed according to a protocol approved by the Institutional Animal Care and Use Committee (IACUC) of the Indiana University School of Medicine.

Thinned-Skull Window Preparation

Reinforced thinned-skull imaging windows were prepared based on a technique described previously (Drew et al., 2010b; Shih et al., 2012b). The mice were anesthetized with an intraperitoneal (i.p.) injection of ketamine/xylazine (87.7/12.3 mg/kg), and the scalp skin was removed to expose the skull. A 2 × 2 mm skull thinning area was prepared on the left parietal cortex, with the rostral edge being 2 mm posterior to the bregma and medial edge being 2–3 mm lateral from the middle line (**Figure 1A**). At the beginning of the surgery, a microdrill was used to thin a 1–2 mm diameter circular skull region to about a half of the thickness, then a 10# surgical blade was used to slowly and carefully thin the skull until surface blood vessels on the cerebral cortex were clearly visible under a light microscope. During this process, 0.9% physiological saline was added to the skull surface from time to time to reduce heat. After the thinned skull became dry, a small drop of thin cyanoacrylate glue (Ted Pella, Inc., Cat# 1003) was applied and a small piece of coverglass (1–1.5 × 1–1.5 mm size) was placed onto the thinned skull. The remaining area of the skull was covered with a layer of cyanoacrylate glue. The mice were allowed to recover for least 2 days before starting imaging sessions.

Preparation of Closed-Head mTBI

Following initial imaging of cerebral vasculature to record baseline conditions, a mouse model of closed-head mTBI was created on the left hemisphere by using a controlled cortical impact device, modified from a previously described technique (Creed et al., 2011). After the mice were anesthetized with ketamine/xylazine (87.7/12.3 mg/kg, i.p.) injection, their heads were stabilized on a stereotaxic apparatus by using a pair of ear rods with the tips enclosed in a piece of sponge. To avoid rigidly holding the head, the incisor hook of the stereotaxic device was not used. The skull orientation was adjusted to make sure it was in a horizontal position and perpendicular to the impactor tip. A 3 mm diameter impactor tip was used to strike the head at 5.0 m/s to a depth of 1.0 mm with a dwell time of 10 ms (Creed et al., 2011). The posterior edge of the impactor tip was targeted to an area ∼1 mm rostral to the anterior edge of the imaging window (**Figure 1A**). The mice of the sham injury group were subjected to the same procedures without receiving an impact. All animals were allowed to recover on a heating pad and were returned to their home cages after recovering from anesthesia. Of 13 and 20 mice of the sham and mTBI groups, 2 and 5 mice were used for *in vivo* imaging, respectively due to poor quality of cranial windows.

Behavioral Testing

To determine the effect of mTBI on cognitive and motor functions in this model, another set of mice were randomly assigned to a sham group ($n = 12$) and a mild TBI group ($n = 10$).

Rotarod Test

Motor coordination was assessed with a Rotarod apparatus (IITC Life Science Inc., CA, United States). Mice were placed on a spinning cylindrical rod accelerating from 0 to 30 rpm and the time to fall off was recorded. The maximum latency if a mouse

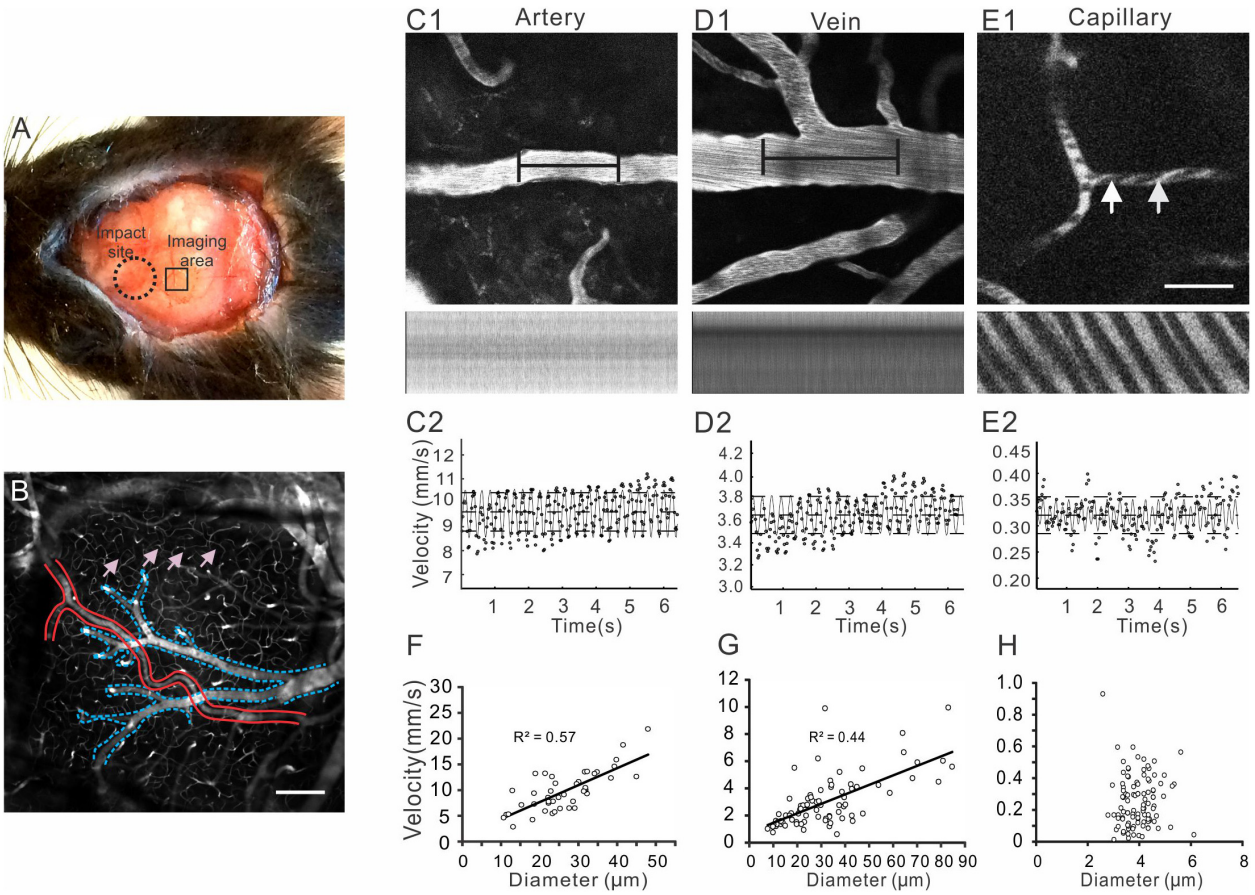

FIGURE 1 | *In vivo* two-photon microscopy for imaging cerebral vasculature and measuring blood flow through a thinned-skull window. **(A)** The skull above left parietal cortex of a mouse was thinned and strengthened by gluing a piece of square coverglass (~ 1.5 × 1.5 mm) for *in vivo* imaging (small square). Closed-head mTBI was induced by using a controlled cortical impact (CCI) device with a 3 mm diameter tip to strike on an area that was about 1 mm rostral to the anterior edge of the imaging window (large dotted circle). **(B)** A representative image of Z series projection of cerebral vessels reveals arteries (delineated in red), veins (delineated in blue), and networks of capillaries (pink arrows). **(C–E)** A segment of arteriole **(C1)**, venule **(D1)**, or capillary **(E1)** was oriented in a horizontal direction (top row) and imaged in line scan mode at 1 ms/line, which generated dark stripes (second row). The measurements were obtained from a single vessel. Velocity of red blood cells (RBC) in each vessel was calculated based on the line scan using a Matlab script **(C2–E2)**; the resulting velocities at different moments (small dots in **C2–E2**) were fitted to a second-order Fourier series (oscillating solid lines); the dashed horizontal lines represented time-averaged velocities. **(F–H)** Analyses of the relationships between RBC velocities and vessel diameters revealed positive correlations in arterioles and venules **(F,G)**, but not in capillaries **(H)**. Scale bars in B and E1 for C1-E1: 50 μm.

did not fall was 120 s. Before injury, each mouse received three training trials per day with inter-trial intervals of 20–30 min, and the latency to fall on the third day was recorded as baseline (day 0). Then the mice were split randomly into the sham and the mild TBI groups, and were tested on days 2, 4, 6, 8, and 10 after sham or mild TBI surgery. The mean latencies to fall off the Rotarod at each time point were used for result analysis.

Morris Water Maze

The water maze was performed in a circular tank (110 cm in diameter) filled with 22°C water, which was made opaque by adding non-toxic white paint. A hidden platform (10 cm in diameter) was placed in the southwestern quadrant 1 cm below the water surface. External cues for spatial reference were attached on the inner walls of the tank. Mice were released into the tank from a random starting point and trained to find the hidden platform for four trials per day. The maximum time for each trial was 60 s. Mice that didn't find the platform within 60 s were manually guided to it and allowed to sit on the platform for 30 s. Escape latency, and swimming distance and velocity were recorded by automated tracking software TopScan (CleverSys). Animals were trained on days 1, 3, 5, 7, and 9 after sham or mild TBI surgery, and the average latency to reach the platform on each training day was computed by averaging the four trials.

In vivo Two-Photon Imaging and Measurements of Red Blood Cell (RBC) Velocity and Blood Vessel Diameters

The mice were anesthetized with ketamine/xylazine (87.7/12.3 mg/kg, i.p.) injection, and received an i.p. injection of 0.1 ml Rhodamine B sothiocyanate-dextran solution (70 KDa,

3 mg/ml in distilled water) at least 15 min before imaging to label blood plasma. The mice were placed on a miniature stereotaxic apparatus and the head position was adjusted so that the cortical surface was horizontal to the microscope objective. The mice were placed on a heating pad to maintain their body temperature, and the arterial blood pressure and heart rate were monitored via the tails using a non-invasive Volume Pressure Recording (VPR) system (CODA Surgical Monitor, Kent Scientific Corporation, CT). To obtain consistent measurements of blood pressure, the animals were placed in position for 5 min prior to obtaining pressure measurements and the tail cuff was positioned to the base of the tail. At each time, at least three measurements were made for each mouse for calculating mean values of diastolic and systolic pressures.

Imaging was made with a two-photon microscope (Ultima Multiphoton Imaging System, Bruker, United States) (Xiong et al., 2017). Excitation was provided by a Maitai diode laser source pumping a Tsunami Ti: sapphire laser (Spectra-Physics, Mountain View, CA, United States) tuned to 870 nm wavelength. Band-pass-filtered fluorescence (560–660 nm) was collected by photo-multiplier tubes of the Prairie View Ultima system. Images (512 × 512 pixels, 0.15 μm/pixel in the *x*- and *y*-axes) or line scans were acquired using Prairie View software (**Figures 1C–E**). The mice were imaged at baseline, and at 0.5, 1, 6 h, and 1 day after mTBI. A Z-series of blood vessel images within 100–200 μm of the pial surface were first captured under a 10X objective. Then an Olympus SUPER 20X water immersion objective was used to image individual blood vessels and take line scan images along the central axis of a vessel at 3X optical zoom. The orientation of a segment of blood vessel (∼35 μm) was adjusted so that it paralleled the direction of the line scan. Typically, each session of line scan consisted of 5000 lines with a spatial resolution of 0.7 μm per pixel and at a speed of about 1 ms per line. The line scan parameters were automatically recorded in the Prairie View software.

For longitudinal imaging, the same imaging fields and segments of line-scanned vessels at different time points after initial baseline imaging were identified based on the location and patterns of vessels. The depth and orientation of the vessels were carefully adjusted so that the same vessels were imaged with the same imaging parameters including pixel size and scanning speed. Each experimental session took 20–30 min. From baseline to 0.5 and 1 h imaging, anesthesia and labeling of blood plasma were carried out only once. For 6 h and 1 day imaging sessions, anesthesia and labeling of blood plasma were done separately. The animals were allowed to recover after each imaging on a heating pad and then returned to their home cages after being awake. Images of microthrombosis were captured in two mice after mTBI. Because the microthrombosis was transient and sporadic, the RBC velocities and diameters of the involved capillaries were not measured.

Imaging analyses were made with Metlab and NIH ImageJ software. Maximal intensity projections of image stacks were made for identifying and confirming imaged vasculature in regions of interest. RBC velocities were calculated from line-scan images using a Metlab script written according to previous work of line-scanning particle image velocimetry developed by Kim et al. (2012). Briefly, this technique determines RBC displacements between pairs of line-scans using spatial cross-correlation analysis. The shift from the origin to the peak center of the cross-correlation was a measure of the distance traveled by RBCs between image frames. After the peak was fitted with a Gaussian distribution to improve calculation accuracy, the shift in pixels was converted to microns and velocity was calculated. The resulting velocities at different moments were fitted to a second-order Fourier series (**Figures 2C2–E2**), time-averaged velocities were obtained (**Figures 2C2–E2**). The diameters of line-scanned blood vessels were determined in ImageJ by manually measuring the maximal widths at the middle of the scanned vessel segment that was filled with fluorescence dye. For each vessel at each time point, three measurements were made and averaged. For measuring vessel diameters at different time points, efforts were taken to make diameter measurements at the same spots as close as possible.

Statistics

The data were averaged among animals in each group and all data are presented as mean ± standard error of the mean (SE). Because of the large variability of the imaged vessels in size and its corresponding blood flow, vessel diameters and RBI velocities are expressed as percent change from baseline. For comparisons of diameters and velocities at different time points between the sham and mTBI groups, data were analyzed with a two-way repeated measures ANOVA using Origin Pro 9.1 software, followed by pairwise comparisons using Bonferroni test. A p value less than 0.05 ($p < 0.05$) was considered statistically significant. Graphs of the data were obtained using GraphPad Prism 5 software.

RESULTS

Imaging Cerebral Blood Vessels Through a Thinned-Skull Window *in vivo*

In this *in vivo* imaging study, we used a thinned skull window preparation, because preparing these windows were less invasive (without exposing the brain) and they usually sustained the physical impacts generated from a CCI device during mTBI model preparation. **Table 1** summarized numbers of measured vessels and numbers of animals in each experimental group. Occasionally, mice with damaged or deteriorating windows were excluded from further experiment and data analysis. As shown in **Figure 1A**, the posterior edge of an impact site was about 1 mm from the anterior edge of an imaging window, which would allow us to observe changes in cerebral vessels after the relatively diffuse brain injury (Drew et al., 2010b; Shih et al., 2012b).

Cerebral vessels including arteries, capillaries, and veins were clearly visible within ∼400 μm below the pial surface (**Figure 1B**). The fluorescence dye (Rhodamine B) revealed the serum in bright red and the RBCs as dark dots due to their impermeability to the dye. RBC velocities of different vessels, which typically represent the velocities of blood flow, were measured using line scan and calculated from the dark strips (**Figures 1C–E**; Drew et al., 2010a; Shih et al., 2012a). The mean velocity at baseline was calculated by combining data from the

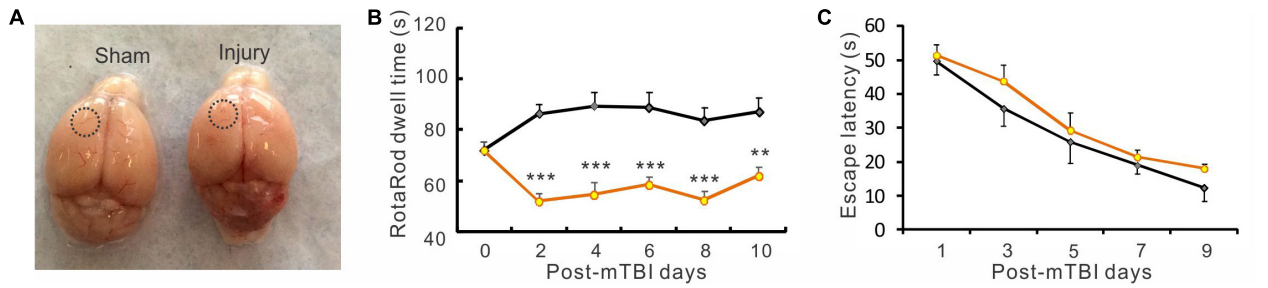

FIGURE 2 | Closed-head mTBI resulted in impaired motor function. **(A)** Morphology of freshly dissected mouse brains from sham injured (left) and mTBI (right) mice. There was no obvious difference between them in gross brain structure. The dotted circles indicate approximate regions of sham or actual cortical impact. **(B)** In repeated RotaRod tests, the dwell times of the mTBI group were highly significantly less than those of the sham group between days 1 and 10 post-mTBI ($F_{(1,100)} = 106.47$, $^{**}p < 0.01$, $^{***}p < 0.001$, two-way ANOVA followed by Bonferroni post-test), suggesting an impaired motor function in these mice. **(C)** The escape latency in water maze test had no significant change after mTBI. (all $p > 0.05$. $n = 12$ in sham and $n = 10$ in mTBI).

shame group and mTBI groups. Arterials were differentiated from veins based on their smaller sizes, smoother vessel walls, fewer branches, and faster RBC velocities. RBC velocities of most arteries were between 5 and 20 mm/s, the velocities of veins ranged between 1 and 10 mm/s, and the velocities of capillaries were less than 1 mm/s with a mean value of 0.25 ± 0.02 mm/s.

We analyzed the relationships between vessel diameters and RBC velocities in arteries, veins, and capillaries. As expected, there were positive correlations between RBC velocities and diameters of arteries and veins, with the correlation coefficients being 0.57 and 0.44 for arteries and veins, respectively (**Figures 1F,G**). In contrast, the diameters of capillaries had no correlation with RBC velocities (**Figure 1H**).

mTBI Induced Motor Deficit but Did Not Impair Learning and Memory Function

Closed-head mTBI induced by the modified CCI technique produced little gross brain structure damage. We observed freshly dissected mouse brains and found that closed-head mTBI induced by the modified CCI technique produced little gross brain structure damage (**Figure 2A**). However, behavioral tests revealed that the mTBI model produced motor behavioral deficits, as indicated by a significant reduction of dwell time in a Rotarod test in the mTBI group than the sham group during a 10-day period after injury (**Figure 2B**. $p < 0.01$ or $p < 0.001$, two-way ANOVA followed by Bonferroni post-test). In contrast, in the water maze test there was no significant difference in the latency of finding the hidden platform between the two groups (**Figure 2C**, $p > 0.05$), indicating that this type of mTBI preparation didn't significantly impair spatial learning and memory in the mice.

TABLE 1 | The number of imaged vessels and animals for each experimental group.

Group	Artery		Vein		Capillary	
	mice	vessels	mice	vessels	mice	vessels
Diameter and velocity relationship	19	44	21	79	16	104
Sham group	11	29	11	54	11	49
mTBI group	15	19	15	41	15	48

No Significant Changes in Arterial Blood Pressure After mTBI

To monitor whether mTBI affected systemic blood pressure, systolic blood pressure (SBP) and diastolic blood pressure (DBP) of mouse tail were measured in the sham and injury groups using a tail cuff. Repeated measurements were carried out in each animal at each imaging time point (**Figures 3A,B**). In the sham group, the SBP and DBP were between 105.1 ± 2.5 and 108.9 ± 3.0 mmHg and between 79.9 ± 2.0 and 82.8 ± 4.0 mmHg, respectively. In the mTBI group, the SBP and DBP were between 107.9 ± 3.0 and 113.0 ± 9.0 mmHg and between 76.5 ± 5.8 and 81.9 ± 9.1 mmHg, respectively. There were no significant differences between the two groups at different time points (all $p > 0.05$).

Significant Decreases in Diameters and RBC Velocities of Arterioles After mTBI

Morphological changes of arterioles at different time points in sham and mTBI groups are shown in **Figure 4A**. In the sham group, arterioles maintained stable morphology overtimes. However, spasm of arterioles was markedly visible at 0.5, 1, and 6 h following closed-head mTBI. Quantitative analysis showed that normalized arterial diameters were 101% ± 2, 101% ± 1, 97% ± 2, and 100% ± 1 at 0.5, 1, 6 h, and 1 day in the sham group (**Figure 4B**, $p > 0.05$). However, the diameter of arterioles decreased significantly at 0.5, 1, and 6 h post-injury (94% ± 3, 93% ± 3, and 93% ± 2, respectively, all $p < 0.05$ when compared with the sham group) and partially recovered at 1 day after mTBI (96% ± 3, $p > 0.05$ when compared with the sham group). The RBC velocities of the sham group were 97% ± 3, 102% ± 4, 100% ± 5, 100% ± 3 at 0.5, 1, 6 h, and 1 day, respectively. It was also significantly reduced at 30 min, 1, and 6 h after injury (**Figure 4C** 79% ± 6, 84% ± 5, and 84% ± 5, respectively, all $p < 0.05$ when compared with the sham group) and recovered partially at 1 day following mTBI

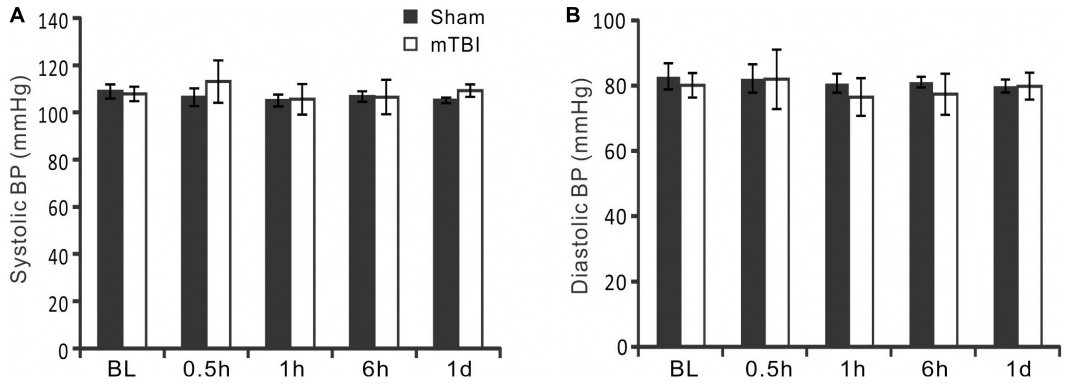

FIGURE 3 | Measurement of systematic blood pressures. **(A,B)** Blood pressure (BP) was monitored by measuring tail artery BP throughout the duration of the imaging experiment. There were no significant changes in systolic BP and diastolic BP at baseline and different times after mTBI ($p > 0.05$, repeated measure ANOVA).

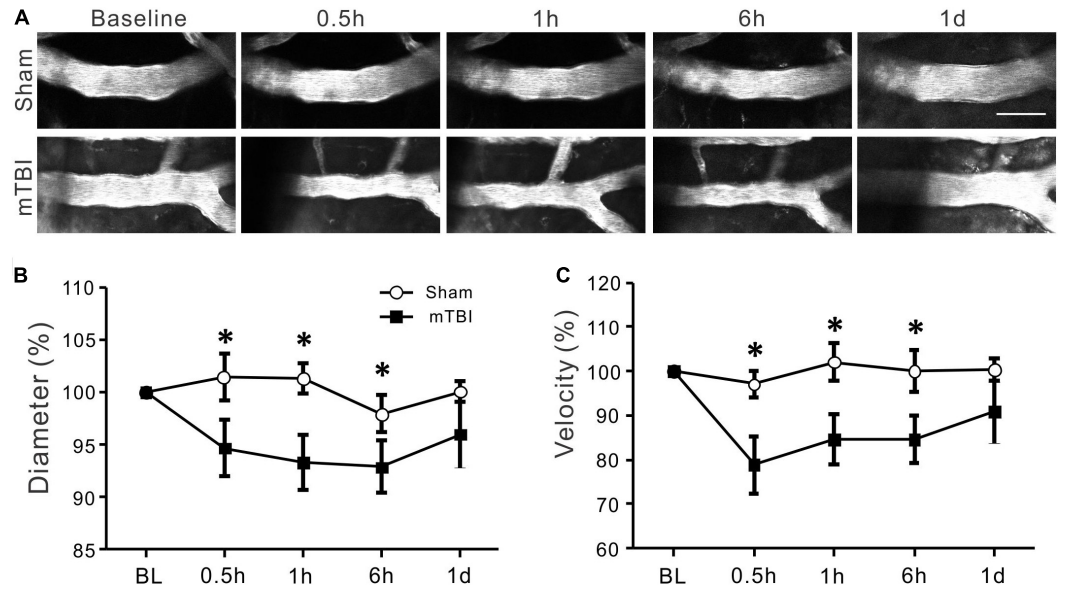

FIGURE 4 | Reduced arterial diameter and RBC velocity after mTBI. **(A)** Changes in cerebral arterial morphology at different time points after mTBI in sham and injury groups. In comparison to the sham group, arteries of the mTBI group showed obvious constriction between 0.5 and 6 h post-mTBI. **(B)** Arterial diameters became smaller between 0.5 and 6 h post-injury ($p < 0.05$ at all time points when compared with the same time points of the sham groups, repeated measure ANOVA), and partially recovered to baseline level at one day post-mTBI ($p > 0.05$). **(C)** Consistent with the reduced diameter, arterial RBC velocity also significantly decreased between 0.5 and 6 h and recover to thebaseline level at 1 day following mTBI (*$p < 0.05$).

(91% ± 4, $p > 0.05$ when compared with the sham group). The data suggest that both the diameter and blood flow of arterials decreased significantly during 0.5–6 h after mTBI and partially recovered in 1 day after mTBI.

Acute Reduction but Earlier Recovery in Diameter and RBC Velocity of Venules After mTBI

The morphology of small veins remained relatively stable at different time points in both sham group and injury group (**Figure 5A**). Quantitative analysis revealed that both diameter and velocity of venules underwent significant reduction in diameter at 1 h (95% ± 3, $p < 0.05$) and in velocity at 30 min (87% ± 6, $p < 0.05$) after mTBI when compared with the sham group at the corresponding time points (**Figures 5B,C**). However, these two parameters gradually recovered close to the normal level from 6 h after mTBI (**Figures 5B,C**).

Decreased Diameter and RBC Velocity and Formation of Microthrombi of Capillaries After mTBI

The movement of individual RBCs in capillaries were quite slow (**Figure 1H**, ∼0.05–0.93 mm/s) and clearly discernible under two-photon imaging (**Figure 6A**). While the capillaries of the

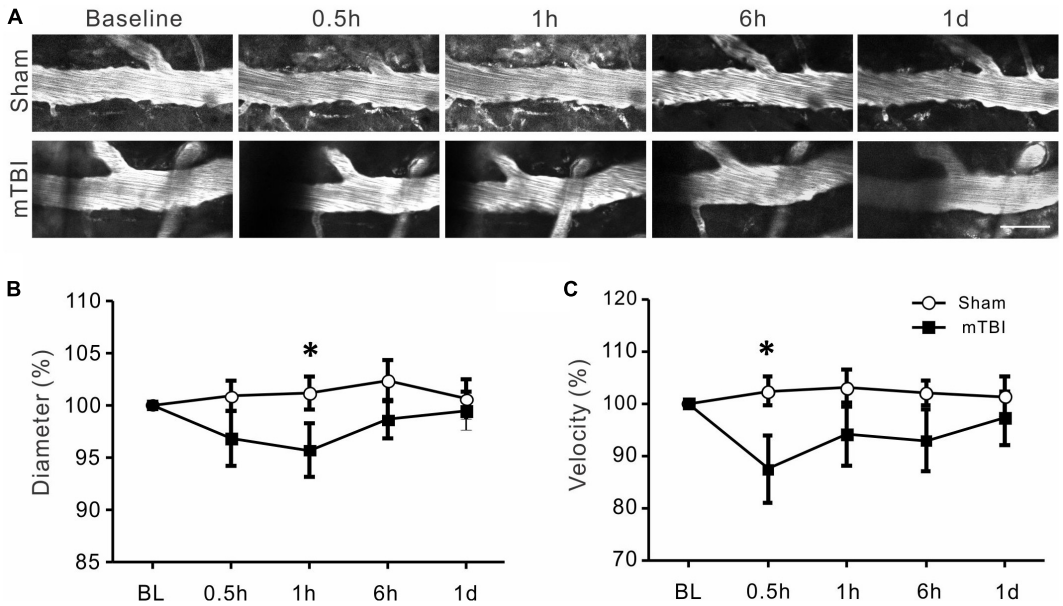

FIGURE 5 | Changes in venous diameter and RBC velocity after mTBI. **(A)** Representative images of cerebral veins at different time points after mTBI of the sham and injury groups. There seems a small decrease in vein diameter within 0.5–1 h post-mTBI, which recovered to baseline level in one day. **(B)** There was a significant decrease in venous diameter at 1 h after mTBI ($p < 0.05$), but insignificant changes at other time points ($p > 0.05$). **(C)** The changes in venous RBC velocity were similar with the changes in vein diameter: a significant decrease in venous RBC velocity occurred at 0.5 h ($p < 0.05$) post-mTBI, which recovered in 1 h to 1 day post-mTBI. *$p < 0.05$.

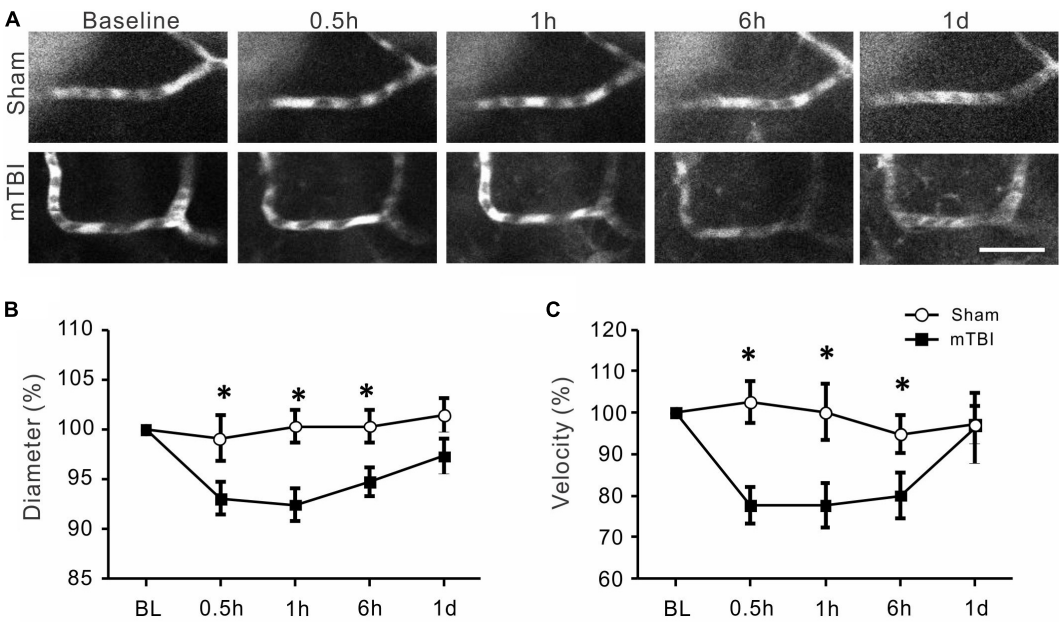

FIGURE 6 | Reduced capillary diameter and RBC velocity after mTBI. **(A)** Representative images of capillary segments at different time points after mTBI of the sham and injury groups. Individual RBCs are discernable as single dark spots inside the capillaries. Scale bar: 25 μm. **(B)** Capillary diameters became smaller between 0.5 and 6 h post-injury ($p < 0.05$ at all time points), and recovered at 1 d post-mTBI ($p > 0.05$). **(C)** Changes in capillary RBC velocity were similar to that of capillary diameter: it decreased during 0.5–6 h post-mTBI and recovered at 1 d post-mTBI. *$p < 0.05$.

sham group maintained relatively stable diameter and RBC velocity, there was a small yet significant decrease in diameters of capillaries at 0.5, 1, and 6 h after mTBI (**Figure 6B**. 94% ± 2, 92% ± 2, and 94% ± 1, respectively, all $p < 0.05$ when compared with the sham group at the corresponding time points), which partially recovered to baseline level at 1 day after mTBI. There

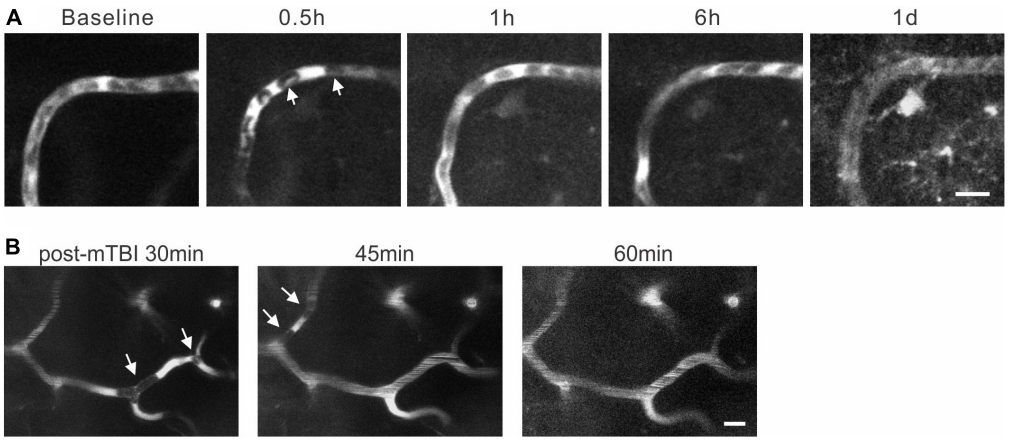

FIGURE 7 | Formation and clearance of transient microthrombi following mTBI. **(A)**. At 0.5 h post-mTBI, RBCs in a segment of capillary (arrows) stopped moving and the fluorescent dye accumulated locally. This type of RBC accumulation was removed at 1 h post-mTBI and smooth blood flow recovered. **(B)** Images of cerebral capillaries between 30 and 60 min after mTBI. At 30 min, formation of microthrombi (white arrows in the left image) completely stopped blood flow in a segment of capillary. The original microthrombi disappeared at 45 min, but new ones formed (white arrows in the middle image) in different locations, which were cleared at 60 min post-mTBI (right image). Scale bars: 10 μm.

were more dramatic decreases in RBC velocity of capillaries at 0.5, 1, and 6 h after mTBI (**Figure 6C**. 78% ± 4, 78% ± 5, 80% ± 5, respectively, all $p < 0.05$ when compared the sham group at the corresponding time points), which also increased to baseline level at 1 day after mTBI.

We also found that mTBI induced transient formation of microthrombi or microthrombus-like structures inside capillaries. These microthrombi consisted of a few RBCs in capillaries and partially or totally blocked blood circulation in the particular segments of capillaries. They appeared as early as 30 min after injury and sustained for a short time period (∼10–30 min) before clearance and re-perfusion of the capillaries (**Figures 7A,B**, $n = 2$ mice). Formation and clearance of the microthrombi occurred simultaneously at multiple locations: while a microthrombus was being cleared in one location (**Figure 7B**, left and middle images), a new microthrombus formed in a nearby capillary, which again disappeared in ∼15 min (**Figure 7B**, the middle and right images). Accompanying with microthrombosis was a reversal of blood flow direction in some capillaries, which changed back once a microthrombus was cleared.

DISCUSSION

In this study, we used *in vivo* two-photon microscopy in a closed-head mTBI model to study longitudinal changes in diameters and blood flow of cerebral arteries, veins, and capillaries within one day after injury. Repeated measurements of vessel diameter and centerline RBC velocity were made before and at different time points after closed-head mTBI. To our best knowledge, this is the first attempt to examine real-time longitudinal dynamics of cerebral vasculature and microcirculation at a vessel-by-vessel level in a closed-head concussion model. The technique convincingly demonstrated that cerebral arteries and capillaries had significant decreases in vessel diameter and RBC velocity from 30 min to 6 h post-mTBI and partially recovered to baseline values at one day post-mTBI. The diameter and RBC velocity of veins underwent reduction in a short time window 0.5–1 h after mTBI. We also observed formation of transient microthrombi and their subsequent clearance. These results suggest that mTBI causes acute spasm of cerebral blood vessels, reduction of blood flow, and impairment of capillary microcirculation.

We used an established closed-head mTBI model that mimics human concussion, the most common type of TBI. Consistent with published results (Schaffer et al., 2006; Drew et al., 2010b), the model induced transient loss of consciousness and impairment of motor behavior in the Rotarod test. Although the escape latency in the water maze test of the mTBI group was not significantly longer than that of the sham group, a trend of longer escape latency existed, particularly in the first 3 d after mTBI (**Figure 2C**), which is consistent with a previous observation of impaired spatial acquisition in 1–3 days but no change in 4–6 days after mTBI (Schaffer et al., 2006).

This model of mTBI not only mimics key features of human concussion such as closed-head injury, subtle yet diffuse structural damages, and behavioral deficits, but also is suitable for *in vivo* two-photon imaging of brain structural damage at the cellular level, including dynamics of cerebral vasculature and microcirculation. A major concern about using *in vivo* two-photon imaging for longitudinal study of mTBI is that the physical impact generated from an impact device will damage the cranial window and make it impossible to follow dynamic changes in structures of neurons, glial cells, or vasculature. By targeting the impactor tip to an area next to a small thinned skull window, we found it feasible to create an mTBI model without damaging the imaging window. We only experienced an occasional crack of window glass or leak of air into the windows. Although the physical impact from an impact device is focal, its effect on the brain is diffuse, including more distant

brain regions, as was validated from our morphological data and behavioral testing results. Thus, the thinned-skull window preparation can sustain the impact of a CCI device and allow longitudinal imaging studies on dynamic changes in neuronal structures as well as vascular structures and blood circulation. This approach may also be used for testing longitudinal effects of therapeutic and rehabilitative interventions on cellular structures and activities after mTBI.

Moderate or severe TBI is known to induce a significant decrease in the cerebral blood flow (CBF) in patients during the acute stage (less than 3 h after head injury) and chronic stage (at least 3 months after TBI), as measured by transcranial Doppler (TCD) ultrasound or arterial spin labeling perfusion fMRI techniques (McQuire et al., 1998; Shi et al., 2010). Cerebral hypoperfusion also appears in rat TBI models with severe damage in the early stage (4 h after cortical contusion) and late stage (9 months after lateral fluid-percussion injury) using arterial spin labeling (ASL) MRI technique or Laser Doppler Flowmetry (LDF) measurement (Thomale et al., 2002; Hayward et al., 2010, 2011). Besides lower CBF, reduction in carotid artery blood flow was also observed after a rapid head rotational injury (Clevenger et al., 2015).

Reduced CBF after mTBI is observed in both animal and human studies. In acute sports-related concussion patients, ASL MRI techniques showed decreased CBF in several brain regions in 24–48 h after injury (Wang et al., 2018). Furthermore, the decrease in CBF in 8 d after injury was more severe and diffuse than at 24 h after injury (Wang et al., 2016). In a rat model of blast-induced mild TBI, a reduction in cerebral perfusion was found with LDF within 2 h after injury (Kawoos et al., 2016). In a mouse closed-head mTBI model, a single concussion caused CBF reduction by $35 \pm 4\%$ at 4 h, which returned to preinjury levels by 24 h (Buckley et al., 2015). These results are generally consistent with our observation that RBC velocity was decreased between 30 min to 6 h after mTBI, before recovering to about baseline level at 24 h. In contrast, an investigation on 14 patients with mTBI using an ASL technique showed increases in regional CBF in the striatum and frontal and occipital cortex in 3 h to 10 days after injury, which was accompanied by high level of oxygen in veins (Doshi et al., 2015). Similarly, increases in cerebral blood flow and pial arteriolar diameter were observed in a fluid percussion model of TBI (Wei et al., 1980, 1981). This discrepancy may originate from the wide range of post-concussion time periods of the patients in that human study (Doshi et al., 2015), or from the difference in injury model and severity as well as animal species (Wei et al., 1980, 1981). Although our results showed recovery of vessel diameter and RBC velocity to baseline level at 1 day after mTBI, such recovery may not be complete and stable. Changes in chronic post-concussion period need to be further determined in future.

There is apparent discrepancy between changes in the diameters and velocities in arterials and venous (**Figures 4**, **5**). Because many other factors also contribute to the blood flow volume, including numbers and lengths of arteries and veins, velocity changes, and extracellular space, it would be difficult to estimate the volume of blood flow by imaging diameter and velocity of a small numbers of vessels of the brain. On the other hand, an assumption that total inflow of blood should equal to outflow may not be true, particularly under pathological conditions such as TBI. Disturbed cerebral microcirculation participated in the pathological process of neurological disease; changes in diameter and velocity of arteries and veins can be quite different in various pathological conditions. For example, in 60 min after subarachnoid hemorrhage, arterioles become dilated but venules do not change (Ishikawa et al., 2016). In diabetic mice, there was no significant change in the blood velocity of arterioles while there was a significant decline in those of venules (Huang et al., 2014). Middle cerebral artery occlusion in diabetic mice can cause the blood velocities of both arterioles and venules to decrease (Huang et al., 2014). Changes of velocities and diameters of arterioles and venules also showed potential discrepancy in recovery one day after mTBI induction in the present study. Gattinoni et al. have proposed that venous and arterial base excess difference is closely related to physiological reality (Lang and Zander, 2002; Gattinoni and Busana, 2019).

The present study showed that the mean RBC velocity in all animals at baseline was 0.25 mm/s (0.05–0.93 mm/s) and the mean value from each animal varied from 0.10 to 0.44 mm/s. In contrast, the mean capillary RBC velocities were within the scopes of 0.1∼1.6 mm/s and 0.05∼0.9 mm/s as reported by Emmanuelle (Chaigneau et al., 2003) and Stefanovic et al. (2008). In some other studies, the velocities in both anesthetized and awake mice were calculated to be approximately 0.7 or 1.3 mm/s (Huang et al., 2014; Wei et al., 2016; Li et al., 2019; Lu et al., 2019). Comparing to these values, our data seemed to be lower. One possible reason may be due to the relatively smaller capillaries (with a mean diameter of 3.96 μm) we imaged than those imaged in prior studies (with mean diameters of 4.7 to 6 μm) (Li et al., 2019; Lu et al., 2019). Small vessels usually have lower RBC velocity. Another possible reason may be due to different effects of anesthetic agents on blood vessel diameters (Slupe and Kirsch, 2018). For example, ketamine has been shown to cause constriction of microvessels (Small et al., 2014).

The mechanism of mTBI-induced decrease in cerebral blood flow may involve vasospasm, edema, and neuroinflammation. A body of studies have reported post-TBI vasospasm (Kramer et al., 2013; Fehnel et al., 2014; Perrein et al., 2015; Ogami et al., 2017). In severe TBI, post- traumatic vasospasm is detected in 30–40% of patients (Perrein et al., 2015). Vasospasm appears in the early stage after TBI and is considered related to delayed ischemic neurological deficit, which contributes to the formation of subarachnoid hemorrhage (DeWitt and Prough, 2003). In the present study, direct measurement of decreased arteriole diameter between 0.5 and 6 h post-mTBI provides strong evidence of vasospasm during the early time period after the injury. A decrease in vein diameter after mTBI was also observed. Since the diameters of cerebral arteries and veins are positively correlated to their RBC velocity (**Figures 1F–H**), the decreased vessel diameters after mTBI likely contribute to the reduced CBF. Mechanistically, calponin phosphorylation and carbon dioxide ($Pa\,CO_2$) may be factors involved in regulation of cerebrovascular reactivity to TBI (Shen et al., 2007; Len et al., 2011). Increases in the level of NO and Ca^{++} in endothelium after TBI are also considered major factors in stimulating vasospasm of cerebral

arteries (Villalba et al., 2014). In addition, we also observed early reductions of diameters and RBC velocity of capillaries in 0.5–6 h after mild TBI in our study. Because cerebral blood flows in the capillary and arteriole are regulated through different signaling cascades (Biesecker et al., 2016; Mishra et al., 2016), it would be interesting to investigate whether different molecular mechanisms are involved in the regulation of blood flow in arteries and capillaries after mTBI.

Edema is known to develop after moderate to severe TBI and contribute to increased intracranial pressure (ICP) (Bolouri et al., 2012). An increase of ICP from tissue edema is thought to be one of the major mechanisms of blood flow loss (Nortje and Menon, 2004). However, increase in ICP after TBI varies considerably in different TBI models as well as in different animal species (Reid et al., 2010). Particularly, TBI alone does not cause significant increase of ICP in either lateral fluid percussion or impact acceleration induced injury in rats (Gabrielian et al., 2011) and closed-head mTBI is shown not to cause edema in a weight drop model in mice (Garcia et al., 1994; Kane et al., 2012). Therefore, edema may not make a significant contribution to the reduced RBC velocity in our mTBI mice.

Microthrombosis resulting from abnormal platelet activation occurs in the early stage after moderate and severe TBI, which can lead to perfusion loss in the peri-contusional cortex (Dietrich et al., 1994; Maeda et al., 1997; Bramlett and Dietrich, 2004). There is a positive correlation between the number of microthrombi and the degree of neuronal necrosis (Stein et al., 2004). In the present study, the observed microthrombi in capillaries seem different from typical microthrombi that occur after more severe TBI. Among all the capillaries being imaged, we observed only three cases of microthrombus formation in the mTBI brain and none in sham brain. Given the rare and transient nature of microthrombosis in this particular model of mTBI, it was not possible to quantify them. These capillary microthrombi were transient and reversible, lasting for only minutes to tens of minutes. They may be regarded as a mild type of microthrombi. Given the transient and microscopic nature of the microthrombi, it would be difficult to capture them using conventional imaging techniques such as CT scan or even tissue histology. Their pathological significance is unclear. In controlled cortical impact and fluid percussion models of TBI, factors that may induce or facilitate microthrombosis include endothelial damage and release of procoagulant molecules such as cardiolipin (Kontos et al., 1981; Zhao et al., 2016; Hall et al., 2017), and release of platelet activating factor and platelet aggregation (Rosenblum et al., 1982; Maeda et al., 1997). While a high density of microthrombi is associate with more severe selective neuronal necrosis (Deng et al., 2005), the transient microthrombi we observed after mTBI may not be severe enough to cause neuronal death. However, their interference with capillary microcirculation likely contributes to exacerbating brain ischemia and acute functional deficits.

In summary, we used an *in vivo* two-photon imaging technique to study acute changes in cerebral vasculature and blood circulation in a model of closed-head mTBI. Our results provide direct evidence that mTBI caused acute decreases in the diameter and blood flow of cerebral arterioles, veins, and capillaries to different degrees within 0.5 to 6 h after injury. These decreases mostly recovered to baseline levels at 24 h after injury. The mTBI also caused microthrombosis in capillaries, which were transient and cleared in a short time period. These vascular changes may contribute to acute brain ischemia and functional impairments and may guide therapeutic development for mTBI.

All datasets generated for this study are included in the article/supplementary material.

ETHICS STATEMENT

The animal study was reviewed and approved by the Institutional Animal Care and Use Committee (IACUC) of the Indiana University School of Medicine.

AUTHOR CONTRIBUTIONS

XJ and YR conceived and designed the experiments. XH and XP performed the experiments:. XH, XP, ZC, L-JS, and CM analyzed the data. XH, ZC, L-JS, CM, XJ, and YR wrote, revised, and commented on the manuscript.

FUNDING

This work was supported in part by the Indiana Spinal Cord and Brain Injury Research Fund from the Indiana State Department of Health (A70-1-079438, A70-3-079971, and A70-4-079956) to XJ. This work was also supported by funding from the China's National 111 project (Grant number B14036) to YR and postdoctoral research start-up funding (3001008-04) from Guangzhou Women and Children's Medical Center.

Du X, Yang J, Liu C, Wang S, Zhang C, Zhao H, Du H and Geng X (2020) Hypoxia-Inducible Factor 1α and 2α Have Beneficial Effects in Remote Ischemic Preconditioning Against Stroke by Modulating Inflammatory Responses in Aged Rats. Front. Aging Neurosci. 12:54. doi: 10.3389/fnagi.2020.00054

Limb remote ischemic preconditioning (RIPC) has been proven to alleviate stroke injury in young rats, but its protective effect and its mechanism in aged rats are still unclear. Hypoxia-inducible factor (HIF) is one of the important markers of stroke, and its high expression plays an important role in the pathogenesis of stroke. In this study, we tested the hypothesis that RIPC could regulate the expression of HIF, leading to reduced inflammatory responses in aged rats. Stroke was induced by transient middle cerebral artery occlusion (MCAo) in aged rats, and RIPC was conducted in both hind limbs. The HIF-1α and HIF-2α mRNA and protein were examined by real-time RT-PCR and western blotting (WB). Inflammatory cytokines in the peripheral blood and brain were measured using AimPlex multiplex immunoassays. The protein levels of p-Akt, Akt, p-ERK, and ERK were examined by WB. We investigated that RIPC reduced the infarct size, improved neurological functions, and decreased the expression of HIF-1α and HIF-2α in the ischemic brain. RIPC reduced the levels of IL-1β, IL-6 and IFN-γ in the peripheral blood and the levels of IL-1β and IFN-γ in the ischemic brain 48 h post-stroke. Moreover, intraperitoneal injection of the HIF inhibitor, acriflavine hydrochloride (ACF), abolished the protection of RIPC with respect to infarct size and neurological functions and neutralized the downregulation of pro-inflammatory IL-1β, IL-6 and IFN-γ. ACF also reversed the activation of the Akt signaling pathway induced by RIPC following stroke. HIF may play a key role in RIPC, which was likely mediated by the Akt signaling pathway and systemic modulation of the inflammatory response in aged rats.

Keywords: cerebral ischemia, remote ischemic preconditioning, hypoxia-inducible factor, Akt signaling pathway, inflammatory cytokines

INTRODUCTION

Ischemic stroke is considered to be the third most lethal and disabling disease in the world. Aging, above all risk factors of stroke, accounts for a large proportion of stroke-related mortality (Mozaffarian et al., 2015). According to the World Health Organization (WHO) statistics, twelve million people will suffer from stroke in the coming decade (Krishnamurthi et al., 2013). At present, however, no alternative neuroprotective agent has been approved by the FDA except for thrombolytic recombinant tissue plasminogen activator (tPA), which is only administrated to a small number of patients. Given the increase of the senior citizen and the aggravating of the associated stroke burden, it is urgent to find effective treatments for this disease. In recent years, remote ischemic preconditioning (RIPC) has become a feasible therapeutic strategy for stroke and has been proven to provide a protective effect on young experimental animals (Wei et al., 2012; Liu et al., 2016; Yang et al., 2018) and in clinical trials (Mi et al., 2016; Zhao S. C. et al., 2017). Nevertheless, its protective effect and its mechanism in the elderlies are still unclear.

Age is an important risk factor for pre-clinical studies on ischemic stroke, which has been largely overlooked. Previous studies have suggested that aged rats, compared with younger ones, represent a more clinically relevant model of ischemic stroke (Mayhan et al., 2008; Modrick et al., 2009). Advanced age increases the expression of immune cells including T cells, neutrophils, macrophages, and dendritic cells in middle cerebral artery occlusion (MCAo) mice, which may be responsible for the exacerbated behavioral deficits in the aged (Manwani et al., 2013). Age also stimulates the activation of macrophages and the expression of inflammatory cytokines in MCAo mice (Zhao S. C. et al., 2017). Although most experimental stroke studies have been conducted on healthy young animals, accumulating evidence points to age-related differences in gene expression and cytokine production (Kuzumaki et al., 2010; Semple et al., 2013; Orre et al., 2014; Suenaga et al., 2015); thus, applying aged animals as models may increase the clinical relevance of the experimental results.

Hypoxia-inducible factor (HIF) is the most crucial regulator of oxygen balance in mammals, and it has been shown to promote tolerance to acute ischemia (Semenza, 2012). HIF-1α and HIF-2α, as the HIF-α subunits, combine with HIF-β to regulate target gene transcription under hypoxic conditions. They share 48% identical DNA binding regions in structure, but each has its own unique biological effects. HIF can easily degrade under normal oxygen conditions within 5 min, while under hypoxia, its stability and transcriptional activity are significantly increased, which induces the expression of its downstream target genes. Because of its particularity of function, HIF is critically related to ischemic stroke (Sharp and Bernaudin, 2004; Ogle et al., 2012). Previous studies showed that suppressing the expression of basal HIF-2α, but not that of HIF-1α, was sufficient to accelerate cell death in nerve growth factor (NGF)-stimulated neurons (Lomb et al., 2009). In addition, the HIF-α subunits HIF-1α, HIF-2α and HIF-3α can be regulated by the phosphoinositide 3-kinase (PI3K) pathway in the brain of MCAo rats (Wei et al., 2017). The interaction between RIPC and HIF has been explored by some studies, where HIF was required for RIPC in protecting heart function in young animal models (Cai et al., 2013; Martin-Puig et al., 2015). Our previous study showed that HIF-1α was indispensable for RIPC against stroke by modulating inflammation in a young rat model of MCAo. Accumulating data provide indications for the roles of HIF-α in neuroprotection of RIPC against ischemia, but there is still a lack of solid evidence of its involvement in an aged model of stroke with RIPC.

After a stroke, systemic inflammation contributes to brain injury, as neuroinflammation occurs not only in the brain but also in the peripheral organs (Nguyen et al., 2016; Shim and Wong, 2016; Yamashiro et al., 2017). RIPC could reduce neuroinflammation in ischemic stroke through modulating the upregulated expression of HIF-1α (Yang et al., 2018), improving the peripheral immune cell response (Liu et al., 2016), activating the adenosine A1 receptor and affecting redox status (Hu et al., 2012), and changing the activation of signaling pathways such as Akt and ERK. All of these findings have focused on young animal models, whereas whether RIPC can regulate neuroinflammation in aged animals remains unclear.

In this study, we aimed to provide insights into the roles of HIF-1α and HIF-2α in RIPC protection in aged stroke rats and explore the regulatory mechanism of inflammatory cytokines. First, we defined the protection of RIPC on aged MCAo rats. Then, we tested the expression of HIF-1α and HIF-2α in penumbra tissue and measured the levels of multiple inflammatory cytokines in the peripheral blood and brain. Furthermore, we used the HIF inhibitor, acriflavine hydrochloride (ACF), to determine the role of HIF in modulating the protective effects of RIPC against stroke. Finally, we studied the activation of the Akt and ERK signaling pathways in this process.

MATERIALS AND METHODS

All procedures in this study were conducted according to ethical standards and in accordance with the Declaration of Helsinki and with national and international guidelines and have been approved by the authors' institutional review board. Male Sprague–Dawley (SD) rats, age-matched 19–20 months, were purchased from Vital River Laboratory Animal Technology Company Limited (Beijing, China). They were housed in a controlled room at a temperature of 24°C with a standard 12-h light/dark cycle, had free access to food and water and were randomly distributed into different groups. The number of animals in each group was 6–8.

Middle Cerebral Artery Occlusion (MCAo)

Most pre-clinical stroke studies exclusively examined the response to stroke in young male animals. This is in part due to the difficulty of performing the surgeries, the high costs, and the poor survival rates in aged animals. In our experiment, rats were anesthetized with 3–5% isoflurane in 70% nitrous oxide and 30% oxygen and then maintained with 1–3% isoflurane. For the MCAo model, ischemia and reperfusion were established as previously described (Ren et al., 2011; Yang et al., 2018). As the aged rat weight was higher than that of younger ones, we chose

a silica gel-coated nylon suture that was appropriate for rats up 450 g. The suture was withdrawn after 90 min of occlusion to allow for the re-opening of the MCA. Rat rectal temperature was maintained at 37 ± 0.5°C during the entire procedure. The cerebral blood flow (CBF) during the surgery before and after occlusion were measured by laser Doppler perfusion monitoring with a laser Doppler probe (PeriFlux System 5000, Perimed AB, Sweden) interfaced to a laptop equipped with the PeriSoft data acquisition software (PeriSoft Systems, Inc., Sweden) as previously described (Chen et al., 2018). The blood gas ($PaCO_2$, PaO_2 [mmHg] and pH) and blood sugar (mmol/L) were also examined during the surgery. The rats in the sham group were subjected to the surgical procedure without MCA occlusion.

Remote Ischemic Preconditioning (RIPC)

RIPC was established as previously described (Yang et al., 2018). Briefly, 24 h before MCAo, RIPC was conducted on both hind limbs of rats anesthetized with 1–3% isoflurane by non-invasive occlusion of hind limb blood flow with a gauge bandage, in contrast to an invasive, direct femoral artery occlusion. The two hind limbs were simultaneously tied with a bandage to occlude blood circulation for 10 min and then released for 10 min to allow for reperfusion. The occlusion/reperfusion cycle was repeated three times.

Behavioral Testing

Behavioral tests were conducted as described previously (Zhao et al., 2005; Yang et al., 2018). The behavioral tests were conducted to evaluate neurological functions after stroke in aged rats, including the tail hang test, home cage, and postural reflex. All behavioral tests were performed by a person who was blinded to the experimental conditions. We handled the rats for 3 days before surgery and tested their baseline on the day before surgery. All behavioral tests were then conducted 48 h after stroke onset.

For the tail hang test, the rat was hung by its tail approximately 10 cm above the floor. Stroke rats will turn to the contralateral side (left) of the ischemic hemisphere, and a head-turn of more than 90° was counted. Each time the rat was hung for no more than 5 s and each rat was hung for a total of 20 times. The percentage of head turns was calculated.

For the home cage limb test, the rat uses its forelimbs to explore the cage edge, and we counted the number of the times the ipsilateral, contralateral or both forelimbs touched the cage wall. A total of 20 contacts were recorded. The percentage of times that the ipsilateral forelimb was used was calculated using the formula: [ipsilateral + (both/2)] × 100%.

In the postural reflex test, the rat was placed on a table, its tail was held by one hand and the other hand was used to push its shoulder by nearly 20 cm three times. Non-ischemic rats gripped the table vigorously during the push, which was given a 0 score. A rat that showed less resistance and become stiff during the push was given a 1 score. A score of 2 was given if the rat had no resistance.

We also measured neurological deficits to evaluate stroke outcomes at 48 h after reperfusion using the method of the Longa scoring system, in which the scores were based on the following criteria: 0 = no deficit, 1 = failure to extend the left forepaw, 2 = circling to the left, 3 = falling to the left, 4 = failure to walk spontaneously and loss of consciousness, 5 = death.

Drug Injections

To study the role of HIF in RIPC, a HIF inhibitor was used. Acriflavine hydrochloride (ACF, A8251, Sigma) was dissolved in phosphate-buffered saline (PBS), adjusted to a concentration of 2 mmol/L with additional PBS, and stored at 4°C. The ACF solution was given by intraperitoneal injection at a dose of 1.5 mg/kg, 24 h before stroke onset and every 24 h thereafter until euthanized (Ogle et al., 2012; Yang et al., 2018).

Infarct Size Measurement

2,3,5-triphenyl-2H-tetrazolium chloride (TTC) staining was used for measuring the infarct size 48 h after reperfusion when the animals were euthanized. The non-ischemic hemisphere and the non-ischemic region in the ischemic hemisphere were measured, from which the infarct size was calculated according to the following formula: [(area of the non-ischemic hemisphere—area of the non-ischemic region in the ischemic hemisphere)/area of the non-ischemic hemisphere] × 100%. The detailed protocol has been described previously (Ren et al., 2009; Yang et al., 2018).

Quantitative RT-PCR Analysis

To measure HIF-1α and HIF-2α mRNA expression, total RNA was isolated from the cortical penumbra, which was collected on ice and stored at −80°C immediately after the animals were euthanized. RNA was extracted with TRIzol reagent (Cat# 15596-026, Life Technologies, Carlsbad, CA, USA) according to the manufacturer's instructions. The purified RNA was then reverse-transcribed into cDNA using the Reverse Transcription System (Cat# E6300S, New England BioLabs® Inc., Ipswich, MA, USA). Quantitative RT-PCR analysis of the mRNA level of HIF-1α (HIF-1α F, GATGAATCAAAAGCAGTGACGAAGG, HIF-1α R, ATGCCTTAGCAGTGGTCATTTCTTG; HIF-2α F, ATCT TCCAGCCGCTCACC, HIF-2α R, GCCCACAGACCACTTCG TA) was performed using the SYBR Green Prime Script kit (RR420A, TAKARA). GAPDH (GAPDH F, TTCCTACCCCC AATGTATCCG; GAPDH R, CCACCCTGTTGCTGTAGCCAT A) was chosen as the housekeeping gene. The real-time PCR program steps were: 95°C for 5 min, 45 cycles at 95°C for 5 s, 60°C for 5 s, and 72°C for 10 s, followed by 72°C for 1 min.

Western Blotting

The cortical penumbra was collected on ice and stored at −80°C immediately after the animals were euthanized. Protein extractions were prepared with lysis buffer (50 mM Tris-HCl, pH 7.4, 150 mM NaCl, 5 mM EDTA, 0.5% NP-40, 0.1% Triton X-100, 0.1% SDS, 1 mM PMSF, 1× protein inhibitor mix Complete Mini). Then, 20 mg of protein per lane were separated by 10% polyacrylamide gel electrophoresis and transferred to nitrocellulose membranes for 2 h. The membranes were blocked with 5% skimmed milk for 1 h and then incubated overnight at 4°C with the primary antibody. Membranes were washed with TBST and incubated with the secondary antibody for 1 h. The signal was visualized by enhanced chemiluminescence. The primary antibodies used were

anti-GAPDH (1:1000; Cat# 5174, Cell Signaling Technology, Inc., Danvers, MA, USA), anti-HIF-1α (1:1000; Cat# 14179, Cell Signaling Technology, Inc., Danvers, MA, USA), anti-HIF-2α (1:500; ab199, Abcam, Cambridge, MA, USA), anti-Akt (1:1,000, Cat# 4691, Cell Signaling Technology, Inc., Danvers, MA, USA), anti-p-Akt (1:1,000, Ser473, Cat# 4060, Cell Signaling Technology, Inc., Danvers, MA, USA), anti-ERK (1:1,000, Cat# 4695, Cell Signaling Technology, Inc., Danvers, MA, USA), and anti-p-ERK (1:1,000, Cat# 4370, Cell Signaling Technology, Inc., Danvers, MA, USA).

AimPlex Multiplex Immunoassays

Peripheral blood and penumbra tissue were collected from the heart and the cortex of the ischemic brain, and an AimPlex rat inflammation assay kit (Beijing Quantobio, China) was used to detect multiple inflammatory cytokines in these samples. Six cytokines: IL-1β, IL-6, TNFα, IFN-γ, IL-4 and IL-10 were measured. The procedure was conducted according to the manufacturer's instructions and as discussed previously (Yang et al., 2018). Briefly, 45 μl of capture bead working suspension and a 45 μl sample were sequentially shaken 750 times per minute for 60 min in the dark, followed by three washings in 100 μl washing buffer. The biotin-conjugated antibodies (25 μl) were added and the wells were sealed and shaken for 30 min in the dark. After washing three times with washing buffer, streptavidin-PE was added and they were shaken for 20 min in the dark. Finally, 100–200 μl 1 × Reading buffer was added to each well and the fluorescence signals of the samples were acquired using a flow cytometer (NovoCyte, ACEA Biosciences, Inc., San Diego, CA, USA), and the levels of the inflammatory factors were analyzed with FCAP Array 3.0 software.

Statistical Analysis

Statistical analysis was performed using Prism 6 (GraphPad Software, Inc., La Jolla, CA, USA). Values are presented as means ± SEM. Differences between experimental groups were analyzed by Student's *t*-test or one-way ANOVA with Newman-Keuls Multiple Comparison test as a *post hoc* test. A value of $P < 0.05$ was considered statistically significant. Before statistical analysis, data were checked for the Gaussian distribution and fitted the normal distribution.

RESULTS

RIPC Protected Against Stroke in Aging Rats

In the previous study, we confirmed that RIPC was neuroprotective in young rats. In the current study, we used the same method we have used previously to detect the neuroprotective ability of RIPC in aged rats. The TTC staining results showed that RIPC induced a 34.64% significantly reduction of infarct size from 38.85 ± 1.15% to 25.39 ± 1.12% compared with MCAo (**Figure 1A** and

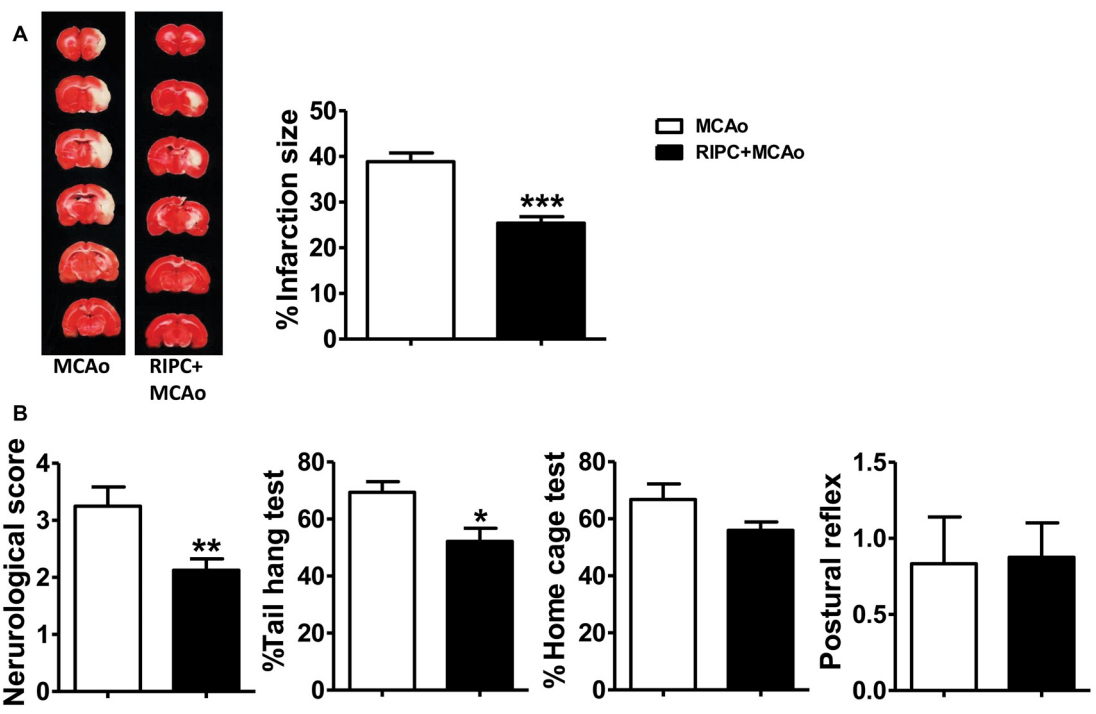

FIGURE 1 | Remote ischemic preconditioning (RIPC) reduced infarct size and improved neurological function and the behavioral test after stroke in aged rats. **(A)** Representative images and infarct volume of 2,3,5-triphenyl-2H-tetrazolium chloride (TTC) staining in the MCAo and RIPC+MCAo group in aged rats. **(B)** Neurological score and behavior tests. Supplementary Figure S2), attenuated neurological scores (**Figure 1B**), and improved behavioral performance in the tail hang test (**Figure 1B**). Although there was no significant difference in the home cage test, RIPC showed a trend towards the promotion of functional recovery in aged rats. There was no significant difference in the postural reflex test (**Figure 1B**). Meanwhile, CBF detected during MCAo surgery had no change between MCAo and RIPC+MCAo group. It was reduced by nearly 80% of baseline during ischemia and reestablished to 78% of baseline following reperfusion (**Supplementary Figure S1**). There were no differences in blood gas and blood sugar between groups, either (**Supplementary Tables S1**, **S2**). These findings confirm that RIPC triggers structural and functional protection against stroke in aged rats.

RIPC Decreased the Expression of HIF in the Ischemic Brain at 48 h Post-stroke

To test whether RIPC could regulate the expression of HIF-1α and HIF-2α in the ischemic tissue in aged rats, we measured HIF-1α and HIF-2α mRNA and protein levels in the penumbra tissue. The real-time RT-PCR results showed that mRNA expression of HIF-1α and HIF-2α were more than 3-fold upregulated 48 h post-stroke in the ischemic brain (**Figure 2A**), whereas RIPC decreased nearly 50% of HIF-1α and 60% of HIF-2α mRNA expression (**Figure 2A**). Similarly, the western blotting (WB) results (**Figure 2B**) and the statistical data showed that RIPC attenuated the protein expression of HIF-1α and HIF-2α in the ischemic brain 48 h post-stroke (**Figure 2B**).

RIPC Downregulated Pro-inflammatory Factors in the Peripheral Blood and Brain

To test if the inflammatory status were regulated by RIPC in aged rats after MCAo, we measured the effect of RIPC on the protein levels of the anti-inflammatory cytokines, IL-4 and IL-10, and that of the pro-inflammatory cytokines, IL-1β, IL-6, TNFα and IFN-γ in the peripheral blood and brain tissue. The results showed that MCAo increased the levels of pro-inflammatory cytokines while RIPC significantly decreased the levels of pro-inflammatory IL-1β, IL-6 and IFN-γ in the peripheral blood (**Figure 3A**) and that of IL-1β and IFN-γ in penumbra tissue (**Figure 3B**) 48 h post-stroke in aged rats. Taken together, these results suggest that RIPC reverses the increase

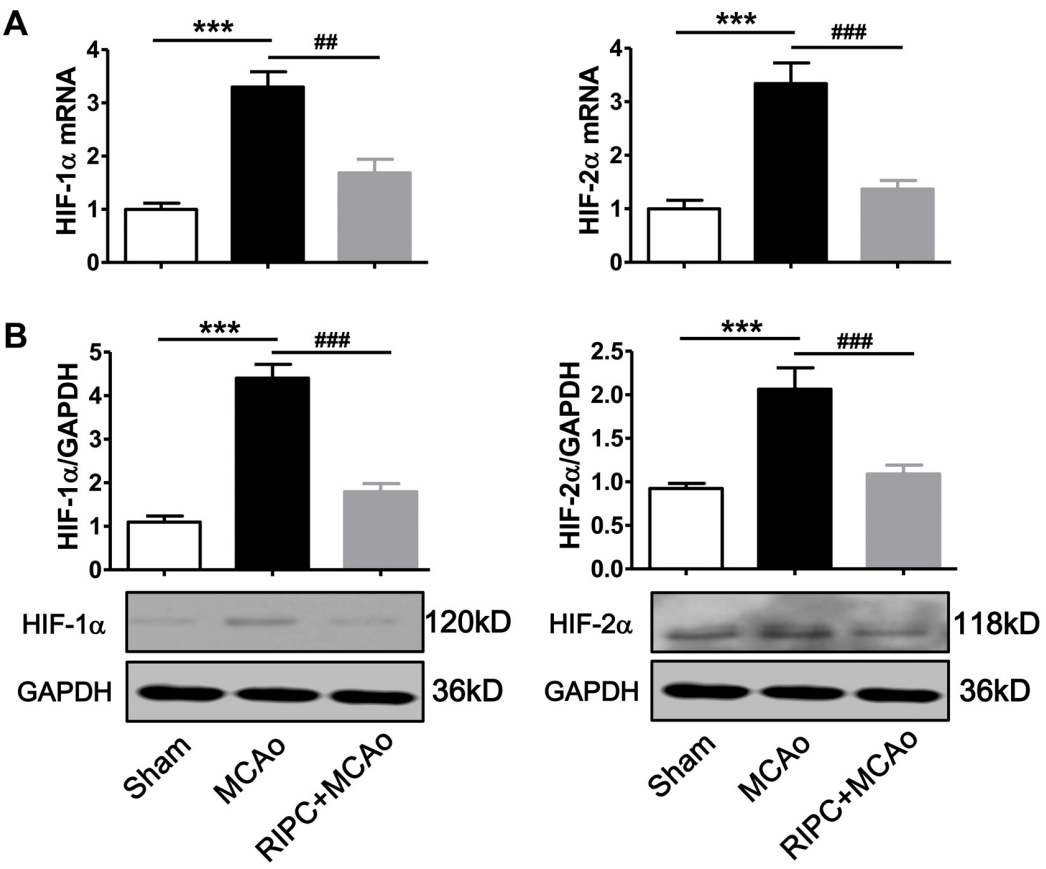

FIGURE 2 | The expression of HIF-1α and HIF-2α in penumbra tissues. **(A)** The mRNA level of HIF-1α and HIF-2α was assessed by real-time RT-PCR. **(B)** Statistical data and representative images of western blot of HIF-1α and HIF-2α protein levels in penumbra tissues in the Sham, MCAo and RIPC+MCAo group. in HIF expression caused by stroke and improves the level of inflammation in the ischemic and peripheral areas.

HIF Inhibition Abolished the Protection of RIPC

If HIF was necessary for the brain protection of RIPC in aged rats, inhibiting HIF activity would contribute to brain injuries induced by stroke. TTC staining results showed that the HIF inhibitor, ACF, abolished the protection of RIPC which ACF induced a 27.02% increase of the infarct size from 25.39 ± 1.12% to 32.25 ± 1.65% compared with RIPC (**Figure 4A** and **Supplementary Figure S2**). In addition, ACF also abolished the protective effects of RIPC as measured by neurological scores and behavioral performance including the tail hang test (**Figure 4B**). The initial decrease in CBF during ischemia and the restoration of CBF during reperfusion, the changes between groups were similar. Blood gas and blood sugar values had no differences between groups (**Supplementary Figure S1** and **Supplementary Tables S1**, **S2**).

HIF Inhibition Neutralized the Downregulation of Inflammatory Cytokines Induced by RIPC

After examining the antagonistic effect of the HIF inhibitor with RIPC on brain injury, we further assessed its effect on inflammatory factors in aged rats. The results of the

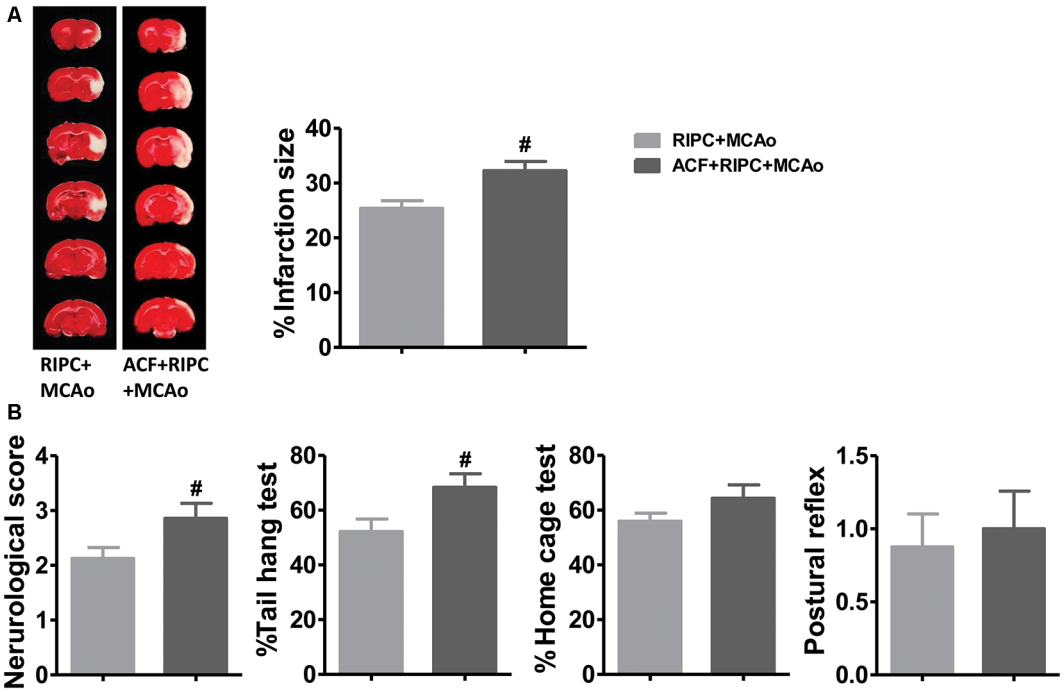

FIGURE 4 | The effects of hypoxia-inducible factor (HIF) antagonist ACF on stroke outcomes in aged stroke animals treated with RIPC. **(A)** Representative images of TTC staining and the statistical results of infarct volume in the RIPC+MCAo and ACF+RIPC+MCAo group in aged rats. **(B)** Neurological score and behavioral tests of the tail hang test, home cage test, and postural reflex test (N = 8–10 per group). $^{\#}P < 0.05$, vs. RIPC+MCAo. ACF, acriflavine hydrochloride, HIF inhibitor.

AimPlex multiplex immunoassays showed that in the peripheral blood, the HIF inhibitor ACF had an antagonist effect on IL-6 and IFN-γ (**Figure 5A**). ACF+RIPC+MCAo increased the expression of IL-6 and IFN-γ at the protein level compared with the RIPC+MCAo group. In addition, ACF had an antagonist effect on IL-1β and IFN-γ in the brain (**Figure 5B**). These results suggest that inhibition of HIF abolished the structural and functional protection of RIPC and neutralized the downregulation of inflammatory responses.

RIPC Activated the Akt Signaling Pathway, While ACF Abolished It

Several studies have demonstrated that under ischemic conditions, the activation of the PI3k/Akt or EKR signaling pathway can be regulated by the expression of HIF, and signaling pathway activation can regulate inflammatory responses. We, therefore, investigated whether the Akt or ERK signaling pathway was involved in the action of RIPC to inhibit cerebral inflammation. Penumbra tissue was collected from the cortex of the ischemic brain. The results showed that the ratios of p-Akt/Akt (**Figure 6A**) and p-ERK/ERK (**Figure 6B**) were decreased 48 h post-stroke, whereas RIPC upregulated the expression of p-Akt not p-ERK (**Figure 6**). RIPC had no effect on the total expression of Akt and ERK. Moreover, ACF decreased the ratios of both p-Akt/Akt and p-ERK/ERK (**Figure 6**). These collective findings suggest that RIPC reverses the reduced expression of p-Akt following a stroke, while inhibition of HIF abolishes the reversion.

DISCUSSION

In the current study, first, we demonstrated that RIPC reduced the infarction size and improved neurological function in aged rats. Second, RIPC has been shown to decrease the expression of HIF-1α and HIF-2α in the ischemic brain and to decrease the protein levels of pro-inflammatory cytokines IL-1β and IFN-γ in both the blood and brain 48 h post-stroke. Third, the HIF-1α inhibitor, ACF, abolished the protective effects of RIPC on infarction and neurological function. Additionally, ACF inhibited the downregulation of pro-inflammatory factors induced by RIPC, including IL-6 and IFN-γ in blood and IL-1β and IFN-γ in the brain. Fourth, RIPC increased the ratio of p-Akt to total Akt, while ACF abolished the activation of the Akt signaling pathway in the brain. Collectively, these data showed that HIF-1α and HIF-2α played key roles in the protective effect of RIPC by modulating inflammatory responses likely mediated by the Akt signaling pathway in the brain and peripheral blood circulation in aged rats.

The success of most stroke models has not been well transformed into clinical practice. One potential reason for this failure is that stroke predominantly afflicts the elderly. Aging is a very important factor in stroke, and it has been found that there are many differences in stroke models between young and old animals such as infarction size, behavior, and expression and distribution of immune cells (Kuzumaki et al., 2010; Manwani et al., 2013; Orre et al., 2014; Zhao W. B. et al., 2017). In the previous study, we demonstrated that HIF-1α played a critical

role in the protective effect of RIPC against stroke, which was likely achieved by modulating neuroinflammation in young rats (Yang et al., 2018). However, whether HIF plays a key role in RIPC in aged stroke is not addressed. Based on these, we chose an aged rats MCAo model and studied the protection and mechanism of RIPC post-stroke. We verified the infarction size was smaller in aged rats but there was worse neurological function than young rats. Further, our data suggested that RIPC protected against stroke not only in young rats but also in aged rats. RIPC reduced the infarction size and improved neurological function and behavior (**Figure 1**).

The HIF protein is a transcriptional factor that exists just a few minutes under normal oxygen levels but accumulates in hypoxic and ischemic cells (Ogle et al., 2012). Previous studies have shown that the neuroprotection against focal cerebral ischemia provided by various agents is mediated through the regulation of HIF (Doeppner et al., 2012; Wang et al., 2012; Meller and Simon, 2015). In the current study, we showed that MCAo upregulated the expression of HIF-1α and HIF-2α mRNA and protein levels in the ischemic brain of aged rats (**Figure 2**), which the evidence has been described in young animals in other reports (Zhong et al., 2012; Zhao et al., 2015; Zong et al., 2015). Further, we found that RIPC reversed this MCAo-induced upregulation of HIFs (**Figure 2**). It was suggested that RIPC improved the regional ischemia in the brain 48 h post-stroke in aged rats. Previous evidence showed that RIPC could regulate the expression of HIF, such as HIF-1α and HIF-2α, and played key roles in ischemic tissue including in the brain and heart in young experimental animals (Cai et al., 2008, 2013; Kapitsinou et al., 2014; Yang et al., 2018). To examine whether HIF also plays an important role in the neuroprotection of RIPC in aged rats, we used the heterodimer inhibitor, ACF, to inhibit HIF activity. The data showed that the injection of ACF abolished the structural and functional protection of RIPC on infarction size, neurological function and the tail hang test, one of the behavioral tests (**Figure 4**). These results demonstrated that HIF-1α and HIF-2α are key factors in the protection of RIPC in aged rats.

HIF is an inflammation mediator and can be stabilized by TNFα and IL-1β (Sharp and Bernaudin, 2004). It has been shown that IL-10 is the main target of HIF-1α in cardiomyocytes of circulating hypoxia-reoxygenation mice. RIPC can increase the plasma concentration of IL-10 and promote the subsequent remote activation of Akt signals in the heart (Cai et al., 2013). These findings are based on young animal models, and the changes in aged animals remain unclear. Our data showed that RIPC reduced the levels of pro-inflammatory cytokines IL-1β, IL-6 and IFN-γ in the blood, and IL-1β and IFN-γ in the brain in aged rats 48 h post-stroke (**Figure 3**), while the changes that were neutralized by the HIF inhibitor (**Figure 5**).

Several reports have identified under ischemic conditions, the activation of the Akt or EKR signaling pathway can be regulated by the expression of HIF (Hausenloy and Yellon, 2007; Cai et al., 2013; Martin-Puig et al., 2015; Meller and Simon, 2015; Ong et al., 2015). However, if HIF is directly affected by RIPC and further regulate the activity of Akt or EKR signaling pathway is unknown. Interestingly, in our study, we found that RIPC activated the Akt but not the ERK signaling pathway and that inhibition of HIF abolished the activation of Akt in aged rats following stroke (**Figure 6**). It suggested that HIF played key roles in RIPC reversed the reduced expression of p-Akt.

In the current study, there are several limitations. First, inhibitors of inflammatory cytokines and signaling pathways were not used. Thus, future studies should examine the infarct size when the inhibitors of inflammatory cytokines and signaling pathways are used; and come to a convincing conclusion the inflammatory responses and Akt/ERK signaling pathway is the cause of the reduced infarct size. Second, RIPC is an endogenous protective mechanism through which short-term sub-lethal ischemia in a remote organ can protect the major organ from further severe ischemia. However, due to the unpredictability of cerebral infarction, its clinical application is limited. Unlike ischemic preconditioning, ischemic postconditioning is a relatively novel concept, which follows reperfusion of a vessel and effectively inhibits inflammatory responses and delays cell death. So many researchers believe that ischemic postconditioning is more suitable for clinical transformation. However, to date, the evidence of cerebral ischemia postconditioning is limited to preclinical studies. Therefore, future studies will address the mechanism of remote ischemic postconditioning in the protection against cerebral ischemia, stimulate the clinical transformation of remote ischemic postconditioning.

CONCLUSION

Our study provided strong evidence that RIPC protected against stroke in aged rats by modulating the expression of HIF-1α and HIF-2α in ischemic tissue, not only affecting the activation of the Akt pathway but also reducing the expression of pro-inflammatory cytokines in the peripheral blood and brain.

DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article/**Supplementary Material**.

ETHICS STATEMENT

The animal study was reviewed and approved by Capital Medical University Animal Review Committee.

AUTHOR CONTRIBUTIONS

XG, HD, and HZ: study concept and design. XD and JY: acquisition of data and wrote the draft. CL: made the figure and statistical analysis. SW and CZ: made a model. All authors contributed to the critical revision of the manuscript and have approved the final version of this review article.

FUNDING

This study was supported by the National Natural Science Foundation of China Grant No. 81701154 and Tong Zhou District Science and Technology Project Grant Nos. KJ2019CX014-31 and KJ2019CX004-03.

ACKNOWLEDGMENTS

We thank Xuan Liu and Haiteng Ji for their long-term feeding of experimental animals.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fnagi.2020.00054/full#supplementary-material.

FIGURE S1 | Cerebral blood flow during the MCAo surgery. Cerebral blood flow was measured at four time-points, baseline, 1 and 5 min of ischemia and reperfusion in the MCAo, RIPC+MCAo and ACF+RIPC+MCAo groups. Data were normalized to baseline and expressed as percentages.

FIGURE S2 | Images of TTC staining. All the panels and representative images of TTC staining were presented. **(A)** MCAo group. **(B)** RIPC+MCAo group. **(C)** ACF+RIPC+MCAo group.

TABLE S1 | Arterial blood gas parameter before and immediately after MCAo.

TABLE S2 | Blood sugar value after surgery in each group.

With increasing distribution of endovascular stroke therapies, transient middle cerebral artery occlusion (tMCAO) in mice now more than ever depicts a relevant patient population with recanalized M1 occlusion. In this case, the desired therapeutic effect of blood flow restauration is accompanied by breakdown of the blood-brain barrier (BBB) and secondary reperfusion injury. The aim of this study was to elucidate short and intermediate-term transcriptional patterns and the involved pathways covering the different cellular players at the neurovascular unit after transient large vessel occlusion. To achieve this, male C57Bl/6J mice were treated according to an intensive post-stroke care protocol after 60 min occlusion of the middle cerebral artery or sham surgery to allow a high survival rate. After 24 h or 7 days, RNA from microvessel fragments from the ipsilateral and the contralateral hemispheres was isolated and used for mRNA sequencing. Bioinformatic analyses allowed us to depict gene expression changes at two timepoints of neurovascular post-stroke injury and regeneration. We validated our dataset by quantitative real time PCR of BBB-associated targets with well-characterized post-stroke dynamics. Hence, this study provides a well-controlled transcriptome dataset of a translationally relevant mouse model 24 h and 7 days after stroke which might help to discover future therapeutic targets in cerebral ischemia/reperfusion injury.

Keywords: stroke, blood-brain barrier, high-throughput nucleotide sequencing, matrix metalloproteinases, reperfusion injury, translational medical research

INTRODUCTION

Over the past decades, management of ischemic stroke has improved dramatically. The "penumbra" concept has given rise to pharmacological and mechanical recanalization therapies which are able to rescue ischemic brain tissue if applied early enough. Unfortunately, only a fraction of all stroke patients benefits from those therapies due to a narrow time window for optimal treatment and relevant contraindications. Additionally, after successful recanalization reperfusion-associated

brain injury occurs due to secondary impairment of the blood-brain barrier (BBB) (Choi and Pile-Spellman, 2018). Despite intensive experimental research, promising drug candidates for acute and postacute stroke treatment have failed to translate into new therapeutic strategies (O'Collins et al., 2006). Better understanding of the processes at the BBB and their temporal dynamics is critical to overcome this "translational roadblock."

Target of many of these experimental approaches is the neurovascular unit (NVU) which comprises brain capillaries as well as adjacent pericytes, astrocytes, along with their extracellular matrix (ECM) in addition to microglia and neurons (Iadecola, 2017). The specialized endothelium of those capillaries forms the BBB, a highly polarized and tightly regulated interface of the brain microvasculature and CNS tissue. The interplay of an unfenestrated network of tight junctions and specialized transporters allows a selective permeability to water and nutrients yet keeping toxins and pathogens out (Cummins, 2012; Knowland et al., 2014).

Ischemic strokes are caused by an acute occlusion of a cerebral vessel leading to oxygen and glucose deprivation in the dependent brain tissue. Due to a consecutive breakdown of the neuronal ionic balance release of glutamate and induction of glutamate-mediated pathways occurs and triggers cell death by massive calcium influx. This so-called glutamate excitotoxicity is one of the first phenomena to take place in the ischemic lesion leading to extensive cell death (Szydlowska and Tymianski, 2010). In parallel, lack of oxygen causes a failure of the respiratory chain and mitochondrial function so that pH is reduced and free radicals expand the local tissue damage (Lipton, 1999). Subsequently, a sterile inflammatory reaction going along with a hyperacute imbalance of matrix metallopeptidases (MMPs), especially MMP-9, and their endogenous counterplayers, tissue inhibitor of metallopeptidases (TIMP)-1 and -2 (Barr et al., 2010; Lenglet et al., 2014) triggers the destruction of the crucial endothelial-ECM interface of the BBB (Edwards and Bix, 2018). On the other hand, a step-wise degradation of endothelial cells in the oxygen-deprived area has been observed in the context of permanent and reperfused stroke even without disintegration of tight junction molecules (Krueger et al., 2015). Altogether, BBB function is disrupted and allows invasion of immune cells and pathogenic factors.

Unfortunately, re-establishment of blood-flow in the occluded vessel does not simply reverse those effects. MMPs stay upregulated after reperfusion and free radicals have been reported to even increase in this context as degraded lipid components serve as substrates for further production of reactive oxidative species (Bai and Lyden, 2015). In combination with a transient hyperemia which can last for hours or even days after recanalization treatment (Kidwell et al., 2001) patients are at risk for secondary vasogenic edema and hemorrhagic transformation of the infarcted area (Yang et al., 2007; Strbian et al., 2008; Sun et al., 2017). This so-called cerebral ischemia/reperfusion (I/R) injury hampers the clinical benefit of recanalization therapies and is target of experimental treatment strategies.

Previous experimental studies have shown a neuroprotective effect of acute MMP-9 inhibition in stroke (Asahi et al., 2000) whereas MMP-9 inhibition in the early recovery phase exacerbated stroke-induced brain damage (Zhao et al., 2006). Several other pathophysiological processes have shown a similar unexpected biphasic function after stroke (Ma et al., 2017; Sandvig et al., 2018). Only long-term observations of cohorts with acceptable survival rates allow to assess the full picture of post-ischemic vascular inflammation, its resolution and tissue repair.

We therefore performed a transcriptomic analysis of brain microvessels of a carefully monitored mouse population at 24 h and 7 days post transient middle cerebral artery occlusion (tMCAO) to depict an early timepoint after transient vessel occlusion, dominated by cytotoxic, protein degrading and inflammatory pathways as well as a later one, displaying first regenerative processes amid persisting immune cell infiltration and cytotoxic conditions. By this, we obtained comprehensive and unbiased insights on the complex molecular changes that occur at the BBB in the first days after cerebral I/R injury in mice.

MATERIALS AND METHODS

Animals

A total of 95 male 10–12 weeks old C57Bl/6J mice (25–30 g) were purchased from Charles River Laboratories (Sulzfeld, Germany) and housed on a 12 h/12 h light/dark cycle with *ad libitum* access to food and water. Due to fight wounds, three mice were excluded before intervention. Experiments were performed in compliance with the ARRIVE guidelines for animal research, in accordance with the German Protection of Animals Act and the guidelines for care and use of laboratory animals by the local committee (Regierungspräsidium Darmstadt, approval number FU/1143).

Transient Middle Cerebral Artery Occlusion and Post-stroke Care

The right middle cerebral artery was occluded as described previously (Pfeilschifter et al., 2012). Briefly, mice were anesthetized with 1.5% isoflurane and kept on a temperature-controlled heating mat throughout surgeries. After ligation of the right common and external carotid arteries, a standard silicone rubber-coated monofilament (6-0 medium, Doccol, Sharon, MA, United States) was advanced until the branching point of the middle cerebral artery, allowing reperfusion after 60 min. In sham controls, the filament was retracted immediately after reaching the branching point. Analgesia was achieved by i.p. injections of buprenorphine (0.1 mg/kg bodyweight) 30 min before surgery and in 8 h-intervals during the first 48 h. Mice were housed in groups of 3–5 animals and cages kept on a heating mat (Beurer, Ulm, Germany). Daily monitoring included body weight, rectal temperature and clinical signs of pain, subarachnoid hemorrhage (SAH) or brain herniation. Experimental design is summarized in **Figure 1A**. On day 1, 3, and 7 after surgery, neurological and general deficits were assessed using the Experimental Stroke Scale (ESS) established by Lourbopoulos et al. (2017). Food and water were supplied adapted to the individual animal's need according to the maximized post-stroke support protocol described there. This procedure included daily monitoring of weight and body temperature and, according to the hereby identified condition of the animals, oral feeding of 1–3 mL of dissolved food pellets

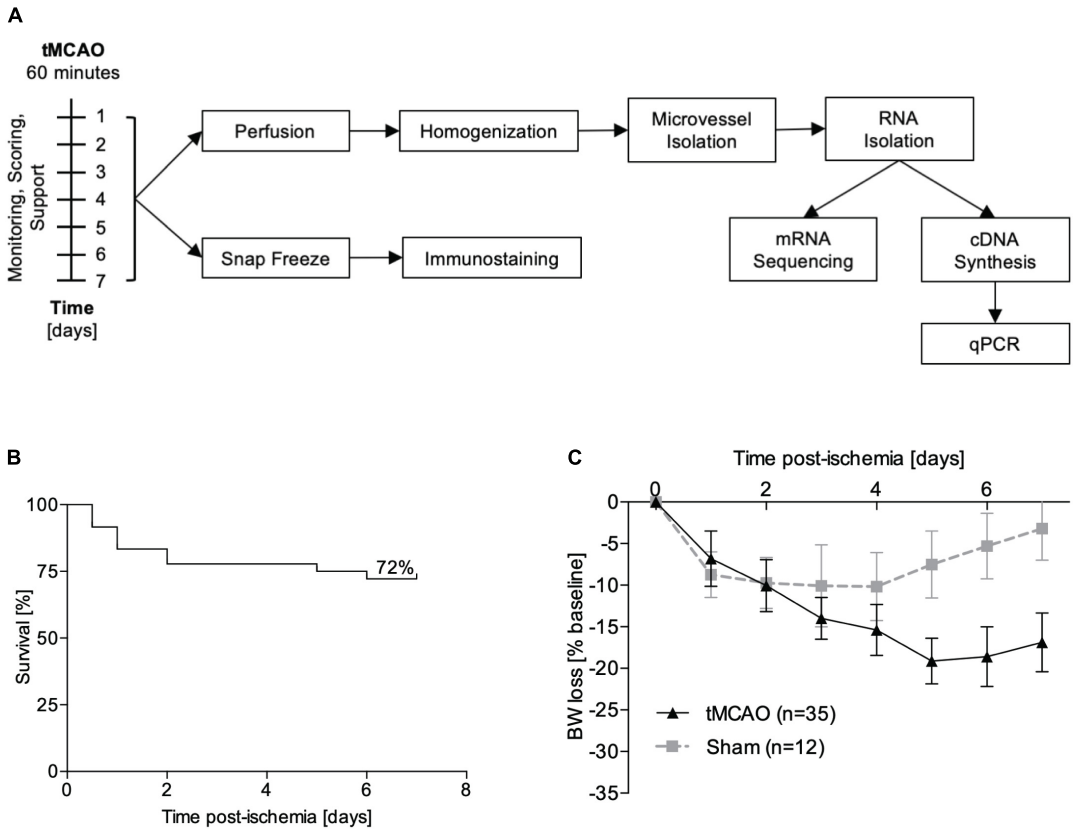

FIGURE 1 | Experimental design. **(A)** Male C57Bl/6 mice underwent tMCAO or sham surgery and were supported for either 24 h or 7 days. For RNA sequencing, perfused microvessels from the ipsi- and contralateral hemispheres were isolated and pooled (n = 3 hemibrains per sample, n = 3 samples per group). For immunofluorescence staining, brains were snap frozen and cut into 10 μm sections. **(B)** Kaplan–Meier plot for survival of animals after tMCAO (n = 35). **(C)** Weight loss after sham (gray line, n = 12) and tMCAO surgery (black line, n = 35) presented as percentage reduction from preoperative body weight ± SD.

per day. Liquids were provided by subcutaneous application of 2–4 mL warmed 0.9% saline given in two doses per day. Additionally, jelly food and food pellets were kept on the cage floor to be easily accessible for recovering individuals. Animals were sacrificed either 24 h or 7 days post-stroke. Stroke-related mortality was 12% in the 24 h- and 28% in the 7 day-cohort. Four mice were excluded from the study and calculation of stroke related mortality: three animals due to proof of artificial SAH in post-mortem autopsy and one sham-operated animal due to stroke symptoms.

Isolation of Mouse Brain Microvessels

Isolation of mouse brain microvessels (MBMVs) were isolated as indicated in **Figure 2A** using a previously described protocol (Gurnik et al., 2016). All steps were performed at 4°C or on ice. In brief, post anesthesia, mice were transcardially perfused with sterile phosphate buffered saline (PBS; Gibco, Thermo Fisher Scientific) for 10 min using a peristaltic pump (Ismatec, Cole-Parmer, Wertheim, Germany). Brains were macroscopically checked for broad cortical infarction and collected in microvessel buffer (MVB: 15 mM HEPES, 147 mM NaCl, 4 mM KCl, 3 mM $CaCl_2$, 1.2 mM MgCl2, 5 mM glucose, and 0.5% BSA, pH 7.4) on ice. Individual stroke volumes could not be quantified during the isolation process without risking loss of vital material and artificial tissue reactions. Medium stroke sizes in our surgery setup covering about 60% of the hemisphere have been reported before (Friedländer et al., 2017). To estimate stroke volumes in the present study, male C57B/6J mice were operated by RK under same conditions as the mice used for mRNA sequencing. After 24 h, mice were sacrificed, brains removed carefully from the skull and cut into 1 mm sections. Subsequently, brain slices were stained in 2% 2,3,5-Triphenyl-tetrazolium chloride (TTC) at 37°C for 5 min and imaged on a flatbed color scanner (CanoScan LiDE 100; Canon, Tokyo, Japan). The hereby obtained Photoshop images were used for semi-automatical stroke volume calculation by an ImageJ macro established by Friedländer et al. (2017). Individual results are summarized in **Supplementary Figure IV** (mean stroke volume 57.2%, median 55.6%).

After removal of the cerebellum, brain stem and olfactory lobes, meninges were peeled off by rolling the cerebrum on autoclaved Whatman filter paper (Schleicher & Schuell, München, Germany). Hemispheres were separated and pooled (from three animals). Tissue was homogenized in MVB using a Dounce homogenizer (Wheaton, 0.025 mm clearance) attached to an electrical overhead stirrer (2000 rpm, VOS 14, VWR) and centrifuged at 400 × g for 10 min. Myelin fat was separated

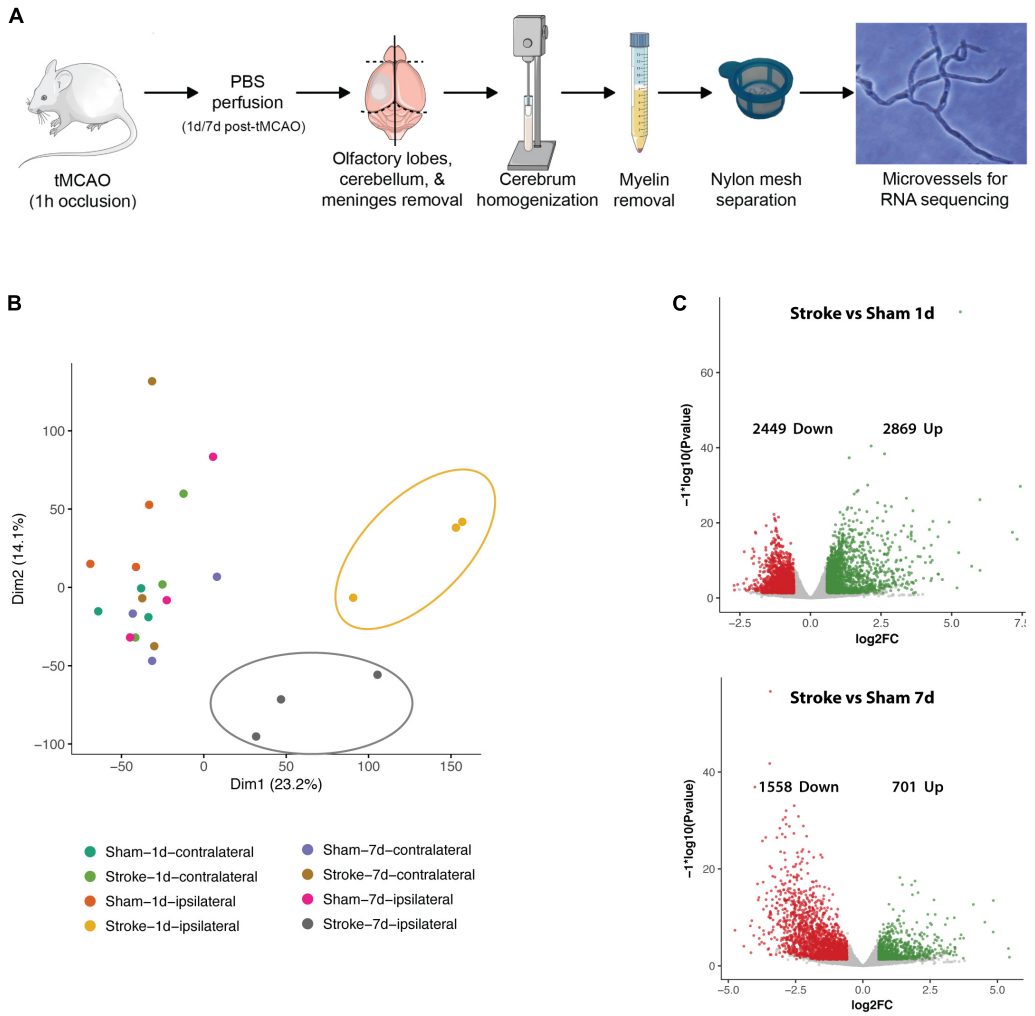

FIGURE 2 | Basic characteristics post-stroke transcriptomics in microvessels. **(A)** Microvessel isolation protocol. **(B)** PCA plot of all samples. Distinct clusters are highlighted (yellow/upper right circle: ipsilateral hemispheres 24 h after tMCAO, gray/central circle: ipsilateral hemispheres 7 days after tMCAO). **(C)** Volcano plots of regulated genes in comparison 5 (stroke ipsilateral versus sham ipsilateral 24 h) and 6 (stroke ipsilateral versus sham ipsilateral 7 days). Transcripts accepted as regulated: mean > 5 counts, $\log_2$fc <> ±0.585, FDR ≤ 0.05.

by resuspension of the pellet in 25% BSA and centrifugation at 2000 × *g* for 30 min. Subsequently, the cell pellet was resuspended in MVB and filtered through a 100 μm cell strainer (Falcon, Corning, NY, United States) to remove large vessel fragments and tissue clusters. The flow-through was filtered through a 40 μm cell strainer (Falcon, Corning, NY, United States) to be cleared from erythrocytes, dead cell nuclei and cell debris. Microvessels were harvested directly from the 40 μm mesh in RLT buffer (Qiagen, Düsseldorf, Germany) containing Dithiothreitol (DTT, 40 mM; Roche Diagnostics, Indianapolis, IN, United States) and stored at −80°C until RNA isolation. Successful isolation of microvessel fragments was verified by light microscopy assessment.

A total of 32 MBMV samples were generated and included into 8 groups (sham ipsilateral 24 h, sham contralateral 24 h, tMCAO ipsilateral 24 h, tMCAO contralateral 24 h, sham ipsilateral 7 days, sham contralateral 7 days, tMCAO ipsilateral 7 days, tMCAO contralateral 7 days). One group consisted of $n = 4$ samples each. One sample was generated by pooling three hemispheres of the same kind after brain removal and separation of ipsi- and contralateral hemispheres. Analysis identified four samples as outliers and further analysis was performed on $n = 3$ samples per group. In total, one group contains brain hemispheres of 3 × 3 = 9 animals. The work flow and experimental design is shown in **Figure 1A**.

mRNA Sequencing From MBMVs

RNA was extracted from MBMVs using Qiagen RNeasy plus Micro Kit (Qiagen, Düsseldorf, Germany) following the instructions provided by the manufacturer. RNA concentration measured by Qubit fluorometer (Thermo Fisher Scientific) did not differ significantly within the samples [mean 24 h 22.24 (ng/μL) ± SD 4.55 (ng/μL), mean 7 d 27.82 (ng/μL) ± SD 2.51 (ng/μL), mean total 25.03 (ng/μL) ± SD 9.05 (ng/μL)].

Samples were deep frozen (−80°C) and transferred to the mRNA sequencing facility at Max Planck Institute for Heart and Lung Research Bad Nauheim.

After verification of RNA quality (LabChip Gx Touch 24, Perkin Elmer), equal amounts of RNA from each sample were subjected to mRNA sequencing using a NextSeq 500 sequencer (Illumina, San Diego, CA, United States). FastQC tool (Babraham Bioinformatics, 2010) was used to verify signal quality, adaptor content and duplication rate. Adapters were removed and data trimmed; reads of a length between 30 and 150 base pairs were accepted for further analysis. Using STAR 2.4.0a, results were aligned to the murine mm10 genome (Ensembl) with maximum ratio of mismatches to mapped length set to 10%. Reads matching multiple genes or regions were excluded.

Quantitative Real Time PCR

Part of the total RNA (40 ng) from each sample was subjected to cDNA synthesis using RevertAid Reverse Transcriptase Kit (Thermo Fisher Scientific, Darmstadt, Germany). Quantitative Real Time PCR (qRT-PCR) was performed using TaqMan Gene Expression Assays in Applied Biosystems 96-well PCR plates (Thermo Fisher Scientific). Plates were sealed with Clear Seal Diamond Heat Sealing Film (Thermo Fisher Scientific) and run in an AB7500 fast system (Applied Biosystems, Thermo Fisher Scientific, Foster City, CA, United States). TaqMan probes (Thermo Fisher Scientific) were used to quantify transcripts of hypoxanthine phosphoribosyltransferase 1 (HPRT, Mm03024075_m1), matrix metalloproteinase 9 (MMP9, Mm00442991_m1) and tissue inhibitor of metalloproteinases 1 (TIMP1, Mm01341361_m1).

Immunohistochemical Staining on Cryosections

After sacrificing the animals, brains were extracted and natively frozen in Tissue TEK O.C.T. Compound (Sakura Finetek, Torrance, CA, United States) on dry ice and stored at −80°C. Coronal 10 μm sections were fixed in 4% PFA for 10 min and blocked in 10% fetal bovine serum in TBS-TritonX 0.3%. Tissue was incubated with primary antibodies (mouse-anti-mouse occludin, Invitrogen/Thermo Fisher Scientific #OC-3F10, 1:200; rat-anti-mouse CD31, BD Biosciences #BD553370, 1:200) for 2 h at room temperature followed by 1 h-incubation using fluorescence-conjugated secondary antibodies (donkey-anti-rat Alexa Fluor 488, donkey-antimouse Alexa Fluor 568, 1:400). After counter-staining for nucleic acids with 4',6-diamidino-2-phenylindole (DAPI, Sigma-Aldrich, St. Louis, MO, United States, 1:1000) sections were mounted with fluorescent mounting medium (Dako, Agilent, Santa Clara, CA, United States). Images were acquired at 40× magnification with a Nikon 80i microscope and quantified using NIS elements software (Nikon, Düsseldorf, Germany). Exposure time and LUTs settings were maintained at same values for all samples.

Statistical Methods

Reads obtained by *mRNA sequencing* were normalized and differentially analyzed using DESeq2 package version 1.14.1 (Love et al., 2014). To define genes as significantly regulated, a logarithmic fold change of at least ± 0.585, a mean value higher than 5 and p-value lower than 0.05 adjusted by Benjamini–Hochberg procedure for multiple comparisons was required.

For *qRT-PCR* validation cDNA levels were normalized to HPRT as this gene was identified as being unchanged between samples from ischemic and non-ischemic hemispheres. Differential expression was calculated by the $2^{-\Delta CT}$ method. Assuming a normally distributed population we used a t-test for separate comparison of sample pairs (sham ipsilateral 24 h versus tMCAO ipsilateral 24 h, sham ipsilateral 7 days versus tMCAO ipsilateral 7 days). A p-value below 0.05 was accepted as significant.

For *IHC* validation on cryosections we normalized occludin staining to CD31 positive vessels. To achieve this, we defined binaries for both antibodies by signal intensity in NIS elements software and measured the respective areas were measured. Afterward, the percentage of the CD31 + occludin-positive fraction from the total CD31-positive area was calculated. Separate comparison of sample pairs (core ipsilateral versus periinfarct ipsilateral 24 h, core ipsilateral versus core contralateral 24 h, core ipsilateral versus periinfarct ipsilateral 7 days, core ipsilateral versus core contralateral 7 days), was performed by t-test. A p-value below 0.05 was accepted as significant.

RESULTS

Establishment of the Post-stroke Care Protocol

Using the post-stroke care protocol of Lourbopoulos et al. (2017) that we established in our facility, we achieved similar survival rates in the tMCAO model as previously reported. With optimized monitoring and feeding support, the mortality at 7 days post-stroke was reduced to 28% (**Figure 1B**) from an expected mortality of at least 59%. The weight loss curve reached the nadir at day 3 for sham operated mice and at day 5 for animals which underwent tMCAO. From day 6 onward, weight either stabilized or started to recover (**Figure 1C**).

Expression Dynamics After Cerebral I/R Injury

Of a total of 141,136 reads in protein coding sequences 12,690 show significant regulation in altogether 7 comparisons (1: stroke ipsi- versus contralateral 24 h, 2: stroke ipsi- versus contralateral 7 days, 3: sham ipsi- versus contralateral 24 h, 4: sham ipsi- versus contralateral 7 days, 5: stroke ipsilateral versus sham ipsilateral 24 h, 6: stroke ipsilateral versus sham ipsilateral 7 days, and 7: stroke ipsilateral 24 h versus 7 days). Principal component analysis (PCA) revealed that all control samples (contralateral hemispheres of mice 24 h and 7 days post-stroke as well as both hemispheres of sham operated animals) cluster together. As no major differences were seen between the different controls we decided to continue analysis on comparisons 5–7. Heatmaps and pathway analyses of comparisons 1 and 2 can be seen

in **Supplementary Figure I**. The ipsilateral hemispheres 24 h post-stroke form a distinctive cluster farthest from the controls. Ipsilateral hemispheres 7 days post-stroke cluster between the acutely ischemic tissue and the controls indicating post-stroke recovery (**Figure 2B**). Volcano plots (significance versus fold-change) show 2869 up- and 2449 downregulated genes in the ipsilateral hemisphere of tMCAO- compared to sham-operated animals 24 h post-surgery and 701 genes up- and 1558 downregulated 7 days post-surgery (**Figure 2C**).

Figure 3 shows top 25 up- and downregulated genes at 24 h and 7 days post-stroke and their bioinformatic pathway analyses using KOBAS (Xie et al., 2011). Several genes belonging to the ECM-receptor interaction such as TIMP1 and cell adhesion molecules are dysregulated at 24 h post-stroke indicating an acute BBB breakdown. Metabolic and inflammatory pathways are highly regulated indicating the ischemic injury and the ensuing immune response (**Figure 3A**). At day 7, cell adhesion molecules and ECM-receptor interaction pathways are still dysregulated compared to sham control indicating BBB impairment also in the postacute phase.

Quantitative Validation of Transcriptional Changes in Proteinases

As a measure of representativeness of the observed dynamics, we aimed to validate the well characterized post-ischemic changes in the MMP/TIMP system. MMP9 expression is dramatically increased after 24 h and still significantly upregulated after 7 days when compared to sham animals. qPCR measurements confirmed the acute overshoot of MMP9 (**Figure 4A**). Similarly, for TIMP1 a massive increase could be detected by RNA sequencing and reproduced by qPCR validation (**Figure 4B**).

Changes in MMP/TIMP expression are paralleled by breakdown of tight junction markers. By immunohistochemical staining (IHC), occludin signal was reduced at both time points within the stroke region in comparison to CD31 staining reaching significance on 7 days post-stroke. Representative images of the stroke core and corresponding area in the contralateral hemisphere as well as quantification of occludin staining fraction of CD31 positive vessels are shown in **Supplementary Figure II**.

Expression Dynamics in the Early Regeneration Phase Post-stroke

In order to characterize the intermediate-term expression dynamics post-stroke, we compared the gene expression pattern relative to sham controls at 24 h post-stroke with that of 7 days post-stroke. We defined four groups, namely resolved, induced, unresolved, and biphasic for further analyses as shown in the Venn diagrams of **Figure 5A**. Genes that are regulated at 24 h but not anymore at 7 days post-stroke belong to the resolved group (771 genes). Genes that are not regulated at 24 h but only at 7 days post-stroke belong to the induced group (131 genes). Genes that are upregulated at both time points (201 genes) along with genes that are downregulated at both time points (796 genes) belong to the unresolved group (201 + 796 = 997 genes). Finally, genes that are upregulated at 24 h but downregulated at 7 days (26 genes) and vice-versa (51 genes) are categorized into the biphasic group (26 + 51 = 77 genes).

Top 25 regulated genes in each direction for all the groups are summarized by heatmaps (**Figure 5B**). Top 20 pathways identified by gene set enrichment analysis (KOBAS KEGG) are shown in **Figure 5C** for all the groups. Several transcripts belonging to metabolic pathways such as PINK1 are resolved at day 7. This is accompanied by induction of pathways of angiogenic/ECM-remodeling (e.g., HIF-1- and proteoglycan-associated pathways) and inflammation at day 7 including genes of innate immunity (e.g., SAMHD1). However, some genes are unresolved by 7 days post-stroke comprising primarily cell adhesion and ECM-endothelial interaction molecules such as ITGB2, ITGA5 indicating persistent disruption of the BBB but also glutamatergic pathways as a hint for ongoing cytotoxicity.

The biphasic group represents genes that are counter-regulated by 7 days compared to 24 h post-stroke potentially in a compensatory manner for neurovascular regeneration. Wnt signaling is one of the major pathways regulated in such a biphasic manner at the NVU (**Figure 5C**). Wnt family members 5A (WNT5a) and 11 (WNT11) are significantly decreased 24 h and strongly induced 7 days after tMCAO. This is paralleled by induction of transcription factor SRY-Box 17 (SOX17) on day 7. Transcripts of LDL receptor related proteins 5 (LRP5) and 6 (LRP 6) which represent direct actors in the Wnt/β-catenin signaling cascade are acutely reduced (**Supplementary Figure III**).

DISCUSSION

The struggle for translation from bench to bedside in preclinical stroke research was paralleled by significant clinical advances that occurred rather independently. To date, patients benefit from effective recanalization therapies (Berkhemer et al., 2015; Lees et al., 2016) and the stroke unit concept which includes close monitoring, treatment of complications and rehabilitation (Indredavik et al., 1991; Stroke Unit Trialists' Collaboration, 2013). Those innovations have changed stroke patients' populations and needs while post-stroke care for mice has not been adapted accordingly.

Brain reperfusion injury after vessel occlusion and recanalization is best modeled by tMCAO but should go along with understanding and careful consideration of surgery-associated side effects. In a recent study, Lourbopoulos et al. (2017) set out to overcome technical confounders and mortality bias of this model by establishing a stroke unit-like post-stroke care protocol. They achieved a relevant increase in survival rates making this model now practicable for long-term observations. From our point of view, this is a fine example of translation from the clinic to the laboratory to make experimental models more reliable which may in turn facilitate translation from the laboratory to the clinic.

Since we are interested in time-dependent transcriptome changes at the NVU to identify potential therapeutic targets beyond the narrow time window of current recanalization-focused interventions, we chose this model to obtain a translationally relevant sample. The recorded transcriptomic

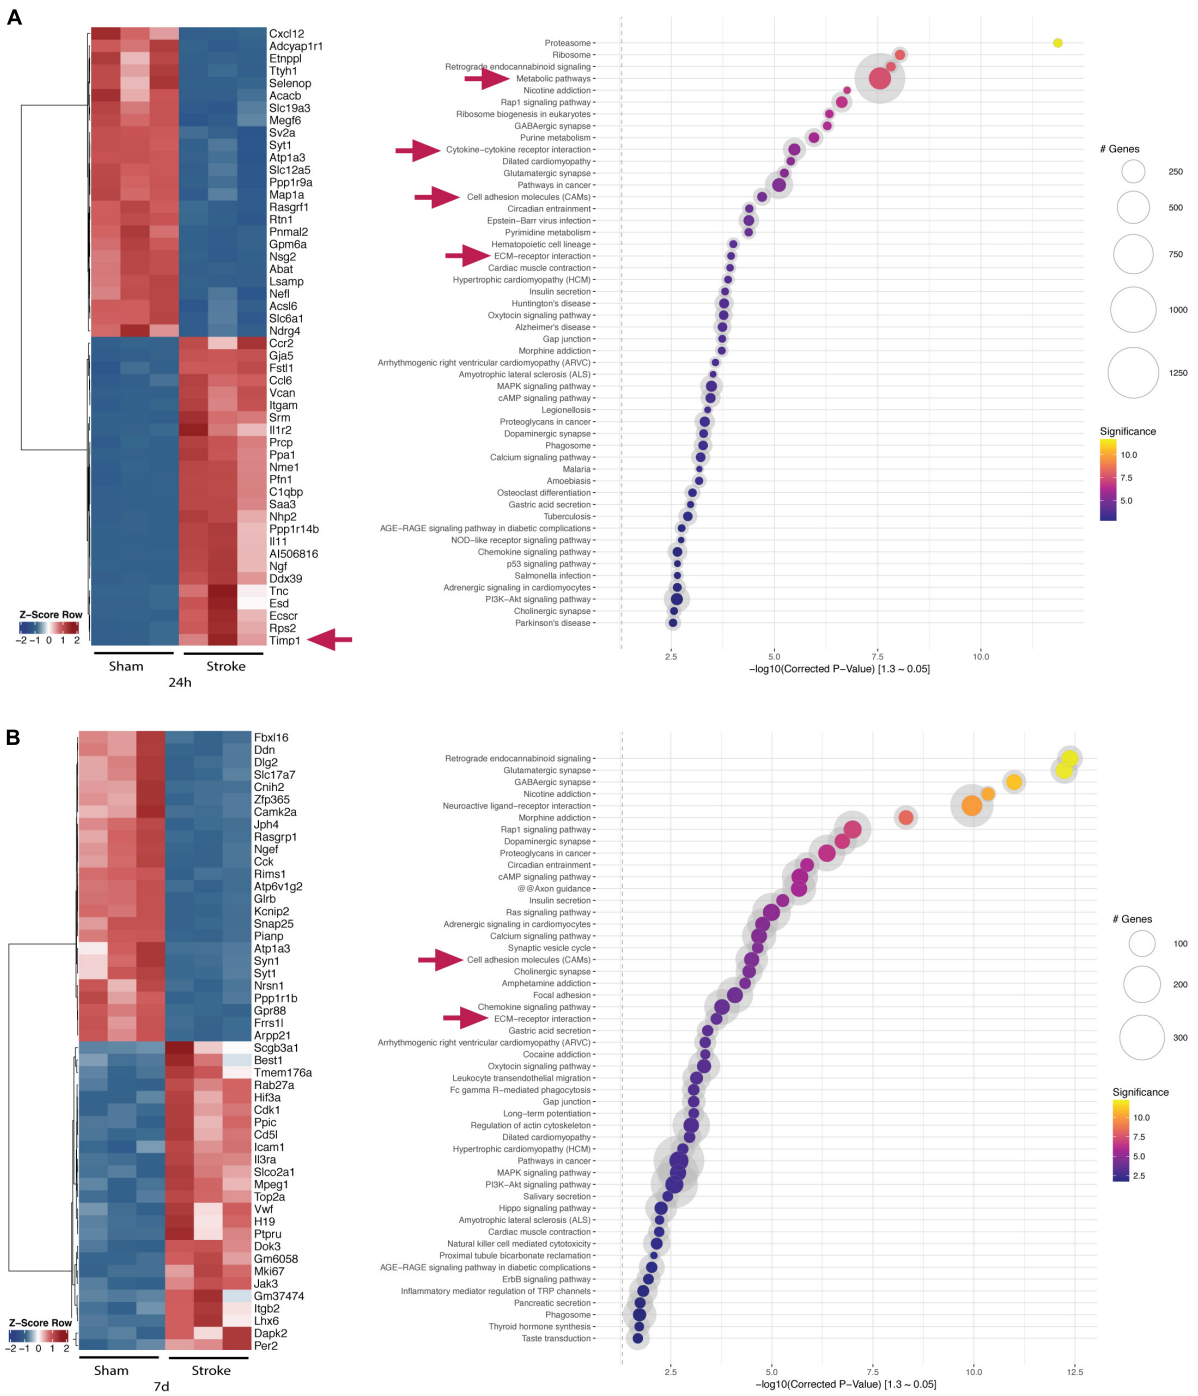

FIGURE 3 | Top-regulated genes and pathways in the acute and postacute stage post-stroke after DESEQ2 normalization. **(A)** *Z*-score of top 25 up- and top 25 downregulated genes in the ipsilateral hemisphere of tMCAO- versus sham-operated animals 24 h post-surgery and gene set enrichment within the identified genes. **(B)** Z-score of top 25 up- and top 25 downregulated genes in the ipsilateral hemisphere of tMCAO- versus sham-operated animals 7 days post-surgery and gene set enrichment within the identified genes. dynamics representatively reflect inflammatory response at the brain microvasculature at an early and a late timepoint, its imbalance of cell adhesion and matrix components, the associated messengers and enzymes and the take-over by regenerative processes. PCA revealed that most dramatic transcriptomic changes occur at 24 h after stroke and already

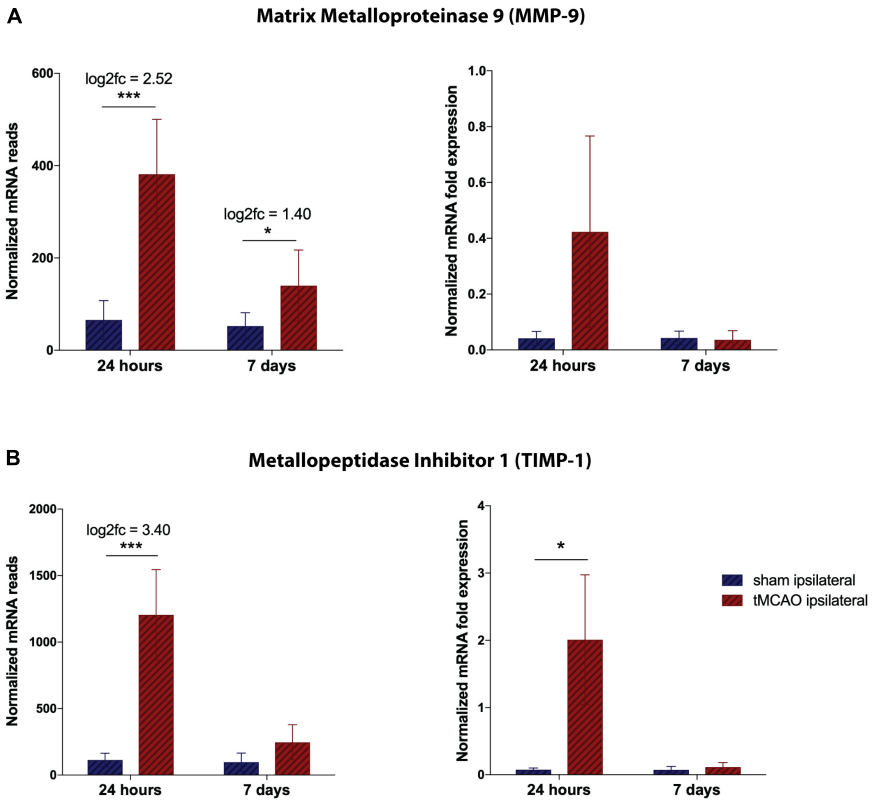

FIGURE 4 | Validation of RNA sequencing dataset by qRT-PCR for proteinases at the NVU. **(A)** Total mRNA reads for TIMP-1 and MMP-9, normalized by DESEQ2. begin to resolve after 1 week. As acute I/R injury-associated breakdown of the BBB, leading to enhanced vascular edema and risk of hemorrhagic transformation gained increasing importance in the light of current stroke treatment, the focus of our study was on the brain microvasculature. Targeting the cellular and extracellular interplay within this compartment might help to overcome present therapeutic limitations (Gurnik et al., 2016; Manley et al., 2000). Exemplarily and as a validation of our dataset, we analyzed MMP-9 and TIMP-1 by quantitative PCR and could confirm the previously observed dramatic imbalance of MMPs and their inhibitors (Lenglet et al., 2014) in our samples.

In order to identify central regulatory pathways that emerge within the first week post-stroke at the BBB, we compared the gene expression patterns at 24 h and 7 days. Gene expression and bioinformatic pathway analyses indicate resolution of several pathways including metabolic and apoptotic signaling cascades by 7 days while – rather surprisingly – glutamatergic pathways remain unresolved (indicated by KEGG pathway terms "glutamatergic synapse" but also "nicotine addiction" and "morphine addiction") (Kegg Pathway Maps, 2020). Late induction of PINK1, a mitophagy regulator to clear damaged mitochondria, indicates potential resolution of mitochondrial dysfunction and repair of I/R injury as shown previously in cardiac and renal ischemia (Siddall et al., 2013; Tang et al., 2018). The role of mitophagy in ischemic stroke is however not fully understood (Guan et al., 2018).

Furthermore, induction of HIF-1- and proteoglycan-associated pathways at 7 days indicate angiogenic remodeling. Mutations in SAMHD1, a dNTPase known to be important for innate immunity, have been shown to lead to cerebral vasculopathy and early onset stroke (Xin et al., 2011). Along this line, our dataset shows an induction of SAMHD1 in the postacute phase suggesting a potential role for SAMHD1 in post-stroke vascular repair and regeneration. However, several genes are unresolved 7 days after tMCAO especially cell-adhesion molecules such as integrins ITGB2 and ITGA5 as reported previously to be dysregulated in the acute phase (Edwards and Bix, 2018). Previous studies support the therapeutic significance of this group for integrin-based therapeutics (Ley et al., 2016).

A unique feature achieved by intermediate-term observation after stroke is the identification of biphasically regulated genes which might otherwise be misinterpreted. These genes are regulated in one direction at 24 h and in the opposite direction at 7 days post-stroke and potentially represent compensatory mechanisms essential for post-stroke recovery. As an intriguing example, actors of the Wnt signaling cascade, namely WNT5a, WNT11 and – as a downstream target of canonical Wnt

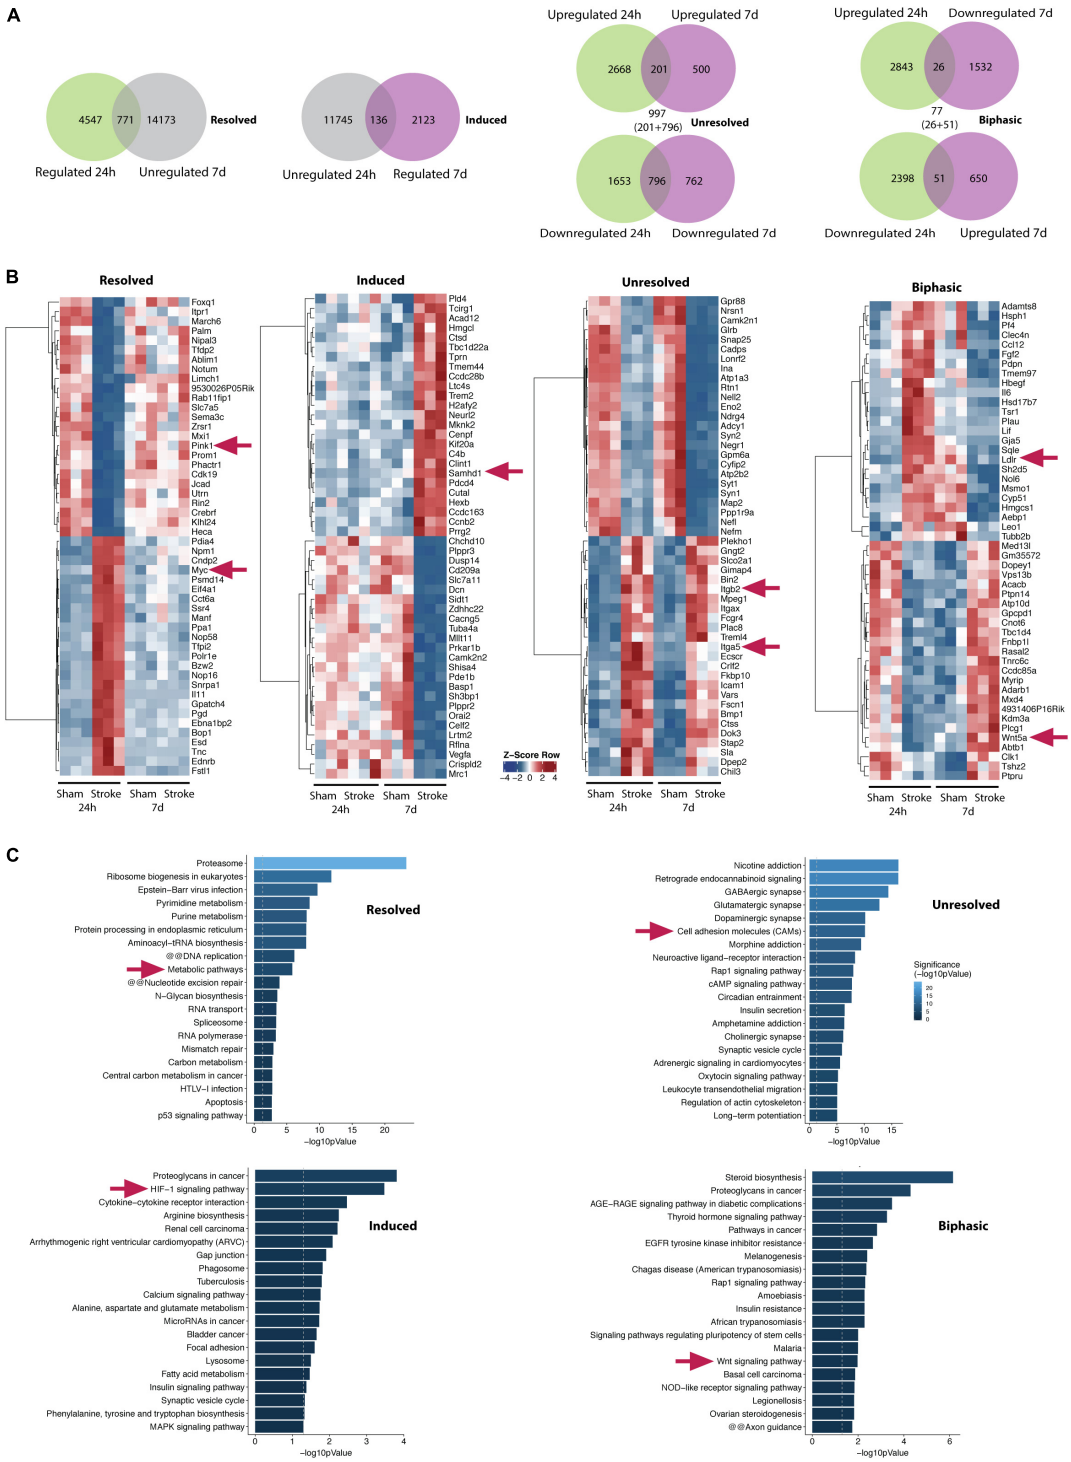

FIGURE 5 | Transcriptomic dynamics at the NVU within one week after stroke. **(A)** Venn diagrams show numbers of genes which are regulated 24 h (first from left, green/left circle) and genes which are not regulated 7 days post-stroke in the ipsilateral hemisphere (first from left, gray/right circle). A total of 771 genes belonging to both groups are defined as resolved (first from left, overlap). A total of 136 genes (second from left, overlap) which are regulated 7 days (second from left, violet/right circle) and not regulated 24 h post-stroke (second from left, gray/left circle) are defined as induced. A total of 997 genes (second from right, sum of overlapping genes) which are either up- or downregulated at both time points are defined as unresolved. A total of 77 genes (first from right, sum of overlapping genes) which are oppositely regulated at both time points are defined as biphasic. **(B)** *Z*-score of top 25 up- and top 25 downregulated genes of induced, resolved and unresolved genes. For biphasic genes top 25 toward each direction are shown (first half: upregulated 24 h and downregulated 7 days post-stroke, second half: downregulated 24 h and upregulated 7 days post-stroke). **(C)** Corresponding bar graphs summarize gene set enrichment within the identified genes. Exemplary genes and gene sets are highlighted (arrows).

signaling – SOX17 show such an expression pattern. While these factors and their direct responders LRP5 and LRP6 are significantly reduced in the acute phase, they show an induction 7 days after tMCAO. This finding is of special interest as Wnt/β-catenin signaling has recently been shown to conduct its crucial role in brain angiogenesis and BBB formation at the NVU (Liebner et al., 2008; Reis et al., 2012) potentially via SOX17 induction (Corada et al., 2018). Furthermore, pharmacological induction of β-Catenin by CHIR99021 was able to reactivate matured cardiomyocytes and therefore suggested as a future approach for regeneration after myocardial infarction (Fan et al., 2018). The same compound has been reported to suppress MMP9 release from macrophages *in vitro* (Kim et al., 2015) which also implies a potential use in BBB protection after cerebral I/R injury. Our current results might help in designing future *in vivo* assessment of this approach according to the biphasic regulation of the Wnt signaling cascade.

Previous RNA sequencing approaches after cerebral I/R injury used either the complete tissue of the affected hemisphere or focused on a specific cell type. Recently, a genome-wide analysis of brain tissue of rats 4.5 and 24 h post tMCAO depicted the acute and hyperacute transcriptional changes within the subcortex of the stroke hemisphere (Dergunova et al., 2018). They identified transcription factors, cytokines and hormones as being regulated already within the first hours after stroke onset and a shift within the expressed cytokine classes until 24 h post-stroke. KEGG pathway analysis showed some common regulations with our dataset e.g., in calcium signaling, MAPK signaling, and ECM-receptor interaction. Interestingly, oxytocine signaling was found to be regulated already at 4.5 h post-stroke which our analysis of microvessels after tMCAO in mice revealed to be unresolved over the first 7 days (**Figure 5C**). In another study by Duan et al. (2019) the affected hemisphere of rats was isolated 4 days after tMCAO and used to identify long non-coding (lnc)RNA transcripts as potential regulators of apoptosis-associated gene expression. They suggest important lncRNA to be co-expressed in KEGG pathway analysis with calcium signaling, TNF and EBV signaling which mainly comprises pro-inflammatory cytokines as well as PI3K-Akt signaling. Our dataset adds the prolonged scope of transcription dynamics with an explicit focus on the NVU including all its cellular compartments which is why in our study BBB-associated gene transcripts are much more prominent than in the aforementioned works.

Isolating microvessel fragments allows us to picture the dynamics in most components of the NVU (mainly endothelial cells, but to a lesser extent also pericytes, astrocytic endfeet, adjacent microglia and neurons). But it also goes along with certain limitations as it does not allow to pinpoint the specific cellular source of the observed changes. To keep contamination by peripheral blood cells to a minimum, all mice underwent thorough transcardial perfusion before brain isolation. Nevertheless, some immune cells might have been trapped in the microvasculature. From our point of view, this is not necessarily a weakness as immune cells play a crucial role in the vascular pathophysiology after I/R injury and contribute to the transcriptional pattern including cytokine-cytokine receptor interactions and expression of cell adhesion molecules. The contralateral hemispheres of the affected mice and both hemispheres of sham operated animals separately served as controls for stroke-associated changes.

Due to the hereby-caused complexity of the dataset our study is limited to a standard ischemia duration of 60 min and two investigated timepoints. Future studies are needed to investigate (a) shorter occlusion times to capture processes in primarily subcortical/minor strokes, (b) permanent filament insertion to assess differential dynamics between cerebral ischemia with and without reperfusion injury, (c) earlier (e.g., 72 h post-stroke, focusing on first- versus second-line inflammatory reaction) and later timepoints (e.g., 1 month after stroke to assess chronic repair processes), and (d) gene expression data from complete hemispheric tissue in relation to data specifically derived from microvessels of the ischemic hemisphere. Another limitation of our approach is that we isolated microvessels from the whole hemispheres as otherwise the material yield would have been too low for representative mRNA sequencing analysis. Therefore, it has to be kept in mind that our results stem from infarcted, peri-infarct and partly from intact brain regions. By this, genes of interest have to be validated subsequently on the spatial level. Exemplarily, we chose immunofluorescence staining to assess the differential expression of occludin in ischemic and non-ischemic vasculature. We found that within the infarct area, occludin expression was still significantly downregulated after 7 days while staining was normalized in the periinfarct cortex at this time point, in accordance with previous reports (Sun et al., 2017).

CONCLUSION

In summary, we provide a well-controlled transcriptome dataset of a translationally relevant mouse cohort after tMCAO. Keeping the above-mentioned limitations in mind, this dataset may help to identify future therapeutic targets in post-stroke inflammation and repair processes including acute BBB alterations, glial scar formation, angiogenesis and neuroregeneration.

DATA AVAILABILITY STATEMENT

The authors declare that all supporting data are available within the article and **Supplementary Material**. The RNA sequencing dataset has been uploaded to GEO (record GSE131193).

ETHICS STATEMENT

The animal study was reviewed and approved by the Regierungspräsidium Darmstadt.

AUTHOR CONTRIBUTIONS

RB, WP, and KD conceived of the presented idea and developed the experimental design together with R-IK. R-IK carried out the surgeries, post-stroke survival care, microvessel and mRNA isolation under support of RV, LH, and KD. SG performed the

mRNA sequencing and supplied the respective graphs upon joined the data analysis with R-IK, FM, KD, WP, and RB. R-IK and FM were carried out the staining and qPCR validation. R-IK, WP, and KD prepared the manuscript.

FUNDING

R-IK, RB, and WP received funding from the Fondation Leducq (SphingoNet) and the German Research Foundation (SFB 1039/TP B08). R-IK was supported by a stipend from the Medical Faculty of Goethe University ("Patenschaftsmodell").

ACKNOWLEDGMENTS

We would like to acknowledge Ricardo Mamede Figueiredo and Elif Fidan for their support in data analysis.

Brain microvasculature forms a specialized structure, the blood-brain barrier (BBB), to maintain homeostasis and integrity of the central nervous system (CNS). The BBB dysfunction is emerging as a critical contributor to multiple neurological disorders, including stroke, traumatic brain injury, autoimmune multiple sclerosis, and neurodegenerative diseases. The brain microvasculature exhibits highly cellular and regional heterogeneity to accommodate dynamic changes of microenvironment during homeostasis and diseases. Thus, investigating the underlying mechanisms that contribute to molecular or cellular changes of the BBB is a significant challenge. Here, we describe an optimized protocol to purify microvessels from the mouse cerebral cortex using mechanical homogenization and density-gradient centrifugation, while maintaining the structural integrity and functional activity of the BBB. We show that the isolated microvessel fragments consist of BBB cell populations, including endothelial cells, astrocyte end-feet, pericytes, as well as tight junction proteins that seal endothelial cells. Furthermore, we describe the procedures to generate single-cell suspensions from isolated microvessel fragments. We demonstrate that cells in the single-cell suspensions are highly viable and suitable for single-cell RNA-sequencing analysis. This protocol does not require transgenic mice and cell sorting equipment to isolate fluorescence-labeled endothelial cells. The optimized procedures can be applied to different disease models to generate viable cells for single-cell analysis to uncover transcriptional or epigenetic landscapes of BBB component cells.

INTRODUCTION

The brain vasculature is a complex system composed of endothelial cells, pericytes, astrocytes, smooth muscle cells, and extracellular matrix components, forming the unique blood-brain barrier (BBB), which lies at the interface between circulating blood and the neural tissue (Abbott and Friedman, 2012; Obermeier et al., 2013). The BBB tightly regulates the transport of ions and nutrients necessary for neuronal health and function. It also prevents harmful substances or cells

from entering into the central nervous system (CNS). Previous literature suggests that the BBB disruption can lead to neuronal injury mediated through peripheral immune cells or harmful agents that enter into the CNS in multiple neurological disorders, such as Alzheimer's disease (AD; Sweeney et al., 2018; Nation et al., 2019), ischemic stroke (Kassner and Merali, 2015), multiple sclerosis (Ortiz et al., 2014), and traumatic brain injury (Alluri et al., 2015). Despite the importance of BBB highlighted in many neurological disorders, the molecular and cellular mechanisms that lead to BBB dysfunction or disruption in these disease conditions remain largely unknown. Therefore, it is vital to develop a method to isolate brain microvasculature with preserved structural integrity to identify subtle aberrations of the BBB in disease animal models. Here, we describe an optimized protocol that would allow isolating brain microvessels that closely resemble *in vivo* structures suitable for downstream applications of molecular and single-cell analyses to characterize molecular signatures of BBB component cells.

MATERIALS AND EQUIPMENTS

Animals

C57BL/6 and *db*/*db* mice were purchased from the Jackson Laboratory and bred at the animal facility of Indiana University School of Medicine. Mice were housed and maintained at 25°C under a 12 h light/ 12 h dark cycle with ad libitum access to food and water. Adult female mice aged 12–16 weeks or 9 months were used for the present study. All animal procedures in this study were conducted following the National Institutes of Health (NIH) Guide for the Care and Use of Laboratory Animals and approved by Purdue Animal Care and Use Committee.

Reagents

(1) Sigma–Aldrich Potassium Chloride (SKU: P9541-500G)
(2) Baker Analyzed® Potassium Phosphate Monobasic, Crystal (CAS: 7778-77-0)
(3) Fisher Sodium Chloride (CAS: 7647-14-5)
(4) Fisher Sodium Phosphate Dibasic Anhydrous (CAS: 7558-79-4)
(5) Fisher Calcium Chloride Dihydrate (CAS: 10035-04-8)
(6) Fisher Magnesium Chloride (CAS: 7791-18-6)
(7) Sigma Aldrich D-(+)-glucose (SKU: G8270-100G)
(8) Sigma–Aldrich Sodium Pyruvate (Product number: P2256)
(9) Thermo Fisher Scientific GE Healthcare Ficoll PM400 (Catalog number: 45-001-745)
(10) Elko Filtering Co 30 micron nylon mesh (Catalog number: NC0478162)
(11) Sefar, 03-100/32, Nylon Mesh Filtering Screen 100 Micron—Open Area %: 32— Width: 38 in, Natural Color (1 Yard; Part number: 3A03-0100-098-00)
(12) Alkali Scientific Inc. 100 micron strainer (Catalog number: TS100)
(13) Thermo Fisher Scientific Sartorius™ glass beads (0.4 mm–0.6 mm; Catalog number: BBI-8541701)
(14) Sigma–Aldrich Bovine Serum Albumin (BSA; Catalog number: A2153)
(15) Sigma–Aldrich Collagenase (Catalog number: C5138)
(16) Sigma–Aldrich DNase I (Catalog number: DN25)
(17) BioLegend APC/Cy7 anti-mouse CD45 (clone: 30-F11)
(18) BioLegend Alexa Fluor 488 anti-mouse CD31 (clone: MEC13.3)
(19) BioLegend 7-AAD Viability Staining
(20) Miltenyi Biotec APC anti-mouse ACSA2 (clone: IH3-18A3)
(21) Miltenyi Biotec FcR blocking reagent—mouse
(22) BioLegend anti-mouse CD140b (clone: APB5)
(23) BD Bioscience anti-mouse CD31 (clone: MEC13.3)
(24) Sigma–Aldrich Rabbit anti-Aqp4 (Catalog number: HPA014784)
(25) Thermo Fisher Scientific Rabbit anti-ZO-1 (Catalog number: 61-7300)
(26) Proteintech Rabbit anti-Occludin (Catalog number: 13409-1-AP)
(27) BD Bioscience Mouse anti-actin (Catalog number: 612656)
(28) Sigma–Aldrich Phosphate Buffered Saline with 10% Bovine Albumin (BSA; Catalog number: SRE0036)
(29) Anaspec HiLyte™ Fluor 488 labeled human amyloid beta-peptide 1–42 (Catalog number: AS-60479-01)
(30) Sigma–Aldrich PSC833 (Catalog number: SML0572)

Isolation Equipment

(1) Milwaukee $\frac{1}{2}$ in (13 mm) drill (Catalog number: 0299-20)
(2) Wheaton Dounce homogenizer—7 ml (Catalog number: 3432T40)
(3) Staco Energy Products Variable Autotransformer (Model: 3PN1010B)
(4) Beckman Coulter Avanti J-E centrifuge
(5) Beckman JA-20 rotor (20,000 rpm)
(6) Fotodyne Stovall The Belly Dancer Hybridization Water Bath (SKU: 7121211)
(7) Eppendorf 5810 R Centrifuge

Analysis Equipment and Software

(1) BD FACSVerse™
(2) Olympus FV10i confocal microscope
(3) Olympus DP72 light microscope
(4) Applied Biosystems StepOne Plus real-time PCR system
(5) NIH ImageJ software
(6) Prism 8

STEP-BY-STEP PROCEDURES

Day Before Experiment

(1) Prepare modified phosphate-buffered saline (PBS, 2.7 mmol/L KCl, 1.5 mmol/L KH_2PO_4, 136.8 mmol/L NaCl, 4.3 mmol/L Na_2HPO_4, 0.7 mmol/L $CaCl_2$, 0.5 mmol/L $MgCl_2$, pH 7.4). The volume of 500 ml modified PBS would be used for 3–5 mice.
(2) Prepare 8 ml of 40% Ficoll solution in modified PBS per group.
(3) Store both the modified PBS and the 40% Ficoll in 4°C.

Day of Experiment

(1) Add D-glucose (5 mmol/L) and sodium pyruvate (1 mmol/L) to the modified PBS.

(2) Prepare 1% BSA in modified PBS.
(3) Place all buffers on ice and pre-cool all tools and centrifuges.

Brain Microvessel Fragments for Molecular Assays

(1) Anesthetize mice using isoflurane. When the animals are asleep, sterilize the animals with 70% ethanol, and decapitate the animals. Extract brains as described in **Figure 2** and transfer brains to a Petri dish containing ice-cold modified PBS. Carefully remove the thin slices of subdural meninges (SDM) on the dorsal surface of the brain. Use the dissecting microscope to validate the removal of SDM quickly. Keep the brain on ice.
(2) Using the brain matrix, remove olfactory bulbs and cerebellum. Cut the brain in half horizontally. Using Needle blade, separate the cortex from the corpus callosum. Place cortices in a glass tube containing 7 ml ice-cold modified PBS.
(3) In a 4°C cold room, homogenize cortices for 35 strokes using an electrical drill (Milwaukee drill connected to the Staco Energy Products Autotransformer)
    (a) Speed for the first 20 strokes: 18
    (b) Speed for the last 15 strokes: 20
    (c) Transfer homogenates to Dounce homogenizer and homogenize manually for additional 10 strokes.
(4) Mix brain homogenate with an equal volume of 40% Ficoll solution to a final concentration of 20% Ficoll PM 400. Shake tubes before centrifuge.
(5) The homogenate will be spun at 5,800× *g*, 4°C for 20 min.
(6) Discard supernatant and vacuum the myelin layer at the top.
(7) The pellet containing enriched microvessels can then be used for molecular assays such as RNA extraction or Western blot analysis. Add the appropriate volume of Trizol or RIPA buffer to the pellet and re-suspend it gently for downstream analyses.

Purification of Brain Capillaries for Imaging/Functional Assays

(1) In a 4°C cold room, take the pellet containing enriched microvessels from the previous step and re-suspend it into 1 ml of 1% BSA/modified PBS.
(2) Filter the solution with 300 μm nylon mesh and wash the mesh with 10 ml of 1% BSA/modified PBS and save the flow-through.
(3) Filter the flow through with 30 μm strainer very slowly by using a 7 ml transfer pipet. The speed of the droplet is 1 drop every 2 s. Capillaries will be captured on top of the strainer.
(4) Carefully invert the 30 μm strainer and wash with 10 ml of 1% BSA/modified PBS.
(5) Prepare an enrichment column in a 4°C room and add a volume of 15 ml glass beads to a 30 ml syringe supported by a 30 μm nylon mesh.
(6) Rinse the column with 10 ml of 1% BSA/modified PBS before adding the capillary solution.
(7) Transfer the capillary solution into the syringe by using a 7 ml transfer pipet.
(8) Gently agitate the beads, but do not touch the bottom 5 ml of beads.
(9) Adjust the flow rate so that the speed of the droplet is 1 drop per every 2 s.
(10) Rinse with 10 ml of 1% BSA/modified PBS one time, gently agitating the beads after adding the buffer.
(11) Rinse with 10 ml of BSA-free PBS twice, gently agitating the beads after adding the buffer.
(12) Brain capillaries will be bound by the glass beads. Collect capillaries by pouring the beads into a sterile glass beaker.
(13) Add 50 ml of BSA-free modified PBS and gently agitate by aspirating the beads with a 25 ml serological pipet.
(14) Filter the solution into a clean 50 ml Falcon tube supported by a 100 μm strainer to capture the glass beads.
(15) Repeat the wash step of glass beads one time with an additional 50 ml of BSA-free modified PBS and filter the solution into another clean 50 ml Falcon tube.
(16) Centrifuge 50 ml Falcon tubes at 1,100 rpm, 4°C for 5 min. At the end of the centrifugation, remove supernatant and combine the pellets into one tube.
(17) Wash the pellet with 50 ml BSA-free modified PBS for an additional two times.
(18) Re-suspend the pellet in 250 μl 1% BSA/modified PBS. The enriched capillaries can be examined by light microscopy.
(19) For imaging, load 20 μl of re-suspended capillaries on a glass coverslip, spreading in a Z-shaped manner gently.
(20) Let the capillaries attach to the glass coverslip at room temperature for 30 min.
(21) Wash with 1 ml of 1% BSA/modified PBS. After wash, the capillaries can be fixed with 2% paraformaldehyde and subjected to immunostaining analyses.

Generation of Single-Cell Suspensions of Brain Microvessels

(1) After the glass bead purification step, the capillary pellet can be used to generate single-cell suspensions. Re-suspend the enriched capillary pellet in 2 ml of 1× $HBSS^{-/-}$ buffer and transfer to a new 50 ml Falcon tube.
(2) Add 0.5 mg/ml collagenase, and incubate the solution in a water bath set to 37°C with gentle shaking for 15 min. Swirl the tube gently every 5 min.
(3) At the end of the incubation period, add 2 μg/ml DNase, and gently pipet up and down with a 1 ml wide-bore tip until aggregate is dissociated.
(4) Incubate the mixture in the hybridization water bath at 37°C for 5 min.
(5) At the end of the incubation period, immediately add 13 ml pre-warmed RPMI-164 media with 10% fetal bovine serum to quench the enzyme activity.
(6) Pass a total of 15 ml of the mixture through a 70 μm strainer and transfer to a new 50 ml Falcon tube. Centrifuge mixture at 1,100 rpm, 4°C for 5 min.
(7) Remove the supernatant carefully using a pipette and re-suspend the cell pellet with ice-cold buffer. Pass cell suspensions through a 40 μm FLOWMI strainer.

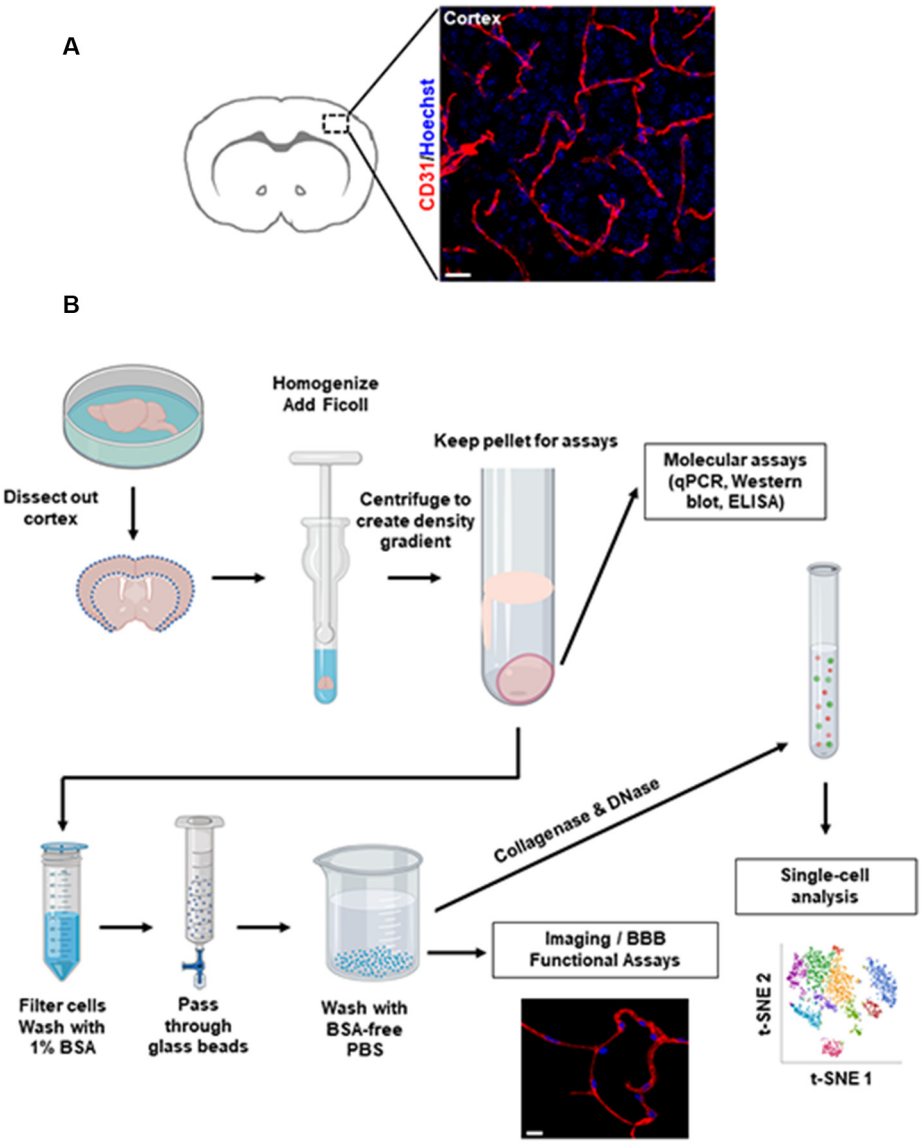

FIGURE 1 | Overview of brain microvessel purification protocol. **(A)** Representative images of microvessels in the mouse cerebral cortex labeled by immunofluorescence staining. Scale bar, 20 μm. **(B)** Flowchart of the isolation procedures. This diagram depicts the major steps to isolate microvessels from freshly harvested mouse brain. Scale bar, 10 μm. Representative single-cell t-SNE plot shows different colored clusters to identify different cell types.

(8) The viability and cell yield can be examined. At this point, the cells are ready for downstream applications, such as single-cell analyses.

RESULTS

To isolate microvessels from the mouse cerebral cortex, as shown in **Figure 1A**, we adapted the protocol initially described by Miller, Bauer, and Hartz groups (Miller et al., 2000; Hartz et al., 2004, 2018b; Wang et al., 2010, 2014). The isolated microvessel fragments using mechanical homogenization described by Miller et al. (2000) retain P-glycoprotein, an ATP-dependent efflux transporter of the BBB and maintain the functional transport activity (Hartz et al., 2010, 2018b; Wang et al., 2010, 2014). We modified the Ficoll density-gradient and homogenization strokes to obtain optimal sizes of microvessel fragments from a pool of dissected cortices. The isolation protocol is overviewed in **Figure 1B**. The procedures described in **Figure 2** yielded intact microvessel fragments as examined under a light microscope, although there was some brain parenchymal debris observed (**Figures 3A,B**). We validated the purity of isolated microvessels by examining the unique mRNAs expressed in different cell types. The isolated microvessels showed a 30-fold enrichment of endothelial cell-specific genes, *Pecam1*, *Cldn5*, and *Cdh5*, compared to other cell types, such as astrocytes, neurons, and microglia (**Figure 3C**). When compared to protein

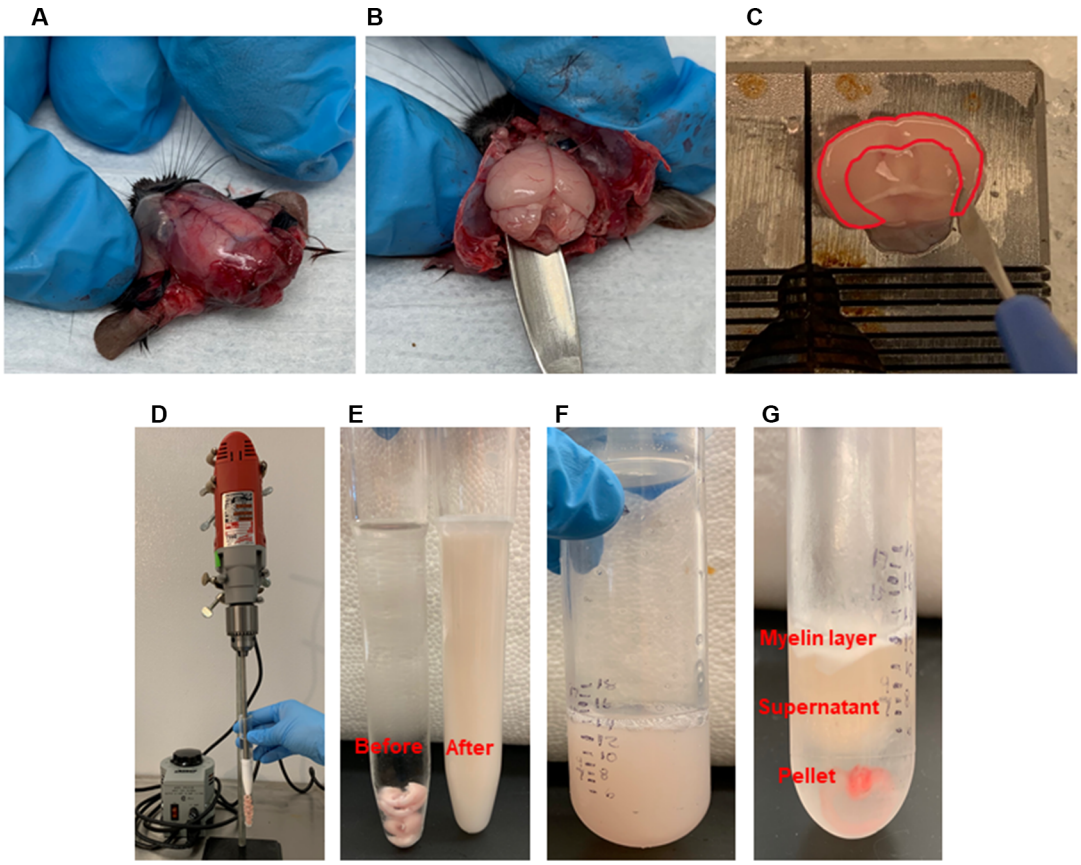

FIGURE 2 | Brain microvessel enrichment. **(A–C)** Tissue harvest and dissection. After head decapitation, peeling the skin to reveal the skull. Extracting the brain with a spatula. After transferring the whole brain into a Petri dish containing modified phosphate buffered saline (PBS) on ice, dissecting the brain regions on ice. Dissecting the cerebral cortex was shown. homogenates of the cerebral cortex, the isolated microvessels showed enrichment of tight junction protein, Zonula Occludens (ZO-1) and Occludin, indicating the intact barrier structure of microvessel fragments (**Figure 3D**). At this point, the isolated microvessel fragments can be used for molecular or biochemical assays to examine changes of tight junction proteins in a disease model. We examined a well-characterized model of human obesity and type 2 diabetes, which carries the mutated leptin receptor (*db*) alleles (Bahary et al., 1990). The *db*/*db* mouse has been reported exhibiting comorbid phenotypes of obesity, diabetes, and cognitive deficits (Erion et al., 2014; Stranahan et al., 2016; Cope et al., 2018). The cerebral vascular abnormalities and BBB damage were suggested contributing to the impairment of cognition observed (Niedowicz et al., 2014; Stranahan et al., 2016). We used this model as our validation studies for this isolation protocol. We isolated brain microvessels from *db*/*db* mice as procedures described above and examined the tight junction protein, Occludin (**Figure 3E**). The levels of Occludin in the microvessel fragments of *db*/*db* mice were significantly reduced compared to the controls. These results demonstrated the applications of this protocol to examine the vascular pathology in a dementia mouse model.

To exclude unwanted cellular debris, further purification of the enriched microvessel fragments was accomplished *via* the filtration through the glass beads column as shown in **Figures 4A–E**. We examined the diameters of the microvessel fragments using a bright-field light microscope. The majority of the microvessel fragments captured were less than 10 μm in diameter (**Figures 4F,G**). We observed that 75.7% of fragments were less than 5 μm, and 21.6% of fragments were between 5 and 10 μm (**Figure 4H**). The results suggested that most of the purified microvessel fragments are brain parenchymal capillaries. This filtration facilitated obtaining stretched and untangled capillaries that are suitable for imaging analyses (**Figure 5A**). We performed immunostaining to characterize the morphology of purified capillaries. Using the immunostaining of endothelial cell marker, CD31, we were able to visualize homogeneously labeled endothelial cells within the intact structure of capillaries (**Figure 5B**). Also, the tight junction protein, ZO-1, was

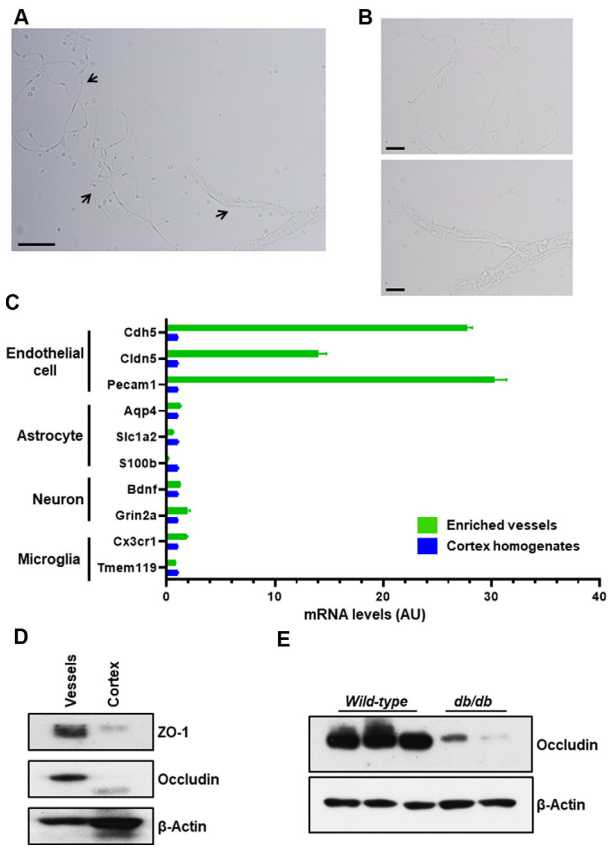

FIGURE 3 | Purity of enriched brain microvessels. The enriched microvessels were examined by light microscope, bright-field directly after isolation and resuspension. **(A)** 100× magnification. Arrows indicate different sizes of microvessel fragments isolated. Scale bar, 50 μm. **(B)** 400× magnification. Top insert depicts a single stretched out capillary. The bottom insert depicts a capillary network attached to smooth muscle cells. Scale bar, 20 μm. **(C)** Endothelial cell markers (Cdh5, Cldn5, and Pecam1), astrocyte markers (Aqp4, Slc1a2 m, and S100b), neuron markers (Bdnf and Grin2a), and microglia markers (Cx3cr1 and Tmem119) were compared between the enriched brain microvessels and the cortex homogenates using qPCR quantification. Data are mean ± SEM, $n = 2$ mice per experiment from two independent experiments. **(D)** Representative Western blot shows that tight junction proteins, ZO-1 and Occludin, were enriched in isolated microvessel fragments compared to the cortex homogenates. The cytoskeletal β-actin was used as a control. Ten microgram of total protein preparation was examined. Data presented are from four independent experiments. **(E)** Representative Western blot of enriched brain microvessels isolated from wild-type C57BL/6 female mice (three samples) and *db/db* female mice (two samples) at age of 9 months. The tight junction protein, Occludin, was diminished in the *db/db* group. $n = 2$ mice per experiment from two independent experiments.

co-labeled with CD31+ endothelial cells with no apparent discontinuity, suggesting that the structure of endothelial tight junctions were preserved in our capillary preparation. The surface of brain capillaries is covered by pericytes and astrocyte end-feet that seals the BBB entirely resulting in the unique characteristics of the cerebrovascular system (Daneman et al., 2010). We performed immunostaining of pericytes and astrocyte end-feet using makers, PDGFRβ and Aquaporin-4 (App4) respectively, to examine the sheathing of isolated capillaries. The PDGFRβ+ pericytes were shown adhered to the surface of isolated capillaries (**Figure 5C**). The water channel Aqp4 is concentrated at the astrocyte end-feet membrane, serving as an influx route of water to maintain homeostasis (Papadopoulos and Verkman, 2013; Camassa et al., 2015). We found that the Aqp4+ end-feet membrane outlined the wall of isolated capillaries (**Figure 5D**). Together, these results suggest that our optimized protocol using mechanical homogenization, but not enzymatic digestion, preserves the structure of the BBB that closely mimic *in vivo* situations.

The purified capillaries using this protocol can be applied for functional transport assays to test small-molecule drugs (Wang et al., 2010, 2014). AD is an age-associated neurodegenerative disorder characterized by the buildup of amyloid-β (Aβ) plaques. The accumulation of Aβ as the result of unbalanced Aβ generation subsequent clearance is reported to contribute to the pathogenesis of AD (Bell et al., 2007; Mawuenyega et al., 2010; Zlokovic, 2011). We used the transport of human $A\beta_{42}$ peptide to validate the function of the purified microvessel fragments (**Figure 6A**). We first used freshly isolated capillaries to examine the transport of $A\beta_{42}$ (Hartz et al., 2010). We incubated HiLyte-Fluor 488 labeled $A\beta_{42}$ peptide ($A\beta_{42-488}$) or non-labeled $A\beta_{42}$ peptide with purified capillaries in modified PBS at room temperature for 1.5 h. We observed the accumulated fluorescence of $A\beta_{42-488}$ in the luminal space of capillaries, compared to non-labeled $A\beta_{42}$ peptide. The P-glycoprotein inhibitor, PSC833, to suppress the transport of $A\beta_{42-488}$ was shown. We tested the ability of purified capillaries to transport $A\beta_{42-488}$ at 4h after purification (**Figure 6B**). The purified capillaries were incubated with modified PBS at room temperature for 4 h and then subjected to the transport assay for 1.5 h as described above. The reduction of $A\beta_{42-488}$ fluorescence in the luminal space suggested that the purified capillaries have reduced function and viability at 5.5 h after purification, as suggested in previous studies (Bauer et al., 2008; Hartz et al., 2010, 2018b). We also found that the CD31 immunostaining signal in purified capillaries is reduced at 4 h and almost diminished at 7 h after purification (**Figure 6C**). Together, these results suggested that the purified capillaries retain the transport function of BBB as *in vivo*, and the viability of purified capillaries can be preserved at modified PBS for up to 5 h.

Transcriptional profiling of the brain vascular endothelial cells provides new insights into the molecular mechanisms of vascular function in health and diseases at a whole-genome level (Guo et al., 2012; Zhang et al., 2014; Sabbagh et al., 2018). The fluorescence-activated cell sorting (FACS) technique enables to purify pre-defined cell populations based on the expression of surface markers or fluorescent reporters (Crouch and Doetsch, 2018; Jung et al., 2018; Munji et al., 2019). The selection of appropriate markers is often challenging, as some common markers being shared among BBB component cells and other types of brain parenchymal cells, such as oligodendrocyte progenitor cells. The enzymatic tissue dissociation before FACS purification is a critical step, as some epitopes required for immunostaining are degraded in a time-dependent manner during tissue dissociation (Crouch and Doetsch, 2018).

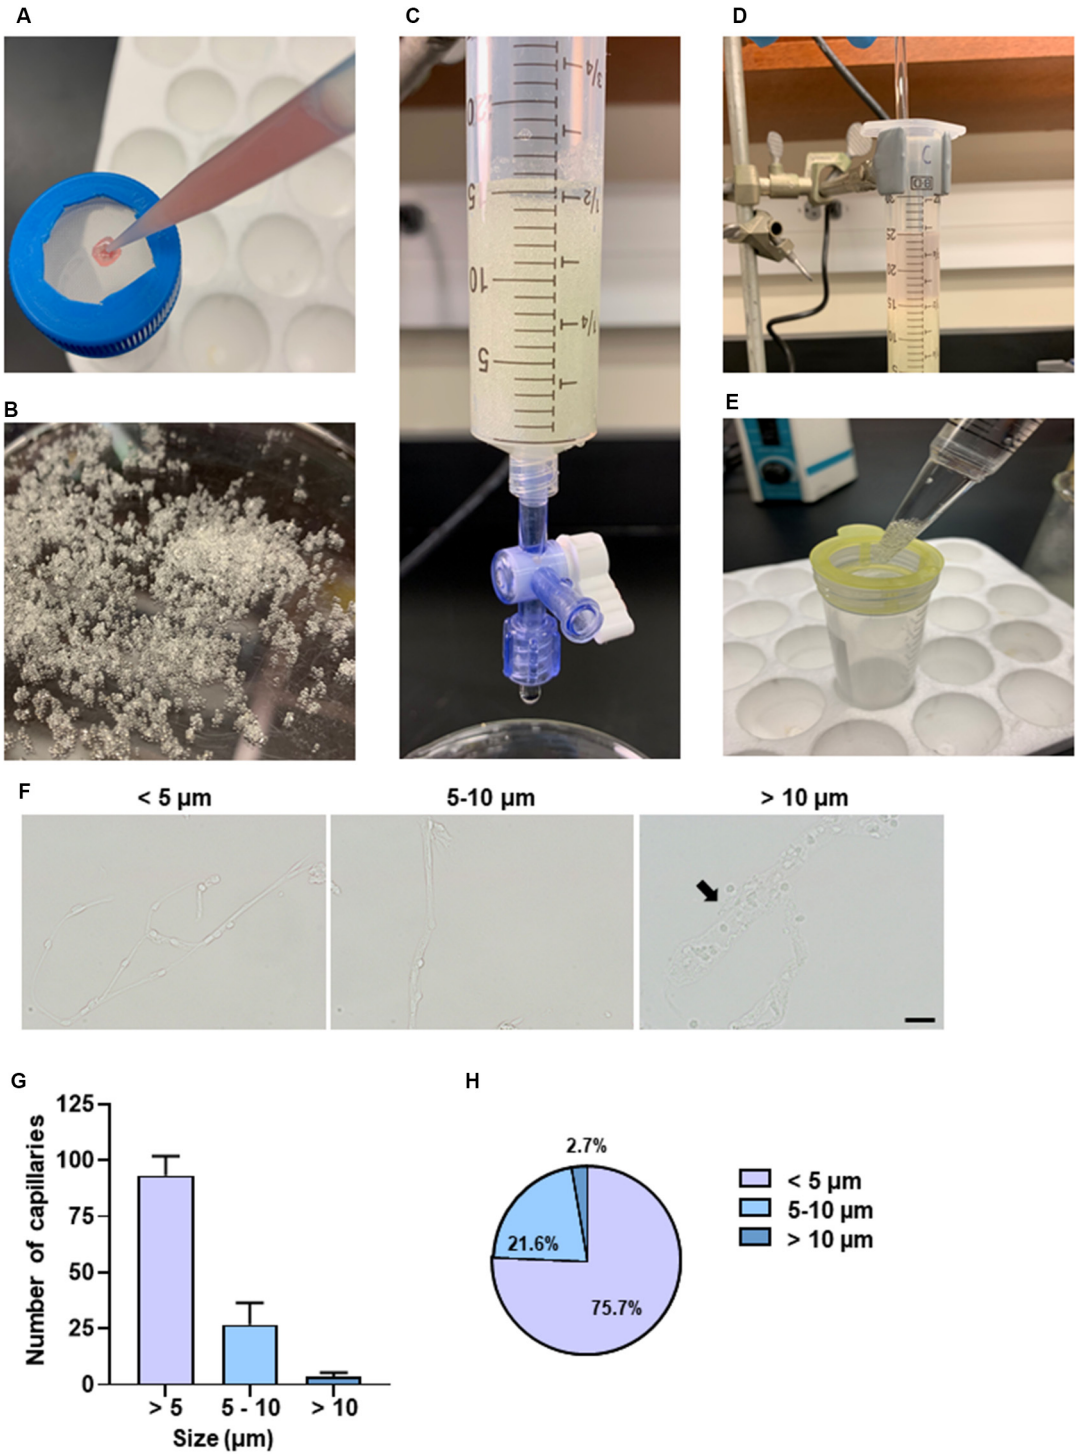

FIGURE 4 | Purification of brain capillaries and characterization of capillary size. **(A)** Passing pellet resuspensions through a 300 µm nylon mesh. **(B)** Example of glass beads used. **(C)** Collection syringe with adjustable flow rate has 15 ml glass beads supported by a 30 µm nylon mesh. **(D)** Gentle agitation using a glass stirrer is necessary for microvessels to adhere to glass beads. **(E)** Filtering solution with a 100 µm filter to remove excess glass beads. **(F)** Representative bright-field images of different sizes of capillaries. The diameters of the capillaries were measured. A total of 70–120 capillaries was examined per experiment. Three independent experiments were performed. Arrow points to the representative capillary with a size between 10 and 20 µm. **(G)** The size of the capillaries was examined from each experimental preparation. Data are mean ± SEM $n = 5$ mice per experiment from three independent experiments. **(H)** Percentages of capillaries based on size. Data are mean ± SEM $n = 5$ mice per experiment from three independent experiments.

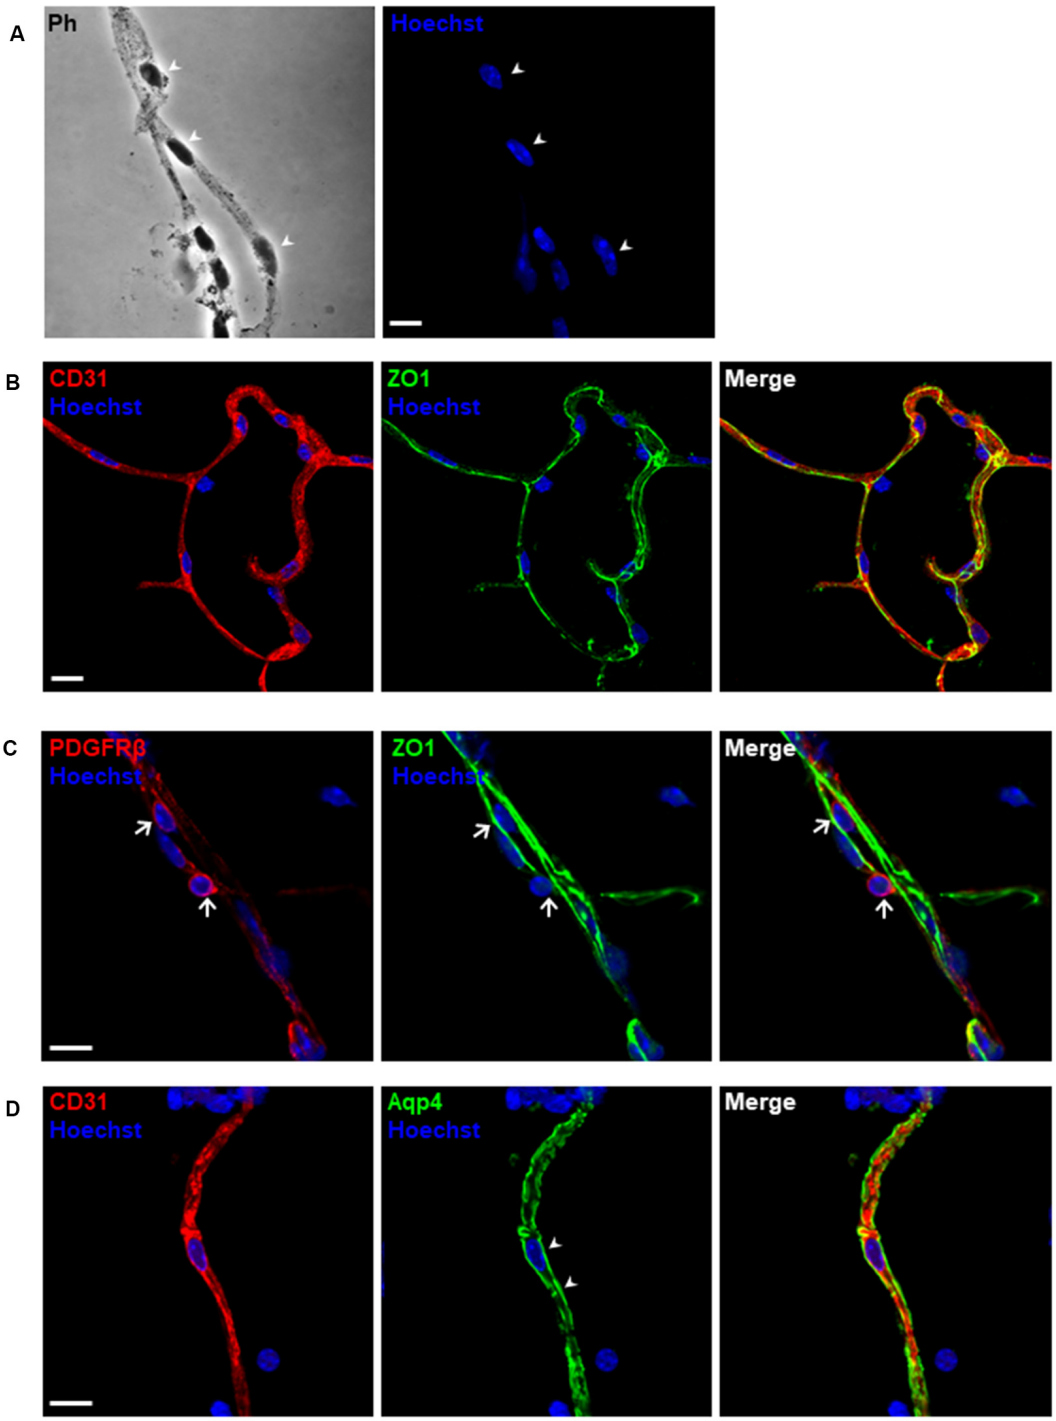

FIGURE 5 | Morphological characterization of purified microvessels. Confocal images of immunostaining for different markers of blood-brain barrier (BBB) cell components. **(A)** Phase-contrast (Ph) image of microvessels. The cell nuclei shown by arrowheads are depicted as blue using Hoechst 33342 staining (1 μg/ml). **(B–D)** Isolated microvessels retain most of the *in situ* structure. **(B)** Endothelial markers, CD31 (red) and tight junction proteins, ZO-1 (green) were detected. **(C)** Pericyte markers, PDGFRβ (red) were detected adhering to the surface of an isolated capillary, as shown by arrows. **(D)** Astrocyte end-feet membranes, pointed by arrowheads, remain attached to the microvessel fragment. Scale bar, 10 μm. The data presented are from three independent experiments.

The development of single-cell technologies opens the opportunity to map cellular heterogeneity within BBB component cells and to unravel the molecular signatures of previously unrecognized cell populations or functional states in

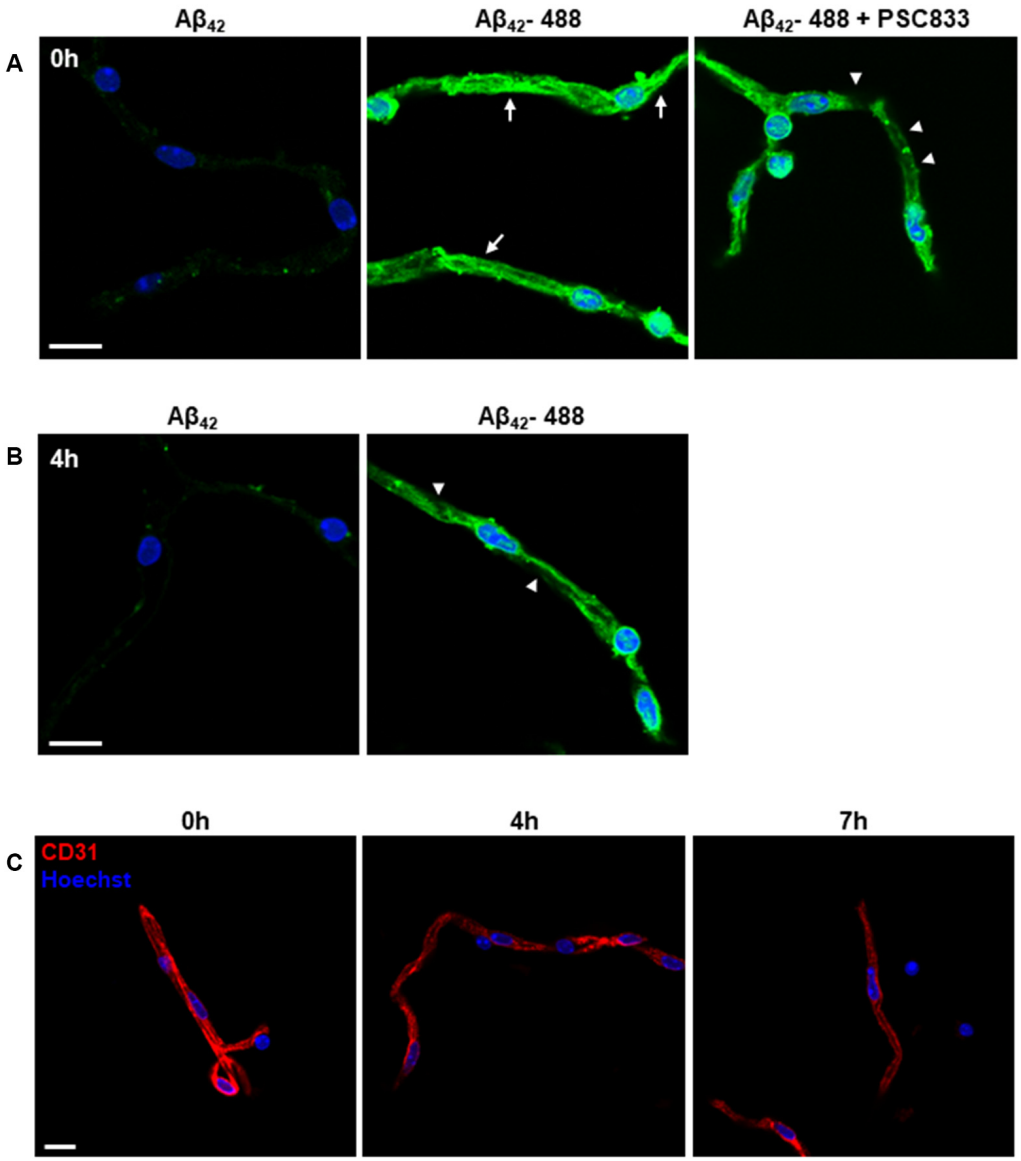

FIGURE 6 | Functional transport characterization of purified microvessels. **(A,B)** Confocal images of $A\beta_{42}$ transport in purified capillaries. **(A)** Freshly prepared capillaries were incubated with 5 μM HiLyte Fluor-488 $A\beta_{42}$ ($A\beta_{42-488}$) peptide or non-labeled $A\beta_{42}$ peptide (as control) in modified PBS at room temperature for 1.5 h. After incubation, capillaries were washed and processed for imaging analysis. Capillary luminal fluorescence (green) of $A\beta_{42-488}$ was examined using a confocal microscope. Cell nuclei are shown as blue using Hoechst 33342 staining (1 μg/ml). A P-glycoprotein inhibitor, PSC833, was co-incubated with $A\beta_{42-488}$ to suppress the transport of $A\beta_{42-488}$ mediated by the P-glycoprotein. Representative images from four independent experiments are shown. $n = 5$ mice per experiment. Arrows indicate the transport of $A\beta_{42-488}$ into the capillary luminal space. Arrowheads indicate the reduced green fluorescence in the capillary luminal space. Scale bar, 10 μm. **(B)** Transport of $A\beta_{42-488}$ in capillaries at 4 h after purification. The assay condition was the same as described in **(A)**. Arrowheads indicate decreased capillary luminal green fluorescence. **(C)** Endothelial markers, CD31, was used to examine the viable endothelial cells in purified capillaries at 0 h, 4 h, and 7 h after purification. The cell nuclei are shown as blue using Hoechst 33342 staining (1 μg/ml). Scale bar, 10 μm.

various subregions of the brain (Saliba et al., 2014; Cembrowski, 2019; Kalluri et al., 2019). Yousef and colleagues recently applied enzymatic digestion procedures following flow cytometry sorting to characterize the molecular phenotype of brain endothelial cells in the aging mouse brain (Czupalla et al., 2018; Yousef et al., 2018, 2019). Since we obtained the structurally and functionally intact brain capillaries, we further optimized the procedures to generate single-cell suspensions with relatively shortened time (15 vs. 50 min) and lowered dose of collagenase (0.5 mg/ml vs. 1 mg/ml) digestion step to minimize the potential of cell activation compared with other methods (Czupalla et al., 2018; Yousef et al., 2018; Kalluri et al., 2019). We used 10% fetal bovine serum to inactivate collagenase activity and stabilize cells rapidly during collection procedures. Following the procedures

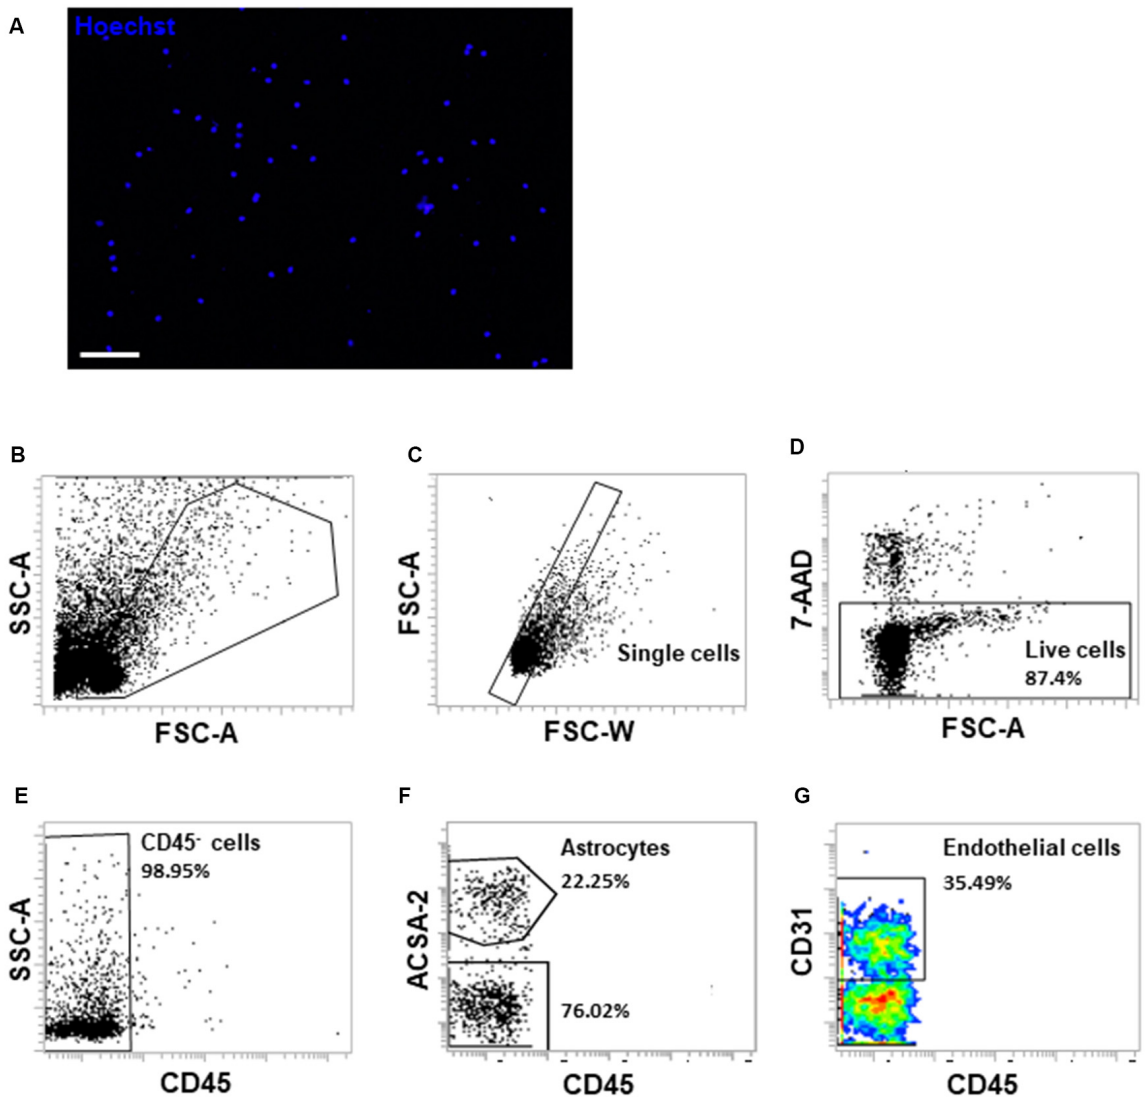

FIGURE 7 | Fluorescence-activated cell sorting (FACS) analysis of single-cell suspensions of isolated brain microvessels. **(A)** Single-cell suspensions were examined under a fluorescent microscope immediately after resuspension. The cell nuclei were stained with Hoechst 33342 (1 μg/ml). Scale bar, 50 μm. **(B)** Single-cell suspensions were gated on FSC-A and SSC-A to exclude cell debris. **(C)** Cells were gated on FSC-W and FSC-A to exclude cell doublets or aggregates. **(D)** 7-AAD uptake indicates dead cells, which account for approximately 13% of cells. **(E)** CD45- cells were gated to exclude monocytes/macrophages and brain resident microglial cells. **(F,G)** ACSA-2 and CD31 staining were applied to examine different cell types within the single-cell suspensions generated from isolated microvessel fragments. Representative FACS images were from three to four independent experiments.

described, we were able to generate single-cell suspensions as examined under a fluorescence microscope (**Figure 7A**). The viable cells accounted for approximately 87% of the total single cells using 7-AAD uptake analysis (**Figures 7B–D**). We observed heterogeneous cell populations with minimal contamination of 2% CD45+ immune cell populations (**Figure 7E**). As we observed astrocyte end-feet covered the wall of isolated brain capillaries, we used astrocyte cell surface antigen-2 (ACSA-2) and CD31 to characterize BBB component cell types within the single-cell suspensions (**Figures 7F,G**). Cumulatively, this protocol is highly reproducible. We were able to yield an average of 4–6 $\times$ 10^5 cells from a pool of cerebral cortices collected from four to five adult mice.

Potential Pitfalls and Troubleshooting

This protocol describes the relative ease in isolating the microvessels from the adult mouse brain. Here, we list several conditions that will facilitate the preservation of cellular interactions between microvascular endothelial cells and mural cells, which is critical for maintaining the molecular phenotypes of BBB component cells.

- Keep all tools and buffers ice-cold to maintain a high viability (>80%). Also, performing the majority of the steps in a 4°C cold room will help keeping the cells viable.
- Each isolation of cerebral microvascular fragments should include experimental and control groups. The number of mice to use per group depends on downstream analyses. The protocol described above, especially the volume of Ficoll, is good for 3–5 mice per group. For biochemical analyses, such as RNA or protein quantifications, a pool of dissected cortices from two young mice (3–4-month-old male or female) is the amount required. For imaging of functional assays and single-cell analyses, a pool of dissected cortices from four to five young mice (3–4-month-old male or female) is the amount required.
- To maintain the high viability and functionality, the maximum number of groups that can be isolated at one time is two sets of mice (4–8 mice total). Increasing the total time for the procedure is detrimental to the procedure. We found that once the cells are in a single-cell suspension, the cells will begin loss of viability after 30 min and will affect the results.
- Modified PBS and the Ficoll must be made the day before the experiment and not any longer. Also, the sodium pyruvate and the glucose can only be added on the day of the experiment and must be used within the day of the experiment. Likewise, the 1% BSA solution is made right after the sodium pyruvate and the glucose are added to the modified PBS.
- The flow rate during the glass beads section is critical for the microvessel fragments to attach to the glass beads. If the flow rate is too fast, the capillaries will not adhere to the glass beads.
- The glass beads can be reused up to five times before brain parenchyma will contaminate the beads, preventing the capillary segments from adhering to the beads. Upon completion of the experiment, the glass beads can be washed by adding deionized water first followed by 95% ethanol to the glass beads, swirling first, then dumping the excess ethanol out. Rinse the glass beads twice with deionized water. Dry beads by immersing them in 100% ethanol overnight. The glass beads must be fully dry before being used again.

DISCUSSION

This protocol will be of significant interest in investigating molecular mechanisms that lead to BBB dysfunction. It describes in detail how to isolate brain microvessels while the isolated fragments retain the structural and functional integrity of the BBB. Freshly isolated microvessels can be used to characterize barrier dysfunction or capillary permeability if a disease mouse model is applied (Hartz et al., 2012). We validated the application of this protocol using a mouse model exhibiting BBB damage and cognitive impairment. Importantly, this protocol describes procedures to generate single-cell suspensions from isolated microvessels. The procedures require approximately 3–3.5 h in total depending on the experiment groups of mice used. The shorten time required from the described protocol can significantly improve the quality of RNA obtained. Moreover, the purified microvessel fragments were demonstrated retaining the *in vivo* structure and function of transport. The highly viable single-cell suspensions obtained from microvessels that retain *in situ* structure provide a valuable resource for identifying unique subpopulations of BBB component cells that might be associated with disease progression using single-cell analyses, such as RNA-sequencing (Yousef et al., 2019), DNA methylation (Hui et al., 2018), or ATAC-sequencing (Lalonde et al., 2019).

This protocol is optimized for the isolation of microvessel fragments and capillaries from the cerebral cortex of the adult mouse brain. However, it is crucial to consider that the dissection of the brain region of interest is required. If other brain sub-regions, such as sub-ventricular zone containing neurogenic niche or highly vascularized hippocampus, are of interest, the microdissection skill, fine forceps, and a dissection microscope will be required. The procedures described during brain harvest remove the thin slices from the dorsal surface of the brain, which contains the subdural meninges. Since we were unable to peel off the pia/arachnoid mater within the brain parenchyma, the isolated microvessels do not contain extra-parenchymal meningeal or large vessels on the surface of the brain as demonstrated in the size characterization of purified fragments. For the study interest of meningeal vessels, other methods should be followed (Park et al., 2011; Faraco et al., 2019).

CONCLUSION

Developing a protocol to isolate microvessel fragments is vital to generate a model to study the BBB dysfunction in diseases. Since the capillaries make up for roughly 1% of the whole brain in humans, using crude brain homogenates will most likely generate weak signals to study the BBB dysfunction as shown in our results and reported literature (Bauer et al., 2008; Hartz et al., 2018a). Here, we show that enrichment of the cerebral capillaries *via* a density gradient and glass beads opens the door for future experiments to examine and characterize the neurovascular unit through various assays and molecular characterization, such as single-cell analysis.

DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article.

ETHICS STATEMENT

The animal study was reviewed and approved by Purdue Animal Care and Use Committee.

AUTHOR CONTRIBUTIONS

J-HY and I-CY conceived the study. HP, XW, and I-CY designed the experiments. HP, XW, P-CK, DF, and BS performed the experiments and analyzed the data. HP wrote the manuscript. J-HY, F-LC, and I-CY reviewed and edited the manuscript.

FUNDING

This project was supported, in part, with support from the Indiana Clinical and Translational Sciences Institute, funded in part by Grant Number UL1TR002529 from the NIH, National Center for Advancing Translational Sciences, Clinical and Translational Sciences Award. The Indiana Clinical and Translation Sciences Award was to I-CY. J-HY was supported by NIH R01NS102449.

Sun X, Zhang H, Tong X, Gao F, Ma G and Miao Z (2020) Effects of Periprocedural Tirofiban vs. Oral Antiplatelet Drug Therapy on Posterior Circulation Infarction in Patients With Acute Intracranial Atherosclerosis-Related Vertebrobasilar Artery Occlusion. Front. Neurol. 11:254. doi: 10.3389/fneur.2020.00254

Background and purpose: Tirofiban and oral antiplatelet drugs can be used to inhibit reocclusion and restore microvascular reperfusion during endovascular treatment (EVT). This study compared recanalization rates, symptomatic intracranial hemorrhage (SICH), 90 day mortality, and functional outcomes between periprocedural tirofiban and antiplatelet therapy in patients with acute intracranial atherosclerosis-related vertebrobasilar artery occlusion.

Methods: A total of 105 consecutive patients with acute intracranial atherosclerosis-related vertebrobasilar artery occlusion who underwent EVT + tirofiban + oral antiplatelet or EVT + oral antiplatelet therapy at the Beijing Tiantan Hospital between January 2012 and July 2018 were included. Baseline characteristics, procedural parameters, and functional outcomes were assessed.

Results: Among the 105 patients, 74 underwent EVT + tirofiban + oral antiplatelet therapy, while 31 underwent EVT + oral antiplatelet drug therapy. EVT + tirofiban + oral antiplatelet therapy resulted in higher recanalization rates compared to EVT + oral antiplatelet drug therapy (93.24% vs. 77.42%; $p = 0.038$), whereas the risk for SICH, 90 day mortality, and functional independence outcomes did not differ between the groups. Logistic regression analysis revealed that EVT + tirofiban + oral antiplatelet therapy had an increased probability of higher recanalization rates (OR 0.18 [95% confidence interval (CI) 1.24–24.39]; $p = 0.025$). There were no differences in SICH (OR 0.00 [95% CI 0.00–Inf]; $p = 0.998$), 90 day mortality (OR 1.19 [95% CI 0.17–4.05]; $p = 0.826$), or functional independence (modified Rankin score 0 to ≤ 2) (OR 1.43 [95% CI 0.23–2.17]; $p = 0.538$) between the groups.

Conclusions: Ninety day functional outcomes of EVT + tirofiban + oral antiplatelet therapy were not superior to those of EVT + oral antiplatelet drug therapy; however, the recanalization rate was higher and the risks for SICH and 90 day mortality were lower.

INTRODUCTION

Many randomized trials have demonstrated the improved efficacy of endovascular treatment (EVT) compared with standard medical care in patients with acute ischemic stroke (AIS) caused by arterial occlusion in the anterior circulation (1–5). For patients with acute ischemia due to basilar artery occlusion, the rates of death or dependency are 76–78% (6), even when these patients are treated with intravenous or intra-arterial thrombolysis agents. Different case scenarios have shown that stent-retriever thrombectomy is a safe and feasible treatment technique in patients with acute basilar artery occlusion (BAO) (7–10). However, for acute intracranial atherosclerosis-related occlusion (ICASO), which is more common in Asia (11–14), salvage therapies (15), such as balloon angioplasty and stent angioplasty, are necessary to increase the rate of successful and complete reperfusion. The associated risks, such as perforator occlusion (16), endothelial damage (17, 18), microvascular dysfunction (19), and reocclusion of recanalized vessels (20–22), may cause intracranial hemorrhage or even worse outcomes.

Many studies have investigated methods to prevent the negative events caused by antithrombotic EVT, either in the anterior or the posterior circulation. A *post hoc* analysis from the Multicenter Randomized Clinical Trial of Endovascular Treatment for Acute Ischemic Stroke from the Netherlands reported that patients on a previous oral antiplatelet drug regimen were twice as likely to experience a favorable functional outcome (23). Injection of low-dose tirofiban combined with EVT can enhance recanalization rates (24–26). However, there have been no studies confirming which method is safer and/or more effective. The aim of the present study, therefore, was to compare outcomes in patients who underwent EVT plus tirofiban (EVT + tirofiban) therapy vs. those who underwent EVT in conjunction with oral antiplatelet drug therapy.

METHODS

Study Design

Consecutive patients presenting with ICAS-related acute BAO who underwent EVT + tirofiban + oral antiplatelet or EVT + oral antiplatelet drug therapy at Beijing Tiantan Hospital (Beijing, China) between January 2012 and July 2018 were included in this retrospective study. Intravenous thrombolysis with tissue plasminogen activator was allowed prior to EVT, consistent with current guidelines (27). The details of patient selection and grouping are presented in **Figure 1** according to previous studies (28–30). Tirofiban was considered for application in the following situations/parameters: (1) rescue treatment with emergency stenting for residual artery stenosis or failed thrombectomy; (2) rescue treatment with emergency balloon angioplasty for residual artery stenosis or failed thrombectomy; (3) local new thrombosis or vascular dissection of the responsible vessel; and (4) severe atherosclerosis lesions with a high possibility of reocclusion after being recanalized. Informed consent was obtained from all participants or their relatives, and the protocol was approved by the Institutional Review Board of Beijing Tiantan Hospital.

Plain computed tomography (CT) of the brain was performed first to exclude intracranial bleeding. Magnetic resonance imaging (MRI) was used to exclude large brainstem infarctions. CT angiography (CTA) or magnetic resonance angiography (MRA) was used to confirm the presence of acute BAO. The clinical and radiological data of these patients were retrospectively collected and analyzed and included age; sex; stroke risk factors, including hypertension, diabetes mellitus, hypercholesterolemia, and current smoking status; initial stroke severity, as reflected by the National Institutes of Health Stroke Scale (NIHSS) score; initial imaging modality; previous intravenous thrombolysis; type of EVT device(s); onset to puncture time; procedure duration; onset to recanalization time; and collateral status.

EVT

The decision to perform EVT was made by a stroke neurologist and a neuroradiologist based on the CT, CTA, or MRA results of the patient. All EVT procedures were performed by a neurointerventionalist with sufficient experience in neurovascular intervention in mechanical thrombectomy for AIS (>50 cases). Cerebral angiography and EVT were performed under general anesthesia or conscious sedation after evaluation by a dedicated anesthesiology team. A stent retriever or aspiration was used first, with a possible switch to another strategy in the case of recanalization failure (mTICI grade = 0–2a) with the first approach. Underlying ICAS was determined when significant stenosis was seen on the initial diagnostic angiography or on follow-up angiography after a mechanical thrombectomy procedure (31). Causes of acute BAO were classified based on our previous research (32). ICAS was defined as significant fixed focal stenosis that could be resolved by means of angioplasty or stent insertion at the site of occlusion. Significant stenosis was defined as (1) fixed stenosis ≥70% or (2) fixed stenosis ≥50% in addition to either angiographical evidence of impaired perfusion or evidence of reocclusion after sufficient treatment with a stent retriever. The cause of acute BAO was classified as embolism based on the following: (1) after clot retrieval, there was no focal stenosis; (2) an embolus was removed with a stent retriever; or (3) MRA or CTA performed within 1 week after the procedure showed lack of stenosis in the responsible artery. In cases of recanalization failure (mTICI grade 0–2a after mechanical thrombectomy within 10 min), intracranial angioplasty or stenting was performed. All patients immediately received a loading dose of 300 mg of aspirin and 300 mg of clopidogrel orally. Patients with daily aspirin (100 mg) or/and clopidogrel (75 mg) medication before the intervention did not receive a loading dose. Alternatively, tirofiban therapy (Grand Pharmaceutical Co Ltd, China) was applied. Standard procedure was to administer 5 mg of tirofiban diluted in 100 ml

of normal saline and infused with a 6- to 8-ml (0.3–0.4 mg) loading dose via a catheter at a rate of 1 ml/min. Intravenous tirofiban was continued at a rate of 0.15 μg/kg/min for the next 24 h. Intravenous tirofiban was continued at a rate of 0.15 μg/kg/min for the next 24 h. If there were no hemorrhagic complications seen on the head CT scan, aspirin and clopidogrel (one tablet each) were used with overlap for 4–6 h during the operation. If CT performed 24 h after the operation revealed no dynamic bleeding or hemorrhagic transformation, dual antiplatelet therapy was maintained for at least 3 months after the procedure, followed by lifelong aspirin or clopidogrel monotherapy thereafter.

Image Interpretation

Diffusion-weighted images were assessed using the pons-midbrain index (using the posterior communicating artery) and the American Society of Interventional and Therapeutic Neuroradiology/Society of Interventional Radiology (ASITN/SIR) (29, 33) grading system. All images were analyzed retrospectively by two neurologists blinded to the patient information and study protocol. If no consensus was reached, a third neurointerventionalist with 20 years of experience made the final decision.

Outcome Measures

For primary effectiveness, outcomes were assessed according to the BASICS definition (34). Functional independence and a favorable outcome were defined as mRS $\leq$ 2 and mRS $\leq$ 3, respectively. Other effectiveness outcome measures included the rates of successful recanalization [modified treatment for cerebral infarction (mTICI) = 2b−3] and complete recanalization (mTICI = 3) (35).

The safety outcome measures included 90 day mortality and rates of intracerebral hemorrhage and symptomatic intracerebral hemorrhage (SICH) within 24 h according to the criteria described in the European Cooperative Acute Stroke Study III (ECASS III) (36).

Statistical Analysis

Study data were collected on standard forms, evaluated for completeness, and double keyed into an EpiData statistics data document. Statistical analysis was performed using R

(http://www.R-project.org, The R Foundation for Statistical Computing, Vienna, Austria) and EmpowerStats (http://www.empowerstats.com, X&Y Solutions, Inc., Boston, MA, USA). Continuous variables are expressed as medians and interquartile ranges (IQRs) and as absolute numbers and percentages, while categorical variables are expressed as the means and standard deviations (SDs). Shapiro–Wilk test, histogram, and QQ chart were used to confirm normal distribution of data. The chi-squared test was used to compare categorical variables, *t*-tests were used to compare continuous variables, and the Mann–Whitney *U* test was used to compare scores. Logistic regression was performed to estimate odds ratios (ORs) for 90 day mortality and primary effectiveness outcomes (mRS $\leq$ 2 and $\leq$ 3). Variables including the NIHSS score, sex, standard preoperative intravascular tissue plasminogen activator, general anesthesia, stent thrombectomy, and intraoperative heparinization were entered into a logistic regression model. All tests were two-tailed, and statistical significance was determined at a *P* level of 0.05.

RESULTS

Of 105 patients, 71 [mean ($\pm$ SD) age, 60.0 $\pm$ 8 years; 86.49% men] underwent EVT + tirofiban + oral antiplatelet drug therapy, whereas 34 (mean age, 60.0 $\pm$ 10 years; 83.87% men) underwent EVT + oral antiplatelet drug therapy.

A comparison of the baseline data and treatment procedures between the two groups is shown in **Table 1**. The NIHSS score was higher in patients who underwent EVT + tirofiban + oral antiplatelet drug therapy (25 [IQR 13–35] vs. 12 [IQR 10–23]; $p = 0.005$) than in those who underwent EVT + oral antiplatelet drug therapy (**Table 1**). More patients in the EVT + tirofiban + oral antiplatelet drug therapy group required stent thrombectomy (77.03% vs. 45.16%; $p = 0.001$) than patients in the EVT + oral antiplatelet drug therapy group, and fewer patients required intraoperative heparinization (40.54% vs. 70.97%; $p = 0.004$), which may have been related to differences in the severity of neurological deficits at the time of admission between the two groups.

A comparison of higher recanalization rates, 90 day mortality, SICH, and functional outcomes between the two groups is summarized in **Table 2**. In both groups, there was a higher rate of successful recanalization (mTICI 2b-3) among patients who underwent EVT + tirofiban + oral antiplatelet drug therapy (93.24% vs. 77.42%; $p = 0.038$). After comparing the two groups, the functional independence outcome rate (mRS 0 to $\leq$ 2) at 90 days (32.43% vs. 51.61%, $p = 0.065$), 7 day intracerebral hemorrhage (16.22% vs. 6.45%, $p = 0.223$), 90 day mortality (16.22% vs. 9.68%, $p = 0.544$), 7 day SICH (4.05% vs. 0.00%, $p = 0.553$), and 30 day responsible artery reocclusion (16.22% vs. 12.90%, $p = 0.773$) was not significantly different. The favorable outcome rate (mRS 0 to $\leq$3) in the EVT + tirofiban + oral antiplatelet drug therapy group was higher than that in the EVT + oral antiplatelet drug therapy group, owing to the differences in severe neurological deficits at admission.

Adjusted logistic regression analysis revealed that treatment with EVT + tirofiban + oral antiplatelet drug therapy was associated with an increased rate of successful recanalization (OR 0.18 [95% confidence interval (CI) 1.24–24.39]; $p = 0.025$), whereas no differences were found in SICH (OR 0.00 [95% CI 0.00–Inf]; $p = 0.998$), 90 day mortality (OR 1.19 [95% CI 0.17–4.05]; $p = 0.826$), or functional independence outcomes (mRS 0 to $\leq$ 2) (OR 1.43 [95% CI 0.23–2.17]; $p = 0.538$) between the groups (**Table 3**).

TABLE 1 | Comparison of baseline data and treatment procedures between patients who underwent ET +tirofiban + oral antiplatelet and those who underwent ET + oral antiplatelet drug therapy.

Baseline characteristics, treatment procedures, and outcomes	Treatment		*P*-value

DISCUSSION

ICAS occlusion is more common in the posterior than in the anterior circulation, especially among the Asian population (22, 37). Therefore, rescue therapies such as emergency angioplasty

or stenting are often required when treating these patients with EVT (15, 21), thereby inducing the removal of *in situ* thrombi (17), instability in the ICAS endothelium (38), and the "snowplow" effect (21). These steps result in perforator occlusion, microvascular dysfunction, and reocclusion of recanalized vessels. Many treatment strategies, including EVT + tirofiban + oral antiplatelet drug therapy (23) and EVT + oral antiplatelet drug therapy (24, 25), have been performed on patients with anterior and posterior circulation infarction in previous studies to prevent these drawbacks.

Due to the disparate characteristics of patients with posterior circulation cerebral infarction, intravascular tirofiban is more convenient than oral antiplatelet drug therapy. First, most patients with posterior circulation infarction exhibit consciousness disorders and difficulty swallowing. Oral antiplatelet drugs need to be administered through a gastric tube, the insertion of which is time-consuming. Second, it is important to differentiate an ICAS occlusion from an intracranial embolism before operating on patients without a clear history of intracranial artery stenosis. For these patients, intravascular tirofiban has the advantage of a rapid onset. Therefore, the present study compared the safety and outcomes in patients who underwent EVT+ tirofiban drug therapy vs. those who underwent EVT + oral antiplatelet drug therapy.

Our study found that acute intracranial atherosclerosis-related vertebrobasilar artery occlusion treated with EVT + tirofiban + oral antiplatelet drug therapy was associated with an increased rate of successful recanalization (OR 0.18 [95% (CI) 1.24–24.39]; $p = 0.025$), whereas no differences were found in SICH (OR 0.00 [95% CI 0.00–Inf]; $p = 0.998$) or 90 day mortality (OR 1.19 [95% CI 0.17–4.05]; $p = 0.826$). Functional independence outcomes at 90 days (mRS 0 to ≤2) were not significantly different (OR 1.43 [95% CI 0.23–2.17]; $p = 0.538$), which may be attributed to the severity of the neurological deficits between the groups at the time of admission and the small sample size. Since the investigation was an observational one based on a single-center prospective registry study, there are several limitations. First, the administration route, dose, and duration of tirofiban used in this study were pragmatic. Furthermore, inherent bias because of the retrospective and monocentric study design was inevitable. Compared to patients with EVT + oral antiplatelet drug therapy, those with EVT + tirofiban + oral antiplatelet drug therapy had a higher NIHSS score at baseline and a more frequent application of stent thrombectomy and intraoperative heparinization. However, after adjusting for potential confounders and conducting a multivariate analysis, we presume that this bias probably had little influence on our results. A multicenter study involving a larger sample size or a randomized controlled trial is needed to verify this result.

CONCLUSIONS

In summary, for patients who have trouble swallowing and those without a clear history of intracranial artery stenosis,

intravascular tirofiban treatment can be performed to save time. Our results demonstrated that EVT + tirofiban + oral antiplatelet drug therapy was not superior to EVT + oral antiplatelet drug therapy in terms of the functional independence outcomes at 90 days. Therefore, a more effective perioperative administration route, time, and dosage await further study.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

All procedures performed in studies involving human participants were in accordance with the ethical standards of Beijing Tiantan Hospital, Capital Medical University medical ethics committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

AUTHOR CONTRIBUTIONS

ZM designed the research and wrote the manuscript. XS and HZ designed the research. XS, HZ, and ZM performed the research. XT, FG, and GM analyzed the data.

FUNDING

This study was supported by the National Key Research and Development Program of China (Grant number 2016YFC1301501).

ACKNOWLEDGMENTS

We thank all relevant clinicians, statistician, and imaging technicians.

Gut integrity impairment leading to increased intestinal permeability (IP) is hypothesized to be a trigger of critically illness. Approximately 15–20% of human ischemic stroke (IS) victims require intensive care, including patients with impaired level of consciousness or a high risk for developing life-threatening cerebral edema. Local and systemic inflammatory reactions are a major component of the IS pathophysiology and can significantly aggravate brain tissue damage. Intracerebral inflammatory processes following IS have been well studied. Until now, less is known about systemic inflammatory responses and IS consequences apart from a frequently observed post-IS immunosuppression. Here, we provide a hypothesis of a crosstalk between systemic acute phase response (APR), IP and potential secondary brain damage during acute and subacute IS stages supported by preliminary experimental data. Alterations of the acute phase proteins (APPs) C-reactive protein and lipopolysaccharide-binding protein and serum level changes of antibodies directed against *Escherichia coli*-cell extract antigen (IgA-, IgM-, and IgG-anti-*E. coli*) were investigated at 1, 2, and 7 days following IS in ten male sheep. We found an increase of both APPs as well as a decrease of all anti-*E. coli* antibodies within 48 h following IS. This may indicate an early systemic APR and increased IP, and underlines the importance of the increasingly recognized gut-brain axis and of intestinal antigen release for systemic immune responses in acute and subacute stroke stages.

INTRODUCTION

Gut integrity (GI) plays an important role in balancing permeable gut functions required for the uptake of nutritional components versus preventive functions such as forming a barrier against pathogen egress (Doig et al., 1998; Otani and Coopersmith, 2019). GI impairment and subsequently increased intestinal permeability (IP) are believed to be a major pathophysiological elements in a number of severe conditions. They have been described in chronic heart failure (Doig et al., 1998; Sandek et al., 2014), complications in intensive care unit (ICU) patients (Klehmet et al., 2009) and in individuals undergoing cardiopulmonary bypass (Riddington et al., 1996), as well as after traumatic brain injury (Bansal et al., 2009). GI impairment and increased IP are supposed to be related to inadequate mucosal perfusion (Doig et al., 1998; Klehmet et al., 2009; Sandek et al., 2014) or a potential epithelial disruption by proinflammatory cytokines such as TNF-α (Triantafilou and Triantafilou, 2002). Decreased intestinal blood flow and increased proliferation of mucosal bacteria were correlated with a higher level of systemic anti-lipopolysaccharide (LPS) IgA in patients with critical chronic heart failure (Sandek et al., 2014).

Despite the recent advances in acute ischemic stroke (IS) management and care (Saver et al., 2016), IS is still a leading cause of chronic disability and death (Zazulia, 2009). Next to primary ischemic and secondary neuroinflammatory brain damage, IS patients also suffer from systemic stroke sequelae such as stroke-induced systemic immune suppression (SIIS) leading to pneumonia or severe gut alterations including dysmotility, microbiotic dysbiosis, and bleedings (Arya and Hu, 2018). While SIIS and related pulmonary infections have been investigated decently (Prass et al., 2003; Dirnagl et al., 2007; Klehmet et al., 2009), not much is known about intestinal epithelial barrier dysfunction following IS. Since GI and increased IP could serve as an important systemic immunological and inflammation trigger, they have recently been discussed as potential elements of systemic IS pathophysiology and as potential therapeutic targets (Zazulia, 2009; Wen and Wong, 2017). Based on a set of preliminary experimental data, we hypothesize that an impaired GI with increased IP can emerge after IS and could potentially pave the way for endogenous gut-borne infections, or fuel reciprocal immune responses leading to secondary brain damage.

INTESTINAL PERMEABILITY AND STROKE MODELS

Recent investigations on the role of the microbiome in mouse IS models suggested a protective function of bacteria in the conventional gut flora as intestinal dysbiosis was associated with poor outcome (Winek et al., 2016; Sadler et al., 2017). However, rodent data on disturbed GI and increased IP following IS are controversial. Some studies report bacterial translocation and sepsis after IS in rats and aged mice (Crasper et al., 2016), while others did not find evidence for increased IP and bacterial translocation 3 days after transient middle cerebral artery occlusion (Oyama et al., 2018). This may raise the question whether these findings from rodent IS models might be breed-, supplier- or even model-specific.

The Stroke Treatment Academic Industry Roundtable (STAIR) expert consortium recommends the additional use of suitable gyrencephalic models of focal cerebral ischemia to increase the validity of experimental findings (Fisher et al., 2009). Due to a closer similarity to humans regarding neuroanatomical and physiological features, large animal models are believed to mimic the clinical situation of human stroke patients realistically (Dirnagl et al., 2013). In particular, large animals might be useful to investigate GI breakdown and increased IP after IS. Ruminants, for which IS models are available (Boltze et al., 2008; Wells et al., 2012), possess a much larger gastrointestinal tract than rodents and humans in both absolute and relative terms, and a higher physiological bacteria load, what may be an advantage when aiming to detect potential systemic immunological consequences.

HYPOTHESIS: STROKE-INDUCED ACUTE PHASE RESPONSE AND INCREASED INTESTINAL PERMEABILITY LEAD TO SECONDARY BRAIN DAMAGE

The mechanism behind a potential GI impairment and increased IP after IS remain poorly understood. Hypothetically, impaired GI and increased IP can be caused by inadequate mucosal perfusion or epithelial breakdown mediated by proinflammatory cytokines such as TNF-α or zonulin. This has been described in the context of ischemic diseases and reduced organ motility (Rahman et al., 2018). Indeed, inflammatory cytokines can compromise intestinal mucosa integrity by affecting endothelial (gate) and tight junction (fence) functions (Bruewer et al., 2003).

Within minutes, IS leads to a four-step process of ischemia-related blood-brain barrier breakdown (BBB) in peri-infarct regions (Ballabh et al., 2004; Sandoval and Witt, 2008; Krueger et al., 2015), accompanied by endothelial cell damage and loss (Krueger et al., 2015). BBB disruption then facilitates exchange of blood components and brain antigens such as brain myelin basic protein (del Zoppo and Mabuchi, 2003; Offner et al., 2006; Krueger et al., 2015). Inflammatory cytokines are released into the circulation in large amounts after IS and hence could inflict "off-site" damage to the intestinal mucosa. Moreover, inflammatory cytokines induce the production of acute phase proteins (APPs) in the liver, but interestingly also in intestinal epithelium (Molmenti et al., 1993; Wang et al., 1998). Some APPs, such as serum amyloid A (SAA) stimulate inflammatory cytokine production themselves, providing a positive feedback mechanism. SAA, once present in the circulation, also increases the recruitment of immune cells to inflammatory sites. Other APPs, such as coagulation factors and plasminogen activator-inhibitor foster coagulation and might negatively affect perfusion, contributing to thromboinflammation in cerebral and intestinal capillaries. A vicious circle finally leading to increased secondary brain damage might evolve (**Figure 1**).

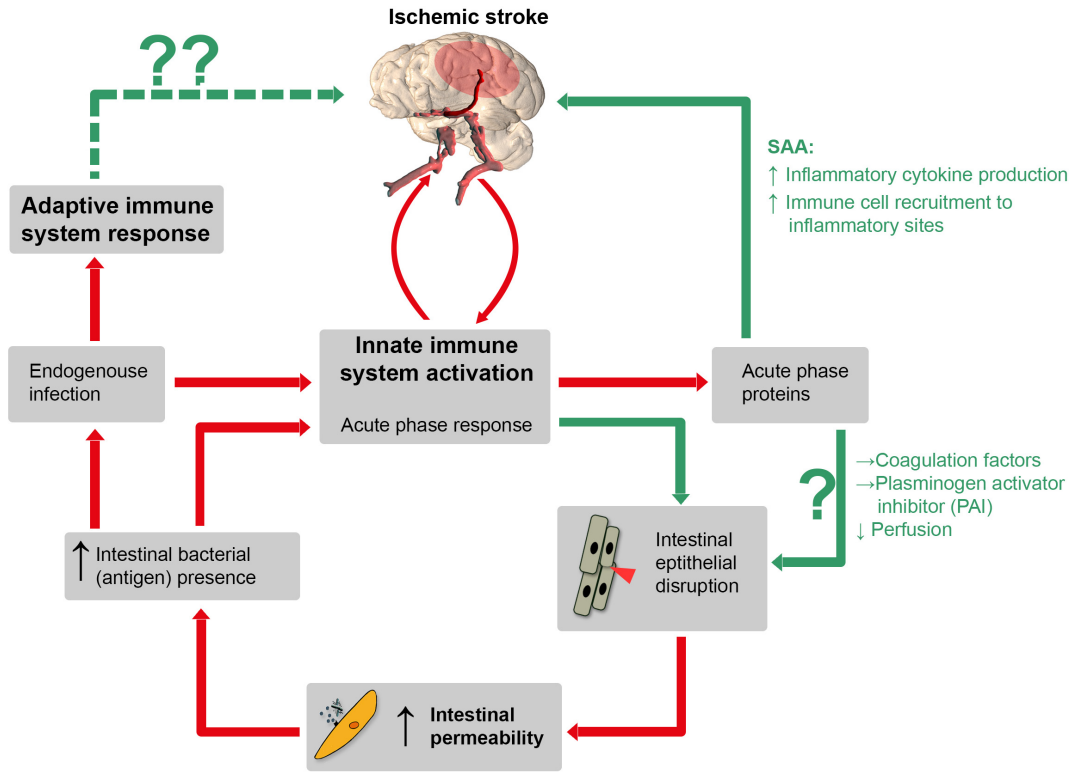

FIGURE 1 | Schematic illustration of a hypothetical pathophysiological cascade following ischemic stroke (IS): the innate immune system is activated by cerebral ischemia due to release of inflammatory cytokines after blood-barrier-breakdown. Hence, these cytokines could directly inflict "off-site" damage to the intestinal mucosa and induce the production of APPs such as serum amyloid A (SAA), coagulation factor and plasminogen activator inhibitor (PAI). SAA itself stimulates further inflammatory cytokine production via positive feedback stimulation. Other APPs, such as coagulation factors and PAI can impair capillary perfusion and, importantly, increase IP which is associated with bacterial translocation. Consequently, both pathways increase the amount of pro-inflammatory mediators, which leads to a prolonged inflammatory stage following IS. Red lines: established mechanisms, green lines: potential mechanisms (according to our hypothesis). Whether or not adaptive immune processes, augmented by the translocation of bacteria and bacterial antigens from the gut, can inflict secondary brain damage is entirely speculative (dotted green line, upper left).

STATEMENT OF HYPOTHESIS

Collection of Preliminary Data to Support the Hypothesis

In order to find support for abovementioned hypothesis, we took advantage of a running experiment in an ovine IS model in which peripheral blood samples were collected at days 1, 2, and 7 following IS. We focused on signs for potential (i) acute phase response (APR), (ii) IP alterations, and (iii) interaction between intestinal antigen translocation and systemic inflammation. Specifically, we determined levels of the APPs C-reactive protein (CRP), lipopolysaccharide-binding protein (LBP), and of and IgA-, IgM-, and IgG-anti-*E. coli* antibodies 1, 2, and 7d following IS. *E. coli* belongs to the physiological adhesive intestinal flora in sheep (Wang et al., 1998), but does not egress from the intestine in the steady state. Hence, changes of IgA-, IgM-, and IgG-anti-*E. coli* antibody levels could reflect IP alterations following IS. Animals were subjected to permanent middle cerebral artery occlusion (pMCAO) as described elsewhere (Boltze et al., 2008). Please refer to the **Supplementary Material** for methodological details.

All animals were considered clinically healthy prior to surgery (for further details see **Supplementary Tables S1** and **Supplementary Tables S2**). Animal health was assessed one day after pMCAO and every second day thereafter. No clinical signs of infection (e.g., fever) were observed. A standardized anesthesia and medication scheme was performed in all animals (see **Supplementary Table S3**). However, two animals with massive strokes were sacrificed 1d post IS due to severe neurological dysfunction and rapid worsening of general condition. These animals were excluded from further analysis. Stroke induction failed in one animal (no IS at day 1). Since this particular animal underwent the same procedure as other pMCAO animals, it was kept and served as a sham reference to control for surgery-related effects in APR.

Findings

Imaging Findings

Combined positron-emission tomography and magnetic resonance (PET/MR) imaging confirmed a perfusion deficit corresponding to the ischemic area within the MCA territory at day 1 after pMCAO in all but the sham reference animal

(**Supplementary Figure SF1B**). Details on the lesion and lesion size (t2w TSE defect volume in ml) at days 1 and 7 post pMCAO are given in **Supplementary Figure SF1** and **Supplementary Table S4**.

Systemic Acute Phase Protein Levels

Average CRP plasma levels tended to increase on day 1 after pMCAO as compared to baseline (p = 0.067), but not on day 2 (p = 0.213) and day 7 (p = 0.241, **Figure 2**). Statistically significantly increased levels of mean LBP were detected on day 1 (p = 0.002) and day 2 (p < 0.001) when compared to baseline (**Figure 2**). At each time point (baseline/1d/2d/7d), a relatively high inter-individual variability could be detected for CRP (39.6%/41.3%/35.7%/43.2%) and LBP (39.5%/41.7%/19.7%/101.5%). Baseline-corrected values showed a significant increase of CRP on day 1 (p = 0.028), while LBP was increased on day 1 (p = 0.002) and 2 (p < 0.001; all **Figure 3**). Baseline APP values in the sham reference animal were higher than in other subjects, but followed a similar kinetic except for a slight decrease of CRP values at d1 (**Figure 2**, green crosses).

IgA-, IgM-, and IgG-Anti-*Escherichia coli* Antibodies

Average plasma levels of IgA-, IgM-, and IgG-anti-*E. coli* antibodies decreased within the first 2 days after pMCAO, followed by an minor increase on day 7 (**Figure 3**). In detail, mean IgG-anti-*E. coli* antibody levels were significantly decreased on day 2 (p = 0.0012), and a significant (p = 0.048) drop of IgM-anti-*E. coli* antibodies levels was observed on day 1 post pMCAO. Additionally, IgA-anti-*E. coli* antibodies were significantly decreased at day 1 (p = 0.006) and day 2 (p = 0.001). Since the coefficient of variation for IgG-anti-*E. coli* (41.3%/55.7%/48.1%/35.4%), IgM-anti-*E. coli* (42.2%/40.0%/45.9%/33.7%) and IgA-anti-*E. coli* (42.8%/48.5%/49.7%/48.6%) was high at each time point, baseline-corrected values were analyzed (**Figure 3**). Values relative to baseline for IgG-anti-*E. coli* significantly decreased on day 1 (p = 0.048), and those for IgM- and IgA-anti-*E.coli* on days 1 (p = 0.008, p = 0.002) and 2 (p = 0.045, p < 0.001) post pMCAO (**Figure 3**). Antibody levels remained almost constant in the sham reference samples, apart from an isolated increase of IgA-anti-*E.coli* on day 2.

Correlation With Ischemic Brain Damage

A negative correlation (r = −0.700, p = 0.036) was found between LBP and IgA-anti-*E. coli* values 1d post pMCAO. Moreover, the levels of IgM-anti-*E. coli* correlated positively with rCBF values (r = 0.927, p = 0.003) 1d after pMCAO. In addition, a negative correlation (r = -0.901, p = 0.014) was detected between total brain volume (excluding IS lesion) 7d following pMCAO and IgG-anti-*E. coli* 2d post pMCAO. We found no further significant correlations between any measured parameters. Detailed results of all correlation analyses are given in **Supplementary Tables S5–S8**.

APP Response Following IS

CRP and LBP are relevant APPs in humans (Schumann and Zweigner, 1999) and sheep (Schroedl et al., 2001; Ulutas and Ozpinar, 2006). In fact, clinical investigations revealed that blood-borne markers of peripheral inflammation, including increased CRP, IL-6 or white cell counts, are present within the first week following IS in human patients, thus providing evidence of early and sustained inflammatory conditions (Emsley et al., 2003). Elevated CRP levels in cardiovascular ischemia are hypothesized to increase myocardial damage in the infarct area, likely by activating the complement cascade (Nijmeijer et al., 2003). Additional myocardial damage can in turn increase CRP levels, forming a part of the rational basis for our hypothesis that a similar mechanism might exist in stroke. This vicious circle is thought to contribute to poor outcome (Gill et al., 2004; Pepys et al., 2006; Slagman et al., 2011). CRP is normally absent from serum, but typically rises within 6 h of inflammation onset in humans with serum levels increasing up to 1000-fold within 24 h in cases of severe inflammation (Roudbary et al., 2011). LBP plays an essential role for the innate immune response against bacterial infection (Triantafilou and Triantafilou, 2002; Worthmann et al., 2015) and is capable of binding bacterial LPS. It activates macrophages and monocytes via CD14 and toll-like receptors (TLR), leading to release of pro-inflammatory cytokines (Schumann and Zweigner, 1999). In healthy humans, LBP serum values fluctuate between 5–10 μg/ml, and can increase up to 10-fold during the acute stage of severe inflammatory processes (Myc et al., 1997). LBP mean levels in our data set increased from 6 up to 47 μg/ml at day 1 after pMCAO, quantitatively resembling the situation in humans. LBP is usually produced in the liver, but can also be produced extrahepatically under pro-inflammatory conditions. For instance, LBP production was observed in murine and human intestinal epithelium in cases of severe systemic inflammation (Vreugdenhil et al., 1999, 2000). High amounts of ruminant LBP is also expressed within the forestomach, small intestine crypts and colon glands, at which it likely plays an important role in mucosal innate pathogen defense (Rahman et al., 2010). The data may further indicate an early increase of local gastrointestinal LBP production in sheep under pro-inflammatory conditions as previously assumed (Rahman et al., 2010). This might indicate a systemic APR in the early stage of experimental IS in sheep, thus supporting the reference of IS-triggered cascade of systemic immunoreactions observed in rodents (Offner et al., 2006) and humans (Emsley et al., 2003).

Connecting APP Response, IP, and Secondary Brain Damage

Ruminants possess a much larger gastrointestinal tract than rodents and humans. The continuous physiological presence of bacteria such as *E. coli* ensures that a "baseline" antibody titer is maintained in the sheep blood. Interestingly, levels of all tested anti-*E. coli* antibodies were reduced during the first 48 h post IS, but recovered to baseline levels 7d post IS. Theoretically, decreased antibody levels may be related to changes of intestinal barrier integrity. We hypothesize that the decreased antibody levels are related to a suddenly increased presence of bacterial antigens in plasma, as a result of translocation through the gut wall, thus leading to initial anti-*E. coli* antibody consumption.

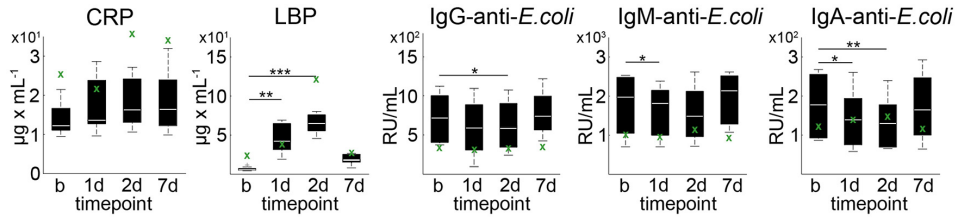

FIGURE 2 | Acute phase proteins and anti-*E. coli* antibodies in plasma. CRP, LBP as well as IgA-, IgM- and IgG-anti-*E. coli* antibodies exhibited a high inter-individual variance at baseline (b) and 1, 2, and 7 days post pMCAO. Boxplots indicate the mean at each time point (white bar), 1st and 3rd quartiles, and 95% confidence intervals. Significance level of paired two-sample *t*-test against baseline were $p < 0.05$ (*), $p < 0.01$ (**), and $p < 0.001$ (***). The green crosses (x) indicate sole data points from the animal with failed pMCAO (no stroke at day 1) serving as a sham reference for surgery-related effects.

Our hypothesis is underpinned by the simultaneously increased LBP levels as well as by a negative correlation between LBP and anti-*E. coli* antibodies within 24 h post IS. Local LBP expression might be increased by pro-inflammatory factors such as LPS (Su et al., 1994; Dentener et al., 2000; Bruewer et al., 2003). However, our results could also be related to SIIS in general. Hence, to substantiate our hypothesis, further investigations should be performed, including measurement of cytokine (e.g., TNF-α) as well as measurements of the sympathetic nervous system status (e.g., catecholamine and cortisol), in order to explore the entire inflammatory and immunosuppression process.

Enhanced IP may enable antigen fluxes through the intestinal wall or could activate the local intestinal immune system. Both events could increase the amount of inflammatory mediators such as intestinal factors including *i*-PAMPs (pathogen associated molecular pattern, e.g., *E. coli* lipopolysaccharide: F-, K-, or H-antigens) F-, K-, or H-antigens or cytokines within the circulation. In summary, increased IP could hypothetically lead to a prolonged inflammatory stage following IS, which may further aggravate IS outcome. We found some indirect indication for a potential relationship between increased IP and a systemic immune reaction. We detected that higher free anti-*E. coli* antibody levels at day 2 were related to smaller lesions (rCBF deficits) 1d following IS (see **Supplementary Table S8**). In turn, higher levels of IgA-anti-*E. coli* (2d post IS) are related to reduced post-stroke total brain volume (indicating post-IS tissue loss) 7d following IS (see **Supplementary Table S8**). This may imply that increased IP could amplify or modify systemic-adaptive and-innate immune reaction patterns, cumulating in secondary brain damage. Subsequent studies must be performed to investigate this assumption, e.g., determination of bacterial antigen, cytokine or endotoxin measurements, histological assessment and CFU content determination in blood, gut lymph nodes, spleen, liver, and lung.

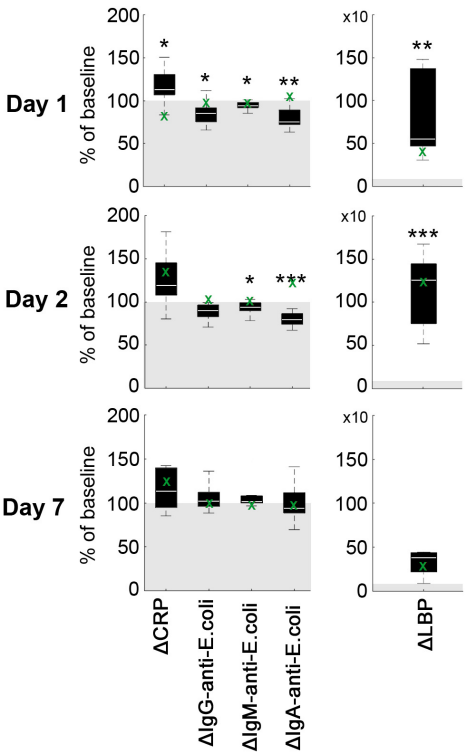

FIGURE 3 | Difference of acute phase proteins ΔCRP and ΔLBP as well as IgA-, IgM- and IgG-anti-*E.coli* antibodies. Values are given as percentage of baseline (gray area). Boxplots indicate the mean difference at each time point (white bar), 1st and 3rd quartiles, and 95% confidence intervals. Significance level of one-sample *t*-test against 100 (baseline) is indicated by $p < 0.05$ (*), $p < 0.01$ (**) and $p < 0.001$ (***). The green crosses (x) indicate sole data points from an animal with failed pMCAO (no stroke at day 1) serving as a sham reference for surgery-related effects.

Critical Appraisal of Preliminary Data and Hypothesis

Rodent brain structure and size, genetic homogeneity, and differences in immunobiology may limit the translation of experimental findings from rodent models to the human patients. Large animal IS models are potentially useful for IP investigations following IS. However, outcome variability is often higher than in rodent models (Herrmann et al., 2019), what may reflect the inter-individual variations observed in human stroke patients. Accordingly, we found a relatively high inter-individual variation for all measured blood parameters, but overall data indeed indicate increased IP after IS.

A limitation of the supporting data is the small statistical sample size and the existence of only one sham case. In consequence, general effects of the surgical procedure, anesthesia

or medication on evaluated blood markers cannot be excluded. The responses of CRP and LBP in the sham subject with identical surgical intervention except for MCA occlusion show a relative similar pattern than that in other animals, apart from a drop in CRP value at day 1 (**Figure 2**). These APPs would be expected to generally increase after tissue trauma (Baumann and Gauldie, 1994; Nijmeijer et al., 2003) as for instance exerted by the invasive MCAO model (trepanation). However, antibody titers relative to baseline remained almost constant in this animal over the course of the experiment. This makes it less likely that the changes observed in the other subjects are simply caused by the surgical intervention itself, supporting our hypothesis.

Potentially, there might be an interaction between medication and post-stroke immune system responses, i.e., clinical signs of infection following pMCAO could be masked by medication. However, there is no evidence of relevant impact of butorphanol-, cyclooxigenase inhibitor flunixin-, or antibiotic treatment (enrofloxacin) on CRP and LBP levels in contemporary literature (Löscher et al., 2014; Henke et al., 2015). However, systemic antibiotic therapy was given in a uniform scheme as required by the experimental protocol of the study these cases were derived from. This may have counteracted some of the consequences of potential *E. coli* traffic across intestinal barriers and on inflammatory response, but post-stroke changes in antibody and APP levels were nevertheless large enough to be statistically significant despite the small sample sizes.

CONCLUSION

We initially characterized the modification of the APR and the interactions between the systemic immune system and IP following IS in an ovine IS model. Our findings confirm the reaction patterns of CRP and LBP as APPs following IS, and revealed preliminary indications for alterations of intestinal barrier functions. In addition, we found indirect indications of IP enhancement in the early stage of IS in sheep. To our knowledge, this was first explored in a large animal model. Further confirmatory investigations, e.g., direct identification of bacterial antigens, endotoxin measurements, histological assessment and colony forming unit (CFU) determination in blood, gut lymph nodes, spleen, liver, or lung, need to be performed. Measurements of inflammatory cytokines as well as potential interaction with the sympathetic nervous system (e.g., catecholamine and cortisol determination) should be conducted to gain a more holistic picture of the entire pathophysiological cascade. Moreover, any effect of antibiotic treatment should be excluded by a carefully planned study design.

DATA AVAILABILITY STATEMENT

All raw data are available upon reasonable request.

ETHICS STATEMENT

The animal study was reviewed and approved by the Experimental Animal Committee of the Regional Council of Leipzig, Germany (animal protocol number 09-11).

AUTHOR CONTRIBUTIONS

FF designed the study, performed the experiments, obtained and analyzed the data, drafted, and reviewed the manuscript. VZ obtained and analyzed the data and reviewed the manuscript. SP helped in performing the experiments and the obtained data. RR and DM performed the experiments and reviewed the manuscript. AD performed the experiments and obtained the data. LP analyzed the data. A-KS helped in performing the experiments. HB obtained and analyzed the data. JB analyzed the data, drafted, and reviewed the manuscript. WS analyzed the data and reviewed the manuscript. BN obtained and analyzed the data, drafted, and reviewed the manuscript. All authors acknowledged the final version of the manuscript.

FUNDING

Parts of this work was supported by the German Federal Ministry of Education and Research (grant number 0315920).

ACKNOWLEDGMENTS

We wish to thank Kerstin Klimke for technical assistance (ELISA), the cyclotron and PET/MR imaging crew members for excellent technical support during the PET/MR investigations. Furthermore, we would also like to thank Franziska Schwarz (Scivisto) for providing graphic tools.

Tanaka K, Matsumoto S, Yamada T, Yamasaki R, Suzuki M, Kido MA and Kira J-I (2020) Reduced Post-ischemic Brain Injury in Transient Receptor Potential Vanilloid 4 Knockout Mice. Front. Neurosci. 14:453. doi: 10.3389/fnins.2020.00453

Background and Purpose: In the acute phase of ischemia-reperfusion, hypoperfusion associated with ischemia and reperfusion in microvascular regions and disruption of the blood–brain barrier (BBB) contribute to post-ischemic brain injury. We aimed to clarify whether brain injury following transient middle cerebral artery occlusion (tMCAO) is ameliorated in *Transient receptor potential vanilloid 4* knockout (*Trpv4*$^{-/-}$) mice.

Methods: tMCAO was induced in wild-type (WT) and *Trpv4*$^{-/-}$ mice aged 8–10 weeks. Ischemia-induced lesion volume was evaluated by 2,3,5-triphenyltetrazolium chloride staining at 24 h post-tMCAO. Tissue water content and Evans blue leakage in the ipsilateral hemisphere and a neurological score were evaluated at 48 h post-tMCAO. Transmission electron microscopy (TEM) was performed to assess the morphological changes in microvasculature in the ischemic lesions at 6 h post-tMCAO.

Results: Compared with WT mice, *Trpv4*$^{-/-}$ mice showed reduced ischemia-induced lesion volume and reduced water content and Evans blue leakage in the ipsilateral hemisphere alongside milder neurological symptoms. The loss of zonula occludens-1 and occludin proteins in the ipsilateral hemisphere was attenuated in *Trpv4*$^{-/-}$ mice. TEM revealed that parenchymal microvessels in the ischemic lesion were compressed and narrowed by the swollen endfeet of astrocytes in WT mice, but these effects were markedly ameliorated in *Trpv4*$^{-/-}$ mice.

Conclusion: The present results demonstrate that TRPV4 contributes to post-ischemic brain injury. The preserved microcirculation and BBB function shortly after reperfusion are the key neuroprotective roles of TRPV4 inhibition, which represents a promising target for the treatment of acute ischemic stroke.

Keywords: ischemic stroke, transient receptor potential vanilloid 4, knockout mice, brain edema, blood–brain barrier

INTRODUCTION

Acute ischemic stroke secondary to large artery occlusion is a common and devastating condition that results in death or long-term disability in a high proportion of patients. Recent advances in revascularization therapies, including mechanical thrombectomy, have enabled rapid and effective recanalization for large artery occlusions in patients with acute ischemic stroke (Goyal et al., 2016). However, despite the high rates of early recanalization, some patients still experience poor outcomes. In these cases, lack of reperfusion due to blockade of the microcirculation leading to hypoperfusion associated with ischemia and reperfusion and disruption of the blood–brain barrier (BBB) may contribute to post-ischemic brain injury (Molina and Alvarez-Sabín, 2009).

Transient receptor potential vanilloid 4 (TRPV4), a member of the TRP vanilloid subfamily, is a non-selective cation channel permeable to Ca^{2+}, Na^{+}, and Mg^{2+} ions (Ramsey et al., 2006). TRPV4 was first described as a cellular osmotic sensor that detects extracellular hypo-osmolarity, and was subsequently shown to be activated by multiple stimuli. TRPV4 is widely expressed in the central nervous system (Nilius and Voets, 2013), and its localization on astrocyte endfeet plays an essential role in the regulation of vascular tone in brain microvessels (Dunn et al., 2013; Filosa et al., 2013). Enrichment of TRPV4 and aquaporins at the endfeet of astrocytes ensures that even small changes in conditions, such as extracellular ion concentrations, result in astroglial swelling, volume regulation, and reorganization of downstream signaling pathways (Ryskamp et al., 2015; Iuso and Križaj, 2016). Pharmacological blockade of TRPV4 results in reduction of brain ischemia-induced lesion volume through inhibition of matrix metalloprotease (MMP) activation, thereby providing protection against BBB disruption following transient focal cerebral ischemia (Li et al., 2013; Jie et al., 2015a,b, 2016). Moreover, TRPV4 contributes to Ca^{2+} influx in both astrocytes and neurons and to extracellular glutamate accumulation during peri-infarct depolarizations (Rakers et al., 2017). These findings indicate that TRPV4 has a large influence on ischemia-induced brain injury and indicate that inhibition of TRPV4 has a neuroprotective role in acute ischemic stroke. However, a recent report demonstrated exacerbation of ischemia-induced brain edema formation in *Trpv4* knockout ($Trpv4^{-/-}$) mice (Pivonkova et al., 2018). Specifically, $Trpv4^{-/-}$ mice showed larger T2-hyperintensity lesions following transcranial permanent middle cerebral artery occlusion (pMCAO) compared with wild-type (WT) mice. Moreover, the report described a minimal involvement of TRPV4 in astrocyte volume regulation *in vivo*. Thus, the mechanism for the neuroprotective effects of TRPV4 in acute ischemic stroke remains inconclusive. Given this context, we aimed to investigate the differences in post-ischemic brain injury between $Trpv4^{-/-}$ and WT mice, and to clarify the mechanism for any identified differences using a transient MCAO (tMCAO) model in the C57BL/6N mouse strain.

MATERIALS AND METHODS

Ethics Statement

The animal experiments were conducted in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals, and all procedures were approved by the Animal Ethics Committee of Kyushu University (Approval Nos. A28-08-4, A30-138-2, 26-60, and 1-48).

Animals

$Trpv4^{-/-}$ mice were transferred from Jichi Medical University (Suzuki et al., 2003). C57BL/6N mice were purchased from Kyudo (Fukuoka, Japan). The $Trpv4^{-/-}$ mouse strain had been backcrossed with the C57BL/6N strain for >10 generations. Inbred adult male mice at 8–10 weeks of age (median [interquartile range] weight: 23.3 [21.7–24.9] g for WT mice and 24.1 [20.8–26.2] g for $Trpv4^{-/-}$ mice) were maintained in a temperature-controlled (22–25°C) specific pathogen-free animal facility on a 12-h/12-h light/dark cycle with free access to food and water.

tMCAO Surgery

tMCAO was performed using a previously described method with modifications (Engel et al., 2011). Mice were anesthetized with 1.5–2.0% isoflurane (Escain; Mylan Seiyaku, Tokyo, Japan) in 30% oxygen-mixed gas under spontaneous respiration. Focal cerebral ischemia was induced by a silicone-coated 6-0 monofilament (#602356; Doccol, Redlands, CA, United States) inserted through a small incision in the right common carotid artery and then advanced through the internal carotid artery to occlude the origin of the MCA. The filament was withdrawn to allow reperfusion of the ischemic hemisphere. Regional cerebral blood flow in the right MCA territory was monitored by laser Doppler flowmetry (Omegaflo FLO-C1; Omegawave, Tokyo, Japan) to confirm vessel occlusion, shown by a rapid and dramatic decrease in brain perfusion (mean reduction: 70–80%) that remained stable until reperfusion. Body temperature was maintained at 37°C based on the rectal temperature. In sham-operated animals, the same procedure was performed except for insertion of the intraluminal filament. The optimal time of tMCAO was determined by a preliminarily experiment in which tMCAO was induced in WT mice for 15, 30, or 45 min. The lesion size at 24 h post-tMCAO became larger and more stable while the mortality rate increased with longer tMCAO induction (≈0% mortality for 15 min, ≈10% for 30 min, ≈20% for 45 min tMCAO). Based on the lesion size and mortality rate, 30 min tMCAO was used in this study.

2,3,5-Triphenyltetrazolium Chloride (TTC) Staining

Transient focal cerebral ischemia was induced in 12 $Trpv4^{-/-}$ and 12 WT mice. At 24 h post-tMCAO, mice were transcardially perfused with cold saline. The brain was removed immediately and cut into serial 1-mm-thick coronal sections. The sections

were incubated in a 2% solution of TTC (Sigma-Aldrich Japan, Tokyo, Japan) for 15 min at 37°C. Images were captured with a Nikon D7100 digital camera (Nikon, Tokyo, Japan). Unstained areas were measured in TTC-stained sections using ImageJ software, version 1.46r (National Institutes of Health, Bethesda, MD, United States) to calculate the infarct volume.

Tissue Water Content

Transient focal cerebral ischemia was induced in 12 *Trpv4*$^{-/-}$ and 12 WT mice. At 48 h post-tMCAO, mice were decapitated under anesthesia and the olfactory bulb, cerebellum, and brainstem were removed from each dissected brain. The ipsilateral and contralateral hemispheres were separated and their wet weights immediately recorded. The dry weights were determined after drying the tissues to a constant weight at 100°C for 48 h. Tissue water content was calculated as % H_2O = (1 − dry weight/wet weight) × 100%.

Evans Blue (EB) Extravasation

Transient focal cerebral ischemia was induced in 12 *Trpv4*$^{-/-}$ and 12 WT mice. At 46 h post-tMCAO, 2% EB dye (Sigma-Aldrich Japan) in normal saline was injected intraperitoneally at a dose of 4 ml/kg body weight. Subsequently, the mice were perfused with cold saline at 48 h post-tMCAO. The ipsilateral hemisphere was collected and incubated with 500 μl formamide (Sigma-Aldrich Japan) at room temperature for 24 h to extract EB. The concentration of dye in the extract was calculated by reference to a standard curve of EB in formamide quantified at 620 nm by spectrofluorophotometry (PerkinElmer Ensight; PerkinElmer, Waltham, MA, United States).

Neurological Scoring

Neurological scores were evaluated at 24 and 48 h post-tMCAO in the *Trpv4*$^{-/-}$ and WT mice subjected to evaluation of tissue water content and EB leakage (n = 24 per group) using a scoring system modified from a neurological scoring system for sensorimotor deficits (Garcia et al., 1995). The highest possible score of 18 indicated no neurological deficit and the lowest score of 3 indicated the most severe impairment.

Western Blot Analysis

Transient focal cerebral ischemia was induced or a sham operation performed in 9 *Trpv4*$^{-/-}$ and 9 WT mice. At 48 h post-tMCAO, mice were transcardially perfused with cold saline and a 1-mm coronal slice of the ipsilateral hemisphere at 4 mm posterior to the olfactory bulb was collected. The brain slice was homogenized in RIPA buffer (50 mM Tris-HCl pH 7.4, 150 mM NaCl, 5 mM EDTA, 1% Nonidet P-40, 1% sodium deoxycholate, 0.1% SDS, 1% aprotinin, 50 mM NaF, 0.1 mM Na_3VO_4, 1% Triton-X100) containing anti-phosphatase PhoSTOP (Roche, Mannheim, Germany) and then centrifuged at 10,000 × g for 10 min at 4°C. The protein sample was separated by 4–15% SDS-PAGE and transferred to a polyvinylidene fluoride membrane. The membrane was incubated with anti-zonula occludens (ZO)-1 (61-7300; Zymed Laboratories, San Francisco, CA, United States; 1:1,000 dilution), anti-occludin (ab167161; Abcam, Cambridge, MA, United States; 1:2,000 dilution), or anti-β-actin (A5441; Sigma-Aldrich Japan; 1:20,000 dilution) primary antibodies at 4°C overnight. After washing in Tris-buffered saline with 0.5% Tween-20, the membrane was incubated with a horseradish peroxidase-labeled secondary antibody (Abcam). Antibody-bound protein bands were visualized by enhanced chemiluminescence (ECL prime; Amersham Biosciences, Piscataway, NJ, United States). The protein levels were quantitatively analyzed using a ChemiDoc Touch Imaging System (Bio-Rad, Hercules, CA, United States) and Image Lab software version 5.2.1 (Bio-Rad). The amount of occludin was defined as the sum of the amounts of its dimeric (120 kDa) and monomeric (64 kDa) forms (Yanai et al., 2017). The protein levels of ZO-1 and occludin were normalized by those of β-actin. One mouse without surgery was used as an external control.

Reverse Transcription-Quantitative Polymerase Chain Reaction (RT-qPCR)

Five *Trpv4*$^{-/-}$ and five WT mice without surgery were evaluated for their baseline gene expression levels of *Trpv4*, *Aqp4*, and *Kcnj10*. The mice were transcardially perfused with cold saline and a 1-mm-thick coronal slice of the hemisphere at 4 mm posterior to the olfactory bulb was collected. Total RNA was extracted using an RNeasy Mini Kit (Qiagen, Valencia, CA, United States). The A260/A280 ratio was measured using a spectrophotometer (Nanodrop 2000; Thermo Fisher Scientific, Wilmington, DE, United States) to determine the purity and concentration of the RNA. Complementary DNA was synthesized from the total RNA using ReverTra Ace reverse transcriptase (Toyobo, Osaka, Japan). Subsequently, RT-qPCR analysis was performed in a 7500 Fast Real-Time PCR System (Applied Biosystems, Foster City, CA, United States) using TaqMan Fast Universal PCR master mixture and TaqMan probes (Applied Biosystems) for *Trpv4* (Hs01099348_m1), *Aqp4* (Hs00242342_m1), *Kcnj10* (Hs01922935_s1), and *Gapdh* (Sp03785097_s1) under standard reaction conditions recommended by the manufacturer. The mRNA levels were normalized by those of *Gapdh*.

Transmission Electron Microscopy (TEM)

Transient focal cerebral ischemia was induced in one *Trpv4*$^{-/-}$ and one WT mouse. At 6 h post-tMCAO (Kurisu et al., 2016), mice were transcardially perfused with 4% paraformaldehyde with 3.4% sucrose. Brain slices including the right striatum were fixed with 2.5% glutaraldehyde in 0.1 M cacodylate buffer at 4°C overnight, post-fixed with 1% OsO_4 in 0.1 M cacodylate buffer on ice for 2 h, dehydrated in a graded ethanol series and propylene oxide, and embedded in epoxy resin. Ultrathin sections were cut at 80-nm thickness with an EM UC7 ultramicrotome (Leica Microsystems, Wetzlar, Germany) and stained with 2% uranyl acetate followed by a mixture of lead nitrate-lead acetate-lead citrate. The sections were observed with a Tecnai 20 electron microscope (FEI Co., Eindhoven, Netherlands) operated at an accelerating voltage of 200 kV and micrographs were recorded at a magnification of 5,000× for at least 10 microvasculatures.

Statistical Analysis

Statistical analyses were performed using JMP version 9.0 software (SAS Institute, Cary, NC, United States). Data are expressed as the median and interquartile range. Statistically significant differences were evaluated by the Wilcoxon rank-sum test or the Kruskal–Wallis test with *post hoc* comparison by Dunn's multiple comparison test. Values of $p < 0.05$ were considered to indicate statistical significance.

RESULTS

Brain Injury After tMCAO Is Reduced in *Trpv4*$^{-/-}$ Mice

To assess the ischemia-induced lesion volume, TTC staining was performed at 24 h post-tMCAO. The ischemia-induced lesion volume was significantly reduced in *Trpv4*$^{-/-}$ mice compared with WT mice ($p = 0.002$; **Figures 1A,B**). Because brain edema progressed to the maximum level on the second and third days, the tissue water content in the ipsilateral hemisphere was measured at 48 h post-tMCAO. The increase in tissue water in the ipsilateral hemisphere was significantly decreased in *Trpv4*$^{-/-}$ mice compared with WT mice ($p = 0.004$; **Figure 1C**). To assess the BBB function, EB leakage in the ipsilateral hemisphere was measured at 48 h post-tMCAO. The extent of EB leakage was significantly smaller in *Trpv4*$^{-/-}$ mice compared with WT mice ($p = 0.002$; **Figure 1D**). To assess the sensorimotor performance, the neurological score was evaluated at 24 and 48 h post-tMCAO in the two types of mice. Performance was impaired in both *Trpv4*$^{-/-}$ and WT mice after tMCAO with no significant difference between the groups at 24 h (12 [11–13] vs. 12 [10–12], $p = 0.307$; **Figure 1E**). However, *Trpv4*$^{-/-}$ mice showed significantly milder symptoms than WT mice at 48 h post-tMCAO (12 [10–13] vs. 10 [9–11], $p = 0.009$).

Preservation of Tight Junction Proteins After tMCAO in *Trpv4*$^{-/-}$ Mice

To assess protein levels in tight junctions of the BBB, western blotting was performed at 48 h post-tMCAO (**Figures 2A,B**). The occludin and ZO-1 protein levels in the ipsilateral hemisphere were significantly lower in WT mice after tMCAO than after sham operation ($p = 0.044$ and $p = 0.019$, respectively), while these changes were not statistically significant in *Trpv4*$^{-/-}$ mice ($p = 0.400$ and $p = 0.535$, respectively).

RT-qPCR Analysis of WT and *Trpv4*$^{-/-}$ Mouse Brains

The expression levels of *Trpv4* and genes associated with astrocyte volume regulation (*Aqp4* and *Kcnj10*) were evaluated by

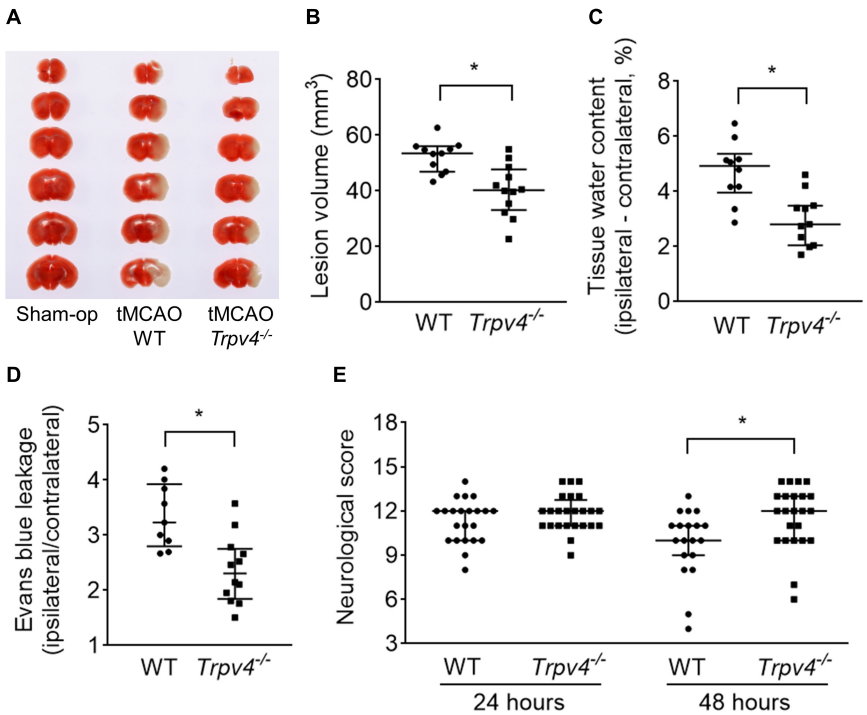

FIGURE 1 | Effects of *Trpv4*$^{-/-}$ on neurological and pathophysiological findings. **(A,B)** Evaluation of ischemia-induced lesion volumes at 24 h post-tMCAO (one WT mouse died within 24 h; therefore, $n = 11$ for WT mice and $n = 12$ for *Trpv4*$^{-/-}$ mice). **(C)** Evaluation of tissue water content by subtraction of the contralateral hemisphere from the ipsilateral hemisphere at 48 h post-tMCAO (two WT mice and one *Trpv4*$^{-/-}$ mice died within 48 h; therefore, $n = 10$ for WT mice and $n = 11$ for *Trpv4*$^{-/-}$ mice). **(D)** Evans blue leakage presented as the ratio of leakage in the ipsilateral hemisphere to that in the contralateral hemisphere at 48 h post-tMCAO (three WT mice died within 48 h; therefore, $n = 9$ for WT mice and $n = 12$ for *Trpv4*$^{-/-}$ mice). **(E)** Evaluation of neurological scores at 24 and 48 h post-tMCAO ($n = 22$ for WT mice and $n = 24$ for *Trpv4*$^{-/-}$ mice at 24 h post-tMCAO; $n = 19$ for WT mice and $n = 23$ for *Trpv4*$^{-/-}$ mice at 48 h post-tMCAO). *$p < 0.05$.

Each group contained nine mice. Protein levels were corrected by β-actin. *$p < 0.05$.

RT-qPCR. The data revealed significantly decreased expression of *Trpv4* in the *Trpv4*$^{-/-}$ mouse brain compared with the WT mouse brain ($p = 0.009$), while *Aqp4* and *Kcnj10* showed no differences ($p = 0.347$ and $p = 0.465$, respectively; **Figure 3**).

Reduction in Astrocyte Endfeet Swelling in Microvessels After tMCAO in *Trpv4*$^{-/-}$ Mice

Given the highly polarized localization of TRPV4 in the astrocyte endfeet surrounding brain capillaries, microvascular morphological changes in the ischemic lesion were analyzed by TEM at 6 h post-tMCAO. As shown in **Figure 4**, there was evidence of widespread endfeet swelling of pericapillary astrocytes in most of the microvasculature in the ischemic lesion. The cytoplasm was expanded, and mitochondria in the endfeet were enlarged and degenerated with swollen cristae. The residual lumen of microvessels was narrowed through compression by the extensive swollen endfeet of perivascular astrocytes in WT mice, but this was markedly suppressed in *Trpv4*$^{-/-}$ mice.

DISCUSSION

This study demonstrated that *Trpv4*$^{-/-}$ mice showed reduced brain ischemia-induced lesion size and preserved BBB compared with WT mice in the acute phase. Astrocyte endfeet swelling and microvascular narrowing shortly after reperfusion were markedly suppressed in *Trpv4*$^{-/-}$ mice.

Previous research using ischemia-reperfusion animal models demonstrated decreased capillary blood flow with narrowed capillary diameters (Hauck et al., 2004). This microvessel narrowing was caused by swelling of perivascular astrocyte endfeet shortly after ischemia-reperfusion (Ito et al., 2011; Kurisu et al., 2016). Furthermore, the astrocyte endfeet swelling was markedly ameliorated by *Aqp4* knockout (Manley et al., 2000) or infusion of cold saline or mannitol (Ito et al., 2014; Kurisu et al., 2016), leading to reduced infarct volumes. Shimbo et al. (2017) demonstrated that infusion of hemoglobin-encapsulating liposomes, which were smaller than red blood cells and could

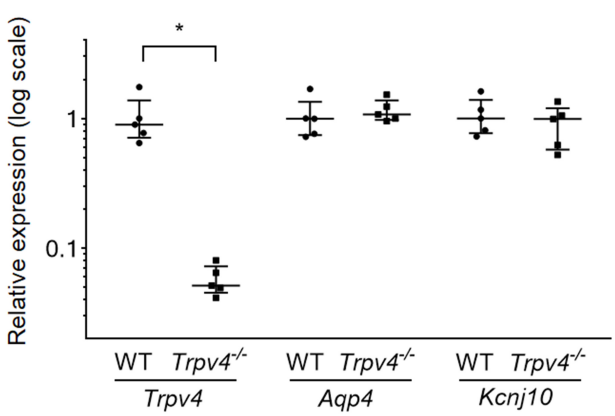

FIGURE 3 | Expression levels of *Trpv4*, *Aqp4*, and *Kcnj10* in WT and *Trpv4*$^{-/-}$ mouse brains. RT-qPCR analyses were performed to measure the mRNA levels of *Trpv4*, *Aqp4*, and *Kcnj10* in the brains of WT and *Trpv4*$^{-/-}$ mice. Expression levels were corrected by *Gapdh*. Each group contained five mice. *$p < 0.05$.

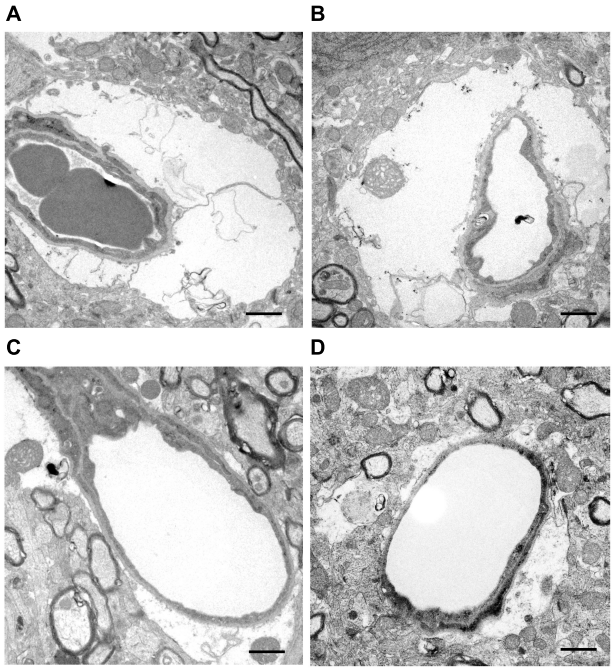

FIGURE 4 | Representative images of microvascular morphological changes evaluated by TEM. **(A,B)** Microvessels are compressed and narrowed by swollen astrocyte endfeet in WT mice. **(C,D)** By contrast, the astrocyte endfeet swelling is milder and the residual vascular lumen is well-preserved in *Trpv4*$^{-/-}$ mice. One WT mouse and one *Trpv4*$^{-/-}$ mouse were assessed. Scale bars = 1 μm.

pass through narrowed blood vessels, reduced the infarction size. These reports indicate that microvascular narrowing may contribute to hypoperfusion associated with ischemia and reperfusion. The mechanism for astrocyte endfeet swelling in acute ischemia was assumed to involve upregulated expression and polarized localization of AQP4 at astrocyte endfeet shortly after reperfusion (Steiner et al., 2012; Kurisu et al., 2016). The present study found similar mRNA expression patterns of *Aqp4* and *Kcnj10* between WT and *Trpv4*$^{-/-}$ mouse brains, in accordance with a previous study (Pivonkova et al., 2018). Blockade of TRPV4 altered hypothermia-induced surface localization of AQP4, despite there being no change in total protein expression levels (Salman et al., 2017). Thus, TRPV4 deficiency may reduce astrocyte endfeet swelling by inhibiting the AQP4 surge or AQP4 surface localization at astrocyte endfeet after ischemia-reperfusion.

This study demonstrated preserved BBB function shortly after reperfusion in *Trpv4*$^{-/-}$ mice, which was similar to that observed after pharmacological blockade of TRPV4 (Jie et al., 2015b). TRPV4-mediated Ca^{2+} influx led to activation of MMPs in lung tissue (Villalta et al., 2014), with subsequent disruption of tight junctions among alveolar epithelial cells (Dagenais et al., 2018). Therefore, TRPV4 deficiency may maintain the BBB via MMP inhibition to preserve tight junction proteins. A TRPV4 antagonist, GSK2798745, is currently being administered to patients in a phase II clinical trial for treatment of congestive heart failure-induced pulmonary edema (NTC02497937) (Stewart et al., 2020). EB leakage might have occurred because of BBB disruption and also because of ischemia-induced opening of connexin hemichannels in neurovascular unit constituent cells, making them permeable to EB dye (Orellana et al., 2013); however, TRPV4 has potential as a therapeutic target for post-ischemic brain injury from the perspective of BBB protection.

An important concern against clinical application of TRPV4 inhibition is that it may lead to increased lesion volumes (Pivonkova et al., 2018). However, this was inconsistent with the findings of the present study. The difference between the two studies may be because of the different model used (pMCAO vs. tMCAO). Although recanalization is considered the most important event, development of collateral circulation is another major determinant for severity of ischemic stroke with large artery occlusions. Dilation of leptomeningeal arteries occurs as early as 6 h after pMCAO via increased phosphorylation of endothelial nitric oxide synthase (eNOS) in response to shear stress (Iwasawa et al., 2018). Meanwhile, *Trpv4*$^{-/-}$ mice exhibited loss of shear stress-induced vasodilatation of the carotid artery (Hartmannsgruber et al., 2007), and endothelial downregulation of TRPV4 was shown to contribute to impairment of eNOS-mediated relaxation of the mesenteric artery (Boudaka et al., 2019). These findings suggest that TRPV4 deficiency may exacerbate ischemic brain injury through impairment of acute collateral development in cases of recanalization failure, such as the pMCAO model.

The neuroprotective effects of TRPV4 inhibition may not be solely derived from astrocytic TRPV4 as suggested in a previous report (Pivonkova et al., 2018), because TRPV4 is also expressed in endothelial cells and neutrophils. TRPV4 deficiency prevented neutrophil responses to proinflammatory stimuli, including formation of reactive oxygen species (ROS), adhesion, chemotaxis to break the alveolar–capillary barrier, and development of acute lung injury (Yin et al., 2016). Neutrophils play an important role in acute stroke pathology, wherein reperfusion provides neutrophils with access to the vulnerable brain (Stowe et al., 2009). TRPV4 deficiency or blockade may suppress neutrophil activation to break the BBB. Moreover, free radical damage was shown to play a key role in ischemia-reperfusion injury (Sun et al., 2018). Activation of TRPV4 enhanced oxidative stress in hippocampal neurons (Hong et al., 2016), and TRPV4 was simultaneously activated by ROS (Badr et al., 2016; Suresh et al., 2018). These observations indicate that TRPV4 and free radicals form a positive feedback loop that is involved in neurotoxicity. Thus, blockade of TRPV4 may have other neuroprotective effects in terms of ROS-mediated brain injury.

This study has several limitations. First, the mouse groups were not randomized for surgery and other tests because of the study design, which may have caused some selection biases. Second, in the TEM analysis, we could not perform a statistical evaluation because of a shortage in the number of detected microvessels in our data. Therefore, we qualitatively described the main observed findings in terms of microvascular morphological changes. Third, the neuroprotective effects in *Trpv4*$^{-/-}$ mice

were only assessed in the acute phase of transient focal cerebral ischemia because most of the mice showed continuous body weight loss that exceeded 20% by 48 h post-tMCAO and thus met the humane endpoint for laboratory animals (Science Council of Japan, 2006). Therefore, the effects of *Tprv4* deficiency on chronic ischemia and delayed ischemic neurological deficits remain to be established. Activation of TRPV4 via 4α-phorbol 12,13-didecanoate was reported to contribute to functional recovery through angiogenesis and neurogenesis at 5 days post-tMCAO (Chen et al., 2018). Further investigations are needed to confirm whether long-term inhibition of TRPV4 in the subacute to convalescent phases plays a neuroprotective role. Finally, we only examined the expression of two genes that regulate astrocyte volume, *Aqp4* and *Kcnj10* (Iuso and Križaj, 2016); therefore, further unbiased gene expression studies using microarray methodology are necessary to reveal any gene expression changes that contribute to ischemia-resistance due to knockout of *Trpv4*.

CONCLUSION

TRPV4 contributes to post-ischemic brain injury following transient focal cerebral ischemia. The preserved BBB function and microcirculation shortly after reperfusion are the key neuroprotective roles of TRPV4 inhibition, which represents a promising target for the treatment of acute ischemic stroke.

Cervical artery dissection (CAD) is an important causal factor for stroke in young and middle-aged individuals and presents a great burden to the individual stroke victim. However, the pathophysiological mechanisms underlying CAD remain unknown. Here, an iTRAQ (isobaric tagging for relative and absolute quantitation)–based quantitative proteomic approach was performed, to identify differentially expressed proteins in serum samples obtained from spontaneous CAD and non-CAD ischemic stroke subjects. Differential protein expression was analyzed for Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway overrepresentation, and six differential proteins were selected for enzyme-linked immunosorbent assay validation. Through KEGG analysis, the significantly differentiated proteins were primarily involved in immunoregulation, blood coagulation, and lipid metabolism. For the first time, differential expressions of apolipoprotein B, apolipoprotein C-I, lipopolysaccharide-binding protein, vascular cell adhesion molecule 1, fibulin-1, and ficolin-2 were confirmed as being significantly upregulated in CAD as compared to non-CAD ischemic stroke subjects. In conclusion, proteomic analysis reveals that early perturbation of immunoregulation and lipid metabolism may be involved in the pathophysiology of CAD. Specifically, the panel of six proteins identified is promising as serum-based biomarkers for the detection of increased CAD risk in stroke subjects.

Keywords: cervical artery dissection, stroke, serum, immunoregulation, lipid metabolism

INTRODUCTION

Cervical artery dissection (CAD) is an important cause of cerebral ischemia in young and middle-aged patients. Although accounting for only 2% of all ischemic strokes, CAD accounts for 8–25% of strokes in patients younger than 45 years (1). Such a high incidence of stroke presents a great burden not only to the individual stroke victim but also to their family, society, and the economy (2). A lack of clinical symptoms associated with CAD is regarded as the main cause of missed diagnoses. Thanks to the development of advanced imaging techniques, CAD has been increasingly

recognized in the past few years as involved in at least some aspects of this disease. However, the underlying pathogenesis responsible for spontaneous CAD is unknown, making the diagnosis of CAD more challenging.

Unfortunately, the search for clinically useful predictors for stroke risk has been inconclusive. One study found that hyperhomocysteinemia and elevated peripheral leukocyte counts have been reported previously in patients with CAD. However, these factors have yielded poor results and lack specificity as a biomarker (3, 4). Currently, the candidate biomarkers for CAD risk that have shown promise include fibrillin-1 (5), serum neurofilament light chain (6), extracellular matrix (ECM)–regulating enzymes (7), and plasma TT MTHFR genotype (8). These factors, however, are neither standardized nor clinically practical as they exhibit low sensitivity and variable specificity.

To address this challenge, several lines of evidence suggest that the peripheral circulation may be adversely affected in individuals at risk of CAD and therefore may serve as a source of useful biomarkers for this disorder (9). Proteomics, the analysis of protein expression in biological samples, can improve our understanding of the pathophysiological mechanisms and aid in diagnostic tool development (10). We hypothesize that a proteomic signature for CAD can be detected in human serum.

In this study, serum samples from spontaneous CAD and non-CAD stroke subjects with ischemic events were analyzed using a quantitative proteomic approach based on isobaric tags for relative and absolute quantitation (iTRAQ) and multidimensional liquid chromatography–tandem mass spectrometry (LC-MS/MS). Differentially expressed proteins were further validated by enzyme-linked immunosorbent assay (ELISA) and analyzed by cluster Profiler R package bioinformatics resources. This proteomic approach may ultimately contribute to a better understanding of the pathophysiology underlying CAD.

MATERIALS AND METHODS

Subjects and Ethics Statement

Fifteen patients with spontaneous CAD admitted to the Department of Neurology, Southwest Hospital, Army Medical University, from February 2014 to December 2016 were prospectively enrolled, all having symptoms of cerebral ischemia. Thirteen age- and sex-matched patients with ischemic stroke unrelated to CAD were admitted to our department during the same period for comparisons. The diagnosis of CAD was based on widely accepted criteria as previously described (11). Symptomatic patients with ischemic stroke within 15 days after the first symptom onset represented the acute stage. Patients with a recent history of head or neck trauma were excluded. Stroke severity was assessed based on the National Institutes of Health Stroke Scale (NIHSS) score. Dual antiplatelet treatment or anticoagulation therapy was utilized in all patients. The study was approved by the local ethics committee. Written informed consent was obtained from each patient or from an authorized family member.

Sample Collection

All blood samples were obtained from non-fasting patients in the morning between 8:00 and 10:00 AM. Serum samples were collected in 10-cc separator tubes (BD Vacutainers, catalog no. 367820; Becton, Dickinson & Co., Franklin Lakes, New Jersey, NJ, USA) and were kept at 4°C for 1 h and then centrifuged at 3,000 revolutions/min for 10 min at 4°C. The serum samples were distributed into 400-μL aliquots and stored at −80°C until use.

Protein Digestion and iTRAQ Labeling

Each sample consisted of a pool of serum from 15 CAD and 13 non-CAD stroke subjects. The proteins in each sample were denatured, reduced, alkylated, and digested with sequencing-grade modified trypsin with a protein-to-enzyme ratio of 20:1 at 37°C overnight and then labeled with the following iTRAQ reagent tags in duplicate: 113 and 116 for CAD, and 115 and 118 for the non-CAD ischemic stroke subjects.

LC-MS/MS Analysis for Peptide Identification and Sequence Database Search

The iTRAQ-labeled peptides were mixed and fractionated by 16 SCX chromatography using the AKTA Purifier system (GE Healthcare, Pittsburgh, PA, USA) and then for LC-MS/MS analysis using Q Exactive mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA). Desalted peptide mixture were loaded onto a Acclaim PePmap C18-reversed phase column (75 μm × 2 cm, 3 μm, 100 *Å*; Thermo Fisher Scientific, Waltham, MA, USA) and separated with reversed phase C18column (75 μm × 10 cm, 5 μm, 300 *Å*; Agela Technologies, Torrance, CA, USA) mounted onto a Dionex ultimate 3000 nano LC system (Thermo Fisher Scientific, Waltham, MA, USA). Peptides were eluted using a gradient of 5% to 80% (vol/vol) acetonitrile in 0.1% formic acid over 65 min at a flow rate of 400 nL min^{-1} combined with a Q Exactive mass spectrometer (Thermo Fisher Scientific, Waltham, MA, USA). The eluates were directly entered Q-Exactive MS (Thermo Fisher Scientific), setting in positive ion mode and data-dependent manner with full MS scan from 350 to 2,000 m/z, full scan resolution at 70,000, MS/MS scan resolution at 17,500. MS/MS scan with minimum signal threshold 1E+5, isolation width at 2 Da. To evaluate the performance of this mass spectrometry on the iTRAQ-labeled samples, two MS/MS acquisition modes, higher collision energy dissociation (HCD) was employed. And to optimize the MS/MS acquisition efficiency of HCD, normalized collision energy was systemically examined 28, stepped 20%.

All LC-MS/MS data were processed using Proteome Discoverer Software 1.3 (Thermo Fisher Scientific, Waltham, MA, USA). MS/MS spectra were searched using MASCOT engine (Matrix Science, London, UK; version 2.3) against the 2019-uniprot-human9606.fasta (downloaded 2011-11-11). For protein identification, the following options were used: peptide mass tolerance, 15 ppm; MS/MS tolerance, 20 mmu; enzyme, trypsin; max missed cleavage, 1; fixed modification, carbamidomethyl (C); variable modification, Oxidation(M) CGln→Pyro-Glu (N-term Q), iTRAQ8plex (K), iTRAQ 8 plex

(Y), iTRAQ8plex (N-term); variable modification, oxidation (M); and decoy database pattern, reverse, and false discovery rate (FDR) <0.01.

Gene Ontology and Pathway Analysis

To obtain ENTREZ Gene IDs, the org.Hs.eg.db R package of Bioconductor was used to search ENTREZ Gene IDs with UniProtKB accession and gene name. Then, using ENTREZ Gene IDs, gene ontology (GO) functional classification and enrichment analyses were performed to identify GO terms that were significantly enriched in differentially expressed proteins using the clusterProfiler R package (12). Furthermore, Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway enrichment analysis was also performed to obtain enriched pathways using the clusterProfiler R package. To obtain further KEGG pathway information, a bioconductor package for pathway-based data integration and visualization was used (13).

Enzyme-Linked Immunosorbent Assay Validation

A total of 28 individual serum samples consisting of CAD ($n = 15$) and non-CAD ischemic stroke ($n = 13$) subjects were employed in the ELISA validation. Six proteins including lipopolysaccharide-binding protein (LBP), vascular cell adhesion molecule 1 (VCAM1), ficolin-2 (FCN2), fibulin-1 (FBLN1), apolipoprotein C-I (APOC-I), and apolipoprotein B (APOB) were analyzed using commercially available kits (Wuhan Colorful Gene Biological Technology, Wuhan, China) following the manufacturers' instructions.

The reason why we selected the six proteins is that mounting evidence suggests a close association between these six proteins and key biological processes underlying CAD. In addition, we should consider the following factors: first, there is a statistically significant difference in expression level of these proteins between CAD and non-CAD group. Second, the result of MS/MS is very reliable. Third, the result from bioinformatics analysis indicated that six proteins might play key role in CAD. Every protein was analyzed in duplicate.

Statistical Analysis

Statistical analysis was performed using the Statistical Package of Social Science (SPSS) for Windows v21.0 (SPSS, Chicago, IL, USA). Data are expressed as mean ± SD. The Student *t* test was applied to identify proteins with significant differences in abundance between the CAD and non-CAD ischemic stroke subjects. All the tests were two-tailed, and the significance threshold was set at $P < 0.05$.

We further evaluated the classification performance and the robustness of panel identification, as well as the six selected proteins using leave-one-out (LOO) cross-validation to alleviate overfitting of classifier training on small size data set. At each step of this procedure, one sample was left out for test, and the remaining 27 samples were used to build the LR classifiers. This process was repeated until all samples were selected as the test set once. So, these processes were cycled for 28 times. In the meantime, the predicted probabilities for each sample being CAD were obtained, from which we draw the receiver operating characteristic (ROC) curves (14). The optimal cutoff points were selected based on the Youden index and should be larger than 0.5.

TABLE 1 | The basic demographic and clinical characteristics of subjects.

	CAD ($n = 15$)	Non-CAD ($n = 13$)	*P*-value
Age, mean ± SD, years	45.27 ± 3.87	48.87 ± 2.68	0.45
Male sex, *n* (%)	11 (73.3)	9 (60.0)	0.46
Hypertension, *n* (%)	5 (33.3)	8 (53.3)	0.28
Diabetes mellitus, *n* (%)	1 (6.7)	4 (26.7)	0.15
Hyperlipidemia, *n* (%)	3 (20)	6 (40)	0.25
Smoking, *n* (%)	4 (26.7)	7 (46.7)	0.27
Symptoms at onset, *n* (%)			
Headache or neck pain	7 (46.7)	3 (20)	0.13
Horner sign	2 (13.3)	1 (6.7)	0.56
Stroke	15(100)	13 (100)	0.27
NIHSS score on admission	4.07±1.14	6.53±0.71	0.07
Site of dissection, *n* (%)			
Internal carotid artery	9 (60)	n/a	
Vertebral artery	5 (33.3)	n/a	
Multiple dissections	1 (6.7)	n/a	
Time to serum sampling, days	13.40 ± 3.21	9.93±1.96	0.12

n/a, not applicable; multiple dissection includes: ICA and VA, bilateral ICA and bilateral VA; ICA, internal carotid artery; VA, vertebral artery.

RESULTS

Subject Characteristics

Demographic and clinical data obtained from patients with CAD ($n = 15$) and patients with non-CAD ischemic stroke ($n = 13$) are provided in **Table 1**. The two groups of subjects were not distinguishable by key demographic characteristics, including age and sex. Patients with CAD had a lower prevalence of traditional vascular risk factors. Headache and Horner syndrome were seen more frequently in the CAD group compared to the non-CAD ischemic stroke group. However, differences were not statistically significant. The frequency of internal carotid artery dissection (nine patients representing, 60%) was higher than vertebral artery dissection (five patients representing 33.3%). In addition, bilateral internal carotid artery dissection was found in one patient. No significant difference was found in the meantime from symptom onset to blood removal between the group of patients with CAD (13.40 ± 3.21 days) and the group of patients with non-CAD ischemic stroke (9.93 ± 1.96 days).

Qualitative Results

The immunodepleted protein fractions were then profiled using iTRAQ coupled to an LC-MS/MS–based approach. The identified proteins in the CAD subjects were used for non-CAD ischemic stroke comparisons. The FDR calculated by searching the data against a decoy database was 1%. Data from the two MS repetitions identified 438 unique proteins according to the parameters set as described above. Differentially regulated

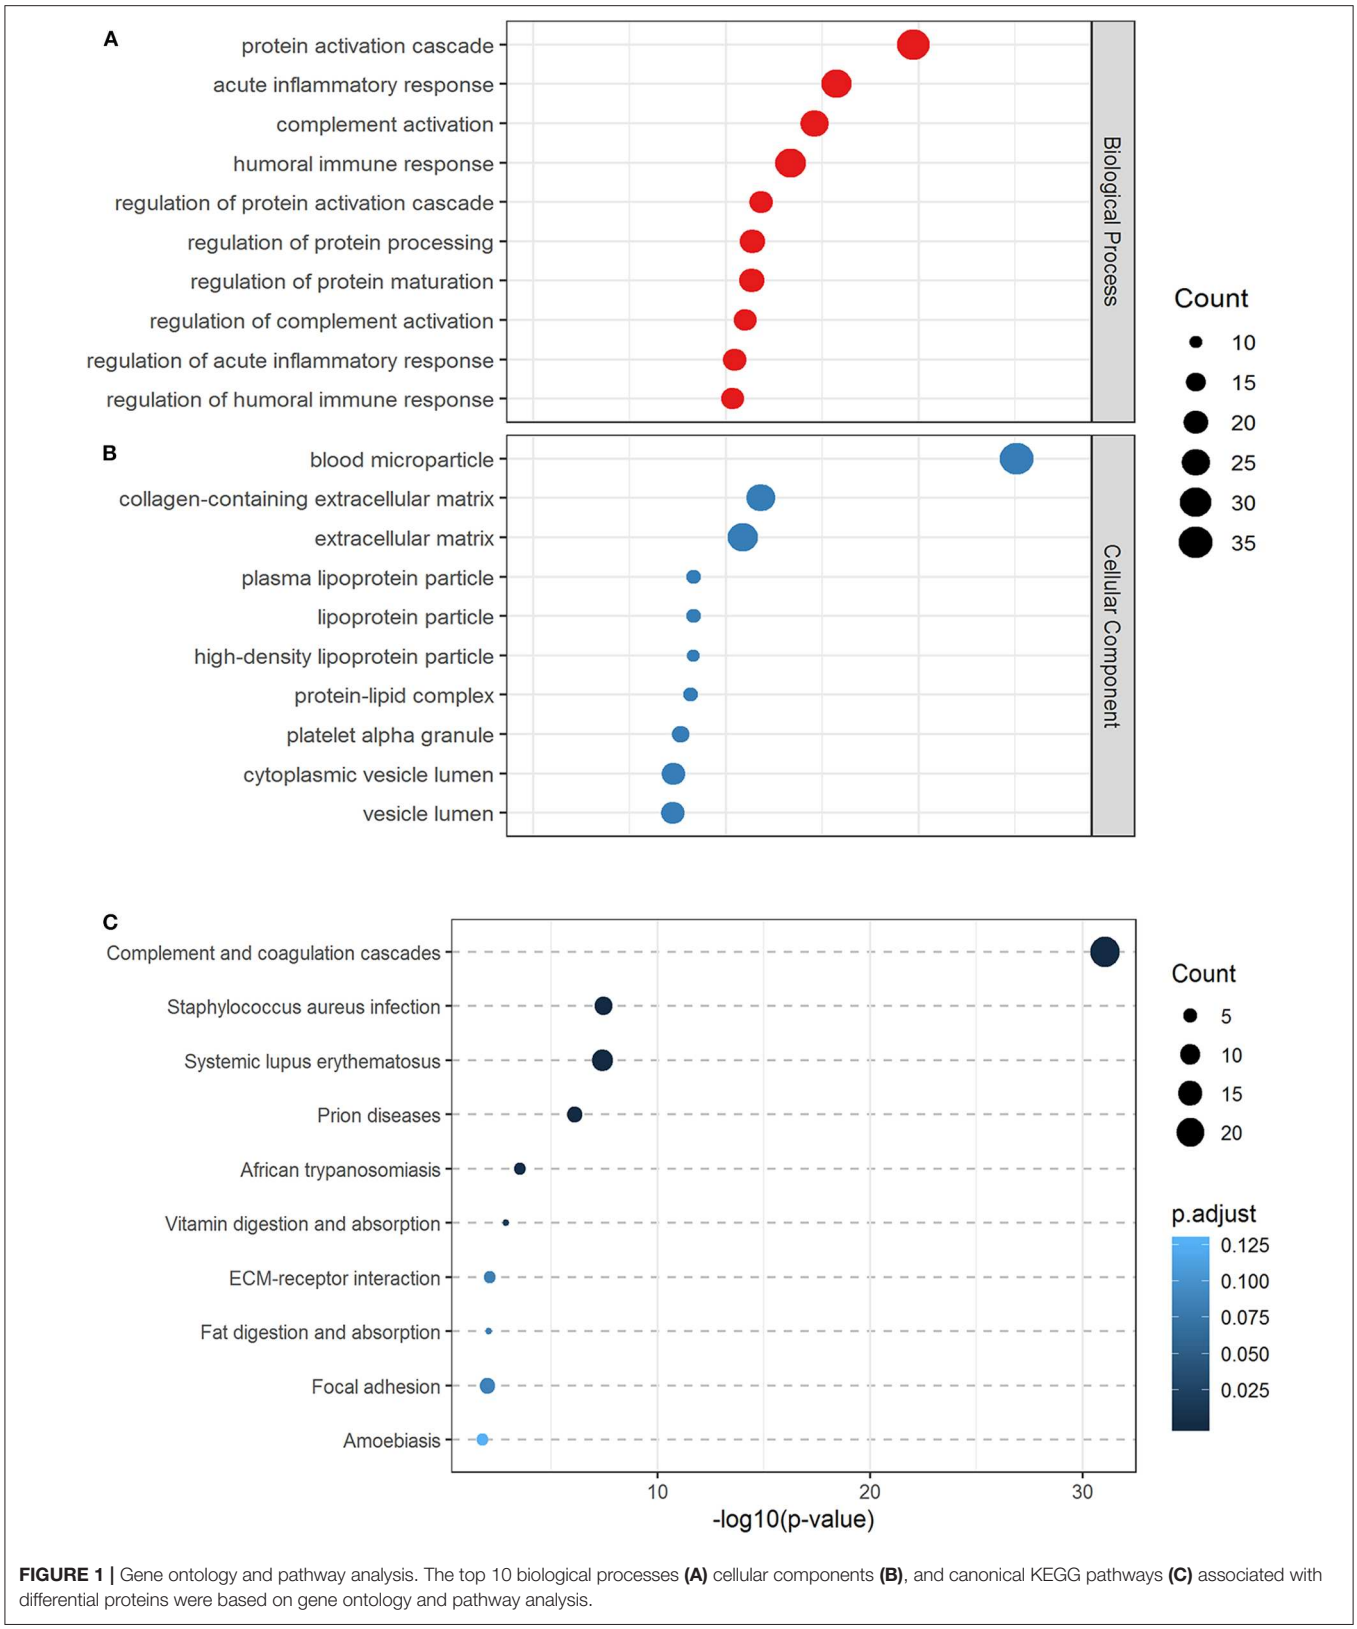

FIGURE 1 | Gene ontology and pathway analysis. The top 10 biological processes **(A)** cellular components **(B)**, and canonical KEGG pathways **(C)** associated with differential proteins were based on gene ontology and pathway analysis.

proteins (1.2-fold change with $P < 0.05$) were selected for further analysis. These cutoffs were selected based on a literature search of the reproducibility of iTRAQ TM quantification (15). One hundred thirty proteins were found to be differentially expressed in the CAD as compared to non-CAD ischemic stroke subjects (**Supplementary Table 1**).

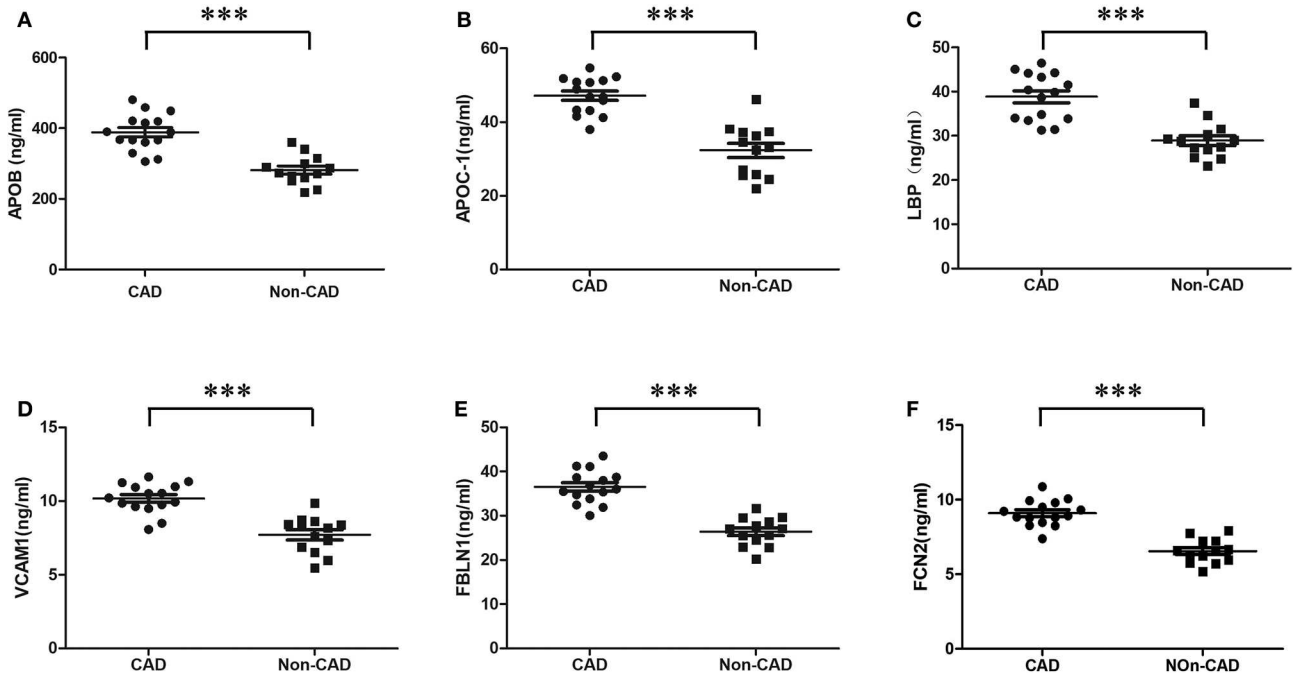

FIGURE 2 | Enzyme-linked immunosorbent assay validation of differential proteins. Six proteins analyzed by ELISA displayed significant changes between CAD ($n = 15$) and non-CAD ischemic stroke ($n = 13$) subjects. **(A)** APOB, **(B)** APOC1, **(C)** LBP, **(D)** VCAM1, **(E)** FBLN1, and **(F)** FCN2 were significantly upregulated in CAD subjects compared to non-CAD ischemic stroke subjects. Statistical analysis was performed using the Statistical Package of Social Science (SPSS) for Windows v21.0. The Student *t* test was applied to identify proteins with significant differences in abundance between the CAD and non-CAD ischemic stroke subjects. All the tests were two-tailed, and the significance threshold was set at $P < 0.05$. $^{***}P = 0.000$. ELISA, enzyme-linked immunosorbent assay; CAD, cerebral artery dissection; APOB, apolipoprotein B; APOC-1, apolipoprotein C-I; LBP, lipopolysaccharide-binding protein; VCAM1, vascular cell adhesion molecule 1; FBLN1, fibulin-1; FCN2, ficolin-2.

Annotation of Identified Proteins

The significantly differentiated proteins were categorized by biological function such as acute inflammatory response, humoral immune response, complement activation, and cellular component (blood microparticle, platelet alpha granule, plasma lipoprotein particle, lipoprotein particle, protein–lipid complex). The biologic processes (**Figure 1A**) and cellular component (**Figure 1B**) attributed to the differentially expressed proteins are displayed.

Altered Biological Pathways Identified by KEGG

The 130 differentially expressed proteins were analyzed for KEGG overrepresentation of pathways. Inflammatory processes were the most statistically overrepresented, including complement and coagulation cascades ranking highest ($P < 0.001$) (**Figure 1C**).

Detection of Differentially Expressed Proteins by ELISA

Six candidate proteins (LBP, VCAM1, FCN2, FBLN1, APOC-I, and APOB) were assessed using individual samples from the CAD and non-CAD ischemic stroke subjects. Consistent with our proteomic findings, the expression levels of all proteins were significantly upregulated in CAD as compared to non-CAD ischemic stroke subjects (**Figure 2**).

Diagnostic Performance

Based on ELISA results, all the six differentially expressed proteins were selected to form a biomarker panel. By LOO cross-validation, we got 28 formulas and 28 prediction scores listed in **Supplementary Table 2**. Receiver operating characteristic curves were constructed, in which the area under the curve (AUC) was 0.954, 0.964, 0.933, 0.931, 0.995, 0.990, and 1 for APOB, APOC-I, LBP, VCAM1, FBLN1, FCN2, and the whole panel, respectively (**Figure 3**). The whole panel exhibited a higher sensitivity (100%) and specificity (100%) than the six proteins individually: APOB (80.0%, 92.3%), APOC-I (93.3%, 92.3%), LBP (86.7%, 84.6%), VCAM1 (86.7%, 92.3%), FBLN1 (93.3%, 92.3%), and FCN2 (93.3%, 92.3%) (**Table 2**).

DISCUSSION

This study is the first reported proteomic-based study investigating putative peripheral biomarkers for CAD. Our analysis revealed immunoregulatory, coagulation, and lipid metabolic dysregulation in CAD, and the potential of using the panel of the six increased proteins with 100% sensitivity and 100% specificity shows to be promising for the detection of increased CAD risk in stroke subjects.

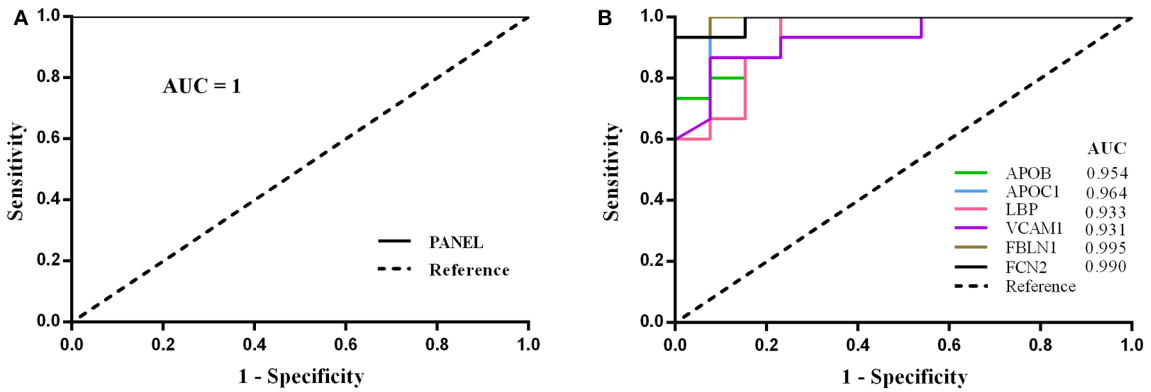

FIGURE 3 | Receiver operating characteristic analyses showing the combined diagnostic utility of the panel including APOB, APOC1, LBP, VCAM1, FBLN1, and FCN2 in CAD. By leave-one-out (LOO) cross-validation, ELISA-based ROC analyses of combined quantitation of APOB, APOC1, LBP, VCAM1, FBLN1, and FCN2 showing promising for the detection of increased CAD risk in stroke subjects (PANEL = APOB + APOC1 + LBP + VCAM1 + FBLN1 + FCN2). The AUC of panel **(A)** was 1, and the panel exhibited a higher sensitivity (100%) and specificity (100%) than the six proteins individually **(B)**.

Inflammatory Response

The complement and coagulation cascade were identified as a significantly altered pathway by KEGG analysis. Gene ontology annotation analysis demonstrated that the inflammatory response was identified as significantly altered ($P < 0.01$). Consistent with our findings, substantial evidence supported the view that dysfunction of the inflammatory response was well established in CAD. In the prospective multicenter CADISP (cervical artery dissection and ischemic stroke patients) trial, acute CAD was associated with particularly high white blood cell counts (4). An elevated leucocyte count was also described by Forster et al. (16) in a retrospective case control study comparing patients with CAD and traumatic CAD. Imaging studies have revealed signs of local inflammation around the affected vessels of patients with CAD, but not in those with traumatic CAD (17). However, the mechanism underlying the association between inflammation and occurrence of CAD remains speculative. It is proposed that inflammation in addition to constitutional connective tissue defects may increase the risk of arterial wall disintegration in CAD (4).

Lipopolysaccharide-binding protein, as a type I acute phase response protein, was considered as a marker for infections in stroke-associated pneumonia but with no data presented on microbiological findings (18). The present study demonstrated for the first time significantly increased levels of LBP in CAD compared to non-CAD ischemic stroke subjects, which were consistent with infection and inflammation as an important risk factor causing a transient arteriopathy linked to spontaneous CAD (19). Furthermore, we speculated that significantly increased LBP in CAD revealed the underlying imbalance of the immune system and increased the risk of infection in CAD subjects. However, the mechanism needs further study.

Vascular cell adhesion molecule 1, as a proinflammatory marker, plays a crucial role in the initiation of inflammatory mechanisms soon after cerebral damage and promotes migration of immune cells across the blood–brain barrier within the cerebral parenchyma (20). Vascular cell adhesion molecule 1 has been reported to be increased early after stroke (21) and may influence peripheral mechanisms such as cell adhesion–regulated processes and may lower nitric oxide (NO) release in the vessels, thereby contributing to decreased vascular endothelial function. Furthermore, VCAM1 has also been found to be associated with impaired endothelial dependent dilation in cerebral artery vasoreactivity, early after stroke with poor prognoses (22). In

our study, the early increased level of VCAM1 may indicate an enhanced inflammatory state and more serious damage to endothelial function in CAD.

Human FCN2 is synthesized in the liver and secreted into the bloodstream where it is one of the few molecules known to activate the lectin pathway of complement (23) and may link complement to the coagulation system (24). Watanabe et al., have observed that serum levels of FCN2 in patients with systemic lupus erythematosus were significantly lower when compared to healthy controls, which is associated with thrombocytopenia (25). Although clinical research involving FCN2 is still in its infancy, evidence is emerging that suggests insufficiency of FCN2 may increase susceptibility to respiratory infections. In the present work, FCN2 was found to be upregulated in CAD subjects, demonstrating more susceptible to infection in the pathophysiology of CAD.

Blood Coagulation

Gene ontology annotation analysis showed that coagulation-related components (blood microparticles and platelet alpha granule) were identified as significantly altered ($P < 0.01$). Inflammation may also impact on the coagulation system resulting in a hypercoagulable state, which may be responsible for ischemic events. Specifically, the physiological crosstalk between inflammation and coagulation may facilitate the formation of arterial and venous thrombosis, not only in the microcirculation, but also in larger vessels, a process that may be further aggravated by a preexisting or newly occurring vessel wall damage, as is the case in CAD (26). Pelz et al. (27) found evidence for a hypercoagulable state in patients with CAD as indicated by a shortened activated partial thromboplastin time, which was associated with a trend to an increased leucocyte count at the same time. Furthermore, the results strengthened the hypothesis that inflammation critically impacts on the occurrence of CAD and linked this condition to a marked effect on the coagulation system.

Fibulin-1, as an ECM protein, was found to be significantly upregulated in CAD as compared to stroke subjects in this study. In addition, FBLN1 has been found to bind to the plasma protein fibrinogen (FG) and to incorporate into fibrin clots formed *in vitro* and *in vivo* (28). It is possible that following vascular injury FBLN1 may be present in the extracellular matrix of the vessel wall and therefore may interact with plasma FG and promote platelet adhesion, leading to the formation of a platelet plug, and could therefore serve as a participant in the earliest events of thrombus formation (29). Mohamed et al. (30) showed that downregulation of FBLN1 may weaken extracellular components in the aorta and/or interfere with the transmission of cellular signals and eventually cause acute aortic dissection. Taken together, our findings supported the hypothesis that increased expression of FBLN1 may represent more serious blood vessel damage and a hypercoagulable state, which would be more likely to cause a more severe ischemic event in CAD subjects.

Lipid Metabolism

Several studies have demonstrated that perturbation of lipid metabolism may be involved in the pathophysiology of both CAD (31) and stroke (32). Our bioinformatics analysis showed that lipid-related components (plasma lipoprotein particle, lipoprotein particle, protein–lipid complex) were identified as significantly altered ($P < 0.01$). This study was the first to report that APOB and APOC-I levels were significantly increased in CAD as compared to stroke subjects, indicating that the dysregulation of lipid metabolism may play an important role in the pathophysiology of CAD.

Apolipoprotein B present in very low-density lipoprotein (VLDL), intermediate-density lipoproteins, large buoyant low-density lipoprotein (LDL), and small dense LDL reflects the total number of atherogenic particles and leads to entrapment of these lipoproteins in the arterial wall. Recent reports suggest that the higher value of the APOB/APOA1 ratio, the more cholesterol is likely to be deposited in the arterial wall, thereby enhancing atherogenesis and increasing vascular risk (33). An additional study has supported the clinical utility of oxidized phospholipids-APOB as a biomarker for the prediction of recurrent fatal or nonfatal stroke, which have augmented proinflammatory responses and enhanced uptake of monocytes into the vessel wall (34). Here, the increased expression of APOB in CAD may indicate an enhanced vascular risk and more severe ischemic events.

Apolipoprotein C-I is a secreted plasma protein present in the circulation in association with LDL and VLDL and is produced by the liver. Kolmkova et al. (35) have shown that APOC-I and APOC-I–enriched high-density lipoprotein activated the neutral sphingomyelinase–ceramide signaling pathway, leading to apoptosis in human aortic smooth muscle cells, which may lead to plaque rupture *in vivo*. However, the potential physiological role and clinical significance of APOC-I in stroke have recently emerged. Allard et al. (36) first reported that APOC-I may be the plasma biomarker capable of accurately distinguishing between ischemic and hemorrhagic stroke in a small number of patients. Recent reports have shown that CAD-related infarcts are likely to be large when the vessel occludes and responds poorly to conventional treatment with antithrombotics, anticoagulants, or intravenous thrombolysis (37). In our study, we were the first to report increased APOC-I in CAD subjects, which may accelerate the plaque rupture, leading to a more severe stroke.

Finally, we conducted an LOO cross-validation to determine the predictive value of the panel combined with six proteins. This method enables ROC analysis to be performed even with the small sample sizes used in our study. We found the greatest predictive utility when combining measurements from our six upregulated proteins, resulting in high sensitivity (100%) and specificity (100%). However, the predicted performance had some limitations which were principally due to the small sample size. But the research gives us a hint that the panel of six proteins identified is promising for the detection of increased CAD risk in stroke subjects. We expect that, with further validation and research using a larger sample size, this panel will provide an early sensitive and specific predictor of CAD with stroke and will open a new avenue for the diagnosis of this disease.

Limitations

The present study had some limitations. First, given the relatively small sample size of the study, some confounding effects could

not be controlled, and this raised the risk of chance findings. Furthermore, the diagnostic efficiency of the model was reduced by the small sample size. Research with larger sample sizes and using healthy controls is necessary for a better comparison. Second, the timeline for this study was limited to acute dissection; subacute and chronic dissections were neglected. In future studies, a longer timeline, such as a 3 months' follow-up after acute stroke, should be implemented. Third, CAD subjects singly manifested with local signs (Horner syndrome and cranial nerve palsy), pain (cervical pain and headache), and transient ischemic attack (TIA) should be included for increased model diagnostic power. Furthermore, to elucidate the pathogenesis, subgroup analysis is necessary. In future studies, patients should be subdivided further on the basis of the following: clinical severity assessed with the (NIHSS) score; radiologic severity, based on the number of dissected arteries and luminal changes for each vessel; different therapeutic approaches with respect to strokes; delayed stroke upon CAD; dissection with and without ischemic events; and patients presented with ischemic events and hemorrhagic strokes. Further studies are needed to understand the mechanism(s) underlying CAD and to develop more diagnostically accurate biomarkers for stroke.

CONCLUSION

In this study, 130 differentially expressed proteins were found in serum sampled from CAD and non-CAD ischemic stroke subjects using an iTRAQ-based proteomic approach. Most of these proteins were associated with inflammatory reactions, lipid metabolism, and coagulation cascades, suggesting that these processes were involved in the pathophysiology of CAD. Through ELISA validation, six differentially expressed proteins were found to be significantly upregulated in CAD relative to non-CAD ischemic stroke subjects. The panel containing the six proteins showed a higher sensitivity and specificity for the prediction of CAD. Further investigation of these proteins in a larger cohort of patients is now needed in order to better understand the underlying pathophysiology of CAD.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by The Ethical Committee of Third Military Medical University. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

ZZ conceived and designed the research. YY did the statistical analysis and wrote the manuscript. JP made subject recruitment and collected the clinical data. JH collected the blood samples of patients and stored the serum samples. HR and SW performed the ELISA validations. KC made the LC-MS/MS analysis and annotated the functions of differentially expressed proteins. All authors reviewed the manuscript before submission.

FUNDING

This work was supported by National Natural Science Foundation of China (Grant No. 81471194) and the clinical novel technology program of military medicine and injury treatment of Southwest Hospital (SWH2016JSTSYB-23, SWH2016JHJC-03).

Galkov M, Kiseleva E, Gulyaev M, Sidorova M and Gorbacheva L (2020) New PAR1 Agonist Peptide Demonstrates Protective Action in a Mouse Model of Photothrombosis-Induced Brain Ischemia. Front. Neurosci. 14:335. doi: 10.3389/fnins.2020.00335

Protease-activated receptors (PARs) are involved not only in hemostasis but also in the development of ischemic brain injury. In the present work, we examined *in vivo* effects of a new peptide (AP9) composing Asn^{47}-$Phen^{55}$ of PAR1 "tethered ligand" generated by activated protein C. We chose a mouse model of photothrombosis (PT)-induced ischemia to assess AP9 effects *in vivo*. To reveal the molecular mechanism of AP9 action, mice lacking β-arrestin-2 were used. AP9 was injected intravenously once 10 min before PT at doses of 0.2, 2, or 20 mg/kg, or twice, that is, 10 min before and 1 h after PT at a dose of 20 mg/kg. Lesion volume was measured by magnetic resonance imaging and staining of brain sections with tetrazolium salt. Neurologic deficit was estimated using the cylinder and the grid-walk tests. Blood–brain barrier (BBB) disruption was assessed by Evans blue dye extraction. Eosin-hematoxylin staining and immunohistochemical staining were applied to evaluate the number of undamaged neurons and activated glial cells in the penumbra. A single administration of AP9 (20 mg/kg), as well as its two injections (20 mg/kg), decreased brain lesion volume. A double administration of AP9 also reduced BBB disruption and neurological deficit in mice. We did not observe the protective effect of AP9 in mice lacking β-arrestin-2 after PT. Thus, we demonstrated for the first time protective properties of a PAR1 agonist peptide, AP9, *in vivo*. β-Arrestin-2 was required for the protective action of AP9 in PT-induced brain ischemia.

Keywords: protease-activated receptor 1 (PAR1), PAR1 agonist peptide, protein C, β-arrestin-2, photothrombosis-induced focal ischemia

INTRODUCTION

Vessel wall damage and hemostatic balance disturbances lead to changes in tissue blood flow and, as a result, to the development of ischemic conditions (Khoshnam et al., 2017). Activation of endothelial cells is a key factor for initiating thrombus formation. A wide range of receptors, which regulate the state of the endothelium and platelets, is involved not only in hemostasis but also in the development of ischemic brain injury. Protease-activated receptors (PARs) are ones of these receptors. PARs belong to the family of G-protein-coupled receptors (GPCRs) and regulate cellular and physiological processes in normal and pathological conditions (Ossovskaya and Bunnett, 2004; Coughlin, 2005).

The mechanism of PAR activation was revealed and thoroughly studied for PAR1 (Vu et al., 1991) and other PAR subtypes (Coughlin, 2005). Proteases cleave the receptor at the specific site of the exodomain that results in formation of a novel N-terminus ("tethered ligand"). This N-terminal sequence interacts with the second extracellular loop and activates the receptor (Ossovskaya and Bunnett, 2004; Coughlin, 2005). It was shown that serine proteases of the blood coagulation system, thrombin and activated protein C (APC), exert multidirectional effects during excitotoxicity and neuroinflammation via PAR1 activation (Suo et al., 2004; Gorbacheva et al., 2008; Griffin et al., 2015).

Thrombin demonstrates procoagulant effects and increases expression of proinflammatory and proapoptotic factors in the nervous tissue (Suo et al., 2004; Coughlin, 2005). APC, in contrast to thrombin, protects neurons and endothelium, stabilizes the endothelial barrier, and controls cytokine gene expression in brain injury (Riewald and Ruf, 2005; Minhas et al., 2009; Zlokovic and Griffin, 2011; Griffin et al., 2015; Roy et al., 2016). Earlier we have shown PAR1-dependent antiapoptotic effects of APC on cultivated hippocampal neurons during glutamate excitotoxicity (Gorbacheva et al., 2009, 2010; Savinkova et al., 2014).

It was found that PAR1 activation initiates multidirectional pathways through both G-proteins (Traynelis and Trejo, 2007) and β-arrestins in cultured endotheliocytes (Soh and Trejo, 2011; Roy et al., 2016). The "molecular ensemble" around the receptor and its pattern of phosphorylation by GPCR kinases provide this signal dualism called "biased agonism" (Premont and Gainetdinov, 2007; Reiter et al., 2012). Cytoprotective signaling by APC involves a novel cleavage of PAR1 N-terminal domain at Arg^{46}–Asn^{47} differing from that of thrombin (Arg^{41}–Ser^{42}) and β-arrestin-2-dependent pathway activation (Soh and Trejo, 2011; Roy et al., 2016). β-arrestin recruitment and activation of the Dvl-2 scaffold initiate APC-induced cytoprotection mediated by Rac1. In this case, activated Dvl-2 may provide a platform that recruits effector proteins, such as Rac1-specific guanine nucleotide exchange factors to promote Rac1 activation (Soh and Trejo, 2011). For APC-induced β-arrestin-2-dependent signaling, the colocalization of PAR1 with the endothelial protein C receptor and thrombomodulin in caveolae is required (Griffin et al., 2015; Roy et al., 2016).

The unique mechanism of PAR activation makes it possible to apply peptide analogs of the "tethered ligand" as receptor agonists (Mao et al., 2008; Ramachandran and Hollenberg, 2008; Mosnier et al., 2013). In the present work, we used a nine-amino-acid peptide (AP9, NPNDKYEPF-NH_2), which mimics PAR1 N-terminus beginning at residue Asn^{47} and generated by APC cleavage at Arg^{46}. The protective effects of AP9 via PAR1 activation were confirmed *in vitro* using primary cultures of neurons, mast cells (Savinkova et al., 2014; Babkina et al., 2016), and human keratinocytes (Kiseleva et al., 2014). Moreover, it was previously shown that another PAR1 peptide agonist, TR47, which also formed after PAR1 cleavage at Arg^{46}, demonstrates the general activity profile of APC (Mosnier et al., 2013). Taken together, these data make it possible to hypothesize that AP9 will demonstrate APC-like protective properties, which are expected to be β-arrestin-2-dependent, in ischemic conditions *in vivo*. To test that hypothesis, we used a model of photothrombosis-induced (PT-induced) focal brain ischemia (Lee et al., 2007; Galkov et al., 2020) and different schemes of AP9 intravenous administration.

PT model based on the generation of reactive oxygen species under the action of light induces endothelium damage and triggers thrombogenesis (Lee et al., 2007). PT-induced pathological processes are similar to endogenously formed ones (Kim et al., 2001; Schroeter et al., 2002; Li et al., 2014; Kang et al., 2015; Cotrina et al., 2017). Moreover, PT-induced focal ischemia is characterized by low invasiveness and high reproducibility of the damage volume (Fluri et al., 2015), as well as the precise localization of lesion area in the cerebral cortex (Harrison et al., 2013).

In the present work, we examined the potential effects of PAR1 agonist peptide, AP9, in the mouse model of PT-induced brain ischemia. The role of β-arrestin-2-signaling in intracellular pathways triggered by AP9 was also revealed.

MATERIALS AND METHODS

Animals

Male mice weighing 25–30 g and aged 2.5–3 months were used in the study. Animals were obtained from the nursery for laboratory animals of Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry (Russian Academy of Sciences, Moscow region) and kept under standard conditions (temperature: 22°C, light cycle: 12 h) with unlimited access to water and food. We used BALB/c mice, β-arrestin-2-knockout mice (β-arrestin-2-/- group) kindly provided by Prof. R.R. Gaynetdinov, and animals of genetically related C57BL/6 strain (wild type) (Bohn et al., 1999) with full β-arrestin-2 expression. The total number of animals used was 177 (141 BALB/c mice, 20 C57BL/6 mice, and 16 knockout animals). Six BALB/c mice and one C57BL/6 mouse died during PT induction.

All animals of each strain were randomized into several groups (control groups and groups treated with AP9 at different doses). The randomization scheme was generated using the website Randomization.com[1]. The number of animals in each experimental group (n) is indicated in section "Results" ($n = 4$–10). All experiments were performed according to the

[1]http://www.randomization.com

Directive 2010/63/EU of the European Parliament and the Council of the European Union. Our experimental protocols were approved by the Bioethics Committee of Lomonosov Moscow State University (protocol no. 2018-10-25-93-0-3). All measurements were carried out in a blinded manner. A researcher did not know which group the animals belonged to during the processing of images and video records, as well as during Evans blue dye extraction.

Mouse Genotyping

Modification of the β-*arrestin-2* gene in mice carried out by homologous recombination (Bohn et al., 1999) was confirmed by polymerase chain reaction (PCR). Genomic DNA was isolated from lysates of tail fragments of wild-type and β-arrestin-2-knockout mice by an Extract DNA kit (Eurogen, Russia). PCR was performed using Taq DNA polymerase and standard set of reagents (Thermo Fisher Scientific, United States). During PCR, three primers were used (Eurogen, Russia): primers flanking the insertion site of the genetic construct (forward 5'-GATCAAAGCCCTCGATGATC-3' and reverse 5'-ACAGGGTCCACTTTGTCCA-3'), as well as the primer complementary to donor DNA sequence in the β-*arrestin-2* gene (forward 5'-GCTAAAGCGCATGCTCCAGA-3'). PCR products were separated on a 2% agarose gel with the addition of ethidium bromide. DNA ladder NL002 (Eurogen, Russia) was used as markers; visualization was performed using UV light in a transilluminator. A fragment of 400bp in length indicated the presence of a knockout allele, a 600-bp fragment indicated a wild-type allele. Animals homozygous for the inactivated allele were selected in the experiment.

Western Blotting

β-Arrestin-2 Expression Level

Overanesthetized gene knockout and wild-type animals were transcardially perfused with heparinized saline (40 units/ml). Fragments of the cerebral cortex were isolated on ice and lysed in RIPA buffer and protease inhibitors (Sigma-Aldrich, United States). Samples containing 20 μg of protein were separated by 10% SDS-PAGE, transferred to nitrocellulose membranes, and blocked with 5% skim milk in TBS-Tween 20 (0.05%) for 1 h. The blot was developed by incubation with antibodies against β-arrestin-2 (1:1,000; ab206972, Abcam, United Kingdom) and β-actin (1:1,000; ab8227, Abcam, United Kingdom) overnight at 4°C, followed by incubation with horseradish peroxidase-conjugated anti-rabbit IgG antibodies (1:3,000; sc-2357, Santa Cruz Biotechnology, United States) for 1 h at room temperature. The presence of the target proteins on the blots was recorded using chemiluminescent ECL kit (Thermo Fisher Scientific, United States) and ChemiDoc MP Imaging System (Bio-Rad Laboratories, United States).

GFAP Expression Level

Overanesthetized control and AP9-treated mice were transcardially perfused 96 h after PT. After decapitation, the brain was isolated on ice, the cortex was separated, and the damaged brain tissue in the ipsilateral hemisphere (IH), as well as in the contralateral hemisphere (CH), was isolated by a circular knife 4 mm in diameter. Seventy micrograms of protein was applied into one gel pocket. Western blotting was carried out as described above. Antibodies against GFAP (1:5,000; ab7260, Abcam, United Kingdom), GAPDH (1:5,000; ab181603, Abcam, United Kingdom), and horseradish peroxidase-conjugated anti-rabbit IgG antibodies (1:3,000; sc-2357, Santa Cruz Biotechnology, United States) were used. Quantitative image processing was performed using the Image Lab software (United States). The data were presented as a relative GFAP level taken in CH for 1.

Induction of Ischemic Stroke

Ischemia was induced by photothrombosis (Lee et al., 2007; Galkov et al., 2020). In brief, the mixture of Zoletil 100 (Virbac Sante Animale, France) and Xyla (Interchemie werken "De Adelaar" B.V., Netherlands) at doses of 35 and 3.5 mg/kg (i.p.), respectively, was chosen for anesthesia. Rose Bengal dye (0.15%; Sigma-Aldrich, United States) was injected through a catheter placed into the jugular vein of animals at a dose of 10 mg/kg. An area of 3 mm in diameter localized with the help of a light-tight mask in the sensorimotor area of the cortex of the left hemisphere (2.2 mm lateral to the midline with the epicenter at *bregma*, Franklin and Paxinos, 2001) was illuminated with green laser (λ = 532 nm; Viacho, China) for 5 min. Illuminance on the skull surface was 55–60 lx (Galkov et al., 2020). Mice were sacrificed by an overdose of anesthesia 24 or 96 h after PT.

Previously, we tested the ischemic model and showed that there was no tissue damage in sham-operated mice (administration of saline instead of Rose Bengal dye) according to MRI and 2,3,5-triphenyltetrazolium chloride (TTC) staining data (**Supplementary Figures 1A,B**). We also showed that there was no Evans blue dye leakage in the IH of sham-operated animals (**Supplementary Figure 1C**).

Assessment of Neurological Status

The cylinder and the grid-walk tests were performed before PT induction and for 4 days after it according to the standard protocol (Baskin et al., 2003). The number of cases, when the mouse forelimb contralateral to the damaged hemisphere went through grid holes (stepping errors), and the number of steps performed by that limb were video registered for 5 min. The animals, which performed less than 100 steps, were excluded from the experiment. Sensorimotor deficit in the cylinder test was calculated according to the following formula: asymmetry index = $(t_{after}/t_{before}) \times 100\%$, where t_{after} and t_{before} were the relative contact time of the fore contralateral limb (the contact time of the ipsilateral limb was taken as 100%) after and before PT, respectively. We processed not less than 10 explorations of cylinder walls by each animal in the video records.

Measurement of Ischemic Damage Volume

Lesion volume was assessed using MRI and staining of brain sections with TTC. MRI studies were performed 24 and 96 h after PT on a 7.05-T MR scanner BioSpec 70/30 USR (Bruker, Germany) equipped with fast gradients (105 mT/m/ms

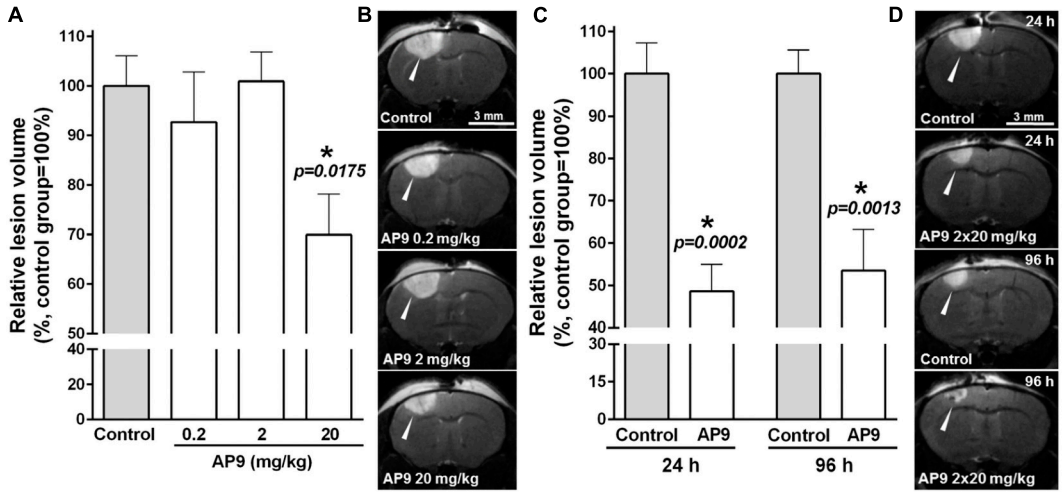

FIGURE 1 | AP9 effects on brain lesion volume after photothrombosis. **(A,B)** A single administration of AP9 at doses of 0.2, 2, and 20 mg/kg: **(A)** relative volume of ischemic damage (one-way ANOVA with Dunnett's correction for multiple comparisons) and **(B)** representative MR images at the level of *bregma* (damaged areas are marked with triangles) 24 h post thrombosis. **(C,D)** A double administration of AP9 at a dose of 20 mg/kg: **(C)** relative volume of ischemic damage (unpaired *t*-test) and **(D)** representative MR images at the level of *bregma* (damaged areas are marked with triangles) 24 and 96 h post thrombosis (*: as compared to the control group).

slew rate). We obtained T_2-weighted MR images using the 2D RARE method with the following scanning parameters: TR/Teeff = 3,000/50 ms; number of slices: 16; slice thickness: 0.4 mm; rare-factor: 4; in-plane resolution: 100 × 100 m; total acquisition time: 9 min 00 s. To measure lesion volume using TTC staining, the animals were decapitated 24 h after thrombosis and the brain was removed. The damage volume was assessed according to the standard protocol as described previously (Galkov et al., 2020).

Digital images were processed in the ImageJ software (NIH, United States). The damage volume was calculated considering an increase in IH size as a result of edema compared with CH (Pialat et al., 2007). Data were presented as relative lesion volume. That parameter in control mice was set as 100%.

Measurement of Blood–Brain Barrier Permeability

Evans blue dye (Sigma-Aldrich, United States) was injected intravenously through a catheter immediately after laser irradiation (80 mg/kg, 2.2% solution). Mice were transcardially perfused with heparinized saline (40 units/ml) 24 h after PT induction. To assess blood–brain barrier (BBB) permeability, dye extraction and determination of its content in both hemispheres were performed as previously described (Kim et al., 2001). The data were expressed as relative Evans blue content in IH. That parameter in CH was taken as 100%.

Tissue Processing and Histological Analysis

Overanesthetized animals were transcardially perfused with 0.1 M phosphate buffer saline (PBS) and 10% formalin 24 or 96 h after PT induction. For immunohistochemistry, the brain was removed, postfixed for 24 h, washed in PBS, and sequentially incubated in 10, 20, and 30% sucrose at room temperature. Then the brain was embedded in an OCT embedding matrix (CellPath, United Kingdom), frozen, and stored at −80°C. For hematoxylin-eosin staining, the brain was removed, fixed in 10% neutral-buffered formalin for 24 h, embedded in paraffin, and cut into 5-μm sections that were stained.

For each animal, cell counting was performed in two sections of the central part of the lesion spaced apart from each other by at least 200 μm. The cells were counted in four non-overlapping fields (300 × 220 μm) of each section both in IH and in CH. The fields of view evenly covered the penumbra region and were located at the outer boundary of the ischemic core in the damaged hemisphere. In CH, we chose mirror areas of the cortex for cell counting (Galkov et al., 2020). Images were processed in the ImageJ software; the obtained data were averaged for one animal.

Hematoxylin-Eosin Staining

The proportion of undamaged neurons was evaluated 24 h after thrombosis. The neurons that were not characterized by nuclear pyknosis, karyorrhexis, karyolysis, hyperchromia, swelling, and alteration of normal cell shape (Hu et al., 2002; Song et al., 2012; Galkov et al., 2020) were considered as undamaged cells. The data were presented as a relative number of undamaged neurons in the penumbra (similar indicator in CH was taken as 100%).

Immunohistochemistry

The number of activated glial cells was evaluated 96 h after thrombosis. Coronal cryosections with 15-μm thickness were immunostained with antibodies against GFAP (1:500; ab10062, Abcam, United Kingdom) and Iba-1 (1:500; 019-19741, Wako, Japan). Secondary antibodies were conjugated with fluorophore Alexa Fluor 594 [anti-mouse IgG (1:1,000; R37121) or anti-rabbit

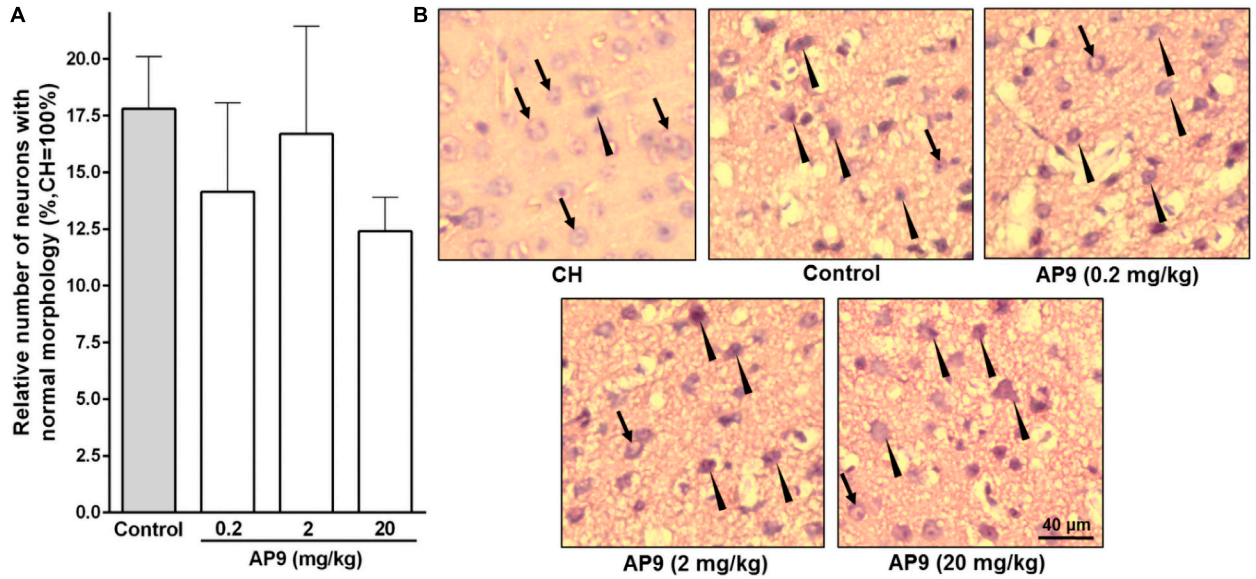

FIGURE 2 | Morphological changes in neurons 24 h post thrombosis in control animals and AP9-treated mice (a single injection, 0.2, 2, and 20 mg/kg). **(A)** Relative number of undamaged neurons in the penumbra (one-way ANOVA). **(B)** Representative micrographs of the penumbral region in IH and a typical micrograph of the mirror region in CH (hematoxylin-eosin staining; arrows indicate cells with normal morphology, triangles indicate cells with signs of damage).

IgG (1:1000; A-11037), Thermo Fisher Scientific, United States]. Cell nuclei were stained with DAPI (Biotium, United States). Images were obtained using confocal laser scanning microscope LSM 710 (Zeiss, Germany). The number of GFAP-positive cells (in two to four layers of cerebral cortex, Cotrina et al., 2017) and Iba-1-positive cells was counted. The data were presented as a relative value taken in CH for 1.

AP9 Structure and Its Administration Scheme

Protease-activated receptor 1 agonist peptide (AP9), consisting of nine amino acids (NPNDKYEPF-NH_2), was synthesized in the Laboratory of Peptide Synthesis of the National Medical Research Center for Cardiology (Moscow) using Fmoc solid-phase synthesis. The homogeneity of the peptide was confirmed by the data of analytical HPLC.

Initially, we used three doses of AP9 (0.2, 2, and 20 mg/kg) dissolved in saline at concentrations of 0.06, 0.6, and 6 mg/ml, respectively. AP9 administration was carried out intravenously 10 min before PT induction (Abdelkarim et al., 2001) through a catheter (as a bolus). In the next experimental series, the injection of AP9 at a dose of 20 mg/kg, which showed maximal efficiency, was performed 10 min before thrombosis and 1 h after PT.

Statistical Analysis

The statistical analysis was performed using the GraphPad Prism 6 software (GraphPad Software Inc., United States). The D'Agostino–Pearson normality test was used to determine correspondence of sample data to normal distribution ($p > 0.1$). The data are expressed as mean ± SEM. The differences between groups were considered as statistically significant at $p < 0.05$. The number of animals (n) and statistical criteria are shown for each experiment. The power analysis performed using the STATISTICA software (StatSoft Inc., United States) showed that the statistical power was more than 0.8 in the case of detecting statistically significant differences between the data groups.

RESULTS

Effect of AP9 on Brain Lesion Volume After Photothrombosis

MRI was used to detect brain damage volume, which directly reflects the severity of ischemia. We found that AP9 effects were dose dependent. AP9 at a dose of 20 mg/kg (a single injection 10 min before PT) caused a statistically significant decrease in lesion volume, which amounted to 69.92 ± 8.21% ($n = 7$) in the AP9-treated group relative to control animals (100.00 ± 6.10%, $n = 7$) 24 h after PT induction. However, we did not observe the effect of AP9 at doses of 0.2 and 2 mg/kg on that parameter, which was 92.70 ± 10.10% ($n = 4$) and 100.90 ± 5.96% ($n = 4$), respectively (**Figures 1A,B**).

The repeated administration of the peptide (i.e., 10 min prior to and 1 h after PT) at a dose of 20 mg/kg enhanced the protective effect of its single injection and led to a statistically significant twofold decrease in lesion volume 24 h after thrombosis. The damage volume was 48.59 ± 6.42% ($n = 7$) in the AP9-treated group and 100.00 ± 7.27% ($n = 7$) in control mice. Moreover, we also evaluated lesion volume 96 h after thrombosis. It was 53.21 ± 9.72% in the AP9-treated group relative to the control value (100.00 ± 5.58%) (**Figures 1C,D**). Thus, MRI results

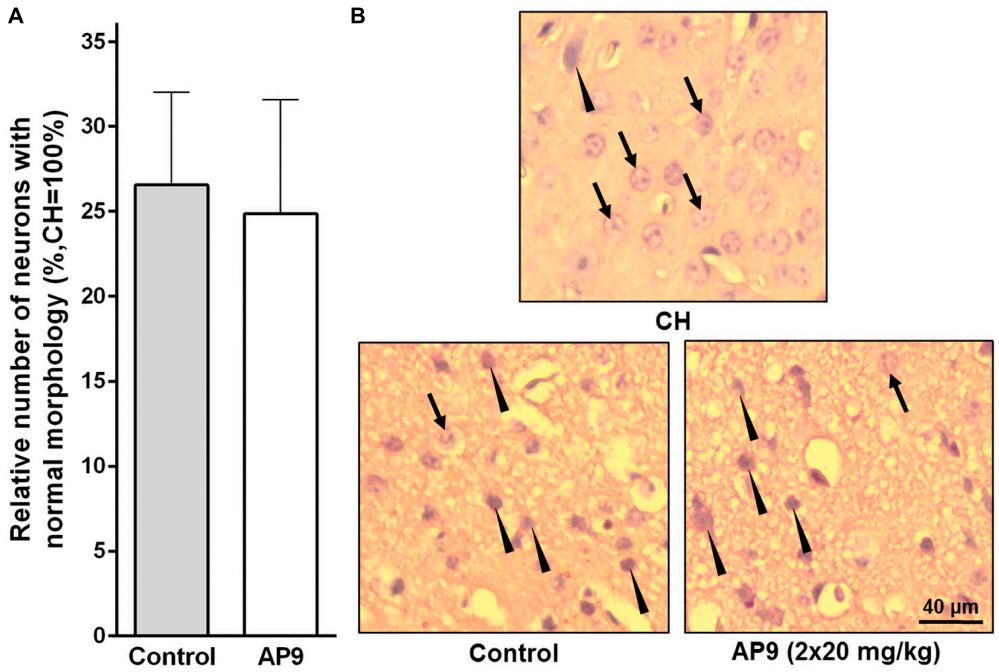

FIGURE 3 | Morphological changes in neurons 24 h post thrombosis in control animals and AP9-treated mice (a double injection, 20 mg/kg). **(A)** Relative number of undamaged neurons in the penumbra (unpaired *t*-test). **(B)** Representative micrographs of the penumbral region in IH and a typical micrograph of the mirror region in CH (hematoxylin-eosin staining; arrows indicate cells with normal morphology, triangles indicate cells with signs of damage).

indicated the preservation of the protective effect of double AP9 administration in the postischemic period.

AP9 Did Not Affect Photothrombosis-Induced Morphological Changes in Neurons

The pathological changes occurring after ischemia induction at the cellular level were assessed by hematoxylin-eosin staining of brain sections. We revealed a significant decrease in the number of neurons without morphological signs of damage in the penumbra compared with the similar areas in CH 24 h after PT (**Figure 2**).

A single injection of the peptide at all three doses used (0.2, 2, and 20 mg/kg) did not affect the proportion of undamaged neurons in IH compared with the control group. These portions were 14.14 ± 3.93% (n = 5), 16.70 ± 4.74% (n = 5), and 12.40 ± 1.50% (n = 7) at doses of 0.2, 2, and 20 mg/kg of AP9, respectively. In the control group of animals, the penumbral region contained 17.80 ± 2.30% (n = 8) neurons with no signs of damage (**Figure 2**).

Two injections (10 min before and 1 h after PT) of AP9 at a dose of 20 mg/kg also did not change the relative number of undamaged neurons in IH. The penumbra was characterized by 26.56 ± 5.47% (n = 5) neurons of normal morphology in the control group of animals and 24.85 ± 6.74% (n = 7) in AP9-treated mice (**Figure 3**).

AP9 Administration Did Not Change Photothrombosis-Induced Glial Cell Activation

According to published data, significant glial cell activation and proliferation are observed in the penumbra 96 h after PT induction. This is supported by enhanced expression of GFAP in activated astrocytes (Li et al., 2014; Cotrina et al., 2017) and Iba-1 in activated microglial cells/macrophages (Li et al., 2014).

In the present study, we also observed a significant increase in the number of activated glial cells in IH compared with CH 96 h after thrombosis induction. However, the effect of AP9 double administration (20 mg/kg, 10 min before and 1 h after thrombosis) on these indices was not found. The relative number of activated astrocytes (GFAP-positive cells) in the penumbra was 8.17 ± 0.51 (n = 5) and 8.55 ± 0.37 (n = 6) in control and AP9-treated animals, respectively (**Figures 4A,B**). For activated microgliocytes/macrophages (Iba-1-positive cells), the values were 6.89 ± 1.04 (control group, n = 5) and 8.52 ± 0.96 (experimental group, n = 6) (**Figures 4C,D**).

Western blotting analysis confirmed that there was no difference between the control group and AP9-treated animals (20 mg/kg, a double administration) in GFAP expression 96 h after photothrombosis. The relative level of GFAP in control animals was 26.74 ± 3.01 in IH and 1.00 ± 0.09 in CH (n = 4). In AP9-treated mice, that parameter was 26.09 ± 2.30 and 1.00 ± 0.10 (n = 4) in IH and CH, respectively (**Supplementary Figure 2**).

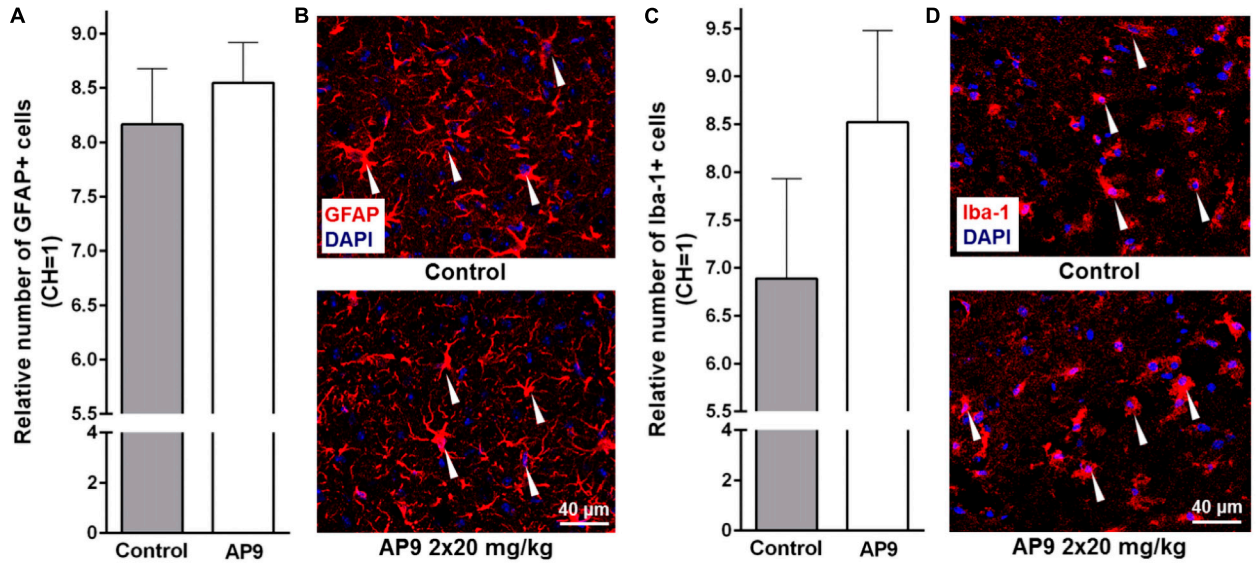

FIGURE 4 | Glial cell activation 96 h post thrombosis in control animals and AP9-treated mice (a double injection, 20 mg/kg). **(A,B)** Immunohistochemistry data on GFAP staining: **(A)** relative number of activated astrocytes (unpaired *t*-test) and **(B)** representative microphotographs of the penumbra. **(C,D)** Immunohistochemistry data on Iba-1 staining: **(C)** relative number of activated microgliocytes/macrophages (unpaired *t*-test) and **(D)** representative microphotographs of the penumbra (GFAP- and Iba-1-positive cells are marked with triangles).

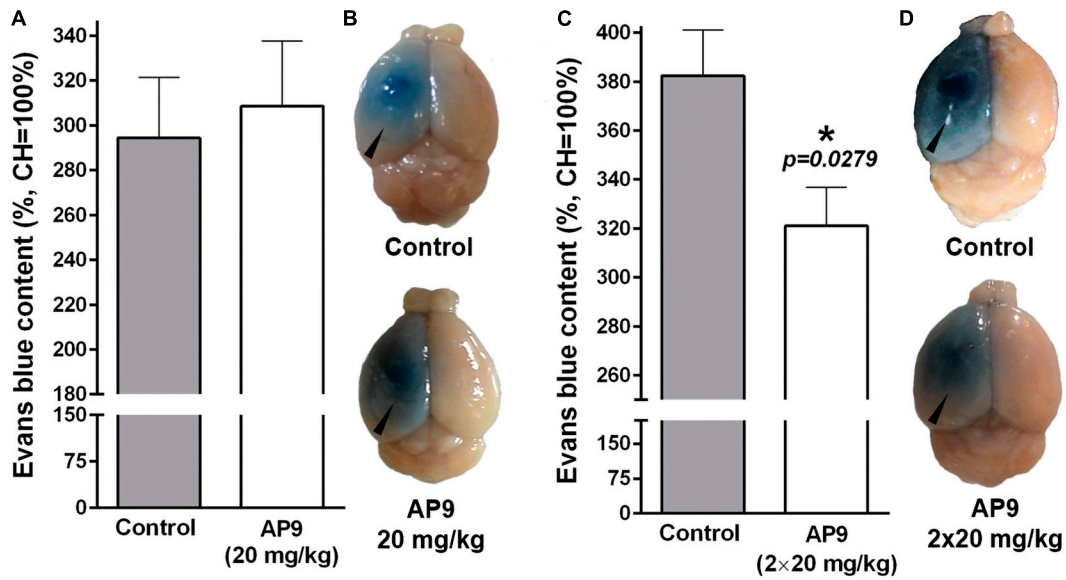

FIGURE 5 | AP9 effects on PT-induced disruption of the BBB 24 h post thrombosis. **(A,B)** A single administration of AP9 (20 mg/kg): **(A)** relative Evans blue dye content in IH (unpaired *t*-test) and **(B)** representative photographs of the whole brains. **(C,D)** A double administration of AP9 (20 mg/kg): **(C)** relative Evans blue dye content in IH (unpaired *t*-test) and **(D)** representative photographs of the whole brains (triangles indicate damaged hemispheres).

Effect of AP9 on BBB Disruption After Thrombosis

Extraction of Evans blue dye is an effective tool to estimate the functional state of the BBB after experimental ischemia (Belayev et al., 1996; Kim et al., 2001). According to published data, the maximal disruption of brain vessel integrity after PT is observed during the first day after its induction (Kang et al., 2015). For this reason, we performed dye extraction from IH and CH 24 h after surgery to assess the potential protective properties of AP9.

A single administration of AP9 at a dose of 20 mg/kg did not affect Evans blue dye content in the damaged hemisphere. That index was 294.40 ± 26.88% (n = 5) and 308.60 ± 28.98% (n = 5) in control and AP9-treated mice, respectively (**Figures 5A,B**). However, a double injection of AP9 (20 mg/kg, 10 min before

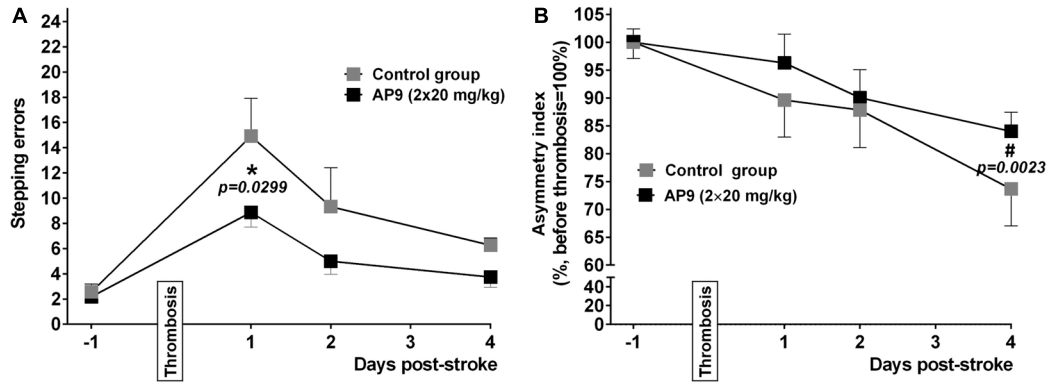

FIGURE 6 | Effects of a double administration of AP9 (20 mg/kg, 10 min before and 1 h after PT) on PT-induced sensorimotor deficit in mice. **(A)** The grid-walk test data. **(B)** The cylinder test data (two-way ANOVA with Šidák correction for multiple comparisons, *: as compared to the corresponding control value, #: as compared to the value before PT).

and 1 h after thrombosis) demonstrated the protective effect. The relative dye content in IH was 382.40 ± 18.67% (n = 6) in control animals. In mice treated with AP9, this parameter statistically significantly decreased down to 321.10 ± 15.69% (n = 7) (**Figures 5C,D**).

Effect of AP9 on Photothrombosis-Induced Sensorimotor Deficit in Mice

Sensorimotor deficit developing in animals after experimental ischemia is a complex indicator of the severity of this pathology at the level of the whole organism. In the present study, we used the cylinder and the grid-walk tests, which previously showed high efficacy in detecting sensorimotor dysfunction in mice (Baskin et al., 2003; Galkov et al., 2020).

We found that a double injection of AP9 at a dose of 20 mg/kg improved the neurological status of mice in both tests. In the grid-walk test, AP9-treated mice made fewer stepping errors (8.88 ± 1.18 errors/100 steps, n = 9) compared with the control group (14.92 ± 3.00, n = 7, two animals were excluded from the experiment due to the insufficient number of steps performed) 24 h after PT induction (**Figure 6A**). A statistically significant decrease in the asymmetry index measured in the cylinder test developed in the control group by 96 h after PT

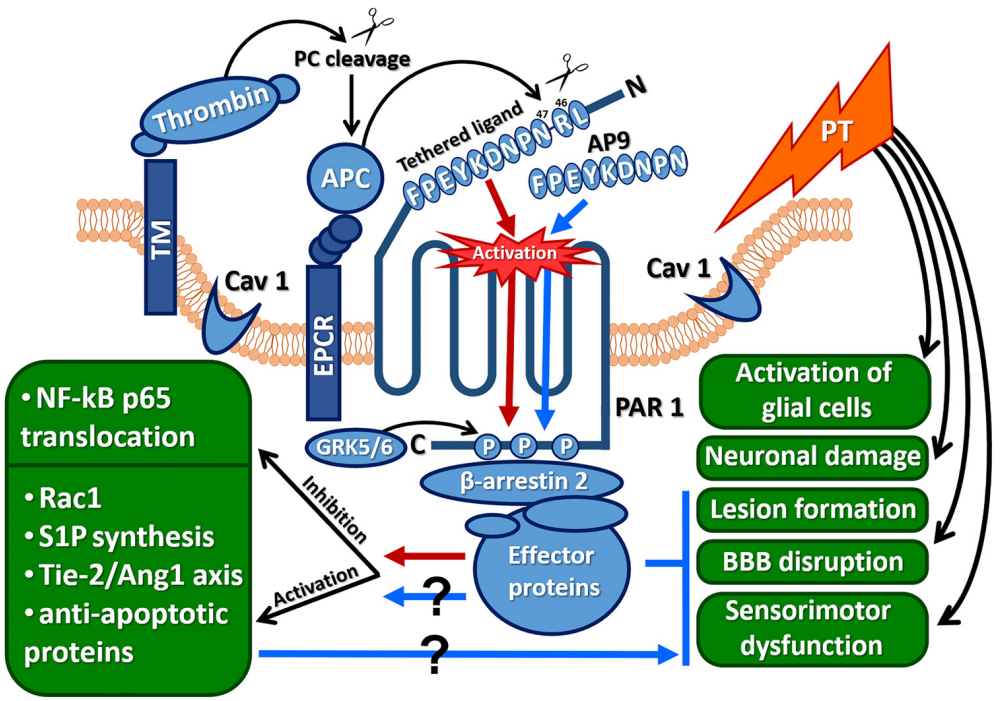

FIGURE 8 | Protective effects of AP9 and possible peptide-triggered cytoprotective pathways similar to those induced by APC (Ang1, angiopoietin 1; AP9, nine-amino-acid peptide analog of PAR1 "tethered ligand"; APC, activated protein C; CAV1, caveolin-1; EPCR, endothelial protein C receptor; GRK 5/6, G-protein-coupled receptor kinases 5 and 6; NF-κBp65, p65 subunit of the nuclear factor κB; PAR1, protease-activated receptor 1; PT, photothrombosis; Rac1, GTPase; S1P, sphingosine-1-phosphate; Tie-2, angiopoietin receptor; red arrows indicate cytoprotective pathways triggered by APC, and blue arrows and lines indicate AP9 effects observed in the present research).

induction (73.64 ± 6.61 and 100.00 ± 2.93% 96 h after PT induction and prior to thrombosis, respectively; n = 7). This decrease was less expressed in the group subjected to AP9 treatment (84.00 ± 3.44 and 100.00 ± 2.39%, respectively; n = 8) (**Figure 6B**).

Impact of β-Arrestin-2 Knockout on AP9 Protective Action in PT

We used mice lacking β-arrestin-2 (Bohn et al., 1999) in order to reveal the contribution of this protein to the protective effects of AP9. According to the data obtained during the genotyping of animals by PCR, all β-arrestin-2-/- mice had knockout of both alleles of the target gene in contrast to wild-type animals. The results of western blotting completely confirmed the absence of β-arrestin-2 expression in knockout animals (**Figure 7A**).

We used TTC staining of brain sections to assess lesion volume. AP9 (20 mg/kg, 10 min before and 1 h after PT) significantly reduced the relative lesion volume in wild-type animals (C57BL/6 strain) 24 h after PT. This parameter was 70.80 ± 8.28% (n = 9) in the treated group and 100.00 ± 9.56% (n = 10) in control mice (**Figures 7B,C**). It was consistent with our MRI data from BALB/c mice. However, we did not find the protective effect of double AP9 injection in β-arrestin-2-/- mice. Lesion volume was 100.00 ± 11.63% (n = 8) in control animals and 89.82 ± 6.91% (n = 8) in AP9-treated mice (**Figures 7B,C**). Thus, β-arrestin-2 expression is required for AP9 protective action in PT-induced brain ischemia.

DISCUSSION

The involvement of hemostatic proteases in the regulation of brain ischemia-induced dysfunctions was demonstrated previously (Xi et al., 2003; Griffin et al., 2004; Suo et al., 2004; Sheehan and Tsirka, 2005). Data on the protective effects of APC and peptide analogs of PAR1 "tethered ligand" generated by APC cleavage at Arg^{46} are of particular interest. The effects of the nine-amino-acid peptide AP9 composed of Asn^{47}–$Phen^{55}$ of PAR1 "tethered ligand" in cultured neurons, mast cells, and keratinocytes were studied in our laboratory. We have shown using selective PAR1 blockers that AP9 increases the survival of neurons after their cocultivation with activated mast cells via PAR1 (Babkina et al., 2016). In addition, the peptide reduced neuronal death under excitotoxic conditions (Savinkova et al., 2014) and accelerated wound healing *in vitro* (Kiseleva et al., 2014). The similarity of PAR1-dependent action of AP9 and APC points to a possibility of AP9 effect implementation through APC-like pathways.

In the present study, we demonstrated for the first time the protective properties of AP9 in the mouse model of ischemic stroke. AP9 injected 10 min before PT at a dose of 20 mg/kg

decreased brain damage volume. The double administration of AP9 (20 mg/kg) 10 min before and 1 h after PT, that is, within the "therapeutic window" (Danton and Dietrich, 2004), reduced not only lesion volume but also BBB disruption and neurological deficit in mice.

It is known that PAR1 is expressed by different components of the neurovascular unit: neurons (Junge et al., 2004; Gorbacheva et al., 2009), astrocytes (Bartha et al., 2000; Wang et al., 2002; Junge et al., 2004), and endothelial cells (Bartha et al., 2000). Accordingly, various types of cells can be considered as a potential target for AP9. Moreover, PT-induced BBB disruption increases the possibility of crossing the BBB by the peptide and leads to expansion of its cell target spectrum.

Nine-amino-acid peptide treatment decreased the lesion volume measured by MRI and Evans blue dye content in the damaged hemisphere after PT. MRI visualizes the brain areas characterized by edema formation (Hoehn et al., 2001), and Evans blue dye extraction allows us to evaluate the functional state of the BBB (Belayev et al., 1996). It indicates that the effects of AP9 are primarily due to the stabilization of the endothelial barrier function after PT-induced ischemia. Our results are in accordance with previous data on the PAR1 peptide agonist TR47, that is, the C-terminal fragment of PAR1 formed after cleavage of the receptor by APC at Arg^{46}. TR47 inhibits endothelial permeability *in vitro* and *in vivo* vascular leakage in mice via APC-like activation of Rac1 (Mosnier et al., 2013).

The observed AP9 effects are similar to those described for APC. In cultured endotheliocytes, APC suppresses NF-κB-modulated genes and inhibits cytokine signaling. Moreover, APC modulates apoptosis pathways, including upregulation of the endothelial Bcl-2 homolog (A1), endothelial NO synthase, and the inhibitor of apoptosis (IAP) (Joyce et al., 2001; Riewald and Ruf, 2005). APC also activates the Ang1/Tie-2 axis (Minhas et al., 2009) and increases S1P synthesis (Feistritzer and Riewald, 2005; Finigan et al., 2005), decreasing disruption of the endothelial barrier. It is possible that all these effects can be triggered in brain endotheliocytes via activation of PAR1 by AP9.

Despite the fact that AP9 beneficial effects were demonstrated on hippocampal neurons under excitotoxic conditions (Savinkova et al., 2014), as well as after their cocultivation with activated mast cells (Babkina et al., 2016), here, AP9 had no neuroprotective action according to histological analysis. It is possible that in addition to glutamate excitotoxicity and immune cell activation, other factors cause neuronal death under ischemic conditions *in vivo* (Durukan and Tatlisumak, 2007). Thus, a direct comparison of the results of *in vivo* and *in vitro* experiments is not applicable. Moreover, the lack of AP9 impact on neurons appears to be related to the method of peptide administration. Endothelial cells are expected to be a direct target of the peptide after its intravenous injection that is confirmed by AP9-mediated BBB stabilization after PT. However, according to the data on the sensorimotor tests, the peptide not only affects endotheliocytes but also indirectly protects other cell types via the regulation of PT-induced edema. Apparently, AP9 prevents cell damage in different components of the neurovascular unit via various cytoprotective pathways similar to APC (**Figure 8**). At the same time, the molecular mechanism of AP9 action needs further detailed study.

The APC-like mechanism of AP9 action is supported by data from β-arrestin-2-knockout animals. The absence of AP9 protective effect in mice lacking β-arrestin-2 indicates that AP9 can trigger β-arrestin-2-dependent pathways. β-Arrestin-2 recruits many effector proteins and provides G-protein-independent signaling via the mechanism of "biased agonism" (**Figure 8**) (Soh and Trejo, 2011; Griffin et al., 2015; Roy et al., 2016). It was previously shown that the localization of PAR1 in caveolae and its association with β-arrestins are necessary for activation of Rac1, which is a key participant in APC-mediated cytoprotective cascades (Soh and Trejo, 2011).

CONCLUSION

In conclusion, the new PAR1 agonist peptide (NPNDKYEPF-NH_2) demonstrates the APC-like protective effects in the mouse model of PT-induced brain ischemia. We suggest that AP9 action is mediated by its effects on the neurovascular unit and brain cells. The molecular mechanism of AP9 action is similar to that of APC. The activation of PAR1 by AP9, as well as APC-mediated PAR1 cleavage induce β-arrestin-2-dependent cytoprotective pathways. Our study shows the potential strategy to the treatment of ischemic brain injury based on a new class of peptide neuroprotectors.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

The animal study was reviewed and approved by the Bioethics Committee of Lomonosov Moscow State University.

AUTHOR CONTRIBUTIONS

MGa performed the research, analyzed the data, and wrote the manuscript. EK performed the histological research. MGu conducted the MRI studies. MS performed the peptide synthesis. LG designed the research and edited the manuscript. All authors contributed to the manuscript revision and read and approved the submitted version.

FUNDING

The work of MGa was supported by the University program "UMNIK" (Lomonosov Moscow State University 2018, project no. 14587Гу/2019) and Russian Foundation for Basic Research (project no. 18-34-00977). The work of EK

was partly conducted in the frame of the IDB RAS state program of Fundamental Scientific Research (project no. 0108-2019-0004).

ACKNOWLEDGMENTS

We are thankful to Alexandra Guseva (Lomonosov Moscow State University) and Ilya Gusev for the help with laser equipment servicing. The team of authors is also thankful to Dmitriy Gorbachev (Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry, Russian Academy of Sciences) and Vladimir Vyushkov (Lomonosov Moscow State University) for the help in mouse genotyping and interpretation of the data obtained.

Li G, Dong Y, Liu D, Zou Z, Hao G, Gao X, Pan P and Liang G (2020) NEK7 Coordinates Rapid Neuroinflammation After Subarachnoid Hemorrhage in Mice. Front. Neurol. 11:551. doi: 10.3389/fneur.2020.00551

Background: Subarachnoid hemorrhage (SAH) is a devastating disease which leads to high morbidity and mortality. Recent studies have indicated that, never in mitosis gene A-related expressed kinase 7 (NEK7), is involved in NLRP3 (NLR family, pyrin domain containing 3) associated inflammation, which may result in subsequent cellular and vascular damage. The aim of this study was to investigate whether NEK7 is involved in the pathophysiology of subarachnoid hemorrhage.

Methods: 455 adult male C57B6J mice, weighing 22 to 30 g, were used to investigate the time course of NEK7 expression in the ipsilateral cortex after SAH, and to investigate the intrinsic function and mechanism of NEK7. A vascular puncture model was used to create the mouse SAH model, and intracerebroventricular injection was used to deliver NEK7 recombinant protein, NEK7 small interfering RNA, nigericin, and MCC950. Neurological score, brain water content, Evans blue extravasation, immunofluorescence, and western blot were evaluated for neurological outcome, neuronal apoptosis, blood-brain barrier damage, microglia accumulation, and the mechanism of NEK7 and NLRP3 activation.

Results: Our results exhibited that intrinsic NEK7 was elevated after SAH in the cortex of the left/ipsilateral hemisphere and was colocalized with microglia, endothelial cells, neuron, astrocyte, and oligodendrocyte, and highly expressed in microglia and endothelial cells after SAH. NEK7 recombinant protein aggravated neurological deficits, brain edema, neuronal apoptosis, BBB permeability, microglial accumulation, and activated caspase-1 and IL-1β maturation, while NEK7 small interfering RNA injection reversed those effects. Nigericin administration enhanced ASC oligomerization, caspase-1 and IL-1β maturation without increasing the protein level of NLRP3, and ASC oligomerization and caspase-1 IL-1β maturation reduced when combined with NEK7 knockdown or MCC950 delivery. We found the level of NEK7 expression increased after SAH and could activate the downstream NLRP3 pathway to induce caspase-1, IL-1β expression and then increased the BBB opening, microglia accumulation and neuronal apoptosis after SAH.

Conclusions: This study demonstrated for the first time that NEK7 mediated the harmful effects of neuronal apoptosis and BBB disruption after SAH, which may potentially be mediated by the NEK7/NLRP3 signal. NEK7 served as a co-component for NLRP3 inflammasome activation after SAH. NEK7 may be a promising target on the management of SAH patients.

Keywords: subarachnoid hemorrhage, microglia, NEK7, NLRP3, neuroinflammation, blood-brain barrier

INTRODUCTION

Despite years of efforts, early brain injury—the main contributor to the mortality and poor prognosis of patients after subarachnoid hemorrhage (SAH)—remains a catastrophic complication of a ruptured intracranial aneurysm (1). The pathophysiology of SAH involves an alteration in the brain neural vascular network, involving the arterial, capillary, venous systems, neurons, microglia, surrounding support cells, and the extracellular matrix (2). The precise mechanism of neuronal apoptosis and BBB damage, however, remains elusive.

The NLR family, pyrin domain containing 3 (NLRP3) inflammasome, consists of NLRP3, apoptosis-associated speck-like domain (ASC) and pro-caspase-1. It is a group of innate immune proteins considered to be sensors of pathogen- and damage- associated molecular patterns (3). NLRP3 inflammasome activation promotes the cleavage of pro-caspase 1 and pro- interleukin (IL)-1β into their mature forms, which contributes to the development of type 2 diabetes (4), atherosclerosis (5), gout (6), and Alzheimer's disease (7). Our previous study showed NLRP3 activation increased BBB extravasation, tight junction protein degradation, as well as neuronal apoptosis after CNS injury (8, 9). As a typical inflammation target, the exact mechanism of NLRP3 activation still remains unclear.

Recent studies reported that NEK7, a serine and threonine kinase involved in mitosis, is an essential activator of the NLRP3 inflammasome (10). NEK7-mutant cells showed lower caspase-1 activation and IL-1β production in response to NLRP3-activating stimuli (11). These data suggested that NEK7 acts as a switch between inflammasome activation and cell division (11). We postulated that NEK7 expression was altered after SAH and targeting NEK7 might inactivate NLRP3-inflammasome and downstream IL-1β to preserve neuronal death and BBB permeability. To elucidate the function of NEK7 after SAH, we analyzed the spatial distribution and time course of NEK expression, neurological function, neuronal apoptosis, and BBB permeability after NEK7 interference, and downstream NLRP3 activation.

Abbreviations: ANOVA, analysis of variance; ASC, apoptosis-associated speck-like protein; BBB, blood–brain barrier; BAX, BCL-2-associated X protein; BCL-2, B-cell lymphoma 2; EBI, early brain injury; IL-1β, Interleukin-1 beta; LRR, leucine rich repeat; NBD, nucleotide-binding domain; NEK7, Never in mitosis gene A-related expressed kinase 7; NLRP3, NLR family, pyrin domain containing 3; PBS, phosphate-buffered saline; PYD, pyrin domain; SAH, subarachnoid hemorrhage; TJs, tight junctions; ZO-1, zonula occludens-1.

MATERIALS AND METHODS

Animals

All experimental procedures were approved by the Ethics Committee of the General Hospital of Norther Theater Command (Shenyang Military Command) and was performed in accordance with the guidelines in the National Institutes of Health Guide for the Care and Use of Laboratory Animals, and followed the ARRIVE guidelines. Four-hundred-and-fifty-five (455) adult male C57B6J mice (22 to 30 g), were provided by the Department of Experimental Animals of the General Hospital of Norther Theater Command (Shenyang Military Command, Shenyang, China). Mice were acclimated in a reversed 12 h dark/12 h light cycle environment and provided with free access to water and food.

Experimental Design

The present study contained three experiments, which were designed as follows.

Experiment I

To investigate the time course of NEK7 expression and cell type location of NEK7 after SAH, 44 mice were randomly assigned to seven groups: Sham ($n = 6$), SAH 3 h ($n = 6$), SAH 6 h ($n = 6$), SAH 12 h ($n = 6$), SAH 24 h ($n = 6$), SAH 48 h ($n = 6$) and SAH 72 h ($n = 6$). NEK7 protein expression was detected by Western blot in cortex isolated from the ipsilateral/left hemisphere. Immunohistochemical staining of NEK7, NeuN (neuron marker), GFAP (astrocyte marker), Lectin (endotheliocyte marker), Iba-1 (microglia marker), and NG2 (oligodendrocyte marker) was performed at 24 h post SAH induction to confirm the spatial distribution of NEK7 in the cortex ($n = 6$).

Experiment II

To define the intrinsic function of NEK7 and to screen for effective dosage of NEK7 recombinant protein after SAH, 162 mice were randomly assigned to eight groups: Sham ($n = 24$), SAH ($n = 18$), SAH+NS (normal saline, 2 μL) ($n = 24$), SAH+NEK7 5 ng/μL ($n = 12$), SAH+NEK7 25 ng/μL ($n = 12$), SAH+NEK7 100 ng/μL ($n = 24$), SAH+Scr (scrambled) siRNA ($n = 24$), SAH+NEK7 siRNA ($n = 24$). Beam balance and modified Garcia tests were performed at 24 and 72 h after SAH to assess the neurological deficits in each group ($n = 6$). Furthermore, brain water content was performed at 24 and 72 h post SAH. Evans blue extravasation assessment test at 24 h post SAH induction to evaluate the blood-brain barrier damage. Immunohistochemical staining was also performed to detect

the neuronal apoptosis, endothelial continuity, and microglia accumulation in the cortex of ipsilateral/left hemisphere at 24 h after SAH induction ($n = 6$).

Furthermore, 30 mice were randomly divided into the following groups: Sham ($n = 6$), SAH+NS ($n = 6$), SAH+NEK7 100 ng/μL ($n = 6$), SAH+Scr siRNA ($n = 6$), SAH+NEK7 siRNA ($n = 6$). Western blot was performed to detect the NEK7, NRLP3, ASC, caspase-1, IL-1β, BCL-2, and BAX expression in cortex of the ipsilateral/left hemisphere in each group.

Experiment III

To validate the function of NEK7-denpdent NLRP3 signal activation after SAH induction, 84 mice were assigned to seven groups: Sham ($n = 12$), SAH ($n = 12$), SAH+Vehicle ($n = 12$), SAH+nigericin ($n = 12$), SAH+nigericin+Scr siRNA ($n = 12$), SAH+nigericin+NEK7 siRNA ($n = 12$), and SAH+MCC950 ($n = 12$). Modified Garcia tests and beam balance were performed at 24 h post SAH to evaluate the neurological dysfunction and brain water content, and Evans blue extravasation assessments were carried out to test the blood-brain barrier permeability.

Furhermore, 72 mice were randomly divided into the following groups: Sham ($n = 6$), SAH+NS ($n = 12$), SAH+Ngericin ($n = 12$), SAH+ Ngericin+Scr siRNA ($n = 12$), SAH+Ngericin+NEK7 siRNA ($n = 12$), and SAH+MCC950 ($n = 12$). Immunohistochemical staining was also performed to detect the neuronal apoptosis, endothelial continuity, and microglia accumulation. Western blot was performed to detect the protein expression of NEK7, NLRP3, ASC, caspase-1, IL-1β, BCL-2, and BAX.

SAH Model

SAH model was performed as previously described (12); mice were anesthetized with pentobarbital sodium (40 mg/kg) by intraperitoneal (i.p.) injection, then exposed the bifurcation of the common carotid artery in supine position. The left external carotid artery (ECA) was isolated and distally cut into a 2-mm stump. A 5-0 sharpened monofilament nylon suture was inserted into the left internal carotid artery (ICA) through the ECA, then advanced 3 mm past the bifurcation of the left ICA, until resistance was felt. Sutures were withdrawn and ICA patency confirmed. In the sham group, sutures were not advanced past the internal carotid artery bifurcation, identical to other procedures.

Intracerebroventricular Injection

The operation of intracerebroventricular injection was as previously described (13). A hole, lateral to the bregma 1.0 mm, was drilled on the skull without puncturing the dura. A needle of a 10-μL Hamilton syringe (Microliter 701; Hamilton Company, Reno, NV, USA) was then stereotactically and vertically inserted into the hole, 3.0 mm under the horizontal plane of the bregma, entering the left lateral ventricle. A total 2 μL volume of recombinant NEK7 protein solution (Sino Biological, Beijing, China, 4 μg dissolved in 2 μL sterile saline), nigericin solution (Sigma-Aldrich, Shanghai, China, 4 μg in 2 μL vehicle, vehicle: 2 μL mixture of 9:1 NS and DMSO), or MCC950 solution (Sigma-Aldrich, Shanghai, China, 2 μg in 2 μL vehicle, vehicle: 2 μL mixture of 9:1 NS and DMSO) was infused at a rate of 0.2 μL/min, 1 h after SAH induction, whereas 500 pmol/2 μL of NEK7 siRNA (Santa Cruz Biotechnology, Santa Cruz, CA, USA, 500 pmol in a 2-μL mixture of 1:1 RNase-free water and lipofectamine) or scrambled siRNA was infused at the identical rate 48 h before SAH induction. The syringe was slowly withdrawn at 10 min after infusion.

Neurological Outcome Assessment

Neurological deficits were accessed as previously described, at 24 and 72 h after SAH induction. The modified Garcia scale and beam balance test were used (14). Two blinded observers were employed for grading mean of the neurological score.

SAH Grade

The SAH severity grading score was implemented as previously described (15). The basal cistern was divided into six segments that could be scored from 0 to 3 according to the amount of subarachnoid blood clotting. The total score was calculated by adding the scores from six segments (0–18 points). Animals that received a score <8 were excluded from the study.

Brain Water Content

The brain samples were quickly removed from the skull, separated into the left and right cerebral hemispheres, the cerebellum, and the brain stem. These four parts of the brain were weighed (wet weight), respectively, and the brain samples were then dried at 55°C for 48 h in an oven and weighed again (dry weight). The water content percentage formula was: ([wet weight - dry weight]/wet weight) ×100%.

Evans Blue Extravasation

Evans blue extravasation was performed as previously described (14). Mice were anesthetized by pentobarbital sodium (40 mg/kg) i.p. injection 24 h post-SAH. Evans blue dye (2%, 5 mL/kg; Sigma–Aldrich, St. Louis, MO, USA) was injected into the left femoral vein over 2 min and circulated for 60 min. Mice were euthanized by an intracardial perfusion of phosphate-buffered saline (PBS). The brains were removed and quickly divided into the left and right cerebral hemispheres, weighed, homogenized in saline, and centrifuged at 15,000 g for 30 min. Subsequently, the resultant supernatant was added with equal volume of trichloroacetic acid, incubated overnight at 4°C and centrifuged at 15,000 g for 30 min. Next, the resultant supernatant was collected and spectrophotometrically quantified at 610 nm for Evans blue dye.

Immunofluorescence Staining

Immunofluorescence staining was performed on fixed frozen brain sections as previously described (16, 17). Mice were deeply anesthetized and transcardially perfused with PBS and 4% PFA at 24 h post SAH. Brain samples were isolated and post-fixed in 4% PFA for 24 h, then soaked in 40% sucrose for 1 day. Coronal brain sections (10 μm) were obtained using a cryostat (Leica, Nussloch, Eisfeld, Germany) and permeabilized using 0.3% Triton X-100 in PBS for 30 min. Sections were blocked with 5% donkey serum for 1 and incubated at 4°C overnight with anti–Occludin (1: 100, Abcam, Cambridge, UK), anti-NEK7 (1: 200, Novus, Bio-Techne China, Shanghai,

China), anti-IL-1β, anti–NeuN, anti–GFAP (1: 100), anti–Iba-1, anti–NG2 (1: 50, Abcam, Cambridge, UK) antibody and Lectin (1:200, Vector Laboratories, Burlingame, CA, USA), then incubated with corresponding secondary antibodies for 4 h at room temperature. Images were obtained atbasal cortex with a fluorescence microscope (Olympus, Melville, NY, USA) from slides. Quantification of immunofluorescence intensity was performed with the Measure tool in ImageJ software (National Institutes of Health, Bethesda, MD, USA) and the results of all the groups were normalized to the Sham group. Six image fields per group were analyzed. To evaluate the continuity of tight junctions of ECs, gaps of tight junctions were quantified as the length percentage of whole Occludin staining as per the previous method (18). The length of gaps and whole Occludin staining was measured by the Line tool in ImageJ software (National Institutes of Health, Bethesda, MD, USA) and the percentage was calculated as follows: Gap formation percentage = gap length/whole Occludin length. At least six vessels in each group were analyzed.

TUNEL

TUNEL staining was performed to test neuron apoptosis. Paraffin-embedded left/ ipsilateral hemisphere basal cortex sections (10 mm) were prepared. Apoptotic cells were stained using a Roche *in situ* cell death detection kit (Roche, Basel, Switzerland) according to the manufacturer's instructions. Fluorescent pictures were captured using a fluorescence microscope (Olympus, Melville, NY, USA). The number of TUNEL-positive cells were counted with ImageJ software. To calculate the apoptotic rates, six slides from one group were chosen and the number of TUNEL+ cells were counted in the range of images. The apoptotic rates were calculated by the formula: apoptotic rates = the number of TUNEL+ neurons in the field/ the number of all neurons in the field × 100%.

Western Blot

Western blot was performed as previously described (19, 20). Briefly, a protein sample was extracted from the cortex of the left/ipsilateral hemisphere. Equal amounts of total protein (30 μg) were loaded in the lane of SDS-PAGE gels. After electrophoresis, the protein was transferred onto a PVDF membrane, which was then blocked with blocking buffer for 2 h at room temperature. Subsequently, the membrane was incubated at 4°C overnight with the following antibodies: anti-NEK7 (1:500; Novus, Bio-Techne China, Shanghai, China), anti-NLRP3, anti-ASC (1:500; Abcam, Cambridge, UK), anti-caspase-1, anti–IL-1β (1:500; Santa Cruz Biotechnology, Santa Cruz, CA, USA), anti-BCL-2, and anti-BAX (1:500; Thermo Fisher Scientific, Waltham, MA, USA). β-actin and α-tubulin were used as internal loading controls, anti–β-actin, and anti-α-tubulin primary antibodies (1:2000; Santa Cruz Biotechnology, Santa Cruz, CA, USA). PVDF membranes were incubated with the appropriate secondary antibodies for 2 h at room temperature. Blots were detected by chemiluminescent (ECL Plus; Amersham Bioscience, Arlington Heights, IL, USA). Data were analyzed by densitometry using Quantity One 4.6.2 (Bio-Rad Laboratories, Berkeley, CA, USA).

Statistical Analysis

Data are shown as the mean ± SD. Chi-square tests and one-way ANOVA, followed by Tukey's multiple comparisons test were used to compare the different groups. SPSS 18 software (IBM, Chicago, IL, USA) was utilized to analyze the data, and $P < 0.05$ was considered as statistically significant.

RESULTS

Expression of NEK7 and Cellular Distribution After SAH

To investigate the expression of NEK7 after SAH induction, protein levels of NEK7 was detected by Western blot analysis. A significant increase of NEK7 were found in the ipsilateral/left hemisphere at 24 and 72 h after SAH (**Figures 1A,B**). Furthermore, immunohistochemical staining in the sham group showed that NEK7 expression was colocalized with the NeuN (neuron marker), GFAP (astrocyte marker), Lectin (endotheliocyte marker), Iba-1 (microglia marker), and nerve/glial antigen (NG) 2 (oligodendrocyte marker) in the left/ipsilateral cortex (**Figure 1C**). At 24 h post SAH, NEK7 was obviously elevated in endothelial cells and microglia (**Figures 1D,E**). None of the sham-operated mice died, and eight mice died within 72 h after SAH, due to severe hemorrhagic volume.

Neurological Functions After Recombinant NEK7 Delivery and Interference of NEK7 Expression After SAH

The NEK7 siRNA used in the present study could effectively inhibit the NEK7 expression after SAH. SAH grading score did not display significant differences among the groups at 24 and 72 h after SAH (**Figures 2A,B**). The SAH group showed significant neurological impairment in the modified Garcia test and beam balance, compared with the Sham group at 24 h after SAH induction (**Figures 2C–F**). Mice in the SAH+NEK7 100 ng/μL group had more severe neurological deficits at 24 h post SAH compared with the SAH+NS group, different to that in the SAH+NEK7 5 ng/μL and SAH+NEK7 25 ng group (**Figures 2C–F**). Furthermore, NEK7 siRNA treatment revealed greater improvements in neurological deficits compared with the SAH+Scr siRNA group at 24 h after SAH (**Figures 2C–F**). The Beam balance test exhibited similar trends (**Figures 2C–F**).

Neuronal Apoptosis and BBB Permeability After Recombinant NEK7 Delivery and Interference of NEK7 Expression

Mice from the SAH, SAH+NS, and SAH+Scr siRNA groups showed increased brain water content in both hemispheres at 24 and 72 h after SAH compared with mice in the Sham group (**Figures 3A,B**). The NEK7 100 ng/μL treatment increased the brain water content compared with the SAH+NS group, while the NEK7 siRNA pretreatment significantly reduced the

brain water content in both hemispheres at 24 and 72 h post SAH (**Figures 3A,B**). Therefore, a dosage of NEK7 100 ng/μL was chosen for further investigation. Apoptosis is a biologically reversible process which is characterized as energy-dependent programmed cell death (21). Neuronal cell apoptosis, a main process of EBI, plays a crucial role in pathophysiology after SAH (22). Mice in the SAH and SAH+NS group showed a significant increase of neuronal apoptosis in the left/ipsilateral cortex. In the SAH+NEK7 100 ng/μL group, mice exhibited a rising number of apoptosis neurons than that in the SAH+NS group, while NEK7 siRNA pretreatment reversed these phenomena (**Figures 3C,D**). Furthermore, the

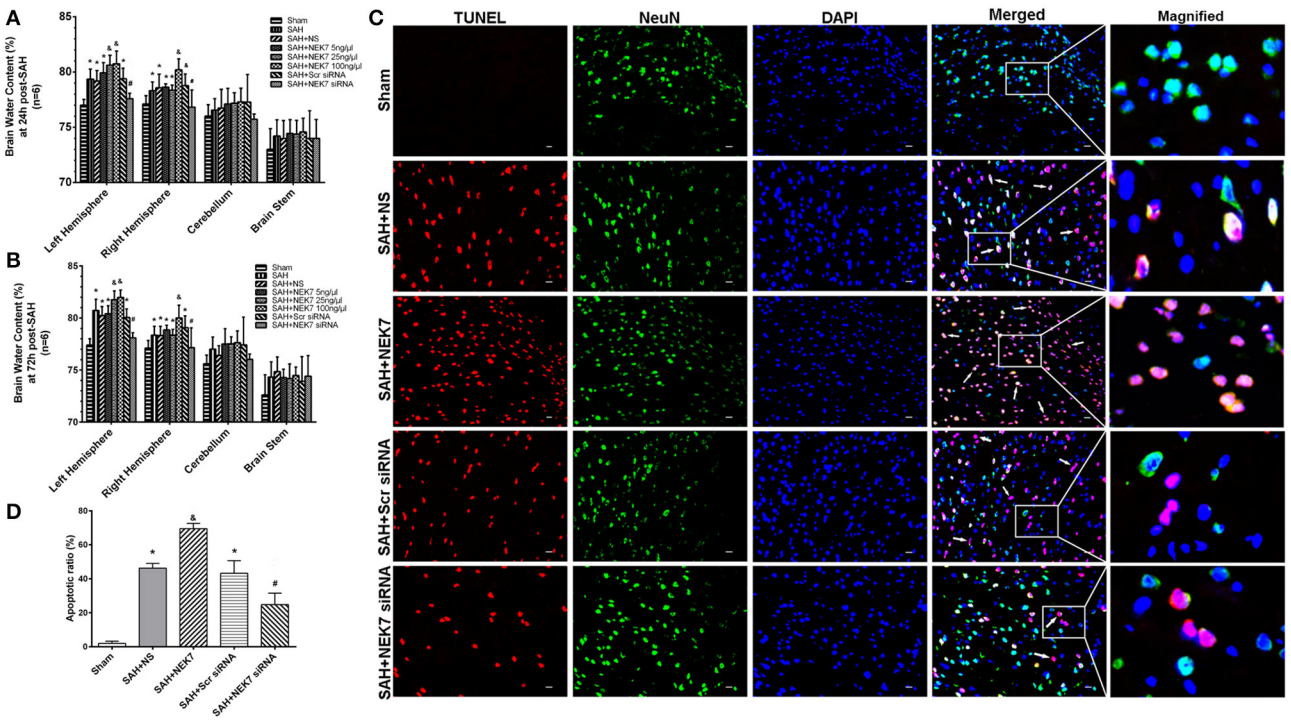

FIGURE 3 | Effects of exogenous NEK7 and NEK7 small interfering RNA treatment on neuronal apoptosis after subarachnoid hemorrhage. **(A,B)** Brain water content assessment at 24 and 72 h after SAH, $n = 6$. **(C)** Representative immunohistochemistry images of TUNEL (red) and NeuN (green) at 24 h after SAH. SAH group demonstrated more Evans blue extravasation than the Sham group in the left/ipsilateral hemisphere (**Figure 4A**). The SAH+NEK7 100 ng/μL mice exhibited increased Evans blue leakage compared with the SAH+NS mice, whereas the NEK7 siRNA pretreatment significantly lowered the Evans blue extravasation compared with the SAH+Scr siRNA group (**Figure 4A**). In the immunohistochemical staining images, continuous endothelial cells (Lectin) and Occludin in the sham group were shown. Th Lectin and Occludin continuous structures broke up at 24 h after SAH, and NEK7 treatment significantly aggravated those damages, however, NEK7 siRNA infusion significantly reversed those disruptions at 24 h after SAH (**Figures 4B,C**). There was a significant accumulation of microglia in the SAH+NS group compared to that in the sham group (**Figure 4D**). IL-1β expression in microglia was elevated in the SAH+NS group after SAH and was aggravated by NEK7 infusion, while NEK7 siRNA administration reversed those effects (**Figure 4E**).

NLRP3 Inflammasome Protein and Apoptosis Related Protein Alteration After Recombinant NEK7 Delivery and Specific Inhibition of NEK7 Expression

Expression of NEK7, NLRP3, ASC, caspase-1, and IL-1β was measured *via* western blot at 24 h after SAH. NLRP3 levels in SAH, SAH+NS, SAH+NEK7 100 ng/μL, SAH+Scr siRNA, and SAH+ NEK7 siRNA elevated significantly at 24 h post SAH (**Figures 5A,B**). NEK7 100 ng/μL infusion after SAH increased ASC expression and caspase-1 and IL-1β maturation, however, NEK7 siRNA pretreatment reduced mature caspase-1 and IL-1β expression (**Figures 5A–G**). BCL-2 (B-cell lymphoma 2), is a member of the BCL-2 family of regulator proteins that inhibit apoptosis. It plays an important role in promoting cellular survival and inhibiting the actions of pro-apoptotic proteins (21). BAX (Bcl-2-associated X protein) is a pro-apoptotic protein in the BCL-2 family, which acts on the mitochondrial membrane to promote permeabilization, which is a vital signal in the apoptosis cascade (23). Mice from the SAH and SAH+NS groups showed significantly increased levels of BAX and decreased BCL-2 (**Figures 5H–J**). In the SAH+NEK7 group, expression of BAX rose and BCL-2 reduced, compared to that in the SAH+NS group. While in the SAH+NEK7 siRNA group, expression of BAX was lower, and BCL-2 was more than that in the SAH+Scr siRNA group (**Figures 5H–J**).

Neurological Functions and Neuronal Apoptosis After Nigericin Delivery, Specific Inhibition of NEK7 Expression, and MCC950 Administration

To study whether NLRP3 activation is dependent on NEK7 after SAH, we used nigericin, an activator of NEK7-dependent NLRP3 signal (10), or MCC950, an inhibitor of the NEK7/NLRP3

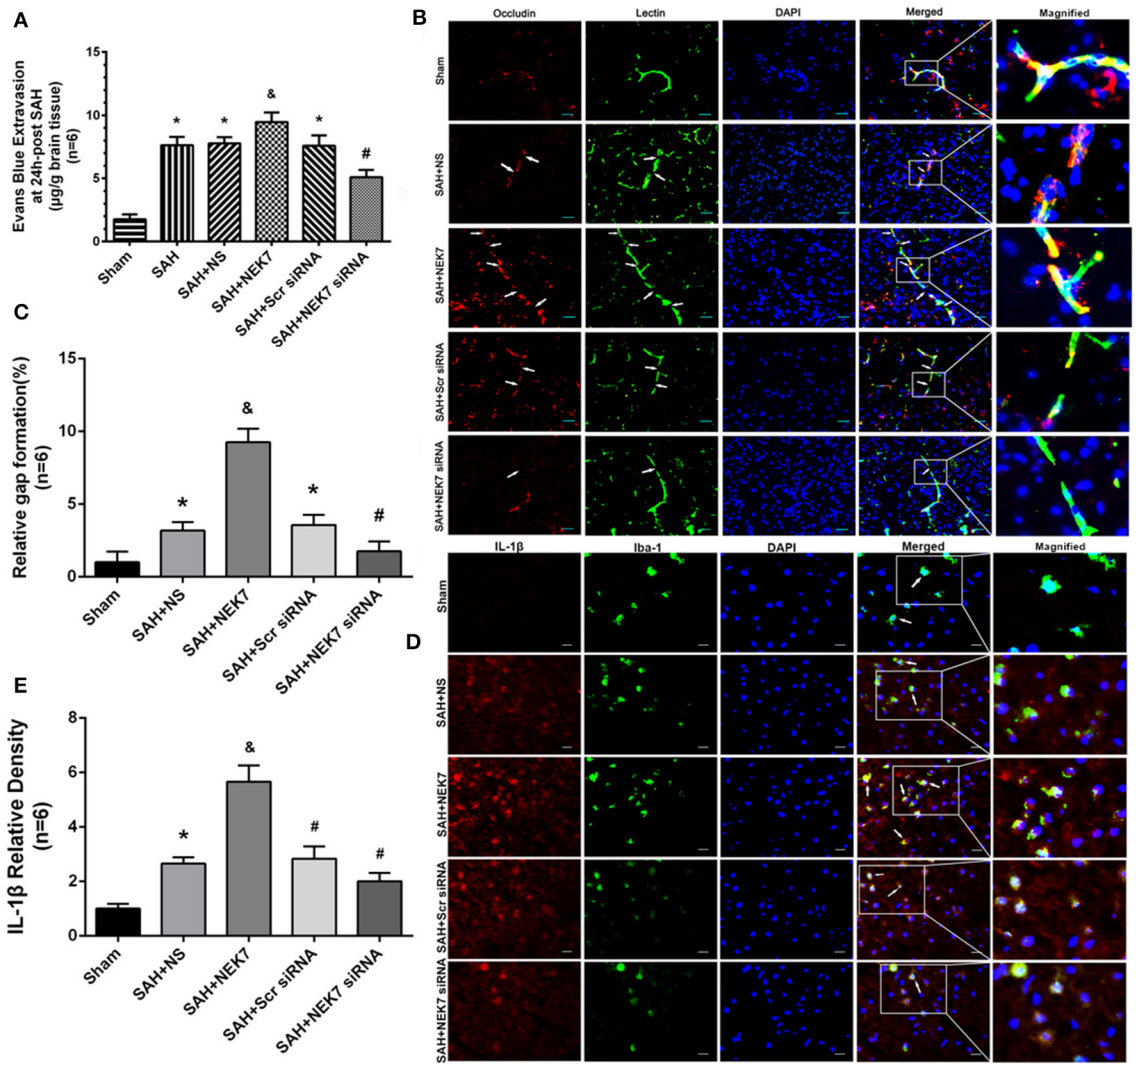

FIGURE 4 | Effects of exogenous NEK7 and NEK7 small interfering RNA treatment on blood–brain barrier and microglia accumulation after subarachnoid hemorrhage. **(A)** Evans blue extravasation evaluation at 24 h after SAH, $n = 6$. **(B)** Representative immunohistochemistry images of Occludin (red) and Lectin (green) at 24 h after SAH. signal (24), to regulate inflammation post SAH. The SAH grading score did not show significant differences among the groups at 24 h post SAH (**Figure 6A**). The SAH and SAH+Vehcile group showed significant neurological impairment in the modified Garcia score and beam balance test compared with the Sham group (**Figures 6B,C**). Mice in the SAH+negricin group had more severe neurological deficits at 24 h post SAH compared with the SAH+Vehicle group (**Figures 6A–C**). NEK7 siRNA treatment or MCC950 ameliorated neurological deficits, however, were comparable to that of the SAH+Scr siRNA group or SAH+Vehicle group, respectively (**Figures 6A–C**). Compared with the Sham group, the SAH+Vehicle group displayed obvious increasing apoptosis neuron numbers at the left/ipsilateral cortex at 24 h post SAH (**Figures 6D,E**). Nigericin administration increased neuronal apoptosis after SAH, while NEK7 knockdown or MCC950 injection reduced neuronal apoptosis (**Figures 6D,E**).

BBB Permeability After Nigericin or MCC950 Delivery and Specific Inhibition of NEK7 Expression

Mice in the SAH and SAH+Vehicle groups showed increased brain water content in left hemispheres 24 h after SAH, compared with the Sham group (**Figure 7A**). The nigericin treatment increased the brain water content compared with the SAH+

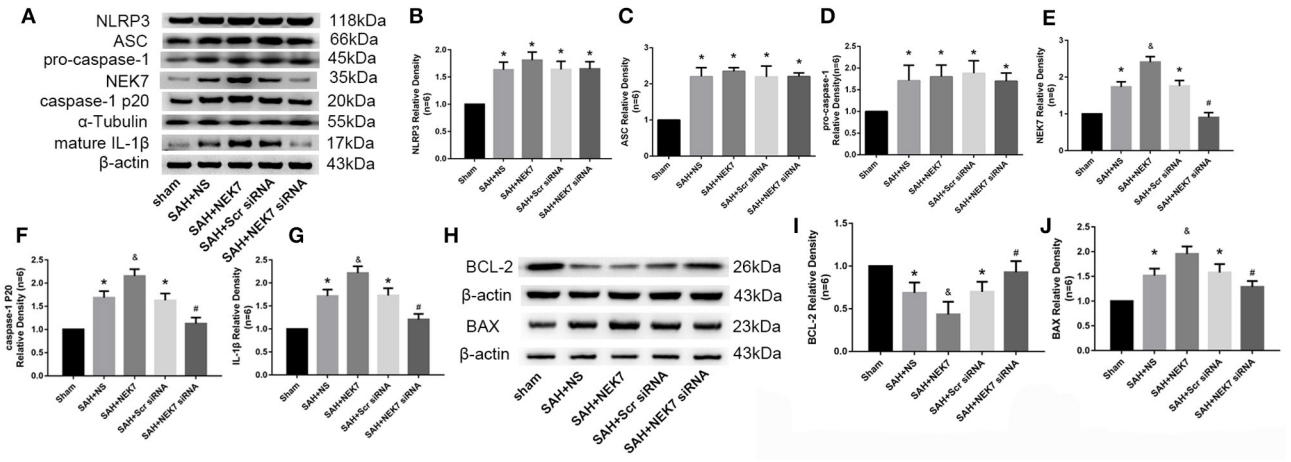

FIGURE 5 | Effects of exogenous NEK7 and NEK7 small interfering RNA pretreatment on NLRP3 activation and apoptosis related protein expression. **(A)** Representative western blot bands of NLRP3, NEK7, caspase-1, ASC, and IL-1β from the ipsilateral cortex after SAH. **(B–G)** Quantitative analysis of NLRP3, ASC, pro-caspase-1, caspase-1 p20, NEK7, and IL-1β, $n = 6$. **(H)** Representative western blot bands of BCL-2 and BAX. **(I,J)** Quantitative analysis of BCL-2 and BAX. Vehicle group, however the NEK7 siRNA pretreatment or MCC950 injection significantly reduced the brain water content (**Figure 7A**). Furthermore, the SAH group showed more Evans blue extravasation than the Sham group (**Figure 7B**). The SAH+Nigericin group exhibited increased Evans blue leakage compared with the SAH+Vehicle group, whereas NEK7 siRNA pretreatment or MCC950 delivery significantly lowered the Evans blue extravasation compared with the SAH+Nigericin+Scr siRNA group (**Figure 7B**). Lectin and Occludin continuous structures broke up at 24 h after SAH, and nigericin treatment significantly aggravated those damages, while NEK7 siRNA injection significantly reversed those disruptions (**Figure 7C**). Microglia accumulation was exacerbated and expression of IL-1β in microglia was elevated *via* nigericin administration and was alleviated after NEK7 siRNA pretreatment or MCC950 injection (**Figures 7D,E**).

NEK7 Coordinated NLRP3 Signal Activation After SAH

Expression of NEK7, NLRP3, ASC, pro-caspase-1, caspase-1 and IL-1β was measured *via* western blot at 24 h after SAH. NLRP3 was activated by various stimuli, and we wondered whether NEK7 coordinates NLRP3 activation after SAH. The expression of NEK7, NLRP3, caspase-1, and IL-1β was significantly increased at 24 h after SAH and NEK7 expression peaked at 24 h (**Figures 5A–G**). NEK7 recombinant protein delivery increased ASC oligomerization, caspase-1, and IL-1β maturation without increasing NLRP3 expression, and this was reversed by NEK7 siRNA infusion or MCC950 injection, which indicated that increasing NEK7 and NLRP3 binding activated the downstream signal (**Figures 5A–G**). BCL-2 protein levels in the SAH group were decreased at 24 h after SAH compared to the Sham group, while BAX increased and BCL-2 decreased in the SAH+Vehicle group compared to the sham group (**Figures 5H–J**). NEK7 recombinant protein infusion lowered BCl-2 and elevated BAX, while NEK7 siRNA relieved those effects (**Figures 5H–J**). Nigericin injection increased the expression of caspase-1, IL-1β at 24 h after SAH, which demonstrated that nigericin increased caspase-1 and IL-1β maturation but did not affect NLRP3 and NEK7 expression (**Figures 8A–G,K–Q**). Caspase-1 and IL-1β maturation were decreased at 24 h after SAH in the SAH+nigericin+Scr siRNA group compared to that in the SAH+nigericin+NEK7 siRNA group (**Figures 8A–G,K–Q**). Nigericin treatment could effectively inhibit their BCL-2 expression and enhance BAX expression (**Figures 8H–J**), however NEK7 siRNA treatment (**Figures 8H–J**) or MCC950 administration significantly reversed those trends (**Figures 8R–T**).

DISCUSSION

The present study demonstrated that NEK7 increased after SAH, peaked at 24 h, and was mainly expressed in microglia and endothelial cells. Exogenous NEK7 protein worsened neurological deficits and brain edema, while NEK7 specific inhibition preserved neurological function, neuronal apoptosis, and brain edema. Administration of Nigericin, a NEK7-dependent NLRP3 activator, aggravated neurological deficits, brain edema, microglial accumulation, and BBB disruption, while NEK7 siRNA infusion reversed these phenomena. By further studying the mechanism it was indicated that NEK7 activated the NLRP3 downstream inflammatory pathway, including caspase-1 and IL-1β maturation in endothelial cells which open, leading to increasing BBB extravasation. The microglia were then activated, which subsequently induced neuronal apoptosis by reducing BCL-2 and increasing BAX. NEK7 was recently reported to be critical for the activation of NLRP3 inflammasome and its

downstream inflammatory pathway, to induce caspase-1 and IL-1β maturation (4, 10, 25). NLRP3 inflammasome, which is important for the activation of caspases-1, maturation, and the secretion of proinflammatory cytokines such as IL-1β and IL-18, is a complex with multi-protein components containing three parts: an amino-terminal pyrin domain, a central nucleotide-binding domain, and a C-terminal leucine rich repeat (26). The ASC, and pro-caspase-1 are closely linked with the formation of NLRP3 inflammasome (27). Under the pathological state, NLRP3 is activated, then inflammasome assembly takes place and leads to the IL-1β shearing from pro-IL-1β, then secretion and maturation, which finally causes cell injury and death (7). NLRP3 inflammasome is involved in the initiation and development of several pathophysiological processes of CNS injury including stroke (28), neurodegenerative disease (7), and multiple sclerosis (29).

NEKs (NIMA-related kinase) are a group of evolutionarily conserved protein kinases sharing high amino acid sequence identity with NIMA which controls initiation of cell mitosis during mitotic cell division (30). A decrease in the centrosomal c-tubulin levels and reduction of the microtubule re-growth activity in the NEK7-suppressed cells was observed (31). The NEK7 amino acid sequence contains all of the amino acids conserved in serine/threonine kinases and have no C-terminal extensions (32), is expressed widely in a mouse brain including the Olfactory bulb, cortex, Thalamus, Midbrain, and the Hindbrain

(33), is considered to be a new inflammasome component, and is also a switch between mitosis and NLRP3 activation (11). A recent study showed that NEK7-mutant mice had a defective IL-1β production response to nigericin (11). NEK7 bound to the leucine-rich repeat domain of NLRP3 in a kinase-independent manner (25) and acted as a coordinator

in NLRP3 inflammasome activation. NLRP3 inflammasome assembly and formation is required for NEK7, which results in the secretion and maturation of IL-1β and IL-18 (11). MCC950 is an orally bioavailable sulfonylurea derived small molecule which selectively interacts with NLRP3 with no effect on NLRC4 and NLRP1 (34), and a number of studies showed its ability to block NLRP3 activation through the NEK7/NLRP3 pathway under pathological conditions (24), however, the precise mechanism is unknown. Some studies have demonstrated that MCC950 could reduce lung ischemia-reperfusion injury and high level of glucose induced retina damage by blocking NEK7-NLRP3 interaction (35, 36). Here we used MCC950 to block NEK7-NLRP3 pathway activation, and found that MCC950 showed similar effects as described in previous publications (37, 38). However, how MCC950 influences the NEK7-NLRP3 pathway still requires further study. Several pathways are pivotal for the NLRP3 inflammasome activation, such as potassium efflux, ROS (reactive oxygen species) signaling, and lysosomal destabilization. 50 mM KCl prevented potassium efflux to inhibit the interaction between NLRP3 and NEK7 induced by ATP, nigericin, or gramicidin in bone-marrow-derived macrophages from C57BL/6J mice carrying mutant NEK7 (25). While LPS-primed $NEK7^{+/+}$or $NEK7^{Cu/Cu}$ macrophages, producing similar amounts of mitochondrial ROS after treatment with nigericin (11). A recent pilot study found that hypokalemia is common in SAH patients (39). Cortical spreading depolarization, a phenomenon which is characterized as serial neuronal exciting *via* K^+ channel open after SAH, was considered as a factor of poor prognosis (40). These studies suggested that K^+ efflux may exist after SAH and could be an activator of NEK7/NLRP3. Recently, NEK7 has been identified as a necessary component of the NLRP3 activation driven by ROS but is independent of K+ efflux (41). The upstream of NEK7/NLRP3 activation after SAH currently remains elusive and requires further investigation.

Microglia are a cluster of specialized macrophages residing in the CNS system and the main source of NLRP3 (42).

Sufficient evidence suggests that they play a critical role in neuroinflammation. Activated microglia produce and secrete pro-inflammatory cytokines, including IL-1β, nitric oxide, and tumor necrosis factor-α, which induce cell death and secondary central nervous system injury. Cultured microglia have recently been shown to produce IL-1β (11), acting as a key mediator of neuronal apoptosis after SAH (43). In addition, Microglia were found to induce neuronal apoptosis *via* reducing BCL-2 and increasing BAX (44). In this study, we showed that NEK7 was expressed in microglia and was elevated after SAH, which in turn elicited neuronal apoptosis by activating NLRP3 and inducing IL-1β releasing. Neuronal apoptosis was alleviated by NEK7 siRNA pretreatment *via* reducing IL-1β and BAX and increasing BCL-2. Microglial accumulation was also found after SAH, providing evidence that targeting NEK7 may reduce neurological deficits by attenuated neuronal apoptosis triggered by microglia activation. Our results displayed that microglial accumulation in the ipsilateral/left cortex was enhanced by exogenous NEK7 administration and nigericin infusion, while it was reversed by NEK7 siRNA pretreatment and MCC950 injection. NEK7 was reported to influence microtubule dynamics, which is also a main factor for cell movement, morphology maintaining, and synaptic outputs of neurons (31, 45, 46). Microtubule activity were also found to be associated with microglia migration (47), however, there are very few studies that mention the exact mechanism of microglia movement after SAH. Based on these results, NEK7 may play a potential role in microglia migration *via* regulating microtubule. Furthermore, Acetylated α-tubulin was recently found to mediate the transport of mitochondria, apposition of ASC to NLRP3 on endoplasmic reticulum, and then activated NLRP3 (48). This indicates that NEK7 might activate NLRP3 *via* activating microtubule acetylation after stroke, which requires further investigation.

The blood-brain barrier can prevent harmful substances from coming into contact with the brain and allows nutrient substances to enter the brain (49). After SAH, the blood-brain barrier opens and leads to blood metabolites coming into direct contact with neurons and surrounding cells, which also leads to vasogenic brain edema (2). Endothelial cells are a main component of the BBB. Endothelial cells maintain the basic function of the BBB though transcellular transport and a tight junction structure. Previous studies indicated that NLRP3 activation induce the BBB open, while NLRP3 deletion preserved BBB permeability by reducing MMP9 and MMP2, which could subsequently degrade the tight junction protein including zonula occludens-1 and TJP2 (50). Expression of NLRP3 rise in endothelial cells after stroke, suggesting that endothelial cells may be a major source of NLRP3 (36, 50). Recent studies reveal that knockdown NEK7 expression could reduce high glucose induced retinal endothelial cell dysfunction (36) and maintain retinal endothelial cell permeability, which suggests that IL-1β itself could increase BBB permeability. In this investigation we demonstrated that brain edema worsened, and Evans blue extravasation increased after SAH, and protein levels of IL-1β rose in endothelial cells. At the same time, knockdown NEK7 ameliorated downstream NLRP3 activation and IL-1β maturation, eventually protecting BBB.

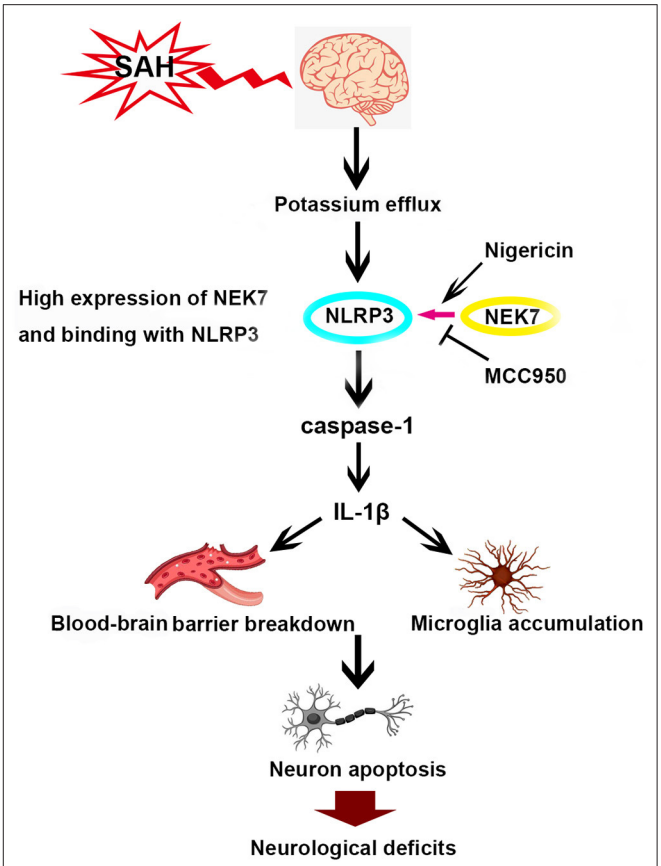

FIGURE 9 | Scheme of NEK7/NLRP3 interaction and downstream signal activation after SAH.

The limitations of this investigation were that data only focused on the NEK7 and NLRP3 inflammasome, while tight junction protein degradation was not studied in detail. After SAH, NF-κB undergoes nuclear translocation, and subsequently, elevated MMP9 transcription and induced basement membrane and tight junction protein degradation, which have all been well-illustrated in other studies. In addition, NEK7 may be located in the extracellular region and could affect surrounding cells. Consistent with previous studies, we found that endothelial cells and microglia highly expressed NEK7, however, whether NEK7-NLRP3 pathway activation in other cells and whether other types of cells secrete NEK7 and have effects on endothelial cells and microglia after SAH, are unknown. Other unknown mechanisms of NEK7 or NLRP3 activation cannot be excluded, therefore, in further studies, more data about the expression of NEK7 in other cell types and the elucidation of mechanisms of other mechanisms are needed.

CONCLUSIONS

This study demonstrated for the first time that NEK7 was elevated in the microglia and endothelial cells of the brain after SAH, and exogenous recombinant NEK7 induced

neuronal apoptosis and blood–brain barrier disruption which subsequently worsens the neurological outcome. This process was potentially mediated by NEK7-NLRP3 activation, which may promote casepase-1 and IL-1β maturation and secretion, and apoptosis related protein alteration in the brain (**Figure 9**). By targeting NEK7, our data and further translational studies may provide benefits for the management of SAH patients.

DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the article/supplementary material.

ETHICS STATEMENT

The animal study was reviewed and approved by Ethic Committee of General hospital of Northern Theater Command.

AUTHOR CONTRIBUTIONS

YD, GLia, and PP designed the experiment. PP, GLi, DL, ZZ, and GH finished the experiments protocols. GLi and DL carried out data analysis. PP, YD, and GLia prepared and revised the manuscript and gave the final approval of manuscript to be published. All authors contributed to the article and approved the submitted version.

Knauss S, Albrecht C, Dirnagl U, Mueller S, Harms C, Hoffmann CJ, Koch SP, Endres M and Boehm-Sturm P (2020) A Semiquantitative Non-invasive Measurement of PcomA Patency in C57BL/6 Mice Explains Variance in Ischemic Brain Damage in Filament MCAo. Front. Neurosci. 14:576741. doi: 10.3389/fnins.2020.576741

Numerous studies on experimental ischemic stroke use the filament middle cerebral artery occlusion (fMCAo) model in C57BL/6 mice, but lesion sizes in this strain are highly variable. A known contributor is variation in the posterior communicating artery (PcomA) patency. We therefore aimed to provide a semiquantitative non-invasive *in vivo* method to routinely assess PcomA patency. We included 43 male C57BL/6 mice from four independent studies using a transient 45 min fMCAo model. Edema-corrected lesion sizes were measured by magnetic resonance (MR) imaging 24 h after reperfusion. Time-of-flight MR angiography was performed 7 days before and 24 h after fMCAo. Scores of PcomA size measured 24 h after, but not scores measured 7 days before fMCAo were negatively correlated with lesion size. Variability in PcomA patency explained 30% of the variance in our cohort ($p < 0.0001$, coefficient of determination $r^2 = 0.3$). In a simulation using parameters typical for experimental stroke research, the power to detect a true effect of $d = 1$ between two groups increased by 15% when an according covariate was included in the statistical model. We have demonstrated that *in vivo* measurement of PcomA size is feasible and can lead to increased accuracy in assessing the effect of treatments.

Keywords: stroke, mouse, angiography, MRI, posterior communicating artery, lesion size

INTRODUCTION

Animal models of focal cerebral ischemia are a cornerstone of stroke research, as indicated by over 1.000 experimental treatments for acute stroke that have been evaluated in these models (O'Collins et al., 2006). A prerequisite for a successful translation of preclinical findings into clinical trial is selection of the correct target in preclinical experiments (Dirnagl and Macleod, 2009; Sena et al., 2010). Possibly the greatest risk to reproducibility of results and correct target selection comes from the omnipresence of small sample sizes and correspondingly low statistical power

(Button et al., 2013). Low statistical power can lead to overestimation of effect sizes and low positive predictive value of positive findings but also increases the risk of overlooking the true effects of therapeutics at an early stage (Button et al., 2013; Munafò et al., 2014). Here, we propose a method to increase power and reduce noise in one of the most widely used stroke models and one of the most common animal strains.

The intraluminal filament method of middle cerebral artery occlusion (fMCAo) is among the most commonly used methods to induce focal ischemic stroke in animal studies (Morris et al., 2016). In order to reduce the imbalance of covariates in preclinical stroke models, standard operating procedures and refinements to the methods have been formulated to control known determinants of outcome variables (Connolly et al., 1996; Dirnagl, 2012; Morris et al., 2016). Often, the variance in lesion size, which is one of the main outcome parameters, is as high as 40% of the mean, rendering the generation of robust and reproducible data with prevalently used small sample sizes difficult (Dirnagl, 2006). The extent of this variability greatly depends on the mouse strain used in the experiment (Yang et al., 1997; Kitagawa et al., 1998). One of the most commonly used mouse strains, but at the same time one of the strains with the largest variability in lesion size, is C57BL/6, due to its widespread use for generating genetically modified mice (Kitagawa et al., 1998; Maeda et al., 1998; McColl et al., 2004). One of the factors determining the variability in lesion size is the patency of the circle of Willis in this strain (Kitagawa et al., 1998; Maeda et al., 1998; McColl et al., 2004). Blood supply to the rodent brain is provided through four main arteries: two vertebral arteries posteriorly and two carotid arteries anteriorly. At the base of the brain, these arteries are connected by anastomoses, forming the circle of Willis, with two posterior communicating arteries and one anterior communicating artery. In 1998, Kitagawa showed that the patency of the posterior communicating artery (PcomA) is a crucial determinant of the lesion size in the fMCAo model (Kitagawa et al., 1998). Of note, nomenclature for the communicating arteries in mice is inconsistent in the literature. In this paper, we adhered to the nomenclature used in the work published by Kitagawa et al. (1998) describing the connecting artery between the superior cerebellar artery (SCA) and the posterior cerebral artery (PCA) as PcomA, which corresponds to the P1 segment of the human PCA (Xiong et al., 2017).

In this study, we sought to establish an *in vivo* imaging approach to assess the patency and size of the PcomA as a determinant of lesion size, to be used in adjusting for pre-existing differences in this important covariate. Including this variable in the statistical model to test for treatment effects in preclinical stroke models might increase power and precision to detect true effects and arrive at more precise estimates of effect sizes.

MATERIALS AND METHODS

Animals and Experimental Groups

All experimental procedures were approved by the "Landesamt für Gesundheit und Soziales Berlin" under registration numbers G0005/16, G0065/17 and G0261/17 and were in accordance with national and institutional guidelines for the care and use of laboratory animals and with directive 2010/63/EU of the European Parliament and of the Council of 22 September 2010. The reporting conforms to the ARRIVE guidelines (Kilkenny et al., 2010). A total of 33 C57BL/6J (group 1–3) and 10 C57BL/6N mice (group 4) (10 weeks old, mean weight 25 ± 2 g) were used from control groups of four studies testing different neuroprotective treatments. C57BL/6J and C57BL/6N mice were purchased from Charles River Germany, and the animals were housed in groups of 3–5 per cage with a standard light-dark cycle (12 h:12 h) and *ad libitum* access to food and water. Animals were rested for 7 days upon arrival to the laboratory. Investigating the association between PcomA patency and lesion size was pre-specified as an independent study goal in the study protocols. The animals included in the analysis for the present study were either naïve or treated with a vehicle depending on the respective group (non-reactive mGo53 Antibodies (Wardemann et al., 2003) for group 1 and 3, phosphate buffered saline for group 2 and no treatment for group 4. Group 1 ($n = 10$) was used to establish the method for MRA acquisition and semiquantitative measurement of PcomA size 24 h after fMCAo described below. Five animals in group 1 were used to study PcomA size *ex vivo* by Evans Blue perfusion after MRA acquisition. Group 2 and group 3 (group 2: $n = 13$; group 3: $n = 10$) underwent the same protocol of 45 min fMCAo followed by magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) 24 h after fMCAo. The sample size for group 2 was calculated assuming an effect size of $r^2 = 0.6$ at an $\alpha = 0.05$ and a power level of 0.8 based on results from group 1.

To test the robustness of the method, we included an additional group from another experimental hardware setup (group 4: $n = 10$). The protocols for 45 min fMCAo were the same in group 4 as in the other groups. The fMCAo surgery and MRI / MRA acquisition were performed by two independent researchers. Groups 2 and 4 underwent additional baseline MRA scans 7 days before fMCAo. **Figure 1** gives an overview of the experiments included in this study.

Randomization, Blinding, and Exclusion Criteria

For randomization, animals were numbered, and operation order was randomly assigned. For all protocols and outcome assessments, the experimenters were blinded. All outcome assessments were performed by observers blinded to previous treatments and outcomes. All animals included in the study ($n = 43$) were included in the analyses.

Model of Middle Cerebral Artery Occlusion in Mice

All experimental procedures were conducted by a trained experimenter following published standard operating procedures (Dirnagl, 2012). A transient fMCAo model was generated as described previously (Engel et al., 2011). Mice were anesthetized using 2.5% (vol/vol) isoflurane for induction and 1.5% (vol/vol) isoflurane for maintenance, mixed in both cases with 30% O_2 and ∼68% N_2O. After permanent occlusion of the ipsilateral external carotid and the common carotid artery, cerebral ischemia was

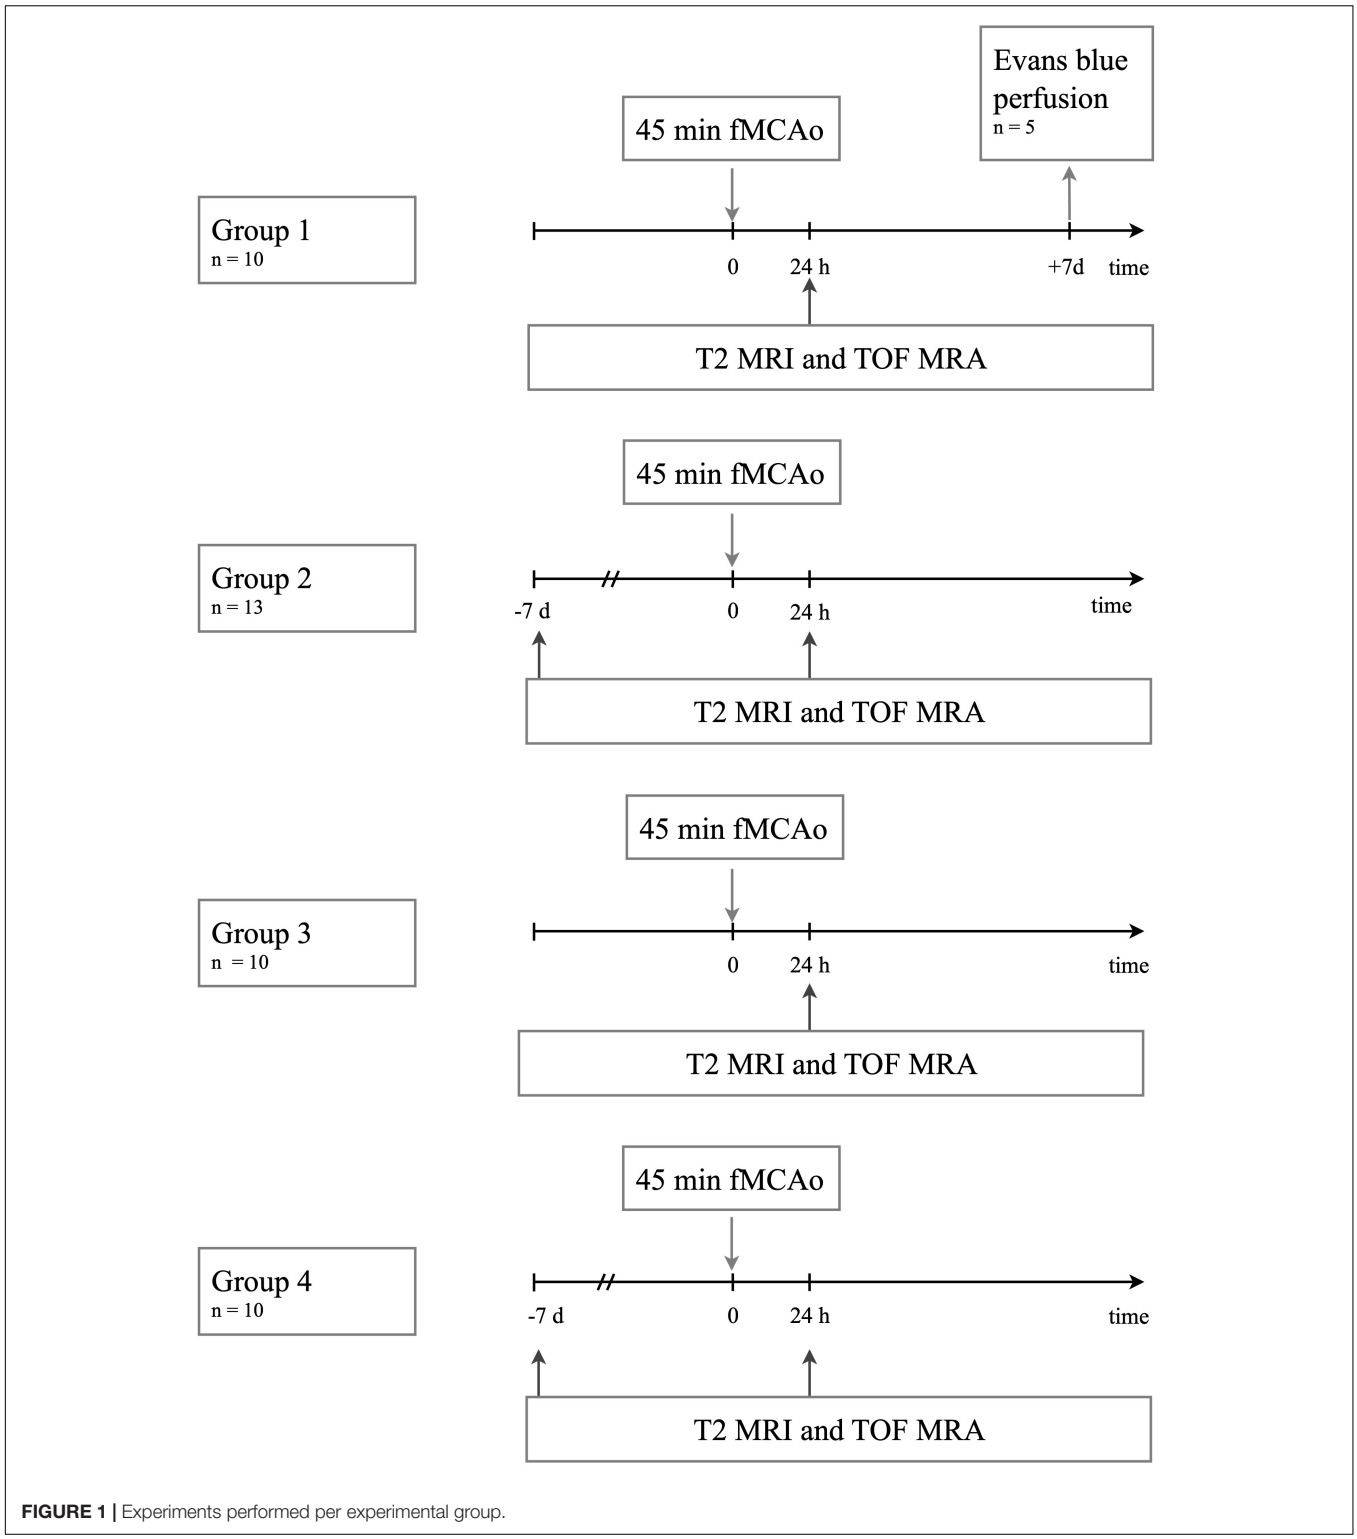

FIGURE 1 | Experiments performed per experimental group.

induced by introducing a 7-0 silicon-rubber-coated fMCAo suture with a coating length of 9–10 mm (monofilament 7019910PK5Re, Doccol Corp., Sharon MA, United States) into the left internal carotid artery and advancing it up to the anterior cerebral artery, thereby occluding the middle cerebral artery. The filament was withdrawn after an occlusion time of 45 min. Rectal temperature was maintained at 37.5 ± 0.5°C throughout the experiment using a feedback-controlled heating pad with a rectal probe (Fine Science Tools GmbH, Heidelberg, Germany). During fMCAo and for at least 2 h after reperfusion, animals

were allowed to recover in a heated cage (Peco Services, Cumbria, United Kingdom). Afterward, they were transferred to the home cage. After fMCAo, animals had access to soft food and were treated with subcutaneous saline injections to ensure adequate hydration after surgery.

Evans Blue Perfusion

For Evans Blue perfusion and vessel fixation, mice were deeply anaesthetized with ketamine and xylazine at the conclusion of the experiment and perfused through the heart with physiological saline followed by 4% paraformaldehyde, Termofisher, W32465, 3% Gelatin (Sigma-Aldrich, G1890), 1% low melting agarose (Sigma Aldrich A4018) and 0.1% Evans Blue (Sigma Aldrich E2129) as described previously (Foddis et al., 2019).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) was conducted on a 7-Tesla rodent scanner running Paravision 5.1 software (Pharmascan 70/16, Bruker, Ettlingen, Germany) with a 16 cm horizontal bore magnet and a 9 cm (inner diameter) shielded gradient with a maximum gradient strength of 300 mT/m. Mice were anesthetized under 1.5% isoflurane in a mixture of 30% O_2/68.5% N_2O and scanned under constant respiration monitoring (Small Animal Monitoring & Gating System, SA Instruments, Stony Brook, New York, United States). Animals were placed prone and head fixed on a heated circulating water blanket to ensure a constant body temperature of $37 \pm 0.5°C$.

For groups 1–3, a 72 mm volume resonator (RAPID Biomedical, Rimpar, Germany) was used for transmission, and an actively decoupled mouse head surface coil was used for signal reception. After coil tuning and matching, scout images were acquired. Similar geometry of all scans across animals was assured by using the anterior commissure as a landmark in rostral-caudal direction and the trachea as a landmark in the other directions. T2-weighted images were acquired using a 2D turbo spin-echo sequence (2D RARE) with repetition time (TR) = 4200 ms, echo time (TE) = 36 ms, echo spacing (ΔTE) = 12 ms, RARE factor = 8, 4 averages, 32 contiguous axial slices with a slice thickness of 0.5 mm, field of view (FOV) = 25.6 × 25.6 mm^2, matrix size MTX = 256 × 256, bandwidth BW = 46875 Hz, and total acquisition time TA = 6 min 43 s). Angiography with matching geometry but higher resolution was performed with a non-flow compensated 3D-FLASH time-of-flight (TOF) sequence with TR/TE = 15 ms/2.5 ms, 1 ms sinc-shaped excitation pulse with 22 kHz bandwidth and flip angle FA = 20°, FOV = 25.6 × 25.6 × 16.0 mm^3, MTX = 256 × 223 × 139 zero filled to 256 × 256 × 160, BW = 98684 Hz, TA = 7 min 50 s.

For group 4, a transmit/receive quadrature volume resonator with an inner diameter of 20 mm (RAPID) was used. T2-weighted images were acquired with the same sequence as groups 1–3. Angiography with FOV centered to the FOV of the T2-weighted sequence was acquired with a 3D-FLASH TOF using identical settings as for groups 1–3 but TR/TE = 14 ms/2.3 ms, FOV = 19.2 × 19.2 × 16.0 mm^3, MTX = 192 × 167 × 139 zero filled to 192 × 192 × 160, TA = 5 min 29 s.

Atlas Registration

T2-weighted images were registered to the Allen Brain Atlas[1] as described previously (Koch et al., 2017) using ANTX[2], a custom MATLAB toolbox comprising a segmentation in SPMMouse[3] followed by non-linear warping of tissue probability maps in ELASTIX[4]. The calculated image transformation could then be applied to other images aligned with the T2-weighted scan, including TOF angiograms and lesion masks.

Corrected Lesion Volume

Lesion volume corrected for brain swelling was calculated as described previously (Koch et al., 2017). Briefly, ischemic tissue appearing hyperintense on T2-weighted images 24 h after stroke was manually delineated by an experienced researcher, carefully omitting ventricles, using ANALYZE 5.0 software (AnalyzeDirect, Overland Park, KS, United States), and masks of the same dimensionality as the T2-weighted image were exported in NIFTI format. Using nearest neighbor interpolation, lesion masks were registered to the Allen Brain Atlas. Edema-corrected lesion volume in percent was defined as the volume of the lesion divided by volume of the hemisphere measured in atlas space.

Semiquantitative Assessment of PcomA Patency

ImageJ distribution 1.51m9 (Schneider et al., 2012) was used for post-processing atlas-registered angiograms to obtain scores for PcomA patency and size. Atlas registration allowed us to determine a set of 10 slices that contained the posterior part of the circle of Willis in all animals. To render pixel intensity comparable between individual datasets, we then calculated the signal-to-noise ratio (SNR) of each dataset adjusted as described previously (Gudbjartsson and Patz, 1995; Boehm-Sturm et al., 2011) and set a threshold to 1/10 of the maximum intensity of the dataset, setting all other values to NaN. In the next step, the area between the superior cerebellar artery (SCA) and posterior cerebral artery (PCA) was manually delineated on all selected slices. The maximum SNR in this area depends on background intensity and on the flow signal present, with higher intensities for higher flow. The only larger vessel in this anatomical area is the PcomA (Xiong et al., 2017). We therefore used the maximum SNR measured over the stack of slices as a correlate and semiquantitative score of the flow and thus the patency of the PcomA. Only the side ipsilateral to the ischemic lesion was assessed. ImageJ code is available on www.figshare.com at https://www.doi.org/10.6084/m9.figshare.8950328.

Validation by Manual *in vivo* and *ex vivo* Assessments of PcomA

The semiquantitative assessment of PcomA patency was correlated to an *in vivo* score of PcomA size in the described

[1]http://portal.brain-map.org/

[2]Latest version available under https://github.com/ChariteExpMri/antx2

[3]http://www.spmmouse.org/

[4]http://elastix.isi.uu.nl/

target region assessed and rated from 0 (meaning no vessel) to 3 (large vessel) using the same postprocessing as described above.

To quantitatively validate *in vivo* assessment of PcomA size, a subset of animals was perfused with Evans Blue and *ex vivo* photographs of excised brains were taken. PcomA size was measured in percent of the basilar artery *in vivo* on maximum intensity projections of raw TOF images and *ex vivo* on Evans Blue labeled vasculature.

Simulation

A statistical program was developed in STATA 13.0 (StataCorp, College Station, United States) to simulate a hypothetical two-arm trial testing the effect of a hypothetical treatment. The simulation code was based on work by Egbewale et al. (2014) describing the method to simulate data for clinical trials. Based on assumptions common in preclinical stroke research (Howells et al., 2012), we set the standardized effect size at $d = 1.0$. Setting the α error probability at 0.05 and the power at 0.8, we set the sample size at $n = 14$ per group. A normally distributed covariate with varying degrees of correlation with the outcome variable was introduced. Five different experimental conditions with correlation coefficients between the covariate and the outcome variable of $r^2 = 0$, 0.01, 0.04, 0.09, 0.16, 0.25, 0.29, 0.36, 0.49, and 0.64 were simulated. Outcome analysis was performed by either ANOVA or ANCOVA adjusting for the covariate in each individual experiment. Each hypothetical scenario and outcome analysis combination was repeated 1000 times to obtain reliable estimates of actual power. STATA code is available on www.figshare.com at https://www.doi.org/10.6084/m9.figshare.9752834.

Statistical Evaluation

Data are represented as the Pearson correlation coefficient r or as the coefficient of determination r^2 and calculated probability value (p-value) using the general linear model. For testing of manual ratings measured on an ordinal scale, data are represented as Spearman rank-order correlation coefficient r_S.

Data Availability

Source code for the simulation in STATA and the code for the macro used to postprocess images for semiquantitative measurement in ImageJ are available in the Appendix. All relevant original and Allen Brain Atlas-registered images are publicly available at http://doi.org/10.6084/m9.figshare.9752864.

RESULTS

TOF MRA Can Image PcomA Size After fMCAo

PcomA size was assessed *ex vivo* 7 days after fMCAo in five animals of group 1 (**Figure 2**). *Ex vivo* PcomA vessel size was measured after Evans Blue perfusion in relation to the size of the basilar artery and compared to corresponding measurements obtained *in vivo* 24 h after fMCAo by MR angiography. PcomA size measured by MRA was highly correlated ($n = 5$, $r^2 = 0.81$) with *ex vivo* PcomA size measurements, yet statistical significance was not reached ($p = 0.057$).

Semiquantitative Measurement of PcomA Patency by MRA Is Correlated With Manual PcomA Size Ratings

To validate the semiquantitative measurement of PcomA patency with an independent data analysis method, we compared semiquantitative measurements to independently conducted manual ratings (**Figure 3**). All imaging studies followed the same procedure of atlas registration before being further processed for unbiased semiquantitative measurement. The same atlas-registered datasets were used for evaluation by three trained raters blinded to the total lesion volume. Raters were trained with a standard set from group 1. There was a good correlation of manually rated PcomA size and semiquantitative measurement of PcomA patency (Spearman rank-order correlation coefficient

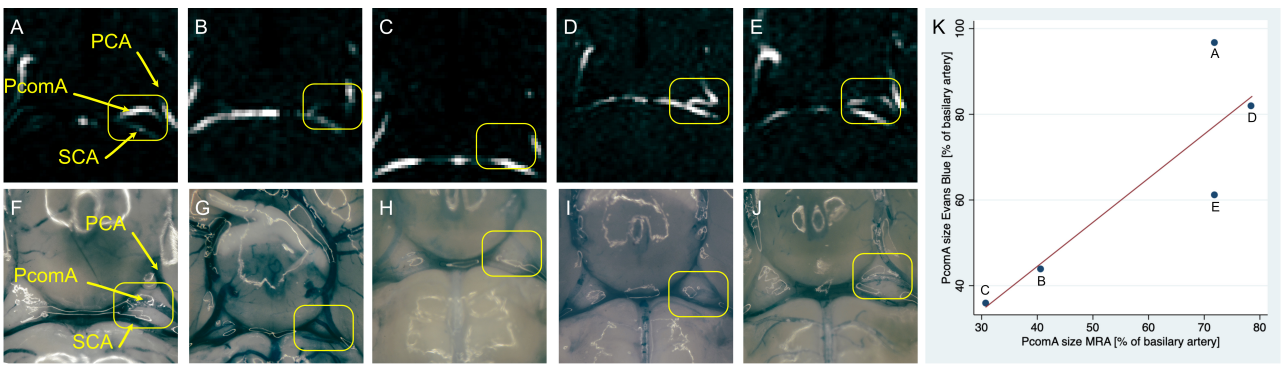

FIGURE 2 | TOF MRA images and corresponding images of vasculature after Evans Blue perfusion. TOF-MR angiography 24 h after fMCAo readily images the circle of Willis and PcomA **(A–E)**. Evans Blue perfusion 7 days after fMCAo clearly depicts the corresponding vasculature **(F–J)**. Yellow boxes highlight the PcomA ipsilateral to the ischemic lesion. $r_S = 0.7$, $p < 0.0001$). Ratings for the size of the PcomA on each side varied between independent raters, but interrater reliability was high (interclass correlation = 0.9, $p < 0.001$).

Semiquantitative Measurement of PcomA Patency Partially Explains Variability in Lesion Size

Unbiased semiquantitative measurement of PcomA patency from TOF angiograms recorded at 24 h after fMCAo significantly negatively correlated with lesion size determined by T2 weighted MRI at 24 h (**Figure 4**) in 4 independent datasets. In the first training set, 62% of intersubject variability of total lesion size was explained by PcomA patency ($r^2 = 0.62$) alone. Applying this algorithm to three independent datasets, 16–49% ($r^2 = 0.16$–0.49) (**Table 1**) of variability in lesion size in these individual groups was explained by differences in semiquantitative PcomA patency measurements. Pooling data from all groups resulted in a highly significant correlation explaining 34% of the variance in the dataset, $r^2 = 0.34$, $p < 0.0001$ (**Figure 5**).

Semiquantitative Measurement of PcomA Patency Prior to fMCAo Cannot Reliably Predict Infarct Size

There was a moderate correlation between mean manual PcomA size ratings before fMCAo and unbiased semiquantitative measurement of PcomA patency 24 h after fMCAo ($r = 0.63$, $r^2 = 0.40$, $p = 0.001$). While there was still a trend for a moderate correlation between mean manual PcomA size ratings before fMCAo and MRI lesion size 24 h after fMCAo (Spearman rank-order correlation coefficient $r = -0.40$, $p = 0.051$), semiquantitative PcomA measurement before fMCAo did not reliably predict lesion size across 2 datasets (group 2 and group

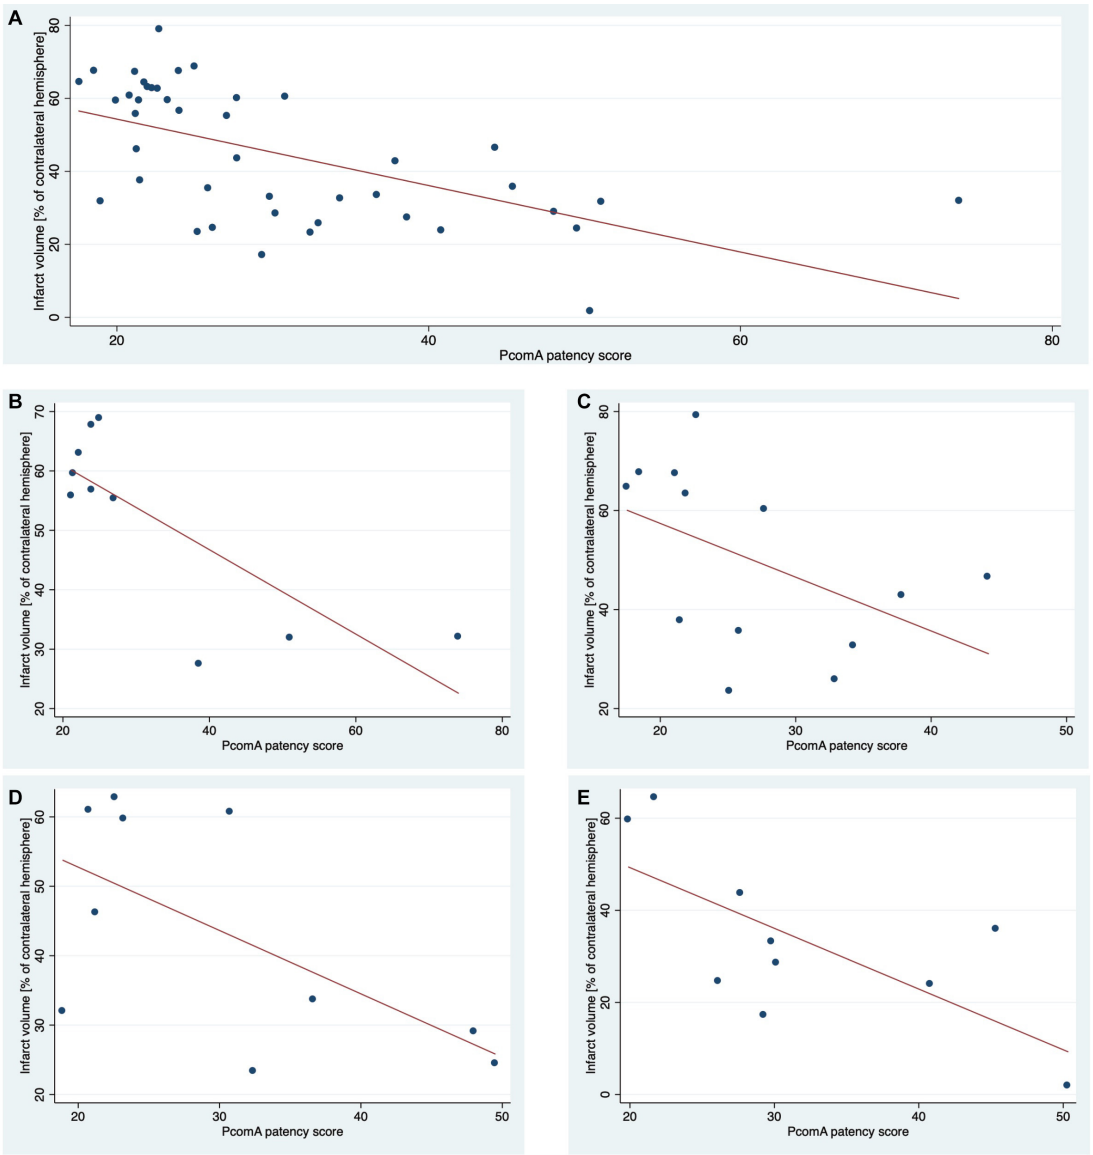

FIGURE 4 | Correlation of PcomA score and lesion size 24 h after fMCAo. Lesion sizes of each animal included in this study and corresponding semiquantitative scores of PcomA patency **(A)**. A method to obtain PcomA scores was developed using group 1 **(B)**. The results were replicated in three additional independent groups 2–4 **(C–E)**.

4; $r = -0.0186$, $r^2 = 0.0003$, $p = 0.933$). For group 1 and group 3, no baseline MRA before fMCAo was recorded.

Including PcomA Size as a Covariate Increases Power in a Simulation Preclinical Stroke Study

We conducted a simulation experiment to test whether the power of the final outcome analysis increases by including a covariate with the magnitude of correlation found for the association between PcomA patency and lesion size in this study. In this simulation, the power to detect an effect with a standardized effect size of $d = 1$ increased by 12% when adjusting for a covariate with a correlation coefficient of $r^2 = 0.25$ and further increased for stronger associations between the covariate and the outcome variable (**Figure 5**).

Distribution of PcomA Phenotypes in C57BL/6 Mice and Correlation With Lesion Size

The vascular anatomy was examined using TOF MRA images recorded 24 h after fMCAo and separate manual ratings of whether the PcomA was patent on each side. In our cohort, we found a complete circle of Willis in 21% (9/43), a patent PcomA on one side in 53% (23/43) and a bilateral lack of patent PcomAs

TABLE 1 | Correlation of semiquantitative scores of PcomA patency and lesion size 24 h after fMCAo.

Group	*n*	Correlation coefficient (*R*)	Coefficient of determination (R^2)	*p*
Group 1	10	−0.76	0.62	<0.01
Group 2	13	−0.4	0.16	0.09
Group 3	10	−0.61	0.38	0.05
Group 4	10	−0.7	0.49	0.023
All Groups	43	−0.58	0.34	<0.0001

in 26% (11/43) of animals. Ischemic lesion size was significantly correlated with PcomA phenotype, with smaller lesion sizes in animals with a complete circle of Willis ($r^2 = 0.32$, $p = 0.0001$).

DISCUSSION

We developed an easy-to-implement semiquantitative method to assess PcomA patency *in vivo* using readily available standard mouse MRI sequences. We demonstrated that the obtained dimensionless score negatively correlates with the lesion size after fMCAo in C57BL/6 mice. In a simulation experiment representative of common study designs in preclinical stroke research, we showed that by including this score as a covariate in the model, the power to detect a true effect increased by almost 20%.

The fMCAo model is widely used to model human focal cerebral ischemia (Kleinschnitz et al., 2015). One of its inherent disadvantages is the high intersubject variability of common outcome parameters. Several variables have been shown to impact lesion volume, one of the most important outcome parameters (Morris et al., 2016); including different parameters of the model itself, such as the occlusion and recovery time (Harada et al., 2005; Liu et al., 2009), the filament and anesthetic used (Michenfelder et al., 1976; Tsuchiya et al., 2003), differences in the surgical technique (Chen et al., 2008) as well as parameters of the animals, such as the species (Carmichael, 2005), strain (Yang et al., 1997; Kitagawa et al., 1998), substrain (Zhao et al., 2019), sex (Alkayed et al., 1998; Zhao et al., 2019), age (Sutherland et al., 1996), and interindividual variation in cerebrovascular anatomy (Barone et al., 1993; Kitagawa et al., 1998; McColl et al., 2004). Species and strain differences in the cerebrovascular architecture and in particular differences in the patency of macroanastomoses formed in the circle of Willis have already been studied previously (Barone et al., 1993; Kitagawa et al., 1998; McColl et al., 2004). In a study in 1998, Kitagawa and colleagues demonstrated species and strain differences of the circle of Willis in mice (Kitagawa et al., 1998; Ankolekar et al., 2012). In the same study, they were able to establish patency of the PcomA as a determinant of parenchymal ATP drop in a model of bilateral carotid artery occlusion and mortality and lesion size in fMCAo. To predict the vascular anatomy, they proposed a method using laser Doppler flow measurement of cerebral microvascular perfusion and a one-minute bilateral common carotid artery (CCA) occlusion. However, this method could neither determine whether the PcomA was patent on one or both sides nor detect the side of a unilaterally patent PcomA. The authors concluded that PcomA

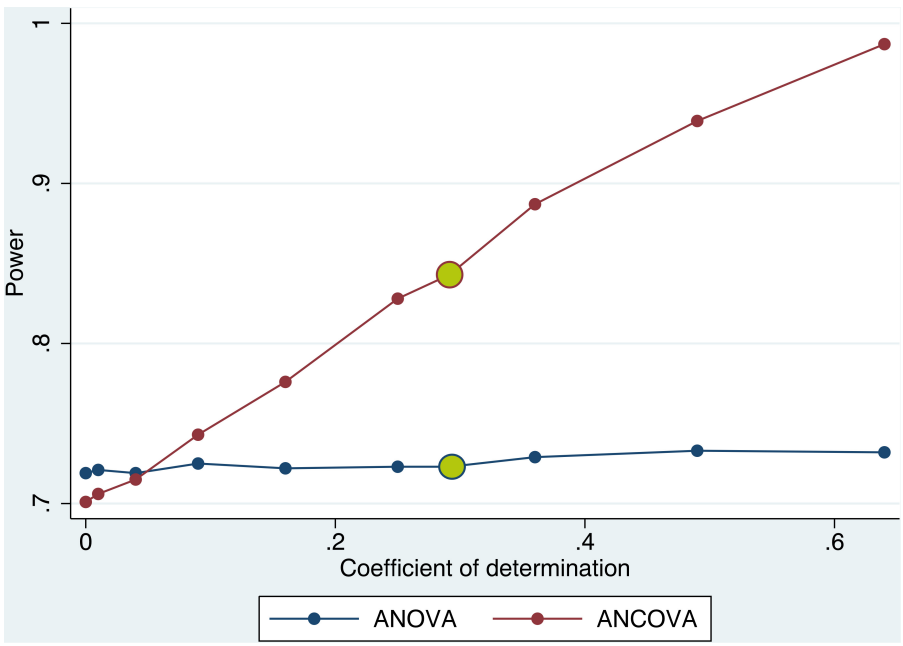

FIGURE 5 | Power to detect an effect of $d = 1$ with and without adjusting for a covariate. Adjusting for a single covariate in the outcome analysis (ANCOVA) increased the power to detect a true effect by up to 25% compared to no adjustment (ANOVA) depending on the magnitude of the correlation coefficient of covariate and outcome variable. Effect size $d = 1$, $n = 14$ per group, 1000 repetitions per condition. Coefficient of determination found in this study for the association of PcomA score and lesion size marked in yellow ($r^2 = 0.34$).

patency should be assessed for every animal in models of cerebral ischemia, but that their own method could be used only to predict forebrain ischemia after bilateral CCA occlusion and not for unilateral MCAo. Additional evidence of the impact of PcomA patency and the variability of PcomA patency in C57BL/6J mice comes from McColl and colleagues: in a small sample of 10 C57BL/6J mice, they found a complete circle of Willis in only 1 animal. In 6 animals, the PcomA was patent only unilaterally, and in another 3 animals, no patent PcomA was found (McColl et al., 2004). In our own cohort of 43 animals, we found a slightly different distribution: we confirmed that a plurality of animals had a single patent PcomA, while almost equal numbers of animals had bilaterally patent PcomAs and complete absence of the posterior part of the circle of Willis. The notion of PcomA patency being one of the main determinants of mortality and lesion size in the fMCAo model is corroborated by a recent exploratory study by Foddis et al. (2019) reporting an almost equal distribution among different PcomA phenotypes (no patent PcomA, unilateral patent PcomA or bilateral patent PcomAs). While the distribution of patent PcomA in C57BL/6 mice in that study differs from the report by McColl and colleagues and our own findings, it still confirms the general conclusion of a high degree of variability in C57BL/6 mice.

Randomization is a cornerstone of all trials of treatment effects. Randomization seeks to prevent bias in the allocation of subjects to treatment groups and is the prerequisite of any statistical testing. To ensure balanced distribution of all known and unknown covariates influencing the dependent variable(s), is the primary goal of randomization. Imbalance in covariates that strongly correlate and determine the outcome variable can lead to an overestimation of the treatment effect or to false negative results, depending on the direction of correlation and the level of imbalance. For clinical trials, methods to adjust for imbalances of known covariates both at the design stage (i.e., stratification) as well as at the stage of data analysis (i.e., by including the covariates in the statistical model) have been commonly adopted (Schneider et al., 2012). The risk of imbalance grows with increasing levels of variability of a given variable in the statistical population and with decreasing sample size. Smaller sample sizes are also associated with an increasing effect of any imbalance in covariates on precision, effect size and power (Button et al., 2013). In preclinical biomedical research, sample sizes are often under 10 animals per group (Button et al., 2013), increasing the impact of imbalance of covariates, especially those (such as PcomA patency) that are strongly correlated with the outcome parameter. We therefore argue that adjustments for imbalances in the distribution of animals with different PcomA statuses could be beneficial for all stroke studies using C57BL/6 mice.

In recent years, high-resolution mouse MRI has become widely available at almost all large stroke research centers. Beckmann and colleagues have demonstrated that high-resolution MRA can be used to non-invasively image cerebrovascular anatomy, including large collaterals in the circle of Willis in mice (Beckmann et al., 1999; Beckmann, 2000). Building on this work, we and others have refined MRA protocols to obtain high-resolution MRA in less than 10 min per animal, rendering the technique applicable for routine use in preclinical stroke research when MRI is included in the study design. Beckman and colleagues proposed using this method for selecting or stratifying animals according to the PcomA status. However, our current data on the inconsistent association of PcomA patency evaluated before fMCAo and the ischemic lesion size, as well as data reported in a recent study by Foddis and colleagues, highlight challenges of this approach (Foddis et al., 2019).

There are several possible explanations for the failure to predict lesion size from pre-fMCAo PcomA evaluation. It is possible that the resolution currently available in TOF MRA sequences is not sufficient to distinguish between smaller PcomA vessel diameters in preischemic conditions. This notion is support by our finding of a moderate, yet statistically not significant ($p = 0.051$), correlation of manual PcomA size ratings before fMCAo and infarct size 24 h after fMCAo, a signal not picked up by our semiquantitative score for PcomA patency. Studies using contrast-enhanced MRA with a cryogenically cooled MR coil and extended recording time demonstrated the technical possibility of imaging vessels with diameters of down to 40 μm (Klohs et al., 2012). Further studies using this technique would be needed to validate this hypothesis. Contrast-enhanced MRA, however, requires long sequences and is inherently invasive, rendering this method less suitable for routine use. In line with the findings reported in this study, Foddis and colleagues found PcomA to be small and not reliably identifiable on MRA in naïve conditions, while under postischemic conditions PcomA is recruited and reaches a vessel size of up to 60% of the basilar artery diameter (Foddis et al., 2019). Despite our finding of a moderate correlation of manual PcomA scores pre-fMCAo and semiquantitative PcomA scores after fMCAo, this might indicate that preischemic PcomA size is only one of several determinants of PcomA perfusion under ischemic conditions. Interindividual differences in collateral recruitment under hypoperfusion might also play a role. In fact, our finding of no reliable prediction of lesion size by preischemic PcomA scores suggests that not the preischemic anatomical size of the PcomA but the postischemic flow after collateral recruitment is what determines ischemic lesion size. Collateral status has recently been shown to be a key predictor of lesion size evolution in the first 24 h in humans (Rao et al., 2020). It can thus be hypothesized that postischemic PcomA flow as measured in this study is only a correlate of a general level of collateral recruitment in the individual animal determining the size of the ischemic lesion. In this scenario, interindividual differences concerning collateral recruitment might be more important for lesion development than the initial PcomA vessel size pre fMCAo. We therefore argue that using a measurement of the postischemic PcomA status by TOF MRA obtained 24 h after fMCAo as a covariate in the outcome analysis is most relevant to adjust for imbalances in interindividual differences of cerebrovascular anatomy and function.

The inaptitude to measure PcomA patency as a determinant of ischemic lesion size in naïve, pre-fMCAo condition is at the same time one to the strongest limitations of the proposed approach. In the case of a treatment paradigm with early treatment within the first 24 h or pre-fMCAo treatment paradigms, the interaction

of the treatment and the PcomA size cannot be excluded. This is particularly problematic for treatments targeting collateral recruitment. In these cases, adjusting for PcomA patency bears the risk of reducing power to detect the treatment effect and cannot be recommended. For experimental paradigms with postischemic treatment randomization later than 24 h after fMCAo, the proposed approach would allow for combining stratified randomization for PcomA status and including PcomA status as a covariate using ANCOVA to control for imbalances of this important covariate. In our study, we focused on variability in acute lesion size as one of the most widely used outcome parameters in experimental ischemic stroke studies and did not include long-term behavioral outcomes. Impact of PcomA patency on long-term behavioral outcomes should be assessed in future studies to test robustness of the proposed approach. To further improve robustness of the described approach and reduce potential bias, we aim to eliminate the currently still required manual input in delineation of the target area and automatise area selection for future studies. A general limitation of the method used, is the indirect measurement of cerebral blood flow (CBF) by morphological TOF MRA imaging. To better assess functional patency and blood flow and relate it to morphological PcomA status, additional measurement of CBF by non-invasive aterial spin labeling (ASL) would be desirable. The scope of the presented work was to use highly standardized widely available sequences easily applicable to routine protocols. We thus did not implement ASL in the current study protocol.

In conclusion, we have shown that including a semiquantitative score of PcomA patency obtained 24 h after fMCAO in the statistical model can explain a large share of previously unexplained intersubject variability in lesion size and thus increase the power to detect treatment effects in preclinical stroke studies. The methods used are easy to implement for study designs with MR imaging. Based on the findings in this study, we therefore suggest to, (i) record an TOF MRA 24 h after fMCAo followed by semiquantitative PcomA measurement in any protocol evaluating experimental stroke therapies in the subacure phase after stroke, (ii) include the semiquantitative score of PcomA patency in the statistical model for outcome assessment. We believe that, mirroring standard procedures in clinical trials for which adjustment for known covariates has become state-of-the-art, similar practices should be adopted for preclinical trials to improve efficiency in therapy selection for clinical translation.

DATA AVAILABILITY STATEMENT

The datasets presented in this study can be found in online repositories. The names of the repository/repositories and accession number(s) can be found below: https://figshare.com/s/117e284677bdbedf08e7; https://figshare.com/s/d1a9072c420c43ed908e; and https://figshare.com/s/e8e03096082a1d5c0f4f.

ETHICS STATEMENT

The animal study was reviewed and approved by the Landesamt für Gesundheit und Soziales Berlin.

AUTHOR CONTRIBUTIONS

SK, CA, UD, SM, CH, CJH, SPK, ME, and PB-S contributed to designing and planning the experiments as well as obtaining official licenses to conduct this study. SK performed the fMCAo surgeries and blinded outcome analyses. CA, SM, and CJH acquired the MRA and MRI datasets. SK, PB-S, and SPK contributed in image normalization and atlas registration. ME, CH, SK, and UD contributed in covariate analysis and simulation design. All authors contributed in drafting and revising the manuscript and approved the manuscript for publication.

FUNDING

Funding was provided by the German Federal Ministry of Education and Research under the ERA-NET NEURON scheme (BMBF 01EW1811), the German Research Foundation (DFG research grant BO 4484/2-1 and EXC NeuroCure) and Fondation Leducq Transatlantic Network of Excellence 15CVD02.

ACKNOWLEDGMENTS

We thank David Schreiber for helping with the logistics of the MRI measurements and Janet Lips for support with animal logistics and handling.

Beta-Hydroxybutyrate Enhances BDNF Expression by Increasing H3K4me3 and Decreasing H2AK119ub in Hippocampal Neurons

*Erling Hu, Huan Du, Sen Shang, Yali Zhang and Xiaoyun Lu**

Key Laboratory of Biomedical Information Engineering of Ministry of Education, School of Life Sciences and Technology, Xi'an Jiaotong University, Xi'an, China

Neurological evidence suggests that beta-hydroxybutyrate (BHBA) has positive effects on the central nervous system. Previous studies have explored the molecular mechanisms by which BHBA affects different brain functions, but the effects of BHBA on epigenetic modifications remain elusive. Here, we showed that BHBA enhanced brain-derived neurotrophic factor (BDNF) expression by increasing H3K4me3 and decreasing H2AK119ub occupancy at the *Bdnf* promoters I, II, IV, and VI in hippocampal neurons. Moreover, BHBA treatment induced the upregulation of H3K4me3 and downregulation of H2AK119ub on the global level, both of which were dependent on the L-type calcium channel. Additionally, the BHBA-activated L-type calcium channel subsequently triggered the activation of Ca^{2+}/CaMKII/CREB signaling, and promoted the binding of p-CREB and CBP to *Bdnf* promoters. These results indicate that BHBA regulates cellular signaling and multiple histone modifications to cooperatively modulate BDNF, suggesting a wide range of regulatory effects of BHBA in the central nervous system.

INTRODUCTION

Beta-hydroxybutyrate (BHBA) has recently gained increasing attention due to its beneficial effects, such as eliciting advantageous changes in metabolism, reducing inflammation and oxidative stress, as well as improving cognition (Tieu et al., 2003; Reger et al., 2004; Shimazu et al., 2013; Fu et al., 2015). The protective effects of BHBA in the brain have been widely studied. BHBA levels in the body are elevated on a ketogenic diet, during caloric restriction or physical excise and either of these states was found to alleviate some pathological symptoms of neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, epilepsy, and ischemia (Suzuki et al., 2002; Tieu et al., 2003; Lutas and Yellen, 2013; Yin et al., 2016). Furthermore, BHBA also exerts beneficial effects under normal physiological circumstances, for example by enhancing the learning and memory ability of healthy mice (Zou et al., 2009). Exercise-induced BHBA elevation promotes the expression of brain-derived neurotrophic factor (BDNF) in the hippocampus (Sleiman et al., 2016). However, although many studies explored the underlying mechanisms, they are still not fully understood. In addition to serving as an endogenous energy source that can be used to synthesize ATP in the brain, BHBA is increasingly understood to have broad cellular signaling functions. These include inhibiting class I histone deacetylases (Shimazu et al., 2013), binding to G-protein-coupled

receptors (GPR) (Newman and Verdin, 2017), inhibiting NLRP3 activation (Youm et al., 2015), preventing autophagosome accumulation (Camberos-Luna et al., 2016), repressing H3K27me3 levels (Hu et al., 2018), and acting as a substrate for posttranslational modification of proteins via beta-hydroxybutyrylation at lysine sites (Xie et al., 2016).

Many studies have revealed that BHBA induces BDNF expression when the supply of glucose is insufficient. Our previous study also showed that BHBA was able to promote BDNF expression under normal energy supply (Hu et al., 2018). BDNF is an important trophic factor associated with the improvement of brain function and significant neuroprotective effects. BDNF is a small dimer synthesized and widely distributed in different brain regions, including the hippocampus, amygdala, cortex, forebrain, striatum, and hypothalamus (Aid et al., 2007). In general, the expression of BDNF is controlled by multi-component transcriptional regulation including cAMP response element (CRE)-binding protein (CREB) and epigenetic factors such as histone modifications. The transcriptional activation marks histone H3 lysine 4 trimethylation (H3K4me3) and histone H3 lysine 27 acetylation (H3K27ac), as well as the transcriptional repression mark H3K27 trimethylation (H3K27me3), can directly regulate *Bdnf* transcription in active or repressive ways, leading to changes of promoter occupancy and BDNF expression (Bernstein et al., 2006; Palomer et al., 2016; Hu et al., 2018). The *Bdnf* gene contains nine exons, each of which is regulated by its promoter. Generally, the expression of transcripts from *Bdnf* exons I, II, IV, and VI increases with time, and is important for brain development (Zheng et al., 2012). Interestingly, H3K4me3 and H3K27me3 are consistently distributed in *Bdnf* promoters I to VIII in a strongly bivalent way, so that the gene can be turned on or off rapidly in response to environmental stimuli (Bernstein et al., 2006). In addition, other histone marks, including histone H2A lysine 119 mono-ubiquitination (H2AK119ub) that play a vital role in transcriptional repression, can also co-localize with H3K27me3 in the same chromatin regions to regulate gene transcription (Muller and Verrijzer, 2009). BHBA can increase BDNF expression by elevating the occupancy of H3K27ac at the *Bdnf* promoters and decreasing that of H3K27me3 (Palomer et al., 2016; Hu et al., 2018), suggesting a yet to be investigated potential role of BHBA in regulating histone modifications. However, the locational interaction between the different histone modifications, for example, H3K27me3 and H3K4me3, indicates that the function of BHBA might not just be limited to affecting H3K27me3/ac, but also the other histone marks.

Here, we demonstrated that BHBA enhanced BDNF expression by elevating the transcriptional activation mark H3K4me3 and decreasing the transcriptional repression mark H2AK119ub in hippocampal neurons both *in vivo* and *in vitro*. Furthermore, both the BHBA-triggered increase of H3K4me3 and the decrease of H2AK119ub depend on the L-type calcium channel. These results corroborate the broad functions and diverse mechanisms by which BHBA regulates neuronal genes. The possibility that BHBA modulates the expression of additional neuronal genes to achieve its globally beneficial effects merits further investigation in future studies.

MATERIALS AND METHODS

Animals

The *in vivo* experiments were conducted with 6- to 8-week-old female C57BL/6 mice. The mice were maintained as described previously (Hu et al., 2018). The mice were treated with 60 mg/kg BHBA (dissolved in physiological saline) or only physiological saline twice daily via intragastric gavage for two days in total. The hippocampi were removed and stored at −80°C before further analysis. For *in vitro* experiments, rat hippocampi were isolated from 1-day-old SD rats for culturing primary hippocampal neurons. All experimental procedures involving animals were in strict accordance with institutional, national, and international animal welfare standards, and were approved by the Research Ethics Committee of Xi'an Jiaotong University (Approval No. 201103). All animals were purchased from the Experimental Animal Center of Xi'an Jiaotong University Health Science Center. All mice were fed a normal diet at libitum and were maintained on a 12-h light/dark cycle.

Culture of Primary Hippocampal Neurons

Primary hippocampal neurons from 1-day-old SD rats were extracted and cultivated as described previously (Hu et al., 2018). The hippocampi were isolated in ice-cold Hank's solution and digested with 0.25% trypsin at 37°C for 15 min, followed by centrifugation for 5 min at 300 × *g*. The pellets were re-suspended in Dulbecco's Modified Eagle's Medium (DMEM)/F12 medium (high glucose; hyclone, United States) with 10% fetal bovine serum (FBS, HyClone, GE Healthcare, United States), supplemented with 100 U/ml penicillin (Beyotime, China) and 100 μg/ml streptomycin (Beyotime, China). The cells were counted and then seeded into plates pre-coated with poly-L-lysine (Sigma-Aldrich, United States). After 2 h, the medium was replaced with Neurobasal™ A Medium supplemented with 2% B27 and 2 mM Gln. Half of the medium was changed every 3 days.

Culture of Murine Hippocampal Neuronal Cell Line HT22

The HT22 cell line was purchased from Shanghai Hongshun Biologicals (China) and maintained in high-glucose DMEM supplement with 10% FBS, 100 U/ml penicillin, and 100 μg/ml streptomycin.

Western Blot Analysis

Rat hippocampal neurons were cultured in 6-well plates at an initial concentration of 2×10^6 cells per well. After culturing for 9–10 days, the neurons were treated with 10 μM manidipine, 5 μM KN-62, or 10 μM H89 for 10 min, or left untreated prior to treatment with 2 mM BHBA for another 1 or 12 h. Subsequently, the cells were lysed using 1× lysis buffer (Beyotime, China) containing protease inhibitor cocktail 2 (Roche, Switzerland) directly in the plates to obtain whole-cell lysates. Proteins were separated on SDS/PAGE gels and electroblotted onto PVDF membranes

(GE Healthcare, United States). The membranes were blocked with 5% (w/v) BSA (bovine serum albumin; Sigma-Aldrich, United Kingdom) for 1 h at room temperature, and subsequently incubated with primary antibodies (tri-methyl histone H3 (Lys4) rabbit mAb, ubiquityl-histone H2A (Lys119) rabbit mAb, phospho-CaMKII (Thr286) rabbit mAb, phospho-CREB (SER133) rabbit mAb, WDR5(A-6), anti-BDNF antibody, anti-beta-actin) at 4°C overnight. Then, TBST was used to wash the membranes 3 times, followed by incubation with the horseradish peroxidase (HRP)-conjugated secondary antibody (Abcam, United Kingdom) for 1 h at room temperature. The protein bands were developed using the ImmobilonTM Western Chemiluminescent HRP Substrate (Millipore, United States) and photographed using the FlorChem FC2 System (Alpha Innotech, United States).

Chromatin Immunoprecipitation Followed by Quantitative PCR

Chromatin immunoprecipitation (ChIP) assays were processed using the SimpleChIP Enzymatic Chromatin IP kit (Catalog#9003, Cell signaling Technology) according to the manufacturer's instructions. Briefly, HT22 cells were fixed in 1% formaldehyde for 10 min at room temperature, after which 0.125 M glycine was used to stop the cross-linking for 5 min at room temperature. Then, the samples were washed 2 times with ice-cold PBS supplemented with 1× protease inhibitor cocktail (PIC; Roche, Switzerland). Subsequently, ice-cold 1× Buffer A plus PIC and DTT were added and the cells were incubated on ice for 10 min. The resulting lysates were centrifuged at 2,000 × *g* for 5 min at 4°C to harvest the pellets. Subsequently, 1× Buffer B plus DTT was added to lyse the nuclei, followed by 0.5 μl micrococcal nuclease per IP prep and incubated at 37°C to digest DNA to a length of approximately 150–900 bp. After 20 min, the digestion was stopped by adding 2 μl 0.5 M EDTA. The resulting lysates were centrifuged at 16,000 × *g* and 4°C to harvest the pelleted nuclei. The samples were resuspended in 1× ChIP Buffer with PIC, incubated on ice for 10 min, and then sonicated using a Bandelin ultrasonicator (Sonics, United States) set to 300 W, 50 cycles (1 s each with a duty cycle of 50%). The resulting sonicated mixture was centrifuged at 9,400 × *g* for 10 min at 4°C to remove insoluble material. Supernatants containing DNA-protein complexes were diluted 1:5 with 1× ChIP Buffer. Subsequently, ChIP assays were performed using anti-p-CREB (cell signaling technology), anti-CBP (cell signaling technology), anti-H3K4me3 (cell signaling technology), or anti-H2AK119ub antibodies (Abcam, United Kingdom) and a negative control comprising normal rabbit IgG (Santa Cruz Biotechnology, Inc., United States). Immune complexes were precipitated by adding the magnetic protein G beads and incubating for 2 h at 4°C. The protein G –antibody/chromatin complexes were washed with low salt wash buffer (three times) and a high salt wash buffer (one time). Protein G–antibody/chromatin complexes, as well as the 2% input solution, were eluted with 150 μl 1× ChIP elution buffer two times, and recovered by adding 5 M NaCl and 100 μg/ml protease K and incubating 2 h at 65°C. The beads were separated from the solution using a magnetic separation device and the supernatant was transferred to a fresh tube. Finally, DNA was purified using a DNA purification Kit (DP214; Tiangen, China) according to the manufacturer's protocol, and eluted with 50 μl sterilized deionized water. A 2 μl aliquot of purified DNA was used to perform qRT-PCR, using the primer pairs *Bdnf*-P1, *Bdnf*-P2, *Bdnf*-P3, and *Bdnf*-P4. Quantitative PCR (qPCR) for the measurement of gene expression was performed using the SYBR Green Master Mix on a CFX96TM Real-time system (Bio-Rad, United States).

Calcium Imaging

Rat hippocampal neurons cultured for 8 to 10 days were used for the test. The cells were washed with standard 2 mM Hank's Balanced Salt Solution (HBSS; ThermoFisher Scientific, United States) two times, after which 5 μM Fluo-4AM was used to stain the cells for 15 min, which were then washed again with standard 2 mM extracellular solution. Time-lapse imaging was used at 500 ms/frame for real-time imaging. Neurons were initially given 30 s 2Ca (2 mM Ca^{2+}) to record the basal line followed by 1 min of 2 mM BHBA stimulation, and then rapidly switched back to 2Ca. The intensity of Fluo-4AM fluorescence was analyzed using ImageJ Software.

Enzyme-Linked Immunosorbent Assay

HT22 cells were treated with 2 mM BHBA for 5, 10, or 20 min, or left untreated, and were collected using 0.25% trypsin followed by centrifugation for 5 min at 300 × *g*. The tubes containing the samples were placed into liquid nitrogen for 20 min, and then transferred into a 37°C water bath for 10 min, which was repeated two times. Subsequently, the samples were centrifuged for 5 min at 12,000 *g*, and the supernatants were collected for the detection of PLC activity, using the mouse PLC activity detection kit (Jianglai Biotechnology Company, Shanghai, China) according to the manufacturer's instructions. Samples comprising 50 μl were added into the wells, after which 100 μl of diluted HRP conjugate was added into each well, and the plate was incubated at 37°C for 60 min. The wells were washed with wash buffer five times, after which 50 μl of chromogenic substrate A and 50 μl of chromogenic substrate B were added into each well, and the plate was incubated in the dark at 37°C for 15 min. Finally, 100 μl of stop solution was added into each well and the absorbance at 450 nm was measured.

Statistical Analysis

The data were analyzed using GraphPad Prism V7.0 (GraphPad 264 Software, Inc., San Diego, CA, United States). Two-group comparisons were performed using Student's *t*-test. Multi-group comparisons were performed using a one-way ANOVA followed by *post hoc* Tukey's test. The error bars indicate the SEM. Differences were considered to be statistically significant at $p < 0.05$.

RESULTS

BHBA Treatment Promotes BDNF Expression and Changes Histone H3K4 Trimethylation and Histone H2AK119 Mono-Ubiquitination in *Bdnf* Promoters

Firstly, we verified the increase of BDNF levels in primary hippocampal neurons following treatment with 2 mM BHBA (**Figure 1A**). Actually, we have previously found that BHBA also could increase BDNF expression in murine hippocampal neuronal cell line HT22 cells (Hu et al., 2018). Additionally, mice were gavaged with 60 mg/kg BHBA, twice a day for two days to further assess the *in vivo* effects of BHBA on BDNF. The BDNF levels in the hippocampi of BHBA-treated mice were much higher than in those of control mice (**Figure 1B**). Histone modifications play essential roles in chromatin remodeling and transcriptional regulation. Previous studies indicated that BHBA regulates the lysine 27 tri-methylation of histone H3 (H3K27me3) in *Bdnf* promoters (Palomer et al., 2016). The transcriptional activation mark H3K4me3 is found in a constant balance with the permissive H3K27me3 (Bernstein et al., 2006). Firstly, murine hippocampal neuronal cell line HT22 was treated with 2 mM BHBA for 1 h, followed by ChIP with an antibody against H3K4me3 antibody and measurement of *Bdnf* transcription using real-time qPCR. The occupancy of H3K4me3 in *Bdnf* promoters I, II, III, and IV were significantly increased by BHBA stimulation (**Figure 1C**). It is believed that BHBA broadly regulates epigenetic modification in multiple ways. In addition to H3K4me3, the transcriptional-repression mark histone H2AK119 mono-ubiquitination (H2AK119ub) is also involved in transcriptional regulation, always occurring together with H3K27me3 in the same chromatin regions (Wang et al., 2004). H2AK119ub was found to be directly bound at *Bdnf* promoters I to IV, while BHBA treatment weakened the occupancy of H2AK119ub at these promoters (**Figure 1D**).

BHBA Treatment Causes an Increase of H3K4me3 and a Decrease of H2AK119ub in Hippocampal Neurons *in vitro* and *in vivo*

The effects of BHBA on the global levels of H3K4me3 and H2AK119ub in hippocampal neurons were investigated. After 1 h of treatment, 2 mM BHBA elevated the global H3K4me3 levels in the primary hippocampal neurons (**Figure 2A**). Accordingly, the untreated hippocampal neurons exhibited high levels of H2AK119ub, whereas BHBA treatment significantly reduced the global abundance of H2AK119ub (**Figure 2B**). The *in vivo* results from showed that the total H3K4me3 levels were much higher, and those of H2AK119ub were much lower in the hippocampi of BHBA-treated mice as than those of the control mice, which was consistent with the *in vitro* results (**Figures 2C,D**).

At the same time, WD repeat-containing protein 5 (WDR5), a core subunit of the mixed-lineage leukemia/SET-domain (MLL/SET) complex, which plays a crucial role in regulating global H3K4me3 levels during vertebrate development and hematopoiesis, was detected both *in vitro* and *in vivo* (Wysocka et al., 2005). WDR5 levels were elevated by BHBA both in cultured hippocampal neurons and hippocampi of mice

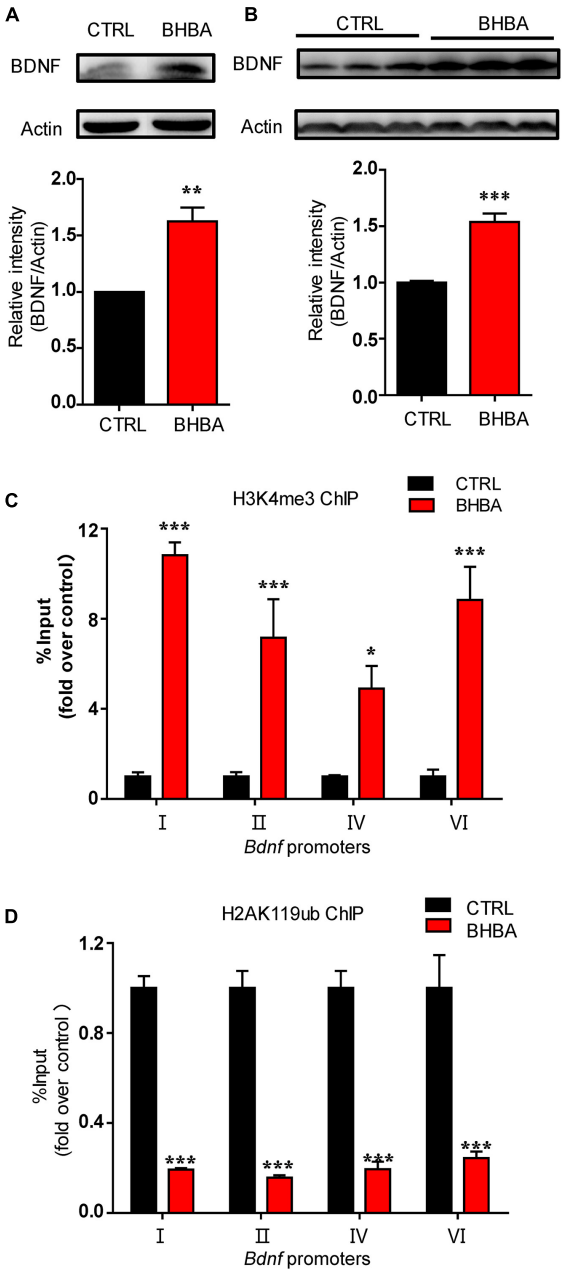

FIGURE 1 | BHBA treatment increased BDNF expression and changed the occupancy of H3K4me3 and H2AK119ub at *Bdnf* promoters in neurons. **(A,B)** Western blot analysis of BDNF levels in hippocampal neurons treated with 2 mM BHBA for 12 h or left untreated ($n = 4$, $F(3, 3) = 27.46$) **(A)**, and in hippocampi of mice treated with 60 mg/kg BHBA, twice 1 day for 2 days and untreated control mice ($n = 8$, $F(3, 28) = 13.19$) **(B)**. **(C,D)** Occupancy of H3K4me3 ($n = 4$, $F(3, 16) = 0.1304$) **(C)** and H2AK119ub ($n = 4$, $F(3, 16) = 3.828$) **(D)** at *Bdnf* promoters from cultured HT22 neurons treated with 2 mM BHBA for 1 h or left untreated. The data represent the mean ± SEM from three independent experiments. $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

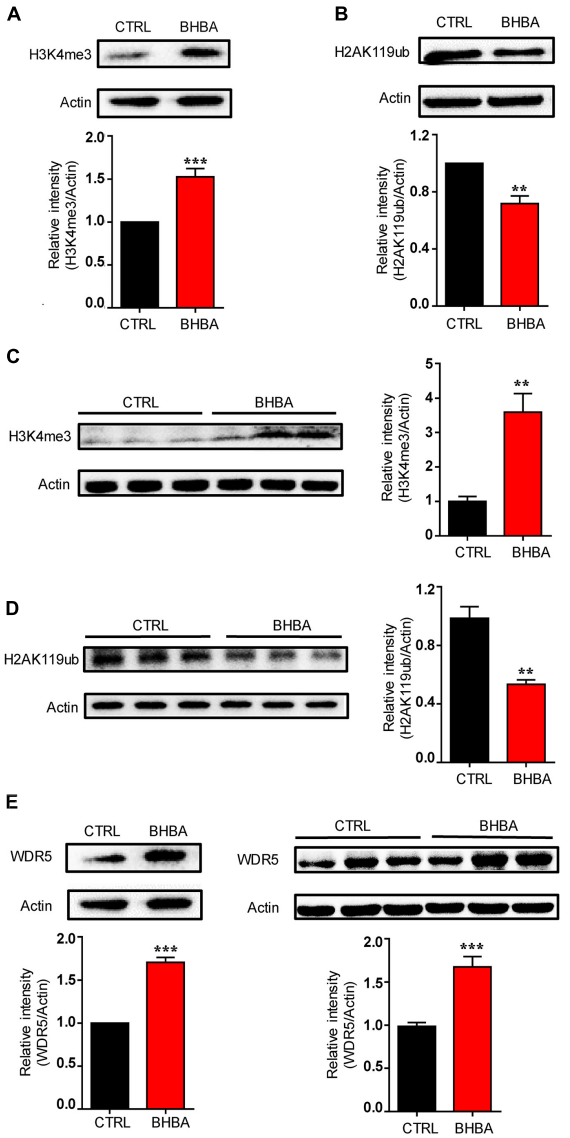

FIGURE 2 | BHBA treatment increased H3K4me3 and decreased H2AK119ub levels in hippocampal neurons both *in vitro* and *in vivo*. **(A,C)** Western blot analysis of H3K4me3 levels in hippocampal neurons treated with 2 mM BHBA for 1 h or left untreated (n = 5, F(4, 4) = infinity) **(A)**, and in hippocampi of mice treated with 60 mg/kg BHBA, twice one day for two days, or untreated control mice (n = 4, F(3, 3) = 23.12) **(C)**. **(B,D)** Western blot analysis of H2AK119ub levels in hippocampal neurons treated with 2 mM BHBA for 1 h or left untreated (n = 4, F(3, 3) = infinity) **(B)**, and in hippocampi of mice treated with 60 mg/kg BHBA, twice 1 day for 2 days, or untreated control mice (n = 4, F(3, 3) = 7.503) **(D)**. **(E,F)** Western blot analysis of WDR5 levels in hippocampal neurons treated with 2 mM BHBA for 1 h or left untreated (n = 3, F(2, 2) = infinity) **(E)**, and from hippocampi of mice treated with 60 mg/kg BHBA, twice 1 day for 2 days, or untreated control mice (n = 4, F(3, 3) = 14.05) **(F)**. The data are presented as mean ± SEM. $^{**}p < 0.01$ and $^{***}p < 0.001$.

(**Figures 2E,F**). These results suggest that BHBA positively regulates H3K4me3, possibly by increasing WDR5 levels in hippocampal neurons. Taken together, these results confirmed the epigenetic regulation of *Bdnf* promoters on H3K4me3 and H2AK119ub in response to BHBA. Therefore, H3K4me3 and H2AK119ub might be involved in regulating BHBA-induced BDNF expression in hippocampal neurons.

BHBA Treatment Activates Calcium Signaling in Neurons

It is believed that changes in epigenetic modifications in cells must be the result of the communication of each cell with the environment, which involves multiple signaling pathways. Calcium signals play crucial roles in these processes. To assess the effects of BHBA on intracellular Ca^{2+} levels, hippocampal neurons were loaded with the calcium-sensitive fluorescence indicator Fluo-4AM, and the changes in fluorescence intensity were measured in all cell bodies of neurons (**Figure 3A**). The hippocampal neurons were kept in PSS (2 mM Ca^{2+}), and PSS was applied for 30 s to obtain the basal Ca^{2+} level. Subsequently, the stimulation was switching from PSS to 2 mM BHBA at the time point of 30 s and maintained for 1 min until the time point of 90 s to switch to PSS again. The intracellular calcium concentration transiently rose after BHBA treatment and was quickly restored to the basal level. Interestingly, another significant rise in intracellular calcium was seen several seconds later (**Figure 3A**). Moreover, phospholipase C (PLC) activity in the hippocampal neurons was also elevated by BHBA (**Figure 3B**). The elevation of cellular Ca^{2+} activates several Ca^{2+}-binding proteins, including calmodulin (CaM) complexes, and promotes the phosphorylation of CaMKII at a threonine residue (T286) in the autoinhibitory domain. In this study, the phosphorylation levels of (CaMKII) in the hippocampal neurons treated with BHBA for 30 min were much higher than in the controls (**Figure 3C**). Significant upregulation of phosphorylated CREB (p-CREB), which is an essential component downstream of p-CaMKII, was also seen in neurons treated with BHBA for 1 h (**Figure 3D**). Similarly, p-CREB levels were much higher in the hippocampi of BHBA-treated mice than in those of control mice (**Figure 3E**). These results demonstrated that BHBA treatment triggered an elevation of intracellular Ca^{2+} and subsequently activated Ca^{2+}/p-CaMKII/p-CREB signaling. Additionally, the binding of p-CREB to *Bdnf* promoters I and II was increased in murine hippocampal cell line HT22 after BHBA treatment for 1 h (**Figure 3F**). Increased binding of nuclear CREB-binding protein (CBP) was also observed in *Bdnf* promoter I. However, no changes were found in *Bdnf* promoter II in both BHBA-treated and untreated neurons (**Figure 3G**). Moreover, CBP levels were also significantly increased in the hippocampi of BHBA-treated mice and hippocampal neurons, repectively (**Figures 3H,I**). Thus, the BHBA-triggered elevation of intracellular calcium levels activated calcium-related signaling, which changed the binding of p-CREB/CBP to the *Bdnf* promoters to facilitate BDNF expression.

Inactivation of Ca^{2+}/CaMKII Inhibits BHBA-Induced BDNF

To assess the role of calcium-related CaM/p-CaMKII signaling in BHBA-induced BDNF, hippocampal neurons were pre-treated

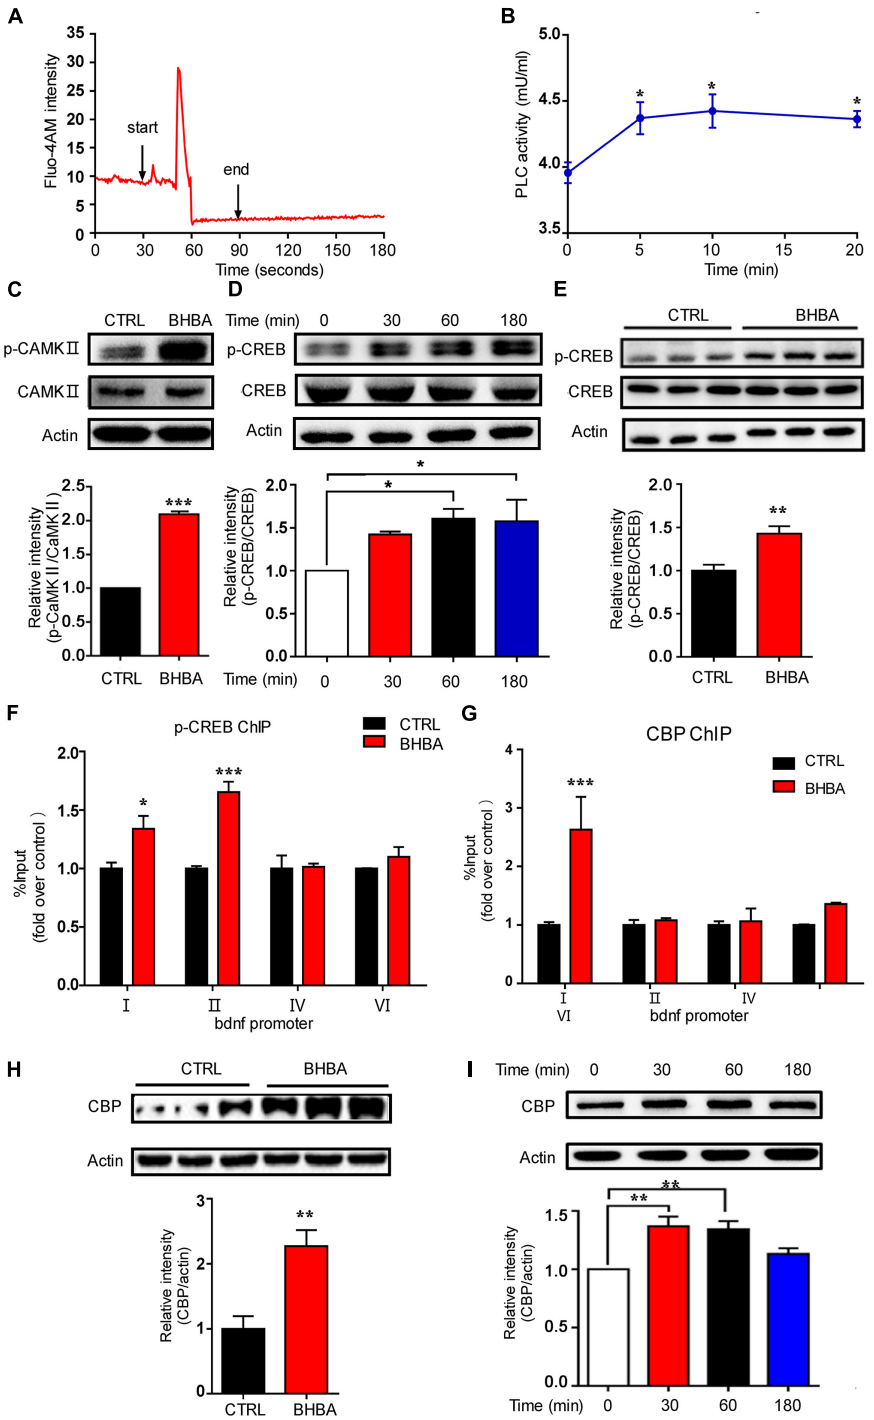

FIGURE 3 | BHBA treatment activated calcium signaling in neurons. **(A)** Representative traces of fluorescence intensity over 3 min of imaging representing intracellular Ca^{2+} concentrations in rat hippocampal neurons stained with Fluo4AM and treated with 2 mM BHBA at the time point of 30 s for another 1 min. **(B)** The activity of phospholipase C (PLC) in rat hippocampal neurons treated with 2 mM BHBA for the indicated time or left untreated (n = 3, $F(3, 8) = 4.589$). **(C)** Western blot analysis of p-CAMKII levels from hippocampal neurons treated with 2 mM BHBA for 1 h or left untreated (n = 3, $F(2, 2)$ = infinity). **(D,E)** Western blot analysis of p-CREB levels in hippocampal neurons treated with 2 mM BHBA for the indicated time or left untreated (n = 3, $F(3, 8) = 3.915$) **(D)**, and from hippocampi of mice treated with 60 mg/kg BHBA, twice one day for two days, or untreated control mice (n = 4, $F(3, 3) = 1.583$) **(E)**. **(F,G)** Occupancy of p-CREB (n = 4, $F(3, 16) = 7.481$) **(F)** and CBP (n = 4, $F(3, 16) = 5.895$) **(G)** at the *Bdnf* promoters of HT22 cells treated with 2 mM BHBA for 1 h or left untreated. **(H)** CBP levels in hippocampi of mice treated with 60 mg/kg BHBA, twice one day for two days, or untreated control mice (n = 4, $F(3, 3) = 1.642$). **(I)** Western blot analysis of CBP levels in hippocampal neurons treated with 2 mM BHBA for the indicated time or left untreated (n = 3 or 4, $F(3, 11) = 8.651$). The data are presented as mean ± SEM. $^*p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

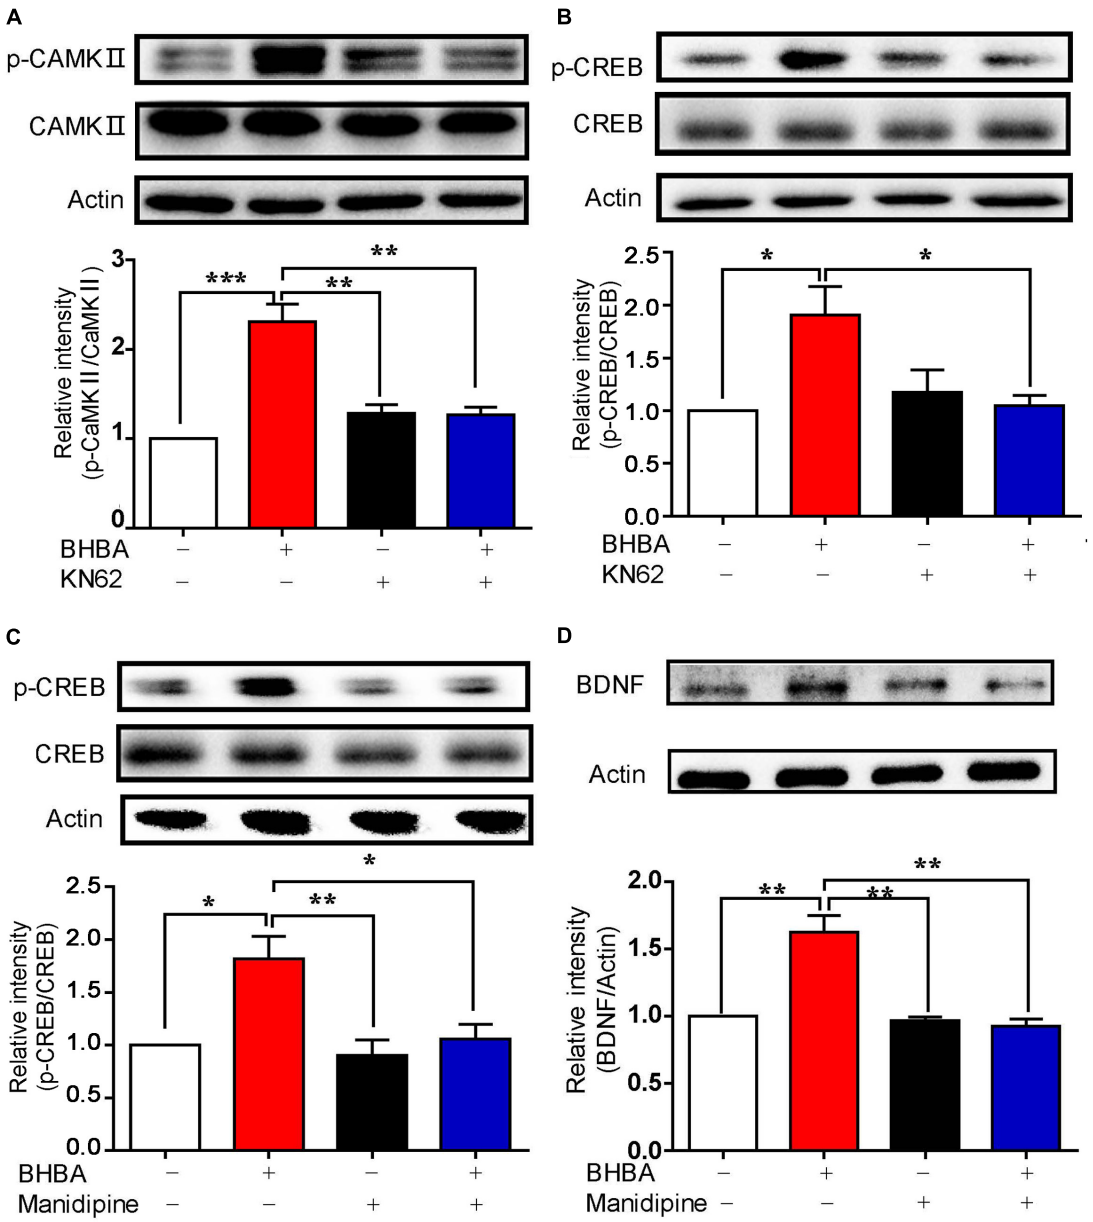

FIGURE 4 | Inhibition of calcium signaling blocked the BHBA-induced increase of BDNF expression. **(A,B)** Western blot analysis of p-CaMKII ($n = 3$, $F(3, 8) = 23.23$) **(A)** and p-CREB ($n = 3$, $F(3, 8) = 5.623$) **(B)** levels in hippocampal neurons treated with 5 μM KN-62 for 10 min prior to treatment with 2 mM-BHBA treatment for another 30 min. **(C)** Western blot analysis of p-CREB levels in hippocampal neurons treated with 10 μM manidipine for 10 min or left untreated prior to treatment with 2 mM BHBA for 1 h ($n = 4$, $F(3, 16) = 8.198$). **(D)** Western blot analysis of BDNF expression in hippocampal neurons treated with 10 μM manidipine for 10 min or left untreated prior to treatment with 2 mM BHBA for 12 h ($n = 4$, $F(3, 12) = 15.43$). The data represent the mean ± SEM from three independent experiments. $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

with KN-62, a selective and specific inhibitor of CaM, before BHBA treatment. As expected, the BHBA-induced increase of p-CaMKII was reduced to the basal level by KN-62 (**Figure 4A**). At the same time, the elevation of p-CREB induced by BHBA was also decreased in KN-62-treated neurons, suggesting that the BHBA-induced rise of p-CREB levels depends on the activation of Ca^{2+}/CaM/CaMKII (**Figure 4B**). Since Ca^{2+} influx through L-type VSCCs is one of the main sources of intracellular Ca2 + , hippocampal neurons were pre-treated with manidipine, a blocker of voltage-gated L-type VSCCs, to assess the role of L-type VSCCs in this process. The BHBA-induced increase of p-CREB levels was inhibited by manidipine, suggesting that L-type VSCCs are responsible for the elevation of p-CREB induced by BHBA (**Figure 4C**). A similar trend was observed for BDNF expression in hippocampal neurons pretreated with manidipine (**Figure 4D**). These findings supported the importance of L-type

VSCCs and Ca^{2+}/CaMKII in regulating the induction of BDNF expression by BHBA in hippocampal neurons.

The BHBA-Induced Changes of H2AK119ub and H3K4me3 Depend on Different Ssignals

To further determine the roles of L-type VSCCs and Ca^{2+}/CaM in regulating the BHBA-mediated increase of H3K4me3, hippocampal neurons were pre-treated with either manidipine or KN-62. The increase of H3K4me3 induced by BHBA was partially inhibited by manidipine, while KN-62 did not affect (**Figures 5A,B**), suggesting that the BHBA-induced upregulation of H3K4me3 is, at least in part, dependent on L-type VSCCs but not on CaM/p-CaMKII signaling. We previously found that BHBA also activated the cAMP/PKA signaling pathway in hippocampal neurons (Hu et al., 2018). To assess whether cAMP/PKA signaling plays a role in the BHBA-induced increase of H3K4me3, the hippocampal neurons were pre-treated with the PKA inhibitor H89 prior to BHBA stimulation. Notably, H89 completely blocked the promotion of H3K4me3 by BHBA, suggesting that cAMP/PKA signaling was responsible for the elevation of H3K4me3 levels following BHBA treatment (**Figure 5C**). Moreover, blocking the L-type VSCCs severely weakened the repression of H2AK119ub levels by BHBA, indicating that the BHBA-triggered activation of L-type VSCC-related calcium signaling resulted in the downregulation of H2AK119ub in hippocampal neurons (**Figure 5D**). The inhibition of BHBA on H2AK119ub level was also totally inhibited by KN-62 (**Figure 5E**). However, H89 did not change the inhibitory effect of BHBA on H2AK119ub at all, suggesting that the decrease of H2AK119ub levels was independent of cAMP/PKA signaling (**Figure 5F**). Collectively, these results demonstrated that the changes in H3K4me3 and H2AK119ub levels in hippocampal neurons following BHBA treatment are dependent on different signaling pathways. Overall, the results indicate that the decrease of H2AK119ub depends on L-type VSCCs and CaM/CaMKII signaling, and the increase of H3K4me3 depends on the activation of cAMP/PKA signaling.

DISCUSSION

It is well known that BHBA has a neuroprotective effect in the central nervous system, but the underlying mechanisms are the subject of ongoing research. As a ketone body synthesized primarily in the liver, BHBA can cross the blood–brain barrier to enter the brain and exert beneficial effects through multiple mechanisms (Newman and Verdin, 2017). In the present study, we showed that BHBA promoted the expression of Bdnf by regulating the histone modification on H2AK119 and H3K4. At the mean time, BHBA triggered an elevation of cytosolic Ca^{2+} in cultured hippocampal neurons. Our results are consistent with a previous study (Cheng et al., 2005), which showed that low concentrations of BHBA (0.02 g/l) can rapidly increase the intracellular Ca^{2+} levels in murine L929 fibroblasts, which was blocked by inhibitors of L-type VSCCs and EGTA. It is interesting that a fast slight increase of cytosolic Ca^{2+} was observed after BHBA stimulation, and then a very significant elevation Ca^{2+} level appeared. While whether these two peak were resulted form the intracellular Ca^{2+} release and the consequent extracellular Ca^{2+} influx, or there were corresponding to the HB induced Ca^{2+} signal and a subsequent neuronal firing are still need to be further investigated. Ca^{2+} signaling plays a pivotal role in regulating neuronal activity, and transient increases in cytoplasmic Ca^{2+} activate a variety of important calcium-dependent cellular events, including both the CaMK and PKA pathways (Bok et al., 2003; Hansen et al., 2003). We previously found that BHBA treatment could activate cAMP/PKA signaling, thereby elevating BDNF expression in hippocampal neurons (Hu et al., 2018). Here, we assessed the p-CaMKII level in hippocampal neurons treated with 2 mM BHBA or left untreated and found that BHBA effectively upregulated the p-CaMKII levels in hippocampal neurons. Although we didn't observe the significant increase of p-CaMKII *in vivo* 12 h after BHBA administration (data not show), it might due to the highly dynamic property of CaMKII phosphorylation and dephosphorylation. CaMKII can phosphorylate CREB at serine 133, and once phosphorylated, CREB can recruit transcription coactivators such as CBP and its paralog p300, thereby activating the transcription of target genes. Moreover, the levels of p-CREB and BDNF in both BHBA-treated cultured hippocampal neurons and hippocampi of treated mice were much higher than those of the untreated control groups. At the same time, the binding of p-CREB and CBP to *Bdnf* promoters also increased, implying the activation of *Bdnf* transcription. These results suggested that the BHBA-triggered elevation of intracellular Ca^{2+} levels resulted in the activation of downstream signaling, which was beneficial to the function of the neurons. Transient elevation of intracellular Ca^{2+} can activate several transcription factors that facilitate neuronal function in addition to BDNF. Although we only detected the neuronal expression of BDNF in this study, it is believed that other Ca^{2+}-dependent target genes are also affected by BHBA treatment, which could cooperatively facilitate neuronal activity. However, identifying those factors will require further analysis by RNA-seq or ChIP-seq in further studies. In addition to affecting L-type VSCCs in murine fibroblast L929 cells, BHBA was also reported to modulate *N*-type calcium channels and Cl^- channel in cultured neurons (Juge et al., 2010; Won et al., 2013). Moreover, it was found that BHBA could regulate the activity of sympathetic neurons via FFA3 (Won et al., 2013). Another study showed that ketone bodies, including acetoacetate and BHBA, inhibited glutamate transport by affecting the Cl^--dependence of VGLUT2 (Juge et al., 2010). These studies are in agreement with a pattern of BHBA modulating cellular functions by first affecting surface receptors. It has been reported that BHBA is a main endogenous ligand for two cell-surface receptors, GPR 109A and 41, both of which are Gi/o-protein-coupled receptors. We previously found that GPR109A but not GPR41 was expressed in the mouse hippocampal neuron line HT22. However, blocking Gi-type GPRs with PTX did not change the BHBA-induced increase of p-CREB, suggesting that GPR109A-coupled Gα/i was not responsible for BHBA-induced BDNF expression in

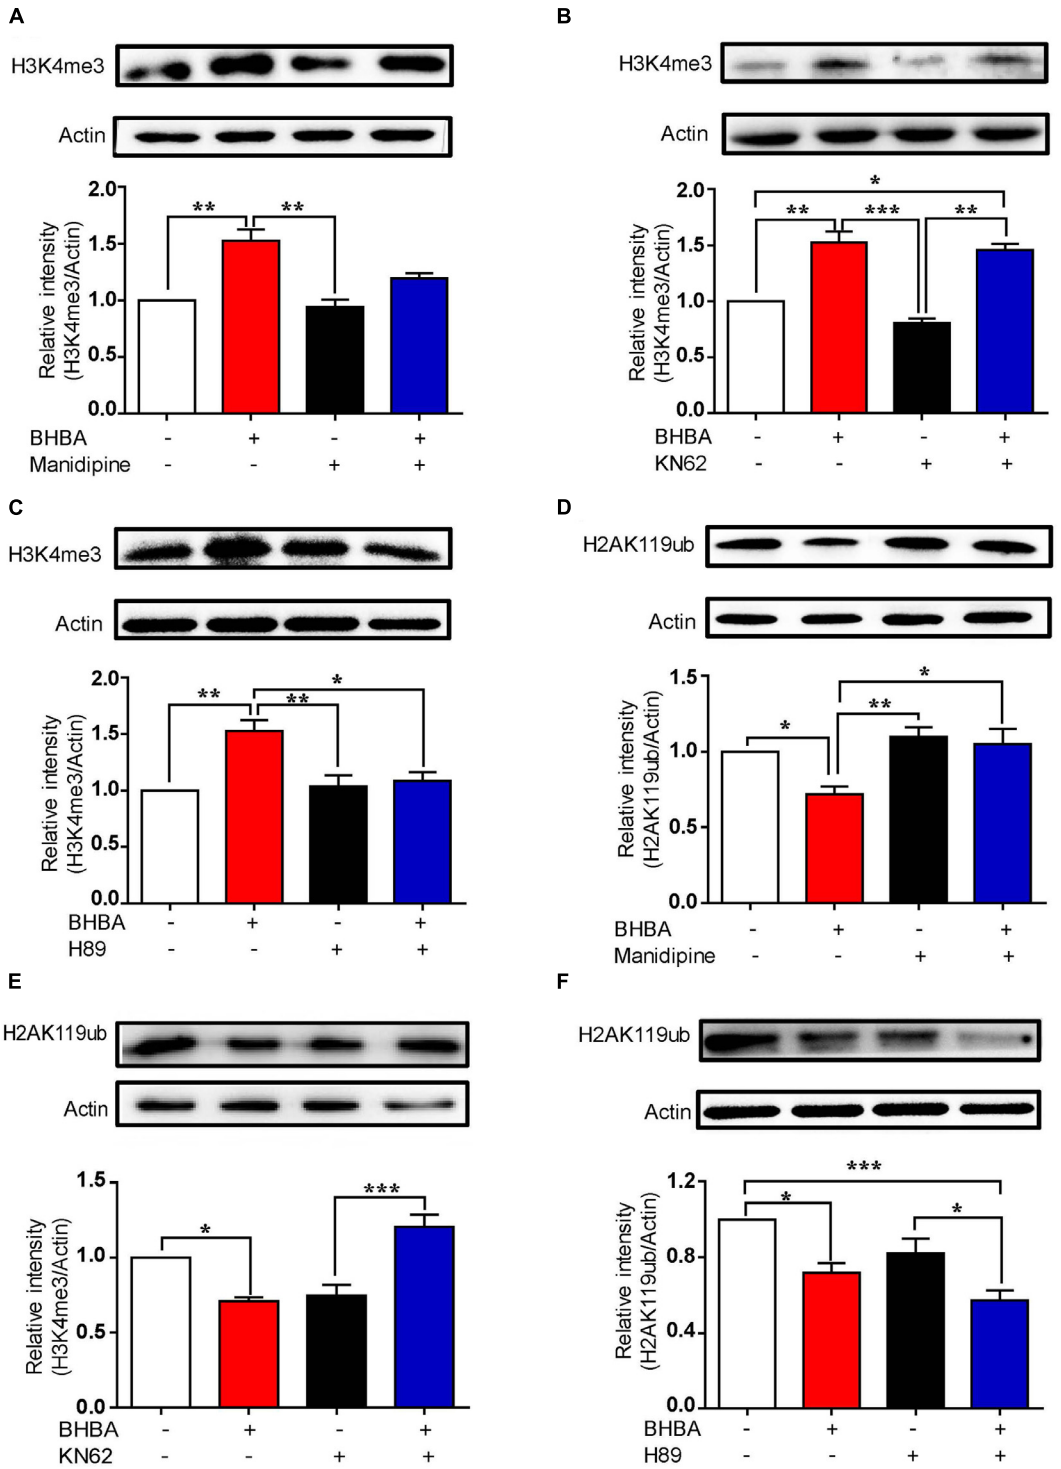

FIGURE 5 | The BHBA-induced changes of H3K4me3 and H2AK119ub depend on different signaling pathways. **(A–C)** Western blot analysis of H3K4me3 levels in hippocampal neurons treated with 10 μM manidipine (n = 3 or 4, $F(3, 10) = 11.27$) **(A)**, 5 μM KN-62 (n = 3 or 4, $F(3, 10) = 18.56$) **(B)**, or 10 μM H89 (n = 3 or 4, $F(3, 11) = 10.84$) **(C)** for 10 min or left untreated prior to treatment with 2 mM BHBA for another 1 h. **(D, E)** Western blot analysis for H2AK119ub levels in hippocampal neurons treated with 10 μM manidipine (n = 3 or 4, $F(3, 10) = 1.898$) **(D)**, 5 μM KN-62 (n = 4, $F(3, 12) = 16.95$) **(E)**, or 10 μM H89 (n = 4, $F(3, 12) = 10.61$) **(F)** for 10 min or left untreated prior to treatment with 2 mM BHBA for another 1 h. The data represent the mean ± SEM from three independent experiments. $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

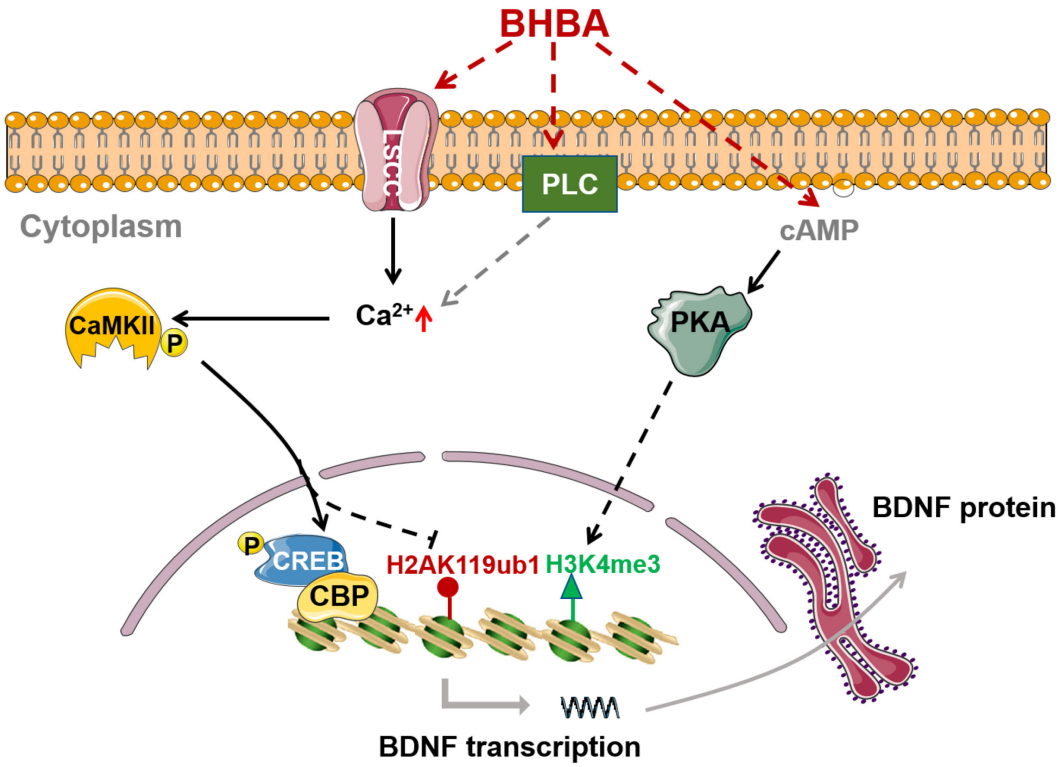

FIGURE 6 | BHBA-induced activation of intracellular signaling and chromatin remodeling in Bdnf promoters in hippocampal neurons. BHBA induces increase of transcriptional mark H3K4me3 as well as decrease of transcriptional mark H2AK119ub occupied in bdnf promoters in hippocampal neurons. Moreover, BHBA-induced changes of H2AK119ub is dependent on the activation of L-type calcium channel and the elevation of intracellular, which subsequently activates Ca^{2+}/CaMKII/p-CREB signaling pathway, and promotes the occupation of p-CREB and CBP in bdnf promoters, thereby enhances BDNF expression. However, BHBA-increased H3K4me3 is dependent on cAMP/PKA activation.

neurons. It has been reported that activation of GPR109A is associated with an increase of intracellular Ca^{2+} levels through the Gβγ subunit/phospholipase Cβ (PLCβ)/inositol-1,4,5-trisphosphate (IP3) pathway in monocyte-derived cells (Offermanns and Schwaninger, 2015).

Our results demonstrated that blocking L-type VSCCs in hippocampal neurons also blocked the effects of BHBA on CaMKII/p-CREB activation, suggesting that the BHBA-induced increase of intracellular Ca^{2+} levels and subsequent activation of CaMKII/p-CREB/BDNF are mediated by L-type VSCCs. However, how BHBA modulates the activation of L-type VSCCs in neurons is still unclear and needs to be further investigated in the future.

It has been reported that BHBA can regulate BDNF transcription by affecting epigenetic modifications, such as increasing the occupancy of the transcriptional activation mark H3K27 acetylation and decreasing that of the transcriptional repression mark H3K27me3 at *Bdnf* promoters (Palomer et al., 2016; Hu et al., 2018). The transcriptional activation mark H3K4me3 was found to act in conjunction with H3K27me3 in a bivalent way in embryonic stem cells, giving them the ability to control gene expression rapidly in response to environmental changes (Bernstein et al., 2006). It has been shown that BHBA treatment decreased the occupancy of H3K27me3 at *Bdnf* promoters II and VI in the hippocampal neuron line HT22 (Hu et al., 2018). In this study, we found that BHBA increased global H3K4me3 levels. Moreover, the H3K4me3 occupancy at *Bdnf* promoters I, II, IV, and VI were also increased after BHBA treatment, indicating that H3K4me3 is involved in the increase of *Bdnf* expression in response to BHBA stimulations, possibly acting cooperatively with H3K27me3. H3K4me3 is a robust epigenetic mark that is involved in regulating synaptic plasticity as well as memory formation and consolidation. Webb et al. (2017) found that a recent contextual fear-conditioned memory elicited memory formation and elevated the global levels of H3K4me3 in the CA1 area. Collins et al. (2019) analyzed H3K4me3 ChIP-seq data from CA1 neurons and found broad H3K4me3 peaks at many learning- and memory-associated genes during memory formation. Moreover, H3K4 is specifically methylated by MLL and SETs, whereby MLL1 is widely expressed throughout the brain and plays crucial roles in synaptic activity and memory (Jakovcevski et al., 2015). The BHBA-induced elevation of WDR5, a core component of the MLL/SET complex, may explain why H3K4me3 levels increased after BHBA treatment since WDR5 is required for the tri-methylation of H3K4 (Wysocka et al., 2005). These results are consistent with

BHBA's neuroprotective role and indicate possible molecular mechanisms of its effects.

The histone site H2AK119 can also be mono-ubiquitinated by polycomb repressive complex 1 (PRC1) and Cullin4B-Ring E3 ligase complex (CRL4B) to repress target genes, and its role in tumorigenesis has been well characterized (Wang et al., 2004; Hu et al., 2012). However, the role of H2AK119ub in the central nervous system is still unclear. We found that the levels of the transcriptional repression mark H2AK119ub were reduced in cultured neurons and the hippocampi of treated mice, indicating that H2AK119ub might be involved in regulating neuronal functions. Other studies have shown that H2AK119ub plays a vital role in transcriptional repression by functionally coordinating with H3K27me3 (Muller and Verrijzer, 2009). In this study, we found that the binding of H2AK119ub to *Bdnf* promoters I, II, IV, and VI was reduced, indicating that H2AK119ub is involved in the BHBA-induced activation of *Bdnf* transcription. H3K27me3 is produced by the histone methyltransferase enhancer of Zeste homolog 2 (EZH2), the catalytic subunit of PRC2, and it is typically added to nucleosomes across upstream promoters and coding regions of PRC2-targeted genes to repress them (Xu et al., 2012). In addition, H3K27me3 was also found to interact with PRC1, while the mono-ubiquitination of H2AK119 by PRC1, in turn, promotes the tri-methylation of H3K27 on H2Aub nucleosomes (Kalb et al., 2014). The fact that H2AK119ub can functionally interact with H3K27me3 also explains the reduction of H2K119ub binding at *Bdnf* promoters after BHBA treatment. Notably, the occupancy of H2AK119ub at *Bdnf* promoters I, II, IV, and VI was decreased, while only the occupancy of H3K27me at *Bdnf* II and VI was found to be reduced by BHBA in our previous study (Hu et al., 2018). CUL4B is a vital component responsible for H2AK119 ubiquitination, acting as a scaffold protein that assembles multiple E3 complexes, including CRL4B via the linker protein DDB1 (Nakagawa and Xiong, 2011a). It has been shown that CUL4B binds to the promoters or enhancer regions of targeted genes, together with EZH2, to silence their transcription by catalyzing H2AK119 mono-ubiquitination and H3K27 tri-methylation (Hu et al., 2012). Although PRC1 and PRC2 usually co-localize at target sites in the chromatin, they rely on different mechanisms. In the "hierarchical" model, the initial event is the binding of PRC2 to chromatin. PRC2 then catalyzes H3K27 tri-methylation, which subsequently recruits PRC1 by interaction with the chromo box (CBX)-containing protein, leading to H2AK119 mono-ubiquitination. In the "alternative" model, PRC1 is recruited to chromatin and then mono-ubiquitinates H2AK119 independently of PRC2 activity (Blackledge et al., 2015). This means that H2AK119ub and H3K27me3 are not always introduced at the same target sites, although most of the time, they work together to inhibit gene transcription. Furthermore, CUL4B can regulate the expression of neuronal genes such as SLC6A12, SYN1, and SNAP2, by targeting the methyltransferase component of H3K4me3, WDR5, for ubiquitination and degradation (Nakagawa and Xiong, 2011b). Together with the discussed literature, our results indicate the possibility that H2AK119ub plays a role in regulating neuronal function by acting cooperatively with H3K4me3 and H3K27me3, allowing neurons to rapidly respond to environmental changes. However, direct evidence for this hypothesis is still lacking. In addition, another study showed that the H2AK119 E3 ubiquitin ligase 2A-HUB can be recruited by N-CoR/HDAC1/3 to form a complex that regulates chromatin remodeling and gene transcription by promoting H2A monoubiquitination (Zhou et al., 2008). Zhu et al. (2007) found that H2A de-ubiquitinase (2A-DUB) interacts with the histone acetyltransferase (HAT) p300/CBP-associated factor (p/CAF) to form an enzymatic complex, which could help HATs provide "optimized" substrates for 2A-DUB to remove the ubiquitin from H2A. As an inhibitor of class-I HADCs, BHBA might affect H2AK119ub levels by changing the interaction of 2A-HUB and N-CoR/HDAC1/3 at the *Bdnf* promoters, or by promoting the formation of p/CAF complexes with 2A-DUB to remove the ubiquitin from H2AK119.

Finally, we found that the BHBA-induced upregulation of H3K4me3 and downregulation of H2AK119ub is dependent on L-type VSCCs by using manidipine to block the impact of BHBA on H3K4me3 and H2AK119ub in neurons. However, we are not aware of reports of any direct evidence demonstrating a relation between H3K4 tri-methylation or H2AK119 ubiquitination with calcium signaling. One study showed that the abundance of the CUL4B-PRC2 complex increases in response to high-glucose stimulus and affects intracellular Ca^{2+} by decreasing Cav1.2 expression (Li et al., 2017). However, in our study, the effect of BHBA on intracellular Ca^{2+} was fast, suggesting that BHBA might directly affect the opening and closing of L-type VSCCs. Moreover, the changes of H3K4me3 and H2AK119ub were found to be downstream of Ca^{2+} signaling. However, it is possible that the BHBA-induced changes of H2AK119ub, in turn, can further influence the Ca^{2+} concentration by affecting the expression of calcium channels such as Cav1.2.

In summary, our study revealed that BHAB stimulation increased histone H3K4me3 and decreased H2AK119ub in hippocampal neurons both *in vitro* and *in vivo*. The occupancy of H3K4me3 and H2AK119ub at *Bdnf* promoters was also correspondingly enhanced and decreased, which contributed to the BHBA-induced expression of BDNF. Moreover, BHBA triggered an increase of intracellular Ca^{2+} via L-type VSCCs, which in turn activated the Ca^{2+}/CaMKII/p-CREB signaling pathway and subsequently induced BDNF expression in primary hippocampal neurons. Furthermore, the BHBA-induced decrease of H2AK119ub was dependent on L-type VSCCs, while the increase of H3K4me3 mainly resulted from BHBA-activated cAMP/PKA signaling (**Figure 6**). Taken together, our findings further enrich the knowledge on the molecular mechanisms by which BHBA induces *Bdnf* expression. We revealed that BHBA also regulates the levels of H2AK119ub and H3K4me3 in addition to the previously reported H3K27me3/ac. These findings broaden the roles of BHBA in modulating the histone code and provides new perspectives for understanding the beneficial effects of BHBA on the CNS.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The animal study was reviewed and approved by the Research Ethics Committee of Xi'an Jiaotong University.

AUTHOR CONTRIBUTIONS

XL, YZ, and EH designed the study. EH, HD, and SS carried out the experiments, the data analysis and contributed to preparing the manuscript. All authors discussed the results and contributed to the final manuscript.

Abnormal cerebral blood flow (CBF) and resting-state functional connectivity (rs-FC) are sensitive biomarkers of disease progression and prognosis. This study investigated neural underpinnings of motor and cognitive recovery by longitudinally studying the changes of CBF and FC in pontine infarction (PI). Twenty patients underwent three-dimensional pseudo-continuous arterial spin labeling (3D-pcASL), resting-state functional magnetic resonance imaging (rs-fMRI) scans, and behavioral assessments at 1 week, 1, 3, and 6 months after stroke. Twenty normal control (NC) subjects underwent the same examination once. First, we investigated CBF changes in the acute stage, and longitudinal changes from 1 week to 6 months after PI. Brain regions with longitudinal CBF changes were then used as seeds to investigate longitudinal FC alterations during the follow-up period. Compared with NC, patients in the left PI (LPI) and right PI (RPI) groups showed significant CBF alterations in the bilateral cerebellum and some supratentorial brain regions at the baseline stage. Longitudinal analysis revealed that altered CBF values in the right supramarginal (SMG_R) for the LPI group, while the RPI group showed significantly dynamic changes of CBF in the left calcarine sulcus (CAL_L), middle occipital gyrus (MOG_L), and right supplementary motor area (SMA_R). Using the SMG_R as the seed in the LPI group, FC changes were found in the MOG_L, middle temporal gyrus (MTG_L), and prefrontal lobe (IFG_L). Correlation analysis showed that longitudinal CBF changes in the SMG_R and FC values between the SMG_R and MOG_L were associated with motor and memory scores in the LPI group, and longitudinal CBF changes in the CAL_L and SMA_R were related to memory and motor recovery in the RPI group. These longitudinal CBF and accompany FC alterations may provide insights into the neural mechanism underlying functional recovery after PI, including that of motor and cognitive functions.

INTRODUCTION

Pontine infarction (PI) accounts for 7% of ischemic strokes and is the most common type of posterior circulation infarction (Wang et al., 2018). Typical clinical manifestations of PI include pure motor hemiplegia, ataxia, dysarthria, dysphagia, and cognitive impairment (Kinjo et al., 2017; Lapa et al., 2017; Li et al., 2020). Long-term follow-up has revealed that some patients with PI

experience a poor prognosis with impaired motor or cognitive function (Mijajlovic et al., 2017; Payabvash et al., 2018). Therefore, understanding the neural mechanisms of behavioral impairment and recovery is crucial in stroke rehabilitation.

In the past few years, neuroimaging studies have been widely used to explore neurobiological mechanisms in the brain under healthy and pathological conditions and have been shown to be useful to predict further behavioral recovery (Haque et al., 2019; Xie et al., 2019; Zhang et al., 2020). Recently, an increasing number of studies have reported that abnormal cerebral hemodynamics represent an important pathophysiological mechanism in the post-stroke brain and that cerebral blood flow (CBF) is disturbed not only in the infarction or peri-infarct areas but also in the remote brain regions that are correlated with injury brain areas (Miao et al., 2018; Wang et al., 2019). Previous studies using single-photon emission computed tomography (SPECT) have also suggested that abnormal perfusion in remote areas, including the cerebellum and supratentorial frontoparietal cortex after PI, and disruption and reorganization of CBF are two of the mechanisms underlying behavioral impairment and improvement (Hoffmann and Watts, 1998; D'Aes and Marien, 2015). However, issues with exposure to ionizing radiation and the use of exogenous tracer agents have limited clinical researches, particularly studies requiring repetitive imaging and longitudinal researches.

Arterial spin labeling (ASL) imaging can quantitatively evaluate regional CBF values using arterial blood as an endogenous diffusion tracer (Deibler et al., 2008). Currently, ASL is a promising alternative technique for investigating the neural basis of various neurological and psychiatric diseases, such as stroke, seizures, Alzheimer's disease, and Parkinson's disease, since the perfusion results detected by ASL are consistent with those detected by conventional techniques. Additionally, ASL detection is non-invasive and non-ionizing (Le Heron et al., 2014; Wiest et al., 2014; Xie et al., 2019; Zhang et al., 2020). Some researchers have investigated CBF patterns of chronic PI by using ASL and have found that patients with PI showed higher CBF values in the contralateral inferior frontal gyrus and lower CBF values in the bilateral cerebellum; moreover, the CBF values in the contralateral cerebellum were closely associated with motor function scores (Wang et al., 2019). However, the processes underlying CBF changes are intrinsic and dynamic during the period of functional damage and subsequent recovery; thus, a longitudinal study is important for gaining comprehensive understanding of the neurobiological underpinnings.

Neurological activity in the brain regions is accompanied by changes of CBF and blood oxygenation, which can be measured by functional magnetic resonance imaging (fMRI) techniques (Detre and Wang, 2002; Fox and Raichle, 2007; Boscolo Galazzo et al., 2014). Resting-state functional connectivity (FC), which is based on detection of the temporal correlations of blood oxygen level-dependent (BOLD) signals between two brain regions, has been used to investigate the cortical reorganization and compensation (Buckner et al., 2013; Guerra-Carrillo et al., 2014). Although early evidence has utilized FC to investigate the neural mechanisms underlying stroke-related behavioral function decline, there is little knowledge about PI, especially longitudinal and within-person changes. In cross-sectional studies, patients with acute PI showed significantly lower FC in the medial prefrontal cortex and precuneus (Jiang et al., 2018), while patients with early chronic PI exhibited decreased FC in the medial prefrontal gyrus, precuneus, right posterior cingulum, and left middle cingulum gyrus (Chen et al., 2019). In a longitudinal-sectional study, some brain regions exhibited special changes during the follow-up period, in which voxel-mirrored homotopic connectivity (VMHC) in the precentral and postcentral gyrus tended to increase gradually, and VMHC in the hippocampus/amygdala was increased throughout the study period, and VMHC in the hippocampus/amygdala and frontal pole in the early stages were associated with the later motor recovery (Shan et al., 2018).

In addition, recent studies have confirmed the association between CBF and FC, and FC might be modulated by regional CBF of the seed (Li et al., 2012; Liu et al., 2013). Network analysis has found that specific network nodes present a higher CBF to main proper network integrity (Liang et al., 2013). According to the neurovascular coupling hypothesis, altered CBF may be coupled with significant changes in the brain FC (Venkat et al., 2016; Zhu et al., 2017). Therefore, some researches have attempted to explore pathophysiological mechanisms and effectiveness of drug therapy in neuropsychiatric disorders using multimodal MRI such as ASL and BOLD fMRI (He et al., 2019; Tan et al., 2020).

Based on the abovementioned knowledge, in order to explore the neural substrates of functional recovery after PI, we first investigated the cross-sectional and longitudinal changes in CBF during the 6 months following PI. After identifying the longitudinal changes in CBF, the progressive FC changes were further explored using these CBF-altered regions as seed. Finally, we also further investigated the relationships among abnormal changes in CBF, FC, and behavioral performance after stroke.

MATERIALS AND METHODS

Participants

Participants were recruited from the First Affiliated Hospital of Zhengzhou University and Tianjin Medial University General Hospital. These subjects provided written informed consent before the study, and the study protocol was approved by the local Research Ethics committee.

The inclusion criteria were as follows: (1) first-onset infarction and within 1 week after onset of symptoms; (2) right-handedness before brain stroke; (2) age from 40 to 80 years; (3) unilateral lesion located in the pontine identified, as identified by MRI examination; and (4) adherence to follow-up tests for 6 months. The exclusion criteria were as follows: (1) secondary hemorrhage and recurrent stroke during follow-up; (2) the score of artery stenosis >2 based on magnetic resonance angiography (Ferguson et al., 1999); (3) severe white matter hyperintensity with a Fazekas scale score >1; (4) history of drug dependence or concomitant neuropsychiatric disorders; (5) severe systemic

comorbidities, including heart failure and cancer; and (6) contraindications for MRI. Finally, 20 patients with unilateral PI were recruited from October 2014 to May 2019, including 10 subjects with lesions on each side. Twenty age-, sex-, and education-matched normal control (NC) subjects were recruited as a control group.

The infarction locations at the acute phase were manually delineated based on the acute diffusion-weighted imaging by using MRIcron software[1]. The lesion masks of all stroke patients were normalized in the Montreal Neurological Institute (MNI) space and then overlaid on a normalized template to generate the lesion distribution probability maps.

Image Data Acquisition

MRI examinations were performed using a 3.0-Tesla MR imaging system (Discovery MR 750, GE Medical Systems, Waukesha, WI, United States) at 1 week, 1, 3, and 6 months after infarction onset in the PI group, while the NC subjects were examined only once in the same manner. All subjects were instructed to hold still, close their eyes, and think of nothing in particular. Comfortable foam padding and earplugs were used to reduce head motion and scanner noise. Brain perfusion imaging was performed using a three-dimensional pseudo-continuous arterial spin labeling (3D-pcASL) sequence with the following parameters: TR/TE = 5,025 ms/11.1 ms; post label delay = 2,025 ms; spiral in readout of eight arms with 512 sample points; FA = 111°; field-of view (FOV) = 240 × 240 mm;

matrix = 128 × 128; slice thickness = 3.0 mm, no gap, 48 slices, number of excitations = 3, and 1.9 × 1.9 mm in-plane resolution. Spatial-3D T1-weighted images were acquired by using a brain volume sequence with the following imaging parameters: TR/TE = 8.2 ms/3.2 ms; FA = 12°; FOV = 256 × 256 mm; matrix = 256 × 256; slice thickness = 1.0 mm; no gap; 188 slices. Resting-state fMRI data were acquired by using a gradient-echo single-shot echo-planar imaging sequence with the following imaging parameters: TR/TE = 2,000 ms/41 ms; FA = 90°; FOV = 220 × 220 mm; matrix = 64 × 64; slice thickness = 4 mm; 0.5 mm gap; 32 slices; 190 time points. Diffusion-weighted imaging sequences were acquired at the axial plane with TR/TE = 6,000 ms/96 ms; FOV = 256 × 256 mm; slice thickness = 5.0 mm; 1.5 mm gap; 21 slices.

Behavioral Evaluation

Clinical stroke severity was assessed using the National Institutes of Health Stroke Scale (NIHSS), which is a 15-item stroke scale and score ranging from 0 to 42, with a higher score indicating a more serious function impairment (Kasner, 2006). They also underwent more detailed behavioral examination about motor and memory functions. Motor impairment was assessed using the Fugl–Meyer test (FMT) for upper and lower extremities, which is a standardized and reliable motor impairment scale. The score ranges from 0 to 100, with the higher score indicating better performance. The Ray Auditory Verbal Learning Test (RAVLT) was used to explore short-term verbal memory function, and the number of correctly recalled words was recorded as the RAVLT scores.

Image Processing

The CBF images were derived from the pcASL difference images by subtracting the labeled images from the control images.

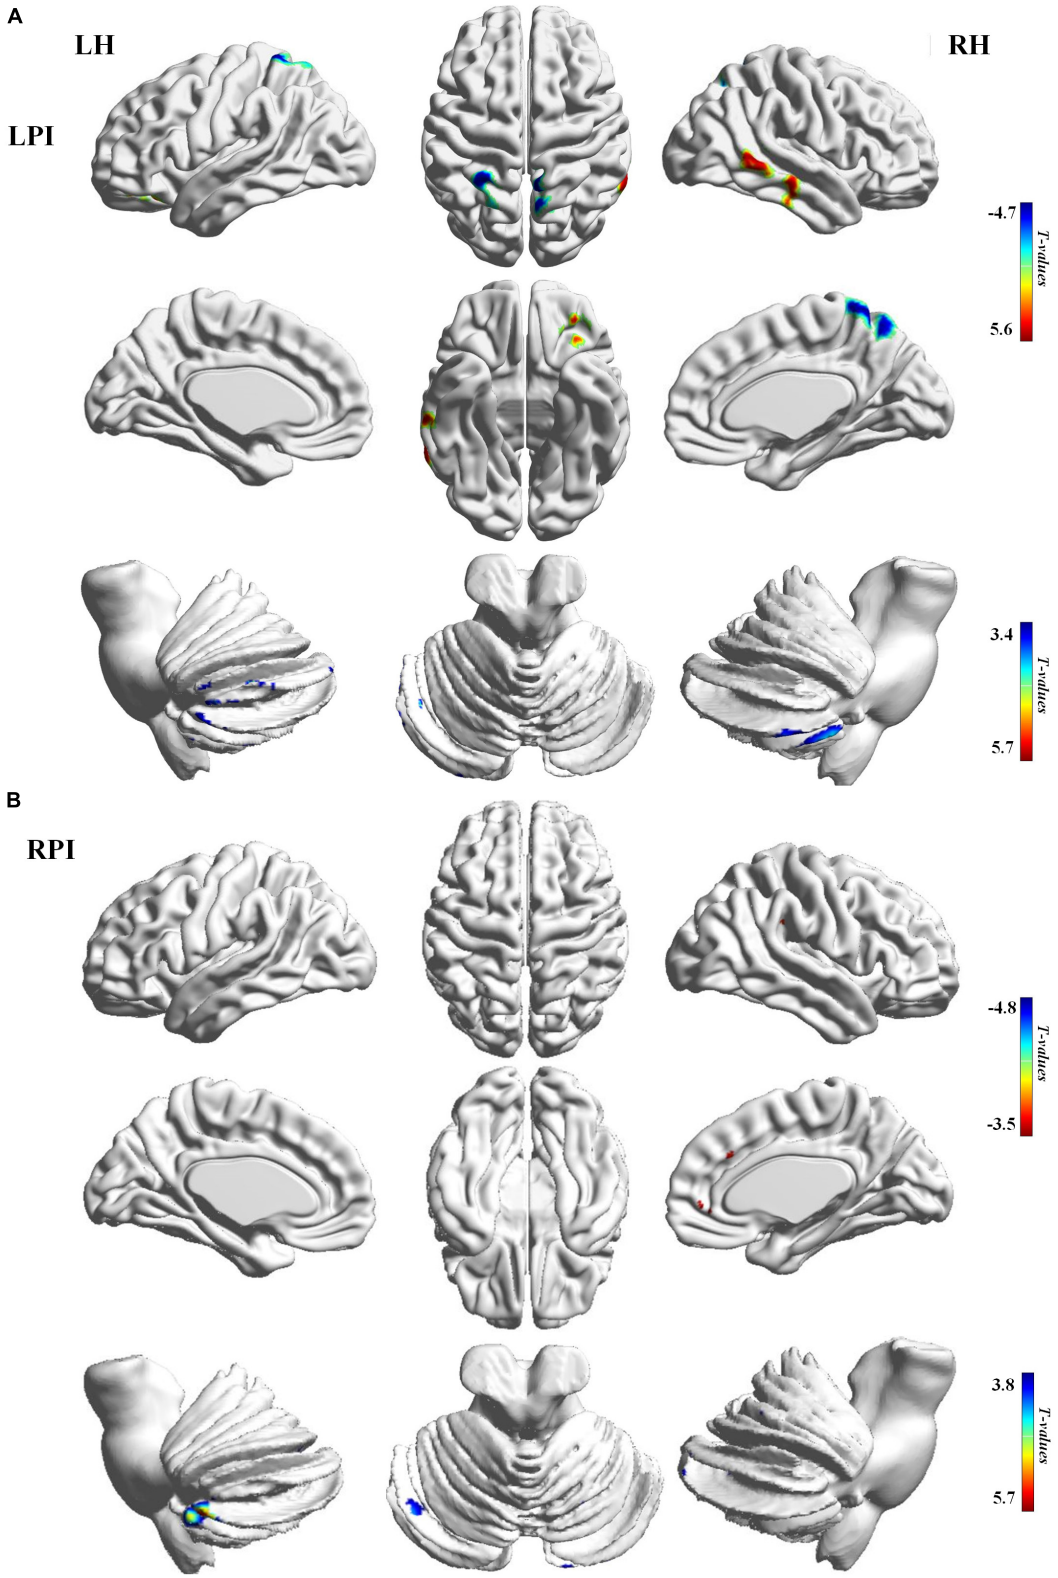

FIGURE 2 | CBF differences between the baseline subgroups of the PI and NC groups. **(A)** Voxel-base analysis showed brain regions with significant CBF alterations in the baseline stage of the LPI group. **(B)** Voxel-base analysis showed brain regions with significant CBF alterations in the baseline stage of the RPI group. CBF images were processed using the SPM8 toolbox[2]. First, the individual 3D T1 images were coregistered to the individual ASL images to produce the new individual 3D T1 images. Second, the new individual 3D T1 images were normalized to a standard T1 template in MNI space and segmented into gray matter (GM), white matter, and cerebrospinal fluid maps. Third, the individual CBF images were subsequently written to the spatially normalized 3D T1 GM maps in MNI space and the voxel size for the normalized written images was $2 \times 2 \times 2$ mm^3. Fourth, to reduce individual variance, the spatially normalized CBF maps were transformed into *z* scores by subtracting the mean and dividing by the standard deviation (SD) of the global value within the GM mask. Finally, the images were spatially smoothed using a Gaussian kernel of 6-mm full width at half-maximum (FWHM).

Resting-state functional MRI (rs-fMRI) data were preprocessed using Data Processing and Analysis of Brain Imaging[3] (DPABI) in the SPM 8 software package. The preprocessing included the following steps. First, the first 20 volumes of subjects were removed to allow the signal to reach equilibrium. Second, the remaining 170 volumes were corrected for time delay between slices. For the head motion, we used a threshold of 2 mm translation and 2° rotation, and no subject exceeded this maximum. In this step, the mean framewise displacement (mean FD) was also calculated to characterize the mean head motion (Power et al., 2012). Third, functional images were co-registered to the 3D T1 images, and the remaining dataset was spatially normalized to MNI space and resampled into a voxel size of $3 \times 3 \times 3$ mm^3. Fourth, the images were smoothed by using a Gaussian kernel of 6-mm FWHM, and several covariates were regressed via linear regression. Finally, a temporal band-pass frequency filter (0.01–0.08 Hz) was performed

to reduce low-frequency drift and high-frequency noise. We used the seed-based functional connective method to explore the different FC values over time in PI patients. Brain regions with significant longitudinal CBF changes in the left pontine infarction (LPI) and right pontine infarction (RPI) groups were respectively defined as seed regions of interest (ROIs), and Pearson's correlation coefficients were calculated between the mean time series of each ROI and each voxel in the whole brain GM as the seed-based FC maps. Then, the FC maps were transformed into Fisher's *z* maps for group analysis.

Statistic Analysis

The data at different time points in the same patients were divided into four subgroups, depending on the follow-up time. The demographic differences between the LPI, RPI, and NC groups were analyzed using independent two-sample *t*-tests or chi-square tests in the SPSS 21.0 software (SPSS, Inc., Chicago, IL, United States). The normality of clinical data distribution was tested using the Shapiro–Wilk test. A two-sample *t*-test was used to analyze behavioral differences between baseline subgroups of the PI and NC groups. One-way repeated-measure analysis of variance (ANOVA) and Bonferroni's *post hoc* tests were used to investigate the mean FD and behavioral changes between different LPI and RPI subgroups. All tests were two-tailed, and the significance threshold was set at $P < 0.05$.

For the cross-sectional comparison of CBF at the baseline stage between PI and NC groups, a voxel-wise two-sample *t*-test was performed, with age, sex, and education years as the covariance factors. For longitudinal comparisons, one-way repeated-measure ANOVA and Bonferroni's *post hoc* tests were used to explore the significance of differences in CBF and secondary FC changes among various time-related subgroups in the LPI and RPI groups. In addition, multiple comparisons were corrected using the AlphaSim program (the voxel-wise, $P < 0.001$; the cluster-wise, $P < 0.005$; 5,000 simulations) in the REST toolbox[4] 1.8. Pearson's or Spearman's correlation coefficients were calculated to test the association of normalized *z*-scored CBF values of each brain region with longitudinal CBF changes and behavioral scores over time. The association between the normalized *z*-scored FC values of each brain region showing longitudinal FC

changes and motor and memory scores was determined using the same methods.

RESULTS

Demographic and Behavioral Measures

Demographic and clinical characteristics of LPI, RPI, and NC subjects are shown in **Table 1**, **Supplementary Figure S1**, and **Supplementary Table S1** in the **Supplementary Material**. Compared with NC subjects, there were no significant differences in age (P'_{LPI} = 0.06, P'_{RPI} = 0.64), gender (P'_{LPI} = 0.64, P'_{RPI} = 0.28), education years (P'_{LPI} = 0.45, P'_{RPI} = 0.13), and the incidence of other concurrent disease in the LPI and RPI groups. In addition, no significant differences in lesion volume (P = 0.11) and the days from stroke to the first follow-up (P = 0.71) were observed between the LPI and RPI groups in the baseline stage. Compared with the NC group, the LPI and RPI groups in the baseline stage showed significant motor and verbal memory impairment (RAVLT scores, $P'_{LPI} < 0.001$, P'_{RPI} = 0.01). Longitudinal clinical examination in the LPI and RPI patients showed significant improvement over time in FMT (P_{LPI} = 0.001, P_{RPI} = 0.005) and RAVLT scores ($P_{LPI} < 0.0001$, $P_{RPI} < 0.0001$), but only the LPI group showed significant decrease in NHISS scores (P_{LPI} = 0.002, P_{RPI} = 0.07). Furthermore, there was no significant difference among different subgroups in mean FD values (P_{LPI} = 0.349, P_{RPI} = 0.864). The lesion distribution probability maps of the LPI and RPI groups in the acute stage are depicted in **Figure 1**.

Comparison of CBF Between the Baseline Subgroup of the PI and NC Groups

Compared to the NC group, patients with LPI at the baseline stage showed lower *z*-scored CBF values in the bilateral cerebellum, including the left lobule VIII (CBE lobule VIII_L), Crus I (CBE lobule Crus I_L), right lobule VIIB (CBE lobule VIIB_R), the left inferior frontal gyrus (IFG_L), the left insula (INS_L), and right inferior and middle temporal gyrus (ITG_R, MTG_R). In addition, the brain regions with significantly higher *z*-scored CBF values were found in the right precuneus (PCUN_R) and left superior parietal gyrus (SPG_L) (AlphaSim correction, $P < 0.005$, cluster size = 43). Patients with RPI at baseline showed significantly lower *z*-scored CBF values in the bialteral cerebellum including left lobule VIII (CBE lobule VIII_L), right lobule VI (CBE lobule VI_R), and Crus II (CBE Crus II_R) and higher *z*-scored CBF values in the right superior frontal gyrus (SFG_R) and right precentral gyrus (PreCG_R) (AlphaSim correction, $P < 0.005$, cluster size = 43) (**Table 2**, **Figure 2**).

Longitudinal CBF Analysis During the Follow-Up Period After PI

For the LPI group, among the four different time subgroups, patients only exhibited significant CBF changes in the right supramarginal gyrus (SMG_R) after the repeated-measure ANOVA test (AlphaSim correction, $P < 0.005$, cluster size = 54). Moreover, *post hoc* analyses revealed significantly lower *z*-scored CBF values of the SMG_R in the Time 4-subgroup (Bonferroni's

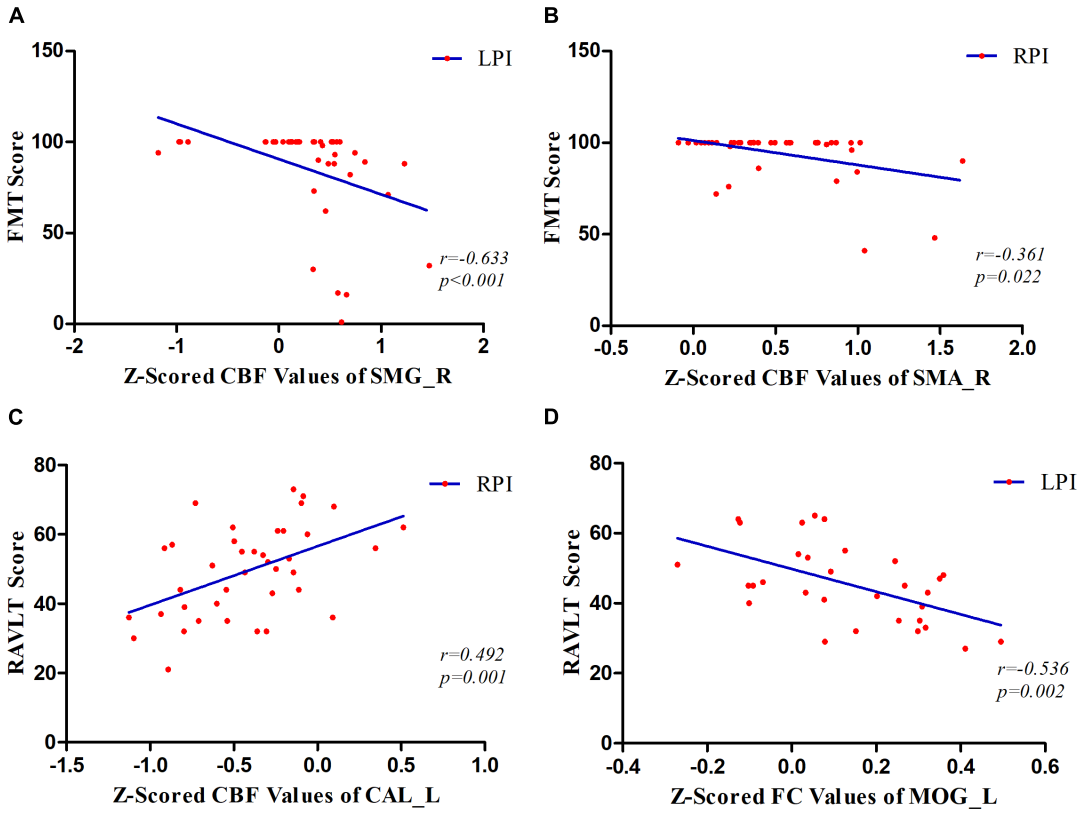

FIGURE 6 | Correlations between *z*-scored CBF values, FC values, and behavioral scores over time. **(A)** The patients in the LPI group showed a significantly negative correlation between dynamic changes of *z*-scored CBF values in the SMG_R and FMT scores over time. **(B)** In the RPI group, the results showed a negative correlation between the longitudinal *z*-scored CBF values of SMA_R and FMT scores. **(C)** In the RPI group, the results showed a positive correlation between longitudinal changes of *z*-scored CBF values in the CAL_L and RAVLT scores. **(D)** In the LPI group, the longitudinal *z*-scored FC values between SMG_R as seed and MOG_L were negatively associated with RAVLT scores. SMG_R, right supramarginal gyrus; SMA_R, right supplementary motor area; CAL_L, left calcarine sulcus; MOG_L, left middle occipital gyrus; FMT, Fugl–Meyer Test; RAVLT, Ray Auditory Verbal Learning Test; LPI and RPI, left and right pontine infarction groups.

post hoc test, $P < 0.001$) (**Table 3**, **Figure 3**). For the RPI group, the patients showed longitudinal changes of CBF in the left calcarine sulcus (CAL_L), left middle occipital gyrus (MOG_L), and right supplementary motor area (SMA_R) (AlphaSim correction, $P < 0.005$, cluster size = 54) (**Table 3**, **Figure 4**). In addition, the *z*-scored CBF values in CAL_L and MOG_L displayed significantly increased trends during the follow-up period. In SMA_R, the *z*-scored CBF values are initially high in the baseline stage, decreasing to a minimum at 1 month, then increasing with time (Bonferroni's *post hoc* test, all $P < 0.001$) (**Figure 4**).

Longitudinal FC Analysis in the LPI and RPI Groups

We further explored longitudinal FC alterations during the follow-up period in the LPI and RPI groups, using brain regions with altered CBF in longitudinal analysis as seed-ROIs. In the LPI group, with the SMG_R as the seed-ROI, patients exhibited significantly altered FC in the left middle temporal gyrus (MTG_L), left middle occipital gyrus (MOG_L), and left inferior frontal gyrus (IFG_L) (AlphaSim correction, $P < 0.005$, cluster size = 16) (**Table 4**, **Figure 5**). Interestingly, *z*-scored FC values in these brain regions showed similar trends of gradual decrease to a minimum at the 3-month time-point, and subsequent increase (Bonferroni's *post hoc* test, all $P < 0.001$) (**Figure 5**), while in the RPI group, there were no brain regions with significant longitudinal differences among the four time-points.

Correlation With Behavioral Function

The correlations between CBF values in brain regions with longitudinal CBF differences and functional improvement are shown in **Figure 6**. We found a significantly negative correlation between dynamic CBF changes in the SMG_R and improvement in motor scores in the LPI group ($r = -0.633$, $P < 0.001$). In the RPI group, the *z*-scored CBF values of the SMA_R showed a significantly negative correlation with motor recovery ($r = -0.361$, $P = 0.022$), and the *z*-scored CBF values of CAL_L showed a significantly positive correlation with verbal memory functional improvement ($r = 0.492$, $P = 0.001$). In addition, correlations between the FC values and behavioral scores over time were also investigated (**Figure 6**). The *z*-scored FC values between the SMG_R and MOG_L were

correlated with verbal memory RAVLT scores (r = 0.536, P = 0.002).

DISCUSSION

In this study, by combining pcASL and rs-fMRI, we investigated the longitudinal changes in CBF and FC during the 6 month follow-up period. These findings suggested that abnormal perfusion first appeared in the acute period and that the LPI and RPI groups at the baseline stage showed significantly lower z-scored CBF values in the bilateral cerebellum and abnormal perfusion in some supratentorial brain regions, as compared with the NC group. The longitudinal study showed the significantly altered CBF in the SMG_R for the LPI group and in the CAL_L, MOG_L, and SMA_R in the RPI group. We further demonstrated that the abnormal perfusion was concomitant with dynamic FC changes during functional recovery. Longitudinal FC changes were found in the MTG_L, MOG_L, and IFG_L when the SMG_R was used as the seed in the LPI group. In addition, these longitudinal changes in the z-scored CBF and FC values were associated with behavioral recovery, including motor and cognitive functions, over time. These results may promote our understanding of the neural pathophysiological underlying recovery from PI.

Cross-Sectional CBF Differences Between PI and NC Subjects

Some cross-sectional studies have investigated abnormal CBF in chronic cortical or subcortical stroke patients (Miao et al., 2018; Obayashi, 2019). A location-dependent study is essential for understanding particular patterns of brain impairment and reorganization after stroke since the location of the lesion plays a vital role in patients' functional outcomes. Our previous studies on CBF changes in chronic PI showed that significantly lower perfusion in the bilateral cerebellum and abnormal perfusion in the ipsilesional cerebellum were associated with motor scores (Wang et al., 2019). In this study, patients with acute LPI showed significantly lower z-scored CBF values in the bialteral cerebellum (left lobule VIII, Crus I, and right lobule VIIB) and ITG_R, MTG_R, IFG_L, and INS_L, and higher z-scored CBF values in the PCUM_R and SPG_L. On the other hand, patients with RPI showed significantly lower z-scored CBF values in the bilateral cerebellum (left lobule VIII, right lobule VI, and Crus II) and higher z-scored CBF values in the SFG_R and PreCG_R at the baseline stage. Coupled with these results, we argued that hypoperfusion of the bilateral cerebellum first appeared at the acute stage and maintained low-level perfusion to the chronic phase. Previous studies have reported that the cerebellum is involved in various motor and cognitive functions, cerebellar anterior lobe lesions may cause the cerebellar motor syndrome, and cerebellar posterior lobe lesions may produce the cerebellar cognitive affective syndrome (Schmahmann, 2004). Therefore, continuous hypoperfusion may be one of the factors in impaired motor and cognitive function after PI. We also found different patterns of CBF changes in some supratentorial brain regions in the LPI and RPI groups. Previous observations have shown that abnormal perfusion of the frontal parietal and temporal areas commonly occurs after unilateral brainstem stroke. Moreover, some studies suggested that factors such as lesion size, number, and location may affect the occurrence of supratentorial hypoperfusion, in which upper PI is more likely to cause ipsilateral supratentorial hypoperfusion, while contralateral supratentorial hypoperfusion is common in the middle pontine to medulla infarctions (Fazekas et al., 1993; Miyazawa et al., 1999; Matsui et al., 2007; D'Aes and Marien, 2015). This may partly explain the inconsistence of supratentorial perfusion patterns in the LPI and RPI groups.

Longitudinal Alterations of CBF in the LPI and RPI Groups

A longitudinal study is an effective way to explore the neurobiological underpinnings of clinical recovery. In our longitudinal investigation, the LPI group showed CBF changes in the SMG_R from baseline to 6 months after infarction and significantly lower z-scored CBF values at the 6 months. The SMG serves as the core region of attentiveness, motor function, and spatial perception (Ciaramelli et al., 2008; Golay et al., 2008). Area-specific cytoarchitecture patterns were investigated in a previous study, which demonstrated that the SMA and pre-SMA were strongly co-activated with the SMG (Ruan et al., 2018). Moreover, a study of chronic stroke patients with upper limb hemiparesis showed better recovery of motor function when the cortical thickness of the SMG was thinner (Ueda et al., 2019). These studies further validated our findings that the CBF changes in the SMG_R correlated with motor recovery after stroke and that the abnormal perfusion of the SMG_R offers a novel approach to explore the neural mechanisms of behavioral recovery. The RPI group showed significant CBF changes in the ipsilateral sensorimotor cortex and contralateral visual cortex, and these brain regions displayed different trends over time. In addition, the dynamic CBF changes in the SMA_R and gradually increased perfusion in the CAL_L were associated with functional recovery in motor and cognitive memory. Some previous studies have demonstrated that memory and attention interact. Rotshtein et al. (2011) suggested that the FC from the thalamus to the visual cortex is associated with working memory performance. Soto and Humphreys (2007) identified increased neural responses in early visual cortices when searching for reappearance of an item from working memory. Thus, the higher z-scored CBF values in the CAL_L may underlie memory recovery over time. Previous studies also have suggested a central role of SMA in the motor network, and early structural and functional changes of SMA are an important predictor of long-term motor outcome (Hannanu et al., 2017; Du et al., 2018). Thus, abnormal perfusion of SMA_R may indicate a neural mechanism of motor recovery after RPI.

At present, the detailed mechanisms underlying CBF changes in local brain regions remain unclear. One possible explanation is the destruction and reorganization of neurovascular coupling.

Numerous studies have demonstrated that neural activity is tightly associated with CBF, and the close temporal and spatial relationship between neural activity and CBF is termed "neurovascular coupling." However, the balance between neural activity and CBF is disrupted after stroke, resulting in hemodynamic abnormalities (Blicher et al., 2012; Bohm et al., 2020). Another possible reason is the disruption of white matter fiber integrity after PI, which may cause progressive anterograde and retrograde degeneration of fiber bundles between original infarction site and the remote regions (Liang et al., 2008). These processes could eventually lead to abnormal CBF patterns in remote regions.

Longitudinal FC Changes in the LPI and RPI Groups

A number of studies have proposed that abnormal perfusion in local brain regions may be a potential cause of local brain structural and functional changes (Yu et al., 2017; Zheng et al., 2019). In this study, we also investigated progressive FC changes during the follow-up period, by taking brain regions with longitudinal CBF changes as seed-ROIs. We found longitudinal FC changes between seeded SMG_R and some regions in the LPI group, including MTG_L, MOG_L, and IFG_L. These FC changes showed a similar trend, gradually decreasing to a minimum at 3 months and then increasing thereafter. Several previous studies have investigated the neural bases of verbal memory and have demonstrated that the left-lateralized frontoparietal network, superior temporal and occipital lobe cortices, and cerebellum are involved in the verbal memory process and that the left SMG is one of the key regions (Emch et al., 2019; Koshy et al., 2019). Impaired verbal memory after disease may lead to functional and structural changes in the homologous brain regions to maintain processing. In our study, the dynamic changes in FC between the SMR_R and MOG_L were associated with RAVLT scores over time in the LPI group. This phenomenon may be a compensatory mechanism aimed at maintaining and promoting the recovery of memory function.

This study had some limitations. First, due to the strict inclusion criteria, the sample size was relatively small, and some studies have suggested that the clinical manifestation and prognosis vary according to the level of PI (Jang, 2012; Huang et al., 2019). In addition, the small sample size also limited the statistical power. Therefore, in further studies, it is necessary to recruit patients with the different level pontine lesions to investigate the mechanisms of behavioral recovery. Second, the recovery of clinical function is a long-term process, and a relatively short follow-up period may be insufficient to observe the exact trends of clinical recovery. We therefore plan to observe these patients in the longer term. Third, in this study, we explored the abnormal perfusion as well as FC in PI during the 6-month follow-up by using ASL and BOLD-fMRI. However, we did not further calculate FC values based on brain regions with abnormal spontaneous BOLD signal oscillation as seeds. Further, we will extend this study through further analysis of BOLD signal changes to comprehensively assess spontaneous brain activity after PI.

In conclusion, we investigated longitudinal alterations of regional CBF and FC in patients with PI. Significantly abnormal perfusion first appeared at the acute stage after infarction. Longitudinal results demonstrated that patients with LPI showed abnormal CBF changes in the SMG_R, while RPI groups showed significant CBF changes in the CAL_L, MOG_L, and SMA_R. Moreover, dynamic CBF changes were accompanied by FC changes during the follow-up period. Correlation analysis demonstrated that longitudinal changes in CBF and FC were significantly correlated with motor or cognitive scores over time. These longitudinal alterations enable us to better understand the neurobiological mechanisms of behavioral recovery after PI.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the First Affiliated Hospital of Zhengzhou University and Tianjin Medial University General Hospital. The patients/participants provided their written informed consent to participate in this study.

AUTHOR CONTRIBUTIONS

YWe, CW, JL, and JC conceived and designed the experiments. YWe, JL, CW, PM, LW, and YWa performed the MRI scans and behavioral assessment. YWe, KW, and JC wrote the manuscript. All authors contributed to the article and approved the submitted version.

FUNDING

This study was supported by the Natural Science Foundation of China (Nos. 81601467, 81871327, and 81601472).

ACKNOWLEDGMENTS

We are grateful to our patients and their families for their continued support for our study.

Front. Aging Neurosci. 12:582455. doi: 10.3389/fnagi.2020.582455

Alzheimer's disease (AD) is the most common form of dementia in the elderly. It may be caused by oxidative stress, inflammation, and cerebrovascular dysfunctions in the brain. LongShengZhi Capsule (LSZ), a traditional Chinese medicine, has been approved by the China Food and Drug Administration for treatment of patients with cardiovascular/cerebrovascular disease. LSZ contains several neuroprotective ingredients, including *Hirudo, Astmgali Radix, Carthami Flos (Honghua), Persicae Semen (Taoren), Acori Tatarinowii Rhizoma (Shichangpu),* and *Acanthopanax Senticosus (Ciwujia)*. In this study, we aimed to determine the effect of LSZ on the AD process. Double transgenic mice expressing the amyloid-β precursor protein and mutant human presenilin 1 (APP/PS1) to model AD were treated with LSZ for 7 months starting at 2 months of age. LSZ significantly improved the cognition of the mice without adverse effects, indicating its high degree of safety and efficacy after a long-term treatment. LSZ reduced AD biomarker Aβ plaque accumulation by inhibiting β-secretase and γ-secretase gene expression. LSZ also reduced p-Tau expression, cell death, and inflammation in the brain. Consistently, *in vitro*, LSZ ethanol extract enhanced neuronal viability by reducing L-glutamic acid-induced oxidative stress and inflammation in HT-22 cells. LSZ exerted antioxidative effects by enhancing superoxide dismutase and glutathione peroxidase expression, reduced Aβ accumulation by inhibiting β-secretase and γ-secretase mRNA expression, and decreased p-Tau level by inhibiting NF-κB-mediated inflammation. It also demonstrated neuroprotective effects by regulating the Fas cell surface death receptor/B-cell lymphoma 2/p53 pathway. Taken together, our study demonstrates the antioxidative stress, anti-inflammatory, and neuroprotective effects of LSZ in the AD-like pathological process and suggests it could be a potential medicine for AD treatment.

Keywords: LongShengZhi capsule, Alzheimer's disease, oxidative stress, amyloid-β, Tau, cognition

INTRODUCTION

Alzheimer's disease (AD) is a disease accompanied by behavioral and cognitive impairment, which potently affects the normal social life of the elderly. More than 40 million people worldwide suffer from AD, and many eventually die from serious complications, such as cerebral thrombosis, aspiration pneumonia, and heart failure (Jankowska et al., 2019). Amyloid-β (Aβ) plaques formed by aggregation of Aβ monomer and neurofibrillary tangles (NFTs) formed by hyperphosphorylation of microtubule-associated protein Tau (p-Tau) are considered the two critical biomarkers in AD brains (Congdon and Sigurdsson, 2018). It has been reported that oxidative stress is a conspicuous cause of Aβ aggravation and p-Tau formation for AD development (Jiang et al., 2018).

Aβ is produced from amyloid-β precursor protein (APP) via the amyloidogenic pathway. APP is widely present in various tissues, with its highest expression in the synapses of neurons. APP is synthesized in the endoplasmic reticulum, then transported to the Golgi apparatus, where it is mistakenly cleaved by β-secretase (BACE1) into β-N-terminal and β-C-terminal fragments. The N-terminal transmembrane region of the β-C-terminal fragment is further hydrolyzed by γ-secretase on the cell membrane to release an Aβ peptide (consisting of 39–43 amino acids), and the peptide further aggregates to form Aβ plaques (Hefter et al., 2020). In physiological conditions, the non-amyloidogenic pathway of APP cleavage, which is hydrolyzed by α- and γ-secretase, generates soluble α-APP, p3, and α-C terminal fragments (Dar and Glazner, 2020). In the brains of AD patients, the amyloidogenic pathway appears to be increased.

Presenilin 1 (PSEN1) is one of the subunits of γ-secretase, the mutation of which is highly expressed in most AD patients and considered to be one of the main genetic factors of familial AD (Kabir et al., 2020). PSEN1 mutation may influence the expression of both β-secretase and other subunits of γ-secretase, including PSEN2, nicastrin, presenilin enhancer 2 (PEN2), and anterior pharynx-defective 1 (APH1), thus enhancing the maturation of Aβ (Li et al., 2011; Liu et al., 2019). Oxidative stress in the brain, which may upregulate β-secretase expression and increase the amyloidogenic cleavage of APP, also promotes AD (Sharma et al., 2019). Some natural ingredients, such as folic acid and berberine, have been shown to inhibit the deposition of Aβ by regulating the expression of b- and γ-secretase, which has become a strategy to alleviate the progression of AD (Tian et al., 2016; Cai et al., 2018).

Moreover, extracellular Aβ plaques interfere with the normal growth of neurons and further enhance oxidative stress, represented by overproduction of reactive oxygen species (ROS) (Sultana et al., 2009). Elevated oxidative stress leads to increased DNA, RNA, lipid, and protein oxidation in the brains of AD patients, which causes neuronal cell death (Halliwell, 2006). Antioxidant factors, such as glutathione peroxidase (GSH-PX) and superoxide dismutase (SOD), have been considered therapeutic targets that inhibit AD pathogenesis (Chen et al., 2019). In addition, ROS and Aβ accumulation in the AD brain can potently activate glial cells to release inflammatory cytokines and cause severe brain inflammation (Houtman et al., 2019). The inflammatory cytokines, including interleukin 1β (IL-1β) in the brain, can increase phosphorylation of Tau and make it dissociate from neuronal synapses (Graham et al., 2017). In a physiological state, Tau maintains the stability of neurons and synapses. However, in the AD condition, dissociated p-Tau forms NFTs in neurons, causing synapse damage, which obstructs transmission of neural signals and further aggravates cognitive dysfunction (Hoppe et al., 2010). Therefore, blocking oxidative stress could be an effective strategy to slow the AD process.

Cerebrovascular function is commonly affected in AD patients (Fouda et al., 2019). The clearance of Aβ could be impaired due to cerebrovascular damage in the early stage, which further accelerates AD (Gupta and Iadecola, 2015). In addition, cerebrovascular damage causes insufficient supply of oxygen and glucose in neurons and glial cells, resulting in decreased ATP production and enhanced oxidative stress (Merlini et al., 2011). Long-term chronic hypoxia ultimately causes irreversible structural damage to cells and tissues of the central nervous system (Daulatzai, 2017).

The LongShengZhi capsule (LSZ), a well-known traditional Chinese herbal medicine, has long been prescribed to patients with cardiovascular and cerebrovascular diseases in China. It offers a potent protection against atherosclerotic lesions, ischemic brain damage, and vascular dementia (Ma et al., 2019; Yang et al., 2020). LSZ is made from 12 traditional Chinese medicines, including *Hirudo* (Shuizhi), *Pheretima* (Dilong), *Astmgali Radix* (Huangqi), *Chuanxiong Rhizoma* (Chuanxiong), *Angelicae Sinensis Radix* (Danggui), *Carthami Flos* (Honghua), *Persicae Semen* (Taoren), *Paeoniae Radix Rubra* (Chishao), *Aucklandiae Radix* (Muxiang), *Acori Tatarinowii Rhizoma* (Shichangpu), *Talxilli Herba* (Sangjisheng), and extract of *Acanthopanax Senticosus* (Ciwujia), as shown in **Table 1** (Wei et al., 2019). The 19 main active ingredients in LSZ are listed in **Table 2**. Many of them have clear protective effects on the central nervous system. For example, *Astmgali Radix* can reduce neuroinflammation and cognitive impairment (Huang et al., 2017). *Carthami Flos* seed can attenuate memory impairment induced by scopolamine in mice by ameliorating cholinergic dysfunction and oxidative stress (Kim et al., 2019). *Acanthopanax senticosus* extract also has a neuroprotective effect on nervous system diseases (Li et al., 2014). Moreover, bioactive components contained in LSZ, such as paeoniflorin, isoflavone glucoside, and syringin, have been reported to inhibit oxidative stress to protect neurons (Ding et al., 2013; Zhong et al., 2015).

Our previous studies have shown that LSZ can reduce thrombosis by inhibiting platelet adhesion through reducing oxidative stress and vascular inflammation in the aorta of atherosclerotic mice (Li et al., 2019; Ma et al., 2019). Moreover, we have demonstrated its strong antioxidant role in heart failure (Xu et al., 2020). These findings suggest a potential role of LSZ in AD treatment. Therefore, in this study, we used human APP and mutant presenilin 1 double transgenic (APP/PS1) mice and HT-22 cells to determine the anti-AD-like pathology effect of LSZ.

TABLE 1 | Main ingredients in LSZ.

Ingredients	Local name	Part used	Biological properties
Hirudo	Shuizhi	Dried body	Anti-thrombosis; protection against cerebral ischemia reperfusion injury
Pheretima	Dilong	Dried body	Anti-cerebral thrombosis; anti-inflammation
Astmgali Radix	Huangqi	Root	Neuroprotection; cognition improvement; glucose and lipid metabolism improvement
Chuanxiong Rhizoma	Chuanxiong	Rhizome	Neuroprotection; anti-neuroinflammation; cerebral vascular function improvement
Angelicae Sinensis Radix	Danggui	Root	Blood vessel protection; neuroprotection; anti-neuroinflammation;
Carthami Flos	Honghua	Flower	Cerebral ischemia improvement; anti-neuroinflammation; angiogenesis promotion
Persicae Semen	Taoren	Dried seed	Anticoagulant; neurotrophic
Paeoniae Radix Rubra	Chishao	Root	Microcirculation improvement; Blood vessel dilation; myocardial ischemia prevention; anti-thrombosis
Aucklandiae Radix	Muxiang	Root	Gastrointestinal function improvement; vascular tension regulation
Acori Tatarinowii Rhizoma	Shichangpu	Root	Antidepressant; neuroprotection; inhibiting glial inflammation; cognition improvement
Talxilli Herba	Sangjisheng	Stem	Anti-oxidation; anti-inflammation; anti-cancer
extract of *Acanthopanax Senticosus*	Ciwujia	Stem	Anti-anxiety; neuroprotection; cerebral vascular function protection

MATERIALS AND METHODS

Chemicals and Antibodies

LongShengZhi Capsule (CAT# A14001035472) was provided primarily by the Buchang Pharmaceutical Co. Ltd. (Xi'an, Shaanxi, China). The LSZ ethanol extract solution (LSZ-EES) in PBS was prepared as follows (Li et al., 2019). Bovine serum albumin (BSA), 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), L-glutamic acid (L-Glu), and thioflavin S were purchased from Sigma Aldrich (St. Louis, MO, United States). 2'7'-Dichlorodihydrofluorescein diacetate (DCFH-DA) was purchased from Meilun Biotechnology (Dalian, Liaoning, China). A cocktail of protease inhibitors, PMSF, and enhanced chemiluminescence (ECL) kits were purchased from Millipore (Darmstadt, Germany). Bromphenol blue, eosin Y, heparin, triton X-100, and sodium dodecyl sulfate (SDS) were purchased from the Solarbio (Beijing, China). 4',6-Diamidino-2-phenylindole (DAPI) was purchased from Santa Cruz Biotechnology (Paso Robles, CA, United States). Hematoxylin staining solution, phosphate buffer saline (PBS), BCA protein assay kit, and 4% polyformaldehyde were purchased from Biosharp (Hefei, Anhui, China). Terminal deoxynucleotidyl transferase (TdT)-mediated dUTP nick end labeling (TUNEL) assay kit was purchased from KeyGen Biotech (Nanjing, Jiangsu, China). FAS siRNA kit (CAT# siB13118141431) was purchased from RiboBio Co., Ltd. (Guangzhou, Guangdong, China). Lipofectamine^{TM} RNAiMAX (CAT# 13778030) was purchased from Thermo Scientific (Waltham, MA, United States). Total RNApure reagent (Tri-zol, ZP401-2) was purchased from Zomen Biotechnology Co. Ltd. (Beijing, China). The HiScript II Q Select RT SuperMix for qPCR and AceQ SYBR qPCR Master Mix were purchased from Vazyme (Piscataway, NJ, United States). Annexin V-PE analysis kit, goat anti-rabbit lgG (H + L)-HRP (CAT# LK2001, 1:10000), and goat anti-mouse lgG (H + L)-HRP (CAT# LK2003, 1:10000) were purchased from Sungene Biotech (Tianjin, China). Rabbit anti-PSEN1 (CAT# 20434-1-AP, 1:100), Tau (CAT# 10274-1-AP, 1:1000), Bax (CAT# 50599-2-lg, 1:8000), Bcl-2 (CAT# 12789-1-AP, 1:1000), Bad (CAT# 10435-1-AP, 1:2000), Iba-1 (CAT# 10904-1-AP, 1:300), and FITC-goat anti-mouse IgG (H + L) (CAT# SA00003-1, 1:100), FITC-goat anti-rabbit IgG (H + L) (CAT# SA00003-2, 1:100), and TRITC-goat anti-rabbit IgG (H + L) (CAT# SA00007-2, 1:100) antibodies were purchased from Proteintech Group, Inc. (Chicago, IL, United States). Rabbit anti-APP (CAT# AF6084, 1:300) antibody was purchased from Affinity Biosciences (Changzhou, Jiangsu, China). Rabbit anti-phospho-MAPT-S404 (p-Tau, CAT# AP0170, 1:1000 for WB; 1:100 for IF), IL-1β (CAT# A17361, 1:1000 for WB; 1:100 for IF), NF-κB (CAT# A16271, 1:1000 for WB; 1:100 for IF), β-actin (CAT# AC026, 1:200000), and mouse anti-GAPDH (CAT# AC033, 1:200000) antibodies were purchased from Abclonal (Wuhan, Hubei, China).

TABLE 2 | Main active components in LSZ-EES.

Component	Proportion (~mg·g^{-1})	Component	Proportion (~mg·g^{-1})
Paeoniflorin	3.9	Senkyunolide I	0.05
Calycosin-7-glucoside	0.75	Dehydrocostus lactone	0.03
Amygdalin	0.7	Calycosin	0.03
Hydroxysafflor yellow A	0.49	Ligustilide	0.01
Syringin	0.25	Senkyunolide A	0.01
Ferulic acid	0.15	Oxypaeoniflora	0.01
Eleutheroside E	0.15	Senkyunolide H	<0.01
Isofraxidin	0.13	Ligustrazine	<0.01
Benzoylpaeoniflorin	0.11	3-n-Butylphthalide	<0.01
Astragaloside A	0.1		

Cell Culture

HT-22 cells, a mice hippocampal neuronal cell line (CAT# CP-H042), were purchased from Procell (Wuhan, Hubei, China) and cultured in Dulbecco's Modified Eagle's Medium (DMEM, Biological Industries, Kibbutz Beit Haemek, Israel) containing 10% fetal bovine serum (FBS, AusGeneX, Brisbane, Australia) as

well as 50 μg/mL streptomycin/penicillin (Hyclone, Logan, UT, United States) at 37°C in an atmosphere of 5% CO_2. Cells at ∼90% confluence were treated in serum-free medium.

Cell Viability Assay

Cell viability was detected using MTT assay. In brief, HT-22 cells were plated into 96-well plates (∼10^4 cells/well) and were treated as indicated. After treatment, the culture medium was removed, and cells were added to MTT (0.5 mg/mL) and incubated for 4 h at 37°C. After washing with PBS 3 times and incubating in DMSO (150 μL/well) for 15 min, the optical density at a wavelength of 550 nm was read by a microplate reader (BioTek Instruments, Winooski, VT, United States). The mean of absorbance was expressed as fold changes compared to control samples.

Cell Death Assay

HT-22 cells were seeded in 6-well plates and pre-treated with LSZ-EES for 3 h followed by co-treatment with L-Glu for another 18 h. Then the cells were lifted by trypsin (without EDTA) and washed with cold PBS twice. After incubation with annexin V-PE and 7-aminoactinomycin D (7-AAD) working solution in darkness at room temperature for 20 min, the fluorescence intensity was measured by the fluorescence-activated cell sorting (FACS) assay using a CytoFLEX (Beckman, Brea, CA, United States).

ROS Determination

HT-22 cells were plated in 96-well plates or 6-well plates and pre-treated with LSZ-EES for 3 h, followed by co-treatment with L-Glu for another 18 h. After treatment and removal of the treatment medium, cells were incubated with DCFH-DA (10 μM) working solution for 20 min at 37°C in darkness. After being washed with PBS 3 times, samples in 96-well plates were measured on a microplate reader at 504 nm (excitation) and 529 nm (emission), while the fluorescence images in 6-well plates were captured with a fluorescence microscope (Leica, Wetzlar, Germany).

siRNA Transfection

HT-22 cells in 6-well plates at ∼40% confluence were transfected with FAS siRNA (siFAS, 50 nM/well) or the corresponding negative control siRNA (siCtrl, 50 nM/well) using Lipofectamine^{TM} RNAiMAX in serum-free medium for 24 h, then incubated in complete DMEM medium for another 24 h, followed by the treatment indicated.

Animals

The experiment was conducted with the approval of the Institution Animal Ethics Committee of Hefei University of Technology (HFUT20190116001). All animal experiments were performed in compliance with the guidelines published in the National Institutes of Health (NIH) Guide for the Care and Use of Laboratory Animals. We used male mice in this study, which is widely accepted in AD-related studies, to avoid the hormonal changes, including estrogen, in female mice in AD progress. In addition, all animals were randomized before received treatment. The animals were maintained at a temperature of 24 ± 2°C with a 12-h light/dark cycle and checked daily during the experiment for food intake, water consumption, and bodyweight.

Both male C57BL/6J wild-type mice and APP/PS1 mice (∼2 months old, ∼20 g) without backcrossing were purchased from the Model Animal Research Center of Nanjing University (Nanjing, Jiangsu, China). All the animals were free to access food and drinking water. C57BL/6J wild-type mice fed normal chow were used as the normal control (Group 1, WT, 12 mice/group). APP/PS1 mice were randomly divided into three groups (12 mice/group) and received the following treatment. Group 2 (AC), APP/PS1 mice were fed normal chow. Group 3 (ALN), APP/PS1 mice were fed normal chow containing LSZ at a normal dose (850 mg/100 g food, based on clinical dosage). Group 4 (ALH), APP/PS1 mice were fed normal chow containing LSZ at a high dose (2000 mg/100 g food). The treatment lasted for 7 months as the pathological changes in the brains of APP/PS1 mice at 9 months old are severe enough to be detected.

Morris Water Maze (MWM) Test

The MWM video tracking analysis system (1056001, Beijing ZS Dichuang Technology Development Co., Ltd., Beijing, China) was used to assess spatial learning and reference memory (Vorhees and Williams, 2006). A circular pool was divided into four quadrants and filled with water (22 ± 2°C). A target platform was fixed and immersed at a depth of 2 cm in the middle of the first quadrant. Titanium dioxide was added to the pool to make the platform invisible. A tracking camera was placed above the pool to record the trajectories of the mice. The MWM experiment consisting of a spatial probe test and a hidden platform trial was performed over the next 6 consecutive days as follows (Nunez, 2008). Briefly, in the acquisition training phase, the mouse was placed into the water facing the wall of the pool and swam freely. The length of time it took the mouse to find the underwater platform was recorded. If the mouse did not find the platform within 60 s, we would guide it to the platform and allow it to remain there for 10 s. After training, the animals were removed, dried, and then returned to the cage. Each mouse was trained 4 times a day for 5 consecutive days, entering the water from a different quadrant each time. On the second day after the final acquisition training (day 6), the platform was removed to perform the 60-s probe trial. The mouse was placed in water in the opposite quadrant from where the original platform was located. The trajectories, times of passing through the target quadrant or the original platform, and escape latency that the mice arrived at the hidden platform were recorded.

Y Maze (YM) Test

The YM video tracking analysis system (1056006, Beijing ZS Dichuang Technology Development Co., Ltd., Beijing, China) was used to test the discriminatory working memory and spatial exploration ability of mice (Oboh et al., 2020). Three arms of the YM were randomly defined as the new arm, the starting arm, and the third arm. Mice were placed into the maze at the end of the starting arm and allowed to explore the maze for 3 min. A camera was fixed 1.5 m above the maze to record the trajectory,

distance, and the time and length of time it took the mice to cross the new arm.

Brain Section Preparation

For histological examination, six mice per group were selected randomly and anesthetized with 2% sodium pentobarbital. Mice were then perfused with PBS and 4% paraformaldehyde, followed by collection of whole brain tissue. The brain tissue was quickly frozen with dry ice and then fixed in 4% paraformaldehyde for 24 h at 4°C. Afterward, the brains were dissected and separated into two hemispheres: one for paraffin section preparation and the other for frozen section preparation. Hemispheres for paraffin sections were dehydrated using a HistoPearl automatic dehydrator (Leica, Wetzlar, Germany) and embedded with paraffin. Hemispheres for frozen sections were dehydrated with 15, 20, and 30% sucrose solutions in turn, each for 24 h, and then embedded in optical cutting temperature compound (OCT) and stored at –80°C until sectioning.

For protein and RNA extraction, another six mice per group were euthanatized, and brain tissue was immediately dissected. The cortex and hippocampus were separated and stored at –80°C until processing.

Immunofluorescence Staining and Thioflavin S Staining

The paraffin-embedded brain was cut into 5-μm sections. Expression of p-Tau, PSEN1, NF-κB, IL-1β was detected as follows (Chen et al., 2014). The frozen brain in OCT was cut into 20-μm sections to determine Iba-1 and Aβ plaques. Aβ plaques were detected by co-staining with APP antibody and thioflavin S. Briefly, the sections were blocked with 3% BSA for 1 h at room temperature and then incubated with diluted primary antibody overnight at 4°C. The sections were washed with PBS 3 times, for 10 min each time, and then incubated with FITC-goat anti-rabbit IgG or TRITC-goat anti-rabbit IgG secondary antibodies for 1 h at room temperature. Samples incubated without primary antibody were used as the negative control (NC) to illustrate the specificity of the primary antibody. The sections were washed with PBS for 3 × 10 min and then stained with DAPI solution for nucleus. For Aβ plaque determination, sections were washed with PBS for 3 × 5 min after DAPI staining. The sections were incubated with 0.5% thioflavin S solution for 10 min at room temperature and then washed with 70% alcohol for 15 min and then with PBS for 5 min. The sections were covered with coverslips and kept in the dark until dry. Images were obtained using a ZEISS Scope A1 fluorescence microscope. The ratio of mean of fluorescence intensity (MFI) to cell number or Iba-1-positive cells to cell number were assessed using Photoshop by a technician who was blind to the experiment.

TUNEL Staining

The paraffin-embedded brain was cut into 5-μm sections to detect cell death in brain tissues using a TUNEL assay kit as follows (Ma et al., 2019). Images were observed with a ZEISS Scope A1 fluorescence microscope. The number of TUNEL-positive cells in more than three random fields was counted and quantitated as per mm^2 by a technician who was blind to the experiment and expressed as fold of the WT group.

Quantitative Real Time PCR (qRT-PCR) and Western Blot

After treatment, the total RNA was extracted from HT-22 cells or 30-mg brain tissues using Trizol as follows (Chen et al., 2014). cDNA was synthesized with the same amount of total RNA from each sample with HiScript II Q Select RT SuperMix (+gDNA wiper). qRT-PCR was then performed using the AceQ SYBR qPCR Master Mix reverse transcriptase kit and the primers listed in **Table 3** on LightCycler96 (Roche, Mannheim, Germany). The mRNA expression was normalized by β-actin mRNA in the corresponding samples.

After treatment, HT-22 cells or 30-mg brain tissues were lysed or grated with lysis buffer (Chen et al., 2012). Protein concentration was determined using the BCA protein assay kit. The same amount of protein (50 μg) from each sample was used to determine protein expression of Tau, p-Tau, FAS, Bcl-2, Bad, Bax, NF-κB, IL-1β, p53, GAPDH, or β-actin by Western blot as described (Sun et al., 2017). The signals were detected on Chemiscope 3000 mini (Qinxiang, Shanghai, China) and the band density was quantified using Photoshop.

Statistical Analysis

Based on a survey of data from published research or preliminary studies, we performed *in vitro* studies at least five independent times and decided on the sample size for the *in vivo* studies. All data were analyzed by a technician who was blind to the experiment design and expressed as

TABLE 3 | Sequences of primers for qRT-PCR assay.

Gene	Forward sequences	Reverse sequences

IL-1β/6/10, interleukin 1β, 6 or 10; TNF, tumor necrosis factor; SOD1, superoxide dismutase 1; SOD2, superoxide dismutase 2; GSH-PX, glutathione peroxidase; Bcl-2, B-cell lymphoma 2; Bad, Bcl-2 associated agonist of cell death; Bax, Bcl-2 associated X protein; Bcl-xL, B-cell lymphoma-extra large; FAS, Fas cell surface death receptor; BACE1, beta-site APP-cleaving enzyme 1; APH1a, anterior pharynxdefective 1a; PEN2, presenilin enhancer 2.

mean ± standard deviation (SD). Graph Pad Prism 7.0 was used for statistical analysis. Two-way ANOVA was used to assess significance in ROS and qRT-PCR of the *in vitro* study. One-way ANOVA was used on the other data to assess significance. The Shapiro-Wilk normality test, White test, and Brown-Forsythe test were conducted on the data to evaluate if the values came from a Gaussian distribution (**Supplementary Material**). The differences were considered significant at $p < 0.05$.

RESULTS

LSZ-EES Rescues L-Glu-Induced HT-22 Cell Death and Oxidative Stress

LongShengZhi Capsule has been reported to reduce thrombosis by inhibiting ROS production in human umbilical vein endothelial cells (Li et al., 2019). Thus, we speculated that LSZ may have similar antioxidant effects on neuronal cells. L-Glu is an excitatory neurotransmitter and induces neuronal death by activating oxidative stress (Kritis et al., 2015). A close association between ROS levels and synaptic dysfunctions has been reported (Li et al., 2017). To determine the protective effects of LSZ against neuronal damage, we initially pre-treated HT-22 cells, a neuronal cell line, with LSZ-EES for 3 h. Cells were then treated with L-Glu to induce HT-22 cell death. We found L-Glu exposure increased ROS production to ∼two-fold (two-way ANOVA, $F_{(2,\ 24)} = 21.11$, $p = 0.0002$) of that in the control group (Ctrl). However, the increase was substantially blocked by LSZ-EES co-treatment (two-way ANOVA, 39%, $F_{(2,\ 24)} = 12.61$, $p = 0.0015$ for 10 μg/mL LSZ-EES; 33%, $F_{(2,\ 24)} = 12.61$, $p = 0.0017$ for 20 μg/mL LSZ-EES) (**Figures 1A,B**).

Next, we determined the effect of LSZ on cell viability using the MTT method. As expected, LSZ-EES alone had little effect on cell viability, indicating its high degree of safety to cells ($F_{(4,\ 20)} = 0.756$, $p > 0.05$) (**Figure 1C**). In contrast, L-Glu clearly reduced cell viability by ∼43% ($F_{(3,\ 20)} = 33.39$, $p = 0.0003$), but the reduction was reversed by LSZ-EES treatment ($F_{(3,\ 20)} = 33.39$, $p = 0.0009$ for 10 μg/mL LSZ-EES, $p = 0.0007$ for 20 μg/mL LSZ-EES) (**Figure 1D**). In addition, the results of the flow cytometry experiment show that L-Glu increased the percentage of cell death at early and late stages from ∼4.5% in the control group to ∼18.2%, but the number was significantly reduced to ∼9.5 or ∼8.3% by LSZ-EES treatment at 10 or 20 μg/mL (**Figure 1E**). These results suggest that LSZ-EES can enhance HT-22 cell viability, which is related to the reduction of L-Glu-induced oxidative stress.

Reactive oxygen species is mainly produced by mitochondria, so the neuroprotection of HT-22 cells by LSZ-EES against L-Glu-induced neurotoxicity may be related to its effect on expression of mitochondrial apoptotic genes. The Bcl-2 family is among the essential factors regulating mitochondrial membrane permeability and the mitochondrial apoptosis pathway (Rong and Distelhorst, 2008). Our results show that L-Glu reduced the anti-apoptotic gene Bcl-xL mRNA level (two-way ANOVA, $F_{(1,\ 16)} = 29.14$, $p = 0.0403$) and Bcl-2 protein expression ($F_{(3,\ 16)} = 11.36$, $p = 0.198$), while inducing pro-apoptotic genes, Bax and Bad expression, at protein ($F_{(3,\ 16)} = 6.192$, $p = 0.0152$ for Bax; $F_{(3,\ 16)} = 21.74$, $p = 0.6742$ for Bad) or mRNA levels (two-way ANOVA, $F_{(1,\ 16)} = 4.902$, $p = 0.0003$ for Bax; $F_{(1,\ 16)} = 188.1$, $p < 0.0001$ for Bad). However, the effect of L-Glu on expression of those genes was significantly reversed by LSZ-EES treatment (**Figures 2A-C**), suggesting the anti-mitochondria-associated apoptotic effect of LSZ-EES.

FAS is a pro-apoptotic gene located on the membrane surface and an upstream molecule of the Bcl-2 family (Strasser et al., 2009). Once activated, FAS transmits stimulus signals into the membrane, and its intra-membrane domain leads to programmed cell death (Kaufmann et al., 2012). To determine if LSZ can block the death signal induced by L-Glu from extra-cellular to intra-cellular, we detected expression of FAS and p53. As shown in **Figure 2A**, the FAS mRNA level was significantly activated by L-Glu (two-way ANOVA, $F_{(2,\ 24)} = 186.6$, $p < 0.0001$), but the activation was antagonized by LSZ-EES treatment (two-way ANOVA, $F_{(2,\ 24)} = 186.6$, $p = 0.0009$). Furthermore, LSZ-EES treatment also inhibited L-Glu-induced p53 protein expression, a pro-apoptotic gene responsible for DNA damage ($F_{(3,\ 16)} = 51.29$, $p < 0.001$) (**Figure 2B**). These results suggest LSZ-EES may enhance neuron survival by regulating FAS/Bcl-2/p53 expression.

Therefore, we transfected HT-22 cells with FAS siRNA to indicate the mechanisms of LSZ-EES in regulating neuronal death. As shown in **Supplementary Figure 1**, in cells not transfected with FAS siRNA, LSZ-EES significantly up-regulated protein expression of Bcl-2 (two-way ANOVA, $F_{(3,\ 32)} = 67.63$, $p < 0.0001$) and mRNA expression of Bcl-xL (two-way ANOVA, $F_{(3,\ 32)} = 27.99$, $p < 0.0001$) and down-regulated protein and mRNA expression of Bax (two-way ANOVA, $F_{(3,\ 32)} = 90.43$, $p < 0.0001$ for protein; $F_{(3,\ 32)} = 22.26$, $p < 0.0001$ for mRNA) and mRNA expression of Bad (two-way ANOVA, $F_{(3,\ 32)} = 12.12$, $p < 0.0001$), while in transfected FAS siRNA cells, compared with the L-Glu-exposed group, LSZ-EES pre-treatment failed to regulate Bcl-2 (two-way ANOVA, $F_{(3,\ 32)} = 67.63$, $p > 0.05$), Bcl-xL (two-way ANOVA, $F_{(3,\ 32)} = 27.99$, $p > 0.05$), Bax (two-way ANOVA, protein: $F_{(3,\ 32)} = 90.43$, $p > 0.05$; mRNA: $F_{(3,\ 32)} = 22.26$, $p > 0.05$), and Bad (two-way ANOVA, $F_{(3,\ 32)} = 12.12$, $p > 0.05$) expression, indicating that silencing of FAS eliminated the regulation of apoptotic factors by LSZ-EES. Taken together, these data indicate that LSZ-EES reduces L-Glu-induced ROS production and inhibits neuronal cell death, at least in part, through the FAS/Bcl-2/p53 pathway.

Elevated ROS production is often accompanied by high levels of inflammation in AD patients (Cooney et al., 2014). NF-κB has been shown to play a role in mediating production of inflammatory cytokines in the AD process (Sandireddy et al., 2014). We found that treatment of HT-22 cells with L-Glu increased protein levels of IL-1β ($F_{(3,\ 16)} = 170.3$, $p < 0.0001$) and NF-κB ($F_{(3,\ 16)} = 9.999$, $p = 0.0010$), which were blocked by LSZ-EES treatment ($F_{(3,\ 16)} = 170.3$, $p < 0.0001$ for IL-1β; $F_{(3,\ 16)} = 9.999$, $p = 0.0013$ for NF-κB) (**Figure 2C**). These results show that LSZ-EES may prevent neurons from inflammation by reducing oxidative stress.

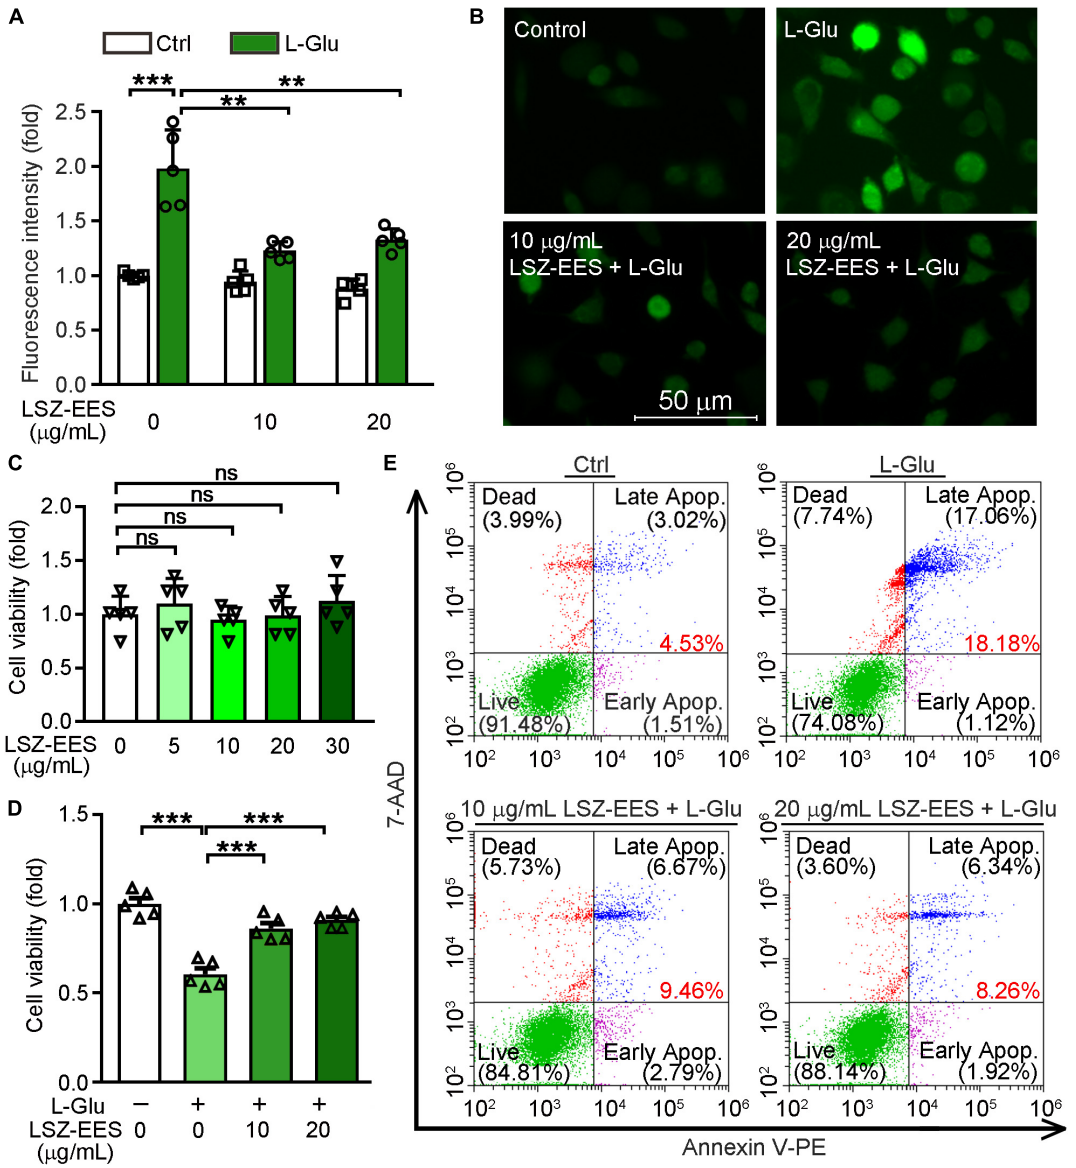

FIGURE 1 | LongShengZhi Capsule Enhances HT-22 Cell Survival by Reducing L-Glu-Induced Oxidative Stress. **(A,B,D,E)** HT-22 cells were pre-treated with LSZ-EES (0, 10, and 20 μg/mL) for 3 h, then co-treated with 20 mM L-Glu for another 18 h; **(C)** HT-22 cells were treated with LSZ-EES at the indicated concentrations for 18 h. ROS levels were detected with DCFH-DA (**A,B**; scale bar: 50 μm). Cell viability was determined by MTT **(C,D)**, and cell death was determined by FACS **(E)**. $^{**}p < 0.01$; $^{***}p < 0.001$; ns, not significant ($n = 5$).

LSZ Improves Cognitive Function in APP/PS1 Mice

Next, we used APP/PS1 mice to determine the cognitive protection of LSZ in the development of AD-like pathology. The 2-month-old APP/PS1 mice were divided into three groups. The animals were fed normal chow, normal chow containing a normal dose (850 mg/100 g food), or a high dose (2000 mg/100 g food) of LSZ, respectively. The age-matched WT mice fed normal chow were used as the normal control. After 7 months of treatment, behavioral experiments, including MWM and YM, were conducted to detect spatial memorizing (**Figure 3A**). In the MWM test, the AC group required significantly more time than the WT group to reach the platform ($F_{(3,\ 20)} = 41.9$, $p < 0.0001$), while LSZ treatment significantly reduced the escape latency ($F_{(3,\ 20)} = 41.9$, $p < 0.0001$) (**Figures 3B,C**). Accordingly, the times for crossing the target platform and quadrant decreased by ∼75% and ∼46%, respectively, in the AC group compared to the WT group ($F_{(3,\ 20)} = 10.29$, $p = 0.0002$ for crossing the target platform, $F_{(3,\ 20)} = 8.663$, $p = 0.0005$ for crossing the target quadrant), while LSZ treatment reversed these parameters by ∼157% for crossing the target platform (AC vs. ALN, $F_{(3,\ 20)} = 10.29$, $p = 0.0068$), and 82% ($F_{(3,\ 20)} = 8.663$, $p = 0.0016$) and ∼64% ($F_{(3,\ 20)} = 8.663$, $p = 0.0129$) for crossing the target quadrant (**Figures 3D,E**).

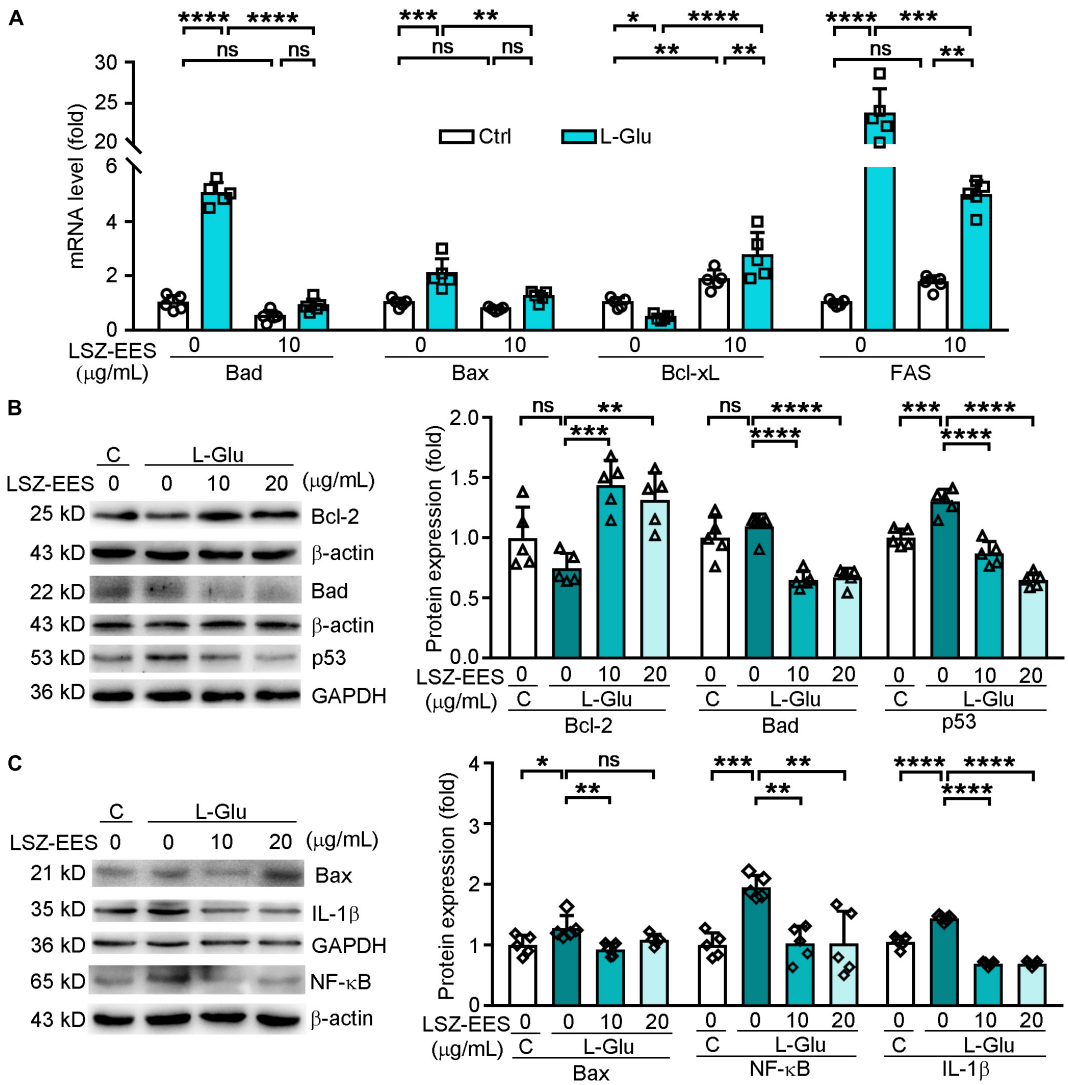

FIGURE 2 | LongShengZhi Capsule Antagonizes L-Glu-induced Expression of Apoptosis-Associated Genes and Inflammatory Cytokines in HT-22 Cells. A: HT-22 cells were pre-treated with LSZ-EES (10 μg/mL) for 3 h, followed by co-treatment with 20 mM L-Glu for another 18 h, or LSZ-EES alone for 21 h; **(B,C)** HT-22 cells were pre-treated with LSZ-EES at the indicated concentrations for 3 h and then co-treated with 20 mM L-Glu for an additional 18 h. Expression of Bad, Bax, Bcl-xL, and FAS mRNA was determined by qRT-PCR **(A)**. Expression of Bcl-2, Bad, p53, Bax, IL-1β, and NF-κB protein was detected by Western blot with quantitative analysis of band density and normalization to β-actin or GAPDH **(B,C)**. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$; $^{****}p < 0.0001$, ns, not significant ($n = 5$).

To eliminate the mutual interference between the two behavioral experiments, the YM test was performed one week later after the MWM test. Our results showed that WT mice had more trajectories in the new arm than the other two arms, showing the normal exploring and learning behavior. In contrast, decreased exploring in the new arm was observed in the AC group but not in the LSZ-treated groups (**Figure 3F**). In addition, compared with the AC group, LSZ treatment increased the relative number (to ∼1.6-fold vs. ∼1.1-fold), distance (to ∼1.6-fold vs. ∼1.5-fold), and time (to ∼1.6-fold vs. ∼1.2-fold) of exploring in the new arm with a greater effect by LSZ at the normal dose ($F_{(3,\ 20)} = 13.13$, $p = 0.0046$ for number; $F_{(3,\ 20)} = 9.215$, $p = 0.0091$ for distance; $F_{(3,\ 20)} = 15.89$, $p = 0.0217$ for time) (**Figures 3G-I**), suggesting that LSZ can enhance the working memory in APP/PS1 mice. Taken together, the results in **Figure 3** indicate that LSZ can repair the cognitive impairment in APP/PS1 mice.

LSZ Attenuates Cell Death and Enhances Antioxidant Enzyme Expression in the APP/PS1 Mouse Brain

Free radical-induced oxidative stress usually occurs in the AD brain (Saito et al., 2019). Excessive oxidative stress promotes neuronal cell apoptosis/death and increases brain damage, which aggravates the AD process (Jiang et al., 2016). In addition, neurons in the CA1 region of hippocampus are more sensitive to age and pathological oxidative stress induced by cerebral

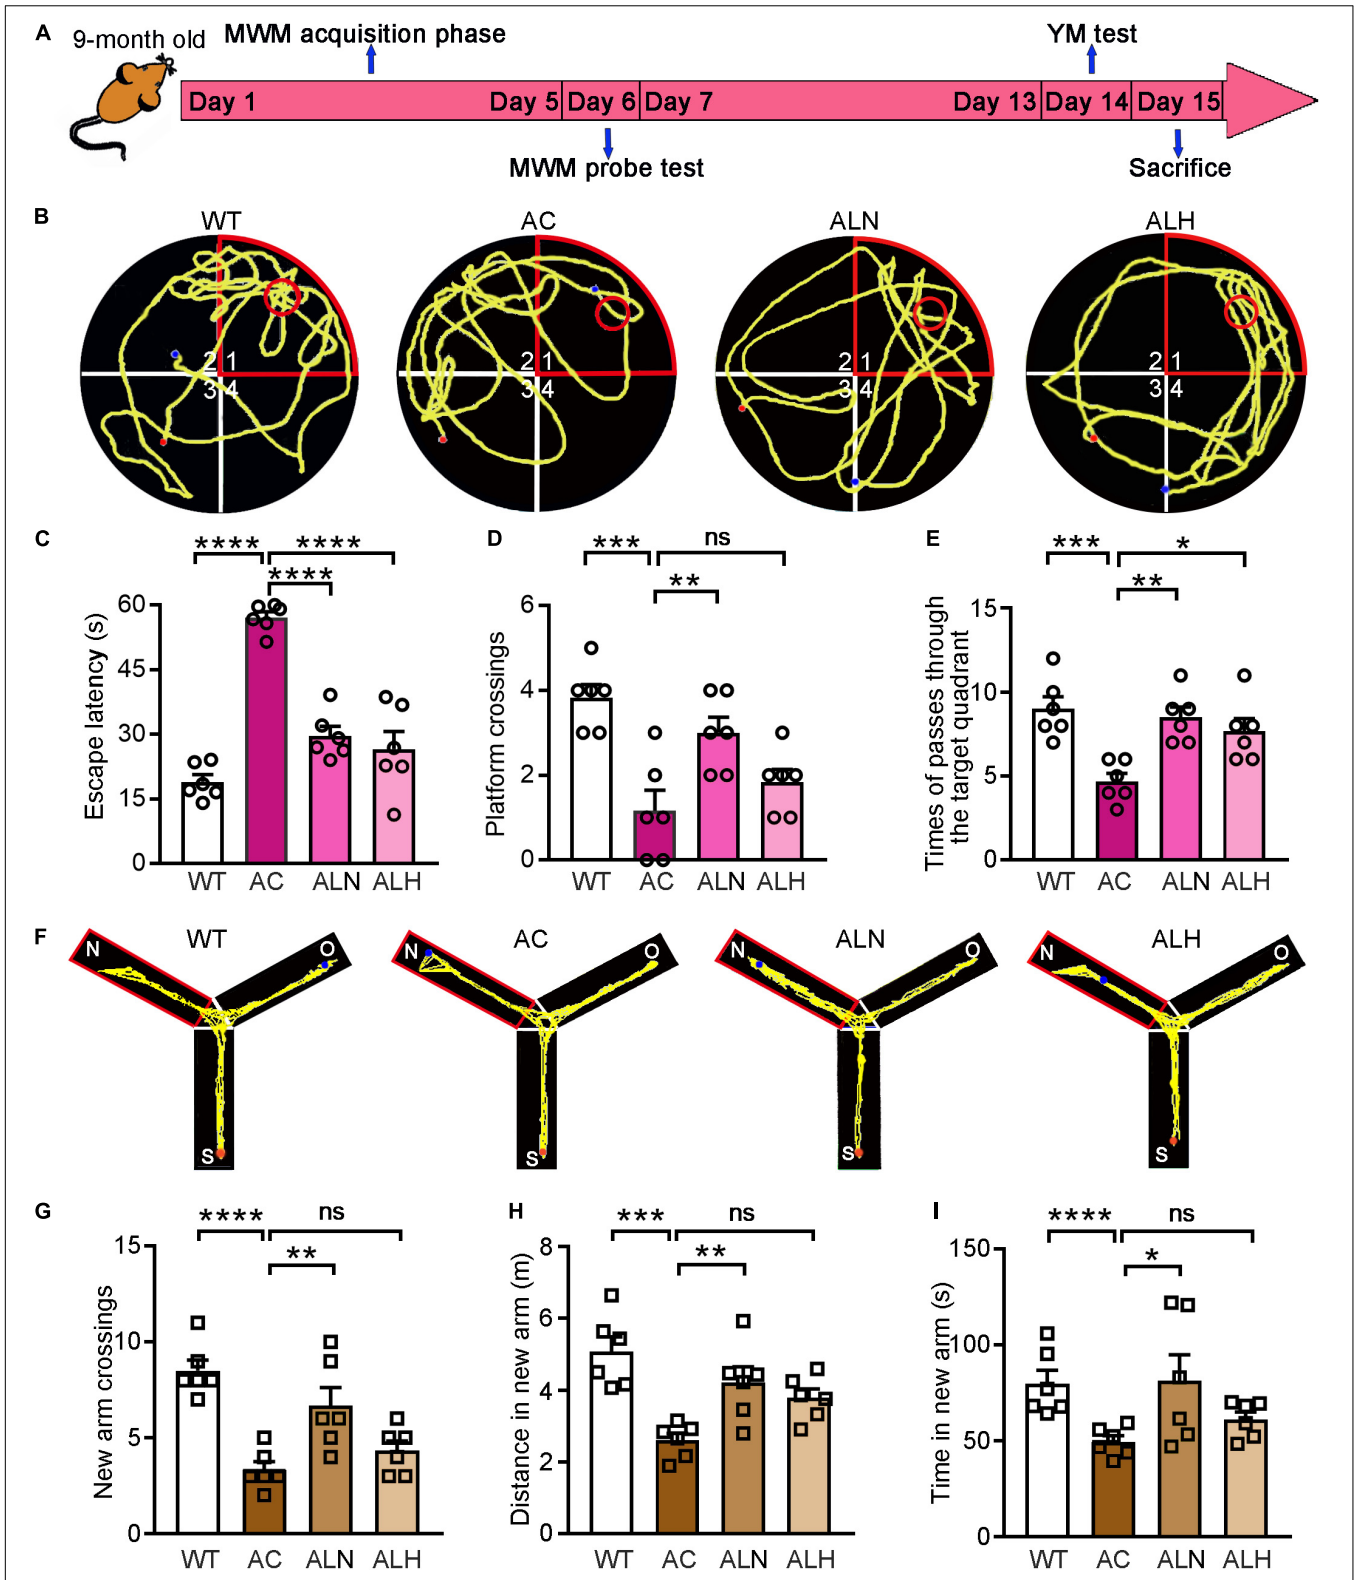

FIGURE 3 | LongShengZhi Capsule Improves Cognitive Functions in APP/PS1 Mice. **(A)** The design of behavioral experiments; **(B–E)** MWM test was conducted on mice. Record of motion trajectory **(B)**, escape latency **(C)**, platform crossings in the target quadrant **(D)**, and times of passing through the target quadrant **(E)** were recorded. The red sector and circle represent the target quadrant and the target platform, respectively, and the yellow curve represents the behavioral track of the mice; **(F–I)** YM test was conducted on mice. Motion behavior track **(F)**, times of crossing new arm **(G)**, distance **(H)**, and time **(I)** in the new arm were recorded. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$; $^{****}p < 0.0001$; ns, not significant ($n = 6$).

ischemia in the AD process (Berkowitz et al., 2017). To determine the neuroprotective effect of LSZ *in vivo*, we performed TUNEL staining on brain tissues. Increased cell death in the CA1 region of the hippocampus ($F_{(3,\ 20)} = 28.97$, $p < 0.0001$) (**Figure 4A**) and cortical areas ($F_{(3,\ 20)} = 13.93$, $p = 0.0003$) (**Figure 4B**) in the AC group was observed, but LSZ treatment significantly reduced cell death in both regions by ∼39% and ∼46% in the hippocampus ($F_{(3,\ 20)} = 28.97$, $p < 0.0001$) and ∼48% in the cortex ($F_{(3,\ 20)} = 13.93$, $p < 0.0001$). Mechanistically, LSZ treatment significantly down-regulated mRNA expression of pro-apoptotic genes, Bax (AC vs. ALN, $F_{(3,\ 20)} = 68.19$, $p = 0.0011$, AC vs. ALH, $F_{(3,\ 20)} = 68.19$, $p = 0.0324$) and Bad (AC vs. ALN, $F_{(3,\ 20)} = 22.73$, $p = 0.0002$; AC vs. ALH, $F_{(3,\ 20)} = 22.73$, $p < 0.0001$), and activated mRNA expression of anti-apoptotic genes, Bcl-xL (AC vs, ALH, $F_{(3,\ 20)} = 65.88$, $p < 0.0001$) and Bcl-2 ($F_{(3,\ 20)} = 135.2$, $p < 0.0001$) in the brains of APP/PS1 mice (**Figure 4C**).

We also examined the mRNA levels of antioxidant genes to determine the association between the neuroprotection effect of LSZ and its antioxidative stress functions in the mouse brain. Compared with the WT group, mRNA levels of GSH-PX, SOD1, and SOD2 in the APP/PS1 mouse brain were slightly affected but potently increased by LSZ treatment (AC vs. ALH, AC vs. ALH, $F_{(3,\ 20)} = 46.99$, $p < 0.0001$ for GSH-PX; AC vs. ALH, $F_{(3,\ 20)} = 24.16$, $p < 0.00015$ for SOD1; AC vs. ALH, $F_{(3,\ 20)} = 19.22$, $p = 0.0194$, AC vs. ALH, $F_{(3,\ 20)} = 19.22$, $p < 0.0001$ for SOD2) (**Figure 4D**). These results show that LSZ can enhance mRNA expression of antioxidant factors and reduce cell death in the brains of APP/PS1 mice.

LSZ Reduces β-Secretase and γ-Secretase Gene Expression and Inhibits Aβ Deposition

Previous studies have shown that the overexpression of mutated PSEN1 in AD brains promotes β-secretase expression and influences γ-secretase activity to enhance Aβ secretion (De Strooper et al., 1998; Al-Atrache et al., 2019). To investigate the effect of LSZ on Aβ secretion and accumulation in APP/PS1 mice, we determined PSEN1 expression by immunofluorescent staining and Aβ accumulation by thioflavin S staining of mouse brain sections. We found in the AC group PSEN1 expression was increased to ∼0-fold of the WT group ($F_{(3,\ 20)} = 188.7$, $p < 0.0001$), while the deposition of Aβ plaques was increased to ∼40-fold of the WT group ($F_{(3,\ 20)} = 192$, $p < 0.0001$) (**Figures 5A-C**). However, PSEN1 expression ($F_{(3,\ 20)} = 188.7$, $p < 0.0001$) and Aβ plaque deposition ($F_{(3,\ 20)} = 192$, $p < 0.0001$) in brain tissues were significantly reduced by LSZ treatment.

Meanwhile, we indicated the specificity of thioflavin S to Aβ plaques by immunofluorescent staining with APP antibody, which can identify the β-C-terminal of APP (**Supplementary Figure 2**). Then we detected that LSZ also reduced the upregulated mRNA levels of BACE1 and γ-secretase subunits, APH1a and PEN2, compared to the AC group ($F_{(3,\ 20)} = 27.62$, $p < 0.0001$ for BACE1; $F_{(3,\ 20)} = 13.08$, $p = 0.001$ for APH1a; $F_{(3,\ 20)} = 46.12$, $p < 0.0001$ for PEN2) (**Figure 5D**). These results indicate that LSZ can reduce Aβ deposition by inhibiting amyloidogenic pathway during the AD-like pathology in APP/PS1 mice.

LSZ Reduces Inflammation and Hyperphosphorylation of Tau in AD Model Mice

Brain inflammation is common in AD patients. It is due to NF-κB-mediated production of inflammatory cytokines by activated microglia, such as IL-1β and TNF (Snow and Albensi, 2016). IL-1β can further promote Tau phosphorylation while TNF increases the β-cleavage of APP, thereby enhancing Aβ production/accumulation and the neuronal cell death (Ghosh et al., 2013). By performing immunofluorescent staining, we found that NF-κB ($F_{(3,\ 20)} = 82.88$, $p < 0.0001$), IL-1β ($F_{(3,\ 20)} = 111.4$, $p < 0.0001$) and Iba-1 (a marker for microglia activation, $F_{(3,\ 20)} = 31.01$, $p < 0.0001$) were increased in the AC group compared with WT mice, but the increases were markedly inhibited by LSZ treatment ($F_{(3,\ 20)} = 82.88$, $p < 0.0001$ for NF-κB; $F_{(3,\ 20)} = 111.4$, $p < 0.0001$ for IL-1β; $F_{(3,\ 20)} = 31.01$, $p < 0.0001$ for Iba-1) (**Figures 6A,B**, **7A**). Similarly, compared with the AC group, LSZ in high dose significantly increased mRNA levels of anti-inflammatory cytokine, IL-10 ($F_{(3,\ 20)} = 12.4$, $p = 0.0009$), and both doses of LSZ treatment decreased mRNA levels of pro-inflammatory cytokines, IL-1β ($F_{(3,\ 20)} = 26.63$, $p < 0.0001$), IL-6 ($F_{(3,\ 20)} = 24.38$, $p < 0.0001$), and TNF (AC vs, ALN, $F_{(3,\ 20)} = 3.799$, $p = 0.0459$; AC vs, ALH, $F_{(3,\ 20)} = 3.799$, $p = 0.0323$) (**Figure 6C**). We further examined Tau expression and its phosphorylation. Compared with the WT group, Tau phosphorylation in the AC group was elevated ($F_{(3,\ 20)} = 106.2$, $p < 0.0001$ for p-Tau MFI/cell number; $F_{(3,\ 20)} = 72.59$, $p < 0.00013$ for p-Tau/total Tau), but the elevation was significantly blocked by LSZ treatment ($F_{(3,\ 20)} = 106.2$, $p < 0.0001$ for p-Tau MFI/cell number; $F_{(3,\ 20)} = 72.59$, $p < 0.0001$ for p-Tau/total Tau), although neither the AD model nor LSZ treatment had an effect on Tau expression (**Figure 7**). Taken together, these results demonstrate that LSZ can reduce NF-κB-mediated brain inflammation and hyperphosphorylation of Tau in APP/PS1 mice.

DISCUSSION

In this study, we used APP/PS1 mice to investigate the therapeutic effect of LSZ on AD-like pathology. We clearly show that LSZ can improve the damaged cognitive functions in APP/PS1 mice (**Figure 3**). LSZ inhibited cell death in the brains of APP/PS1 mice and reduced oxidative stress and consequently regulated Bcl-2 family gene expression (**Figure 4**). LSZ also significantly inhibited glia activation and protein or mRNA expression of inflammatory cytokines (**Figures 6**, **7**). Pathologically, LSZ reduced Aβ accumulation and Tau hyperphosphorylation (**Figures 5**, **7**). Similar to the *in vivo* study, *in vitro* LSZ decreased L-Glu-induced ROS production and enhanced survival of HT-22 cells (**Figure 1**). The neuroprotective effect of LSZ was partly through the FAS/Bcl-2/p53 pathway and NF-κB-mediated inflammation response (**Figure 2** and **Supplementary Figure 1**).

LongShengZhi Capsule as a traditional Chinese medicine for treatment of atherosclerotic cerebral infarction is usually used to treat hemiplegia and stroke caused by atherosclerosis with a high degree of safety. In our previous study, we showed LSZ has few side effects (Li et al., 2019; Ma et al., 2019; Xu et al., 2020). Similarly, in this study, we treated the animal with LSZ for 7 months and found no difference in bodyweight gain, food intake, and the external appearance between control and LSZ-treated groups, which further confirms the high degree of safety of the long-term LSZ treatment.

Oxidative stress and inflammation in the brain are considered important causes of AD. Many factors, such as brain injury, hypoxia, and insufficient cerebral blood flow, can cause excessive production of ROS in the brain. Recent studies have shown a significant decline in cerebral perfusion in the early stages of AD (Fouda et al., 2019). The

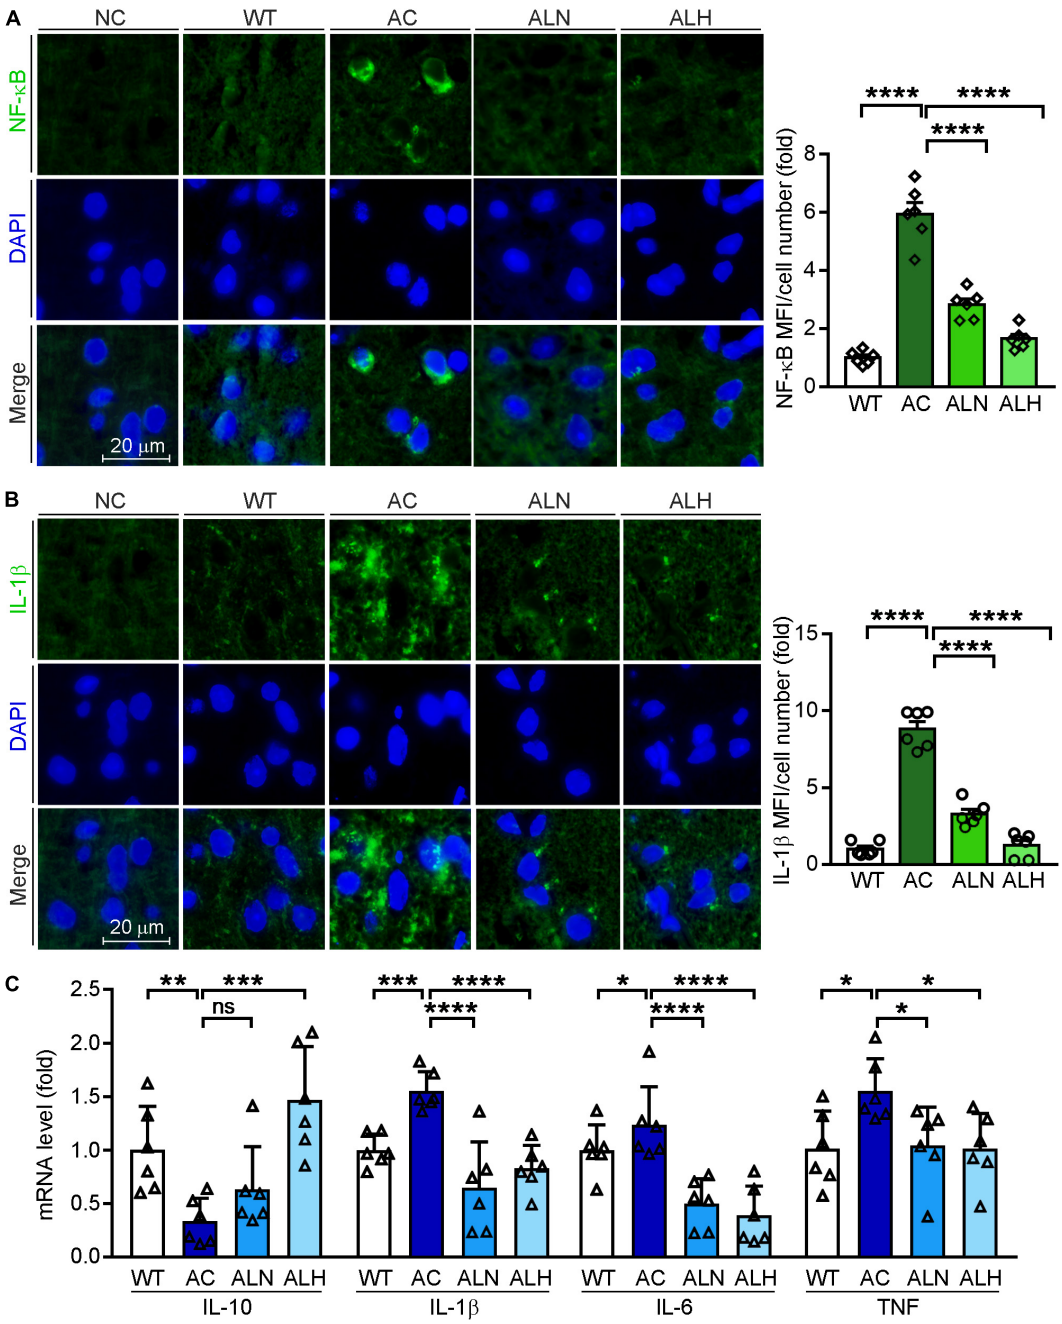

FIGURE 6 | LongShengZhi Capsule Inhibits NF-κB, IL-1β, IL-6, and TNF, but Induces IL-10 Expression. Expression of NF-κB **(A)** and IL-1β **(B)** protein (green) in mouse brain sections was determined by immunofluorescent staining with quantitation of MFI/cell number. The nucleus was stained with DAPI (blue). NC, Negative control (scale bar: 20 μm); **(C)** mRNA levels of IL-10, IL-1β, IL-6, and TNF in the mouse brain was detected by qRT-PCR. $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, $^{****}p < 0.0001$; ns, not significant ($n = 6$).

early defect of cerebral perfusion reduces the removal of Aβ and exacerbates brain oxidative stress (Tarasoff-Conway et al., 2015). Oxidative stress impairs the normal growth of neurons and synapses, as well as the transmission of nerve signals, thereby promoting cognitive damage (Li et al., 2017). Therefore, enhancing cerebral perfusion could be a potential therapeutic for AD. Preclinical experiments have shown that LSZ can also increase cerebral blood flow in experimental animals and reduce cerebral vascular resistance. LSZ improves cerebral blood flow, which suggests an anti-AD potential by targeting Aβ clearing.

In terms of the composition, many components in LSZ have been proven to resist AD. For example, paeoniflorin, the most abundant component in LSZ, reduces the age-onset Aβ

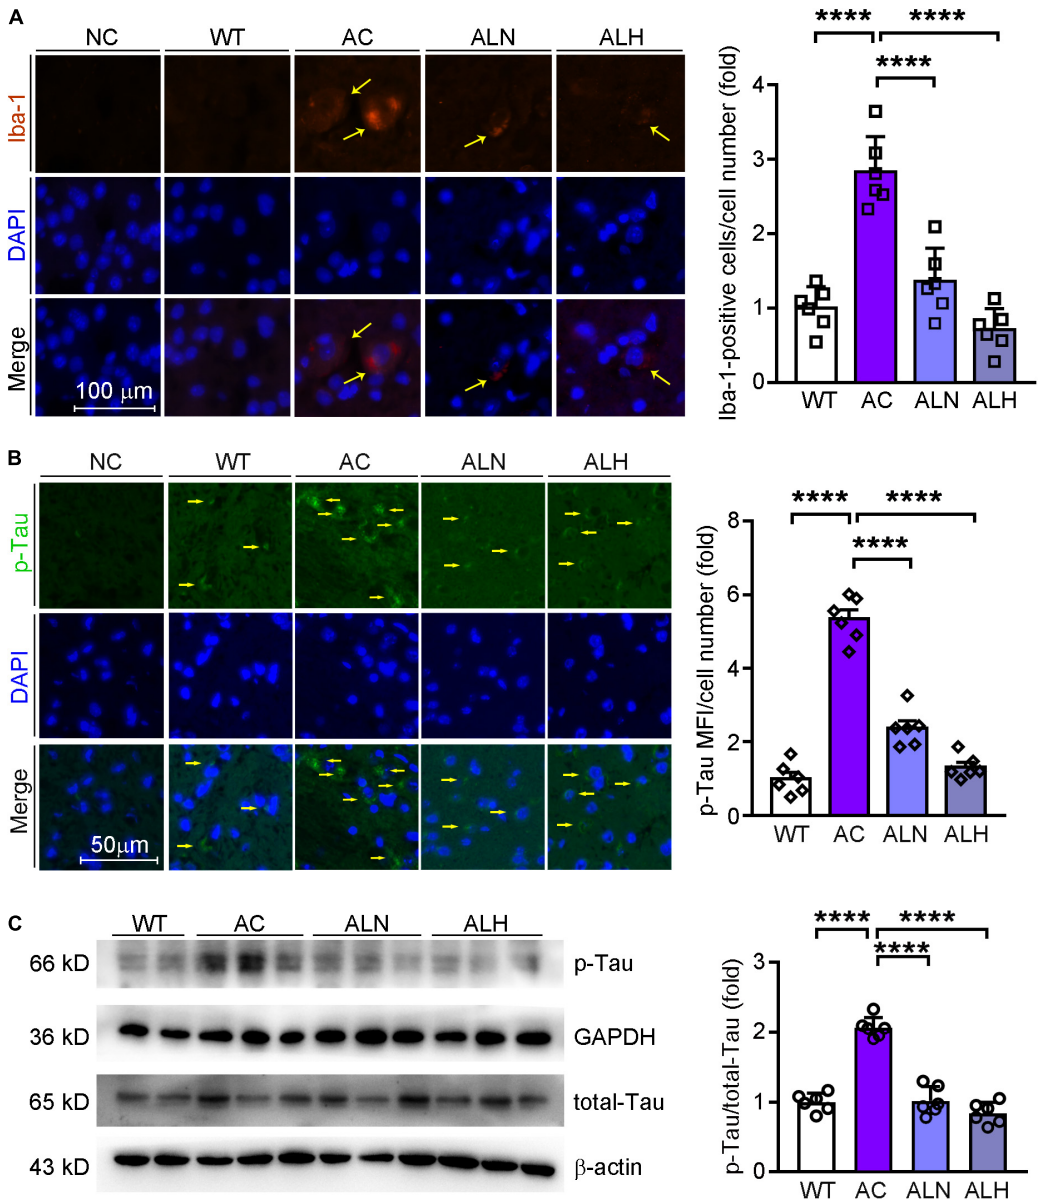

FIGURE 7 | LongShengZhi Capsule Inhibits Microglia Activation and Tau Phosphorylation in APP/PS1 Mouse Brain. Iba-1 (red, **A**) in mouse brain sections was determined by immunofluorescent staining with quantitation of Iba-1-positive cells/cell number, and phosphorylated Tau (p-Tau, green, **B**) in mouse brain sections was determined by immunofluorescent staining with quantitation of MFI/cell number. proteotoxicity by antioxidative stress (Ai et al., 2018). It has strong neuroprotective effects and cognitive preservation effects in intracerebroventricular streptozotocin-induced mice (Wang et al., 2018). Isoflavones, another high-content component in LSZ, have obvious neuroprotective effects (Wang et al., 2018). Isoflavones can attenuate oxidative stress and improve parameters related to AD-like pathology in D-galactose-treated C57BL/6J mice (Hsieh et al., 2009). These studies suggest that LSZ may protect against oxidative stress in AD through these active ingredients. We found LSZ significantly improved the damaged cognitive functions in 9-month-old APP/PS1 mice. Little has been reported thus far about the potential protective effects of LSZ on neurodegenerative diseases and its use as a prescribed medicine for treatment of cerebrovascular disease. However, many bioactive components in LSZ have been demonstrated to improve cognition. For example, paeoniflorin contained in LSZ can significantly improve the performance of aged wild-type rats in passive avoidance tasks (Baltina et al., 2019). Ferulic acid was reported to improve the escape latency of normal mice (Zafeer et al., 2019). These studies

imply that LSZ may protect normal cognition against the damages caused by AD.

Furthermore, we determined that LSZ significantly reduced ROS levels in HT-22 cells and enhanced expression of antioxidant factors, SOD1, SOD2, and GSH-PX, in the APP/PS1 mouse brain. These results suggest that the anti-AD-like pathology effect of LSZ is partly associated with antioxidative stress. The oxidative stress–promoted cell death mainly occurs through mitochondrial pathways, including the Bcl-2 family, FAS, and p53. Aβ can induce expression of apoptosis-related factors by activating the FAS/FASL pathway (Morishima et al., 2001). Aβ can also promote p53 stabilization, which leads to neuronal damage (Lapresa et al., 2019). As expected, in addition to the decline in oxidative stress, cell death was significantly reduced by LSZ treatment both *in vivo* and *in vitro*. We detected that LSZ largely enhanced expression of anti-apoptotic factors Bcl-2 and Bcl-xL while inhibiting expression of pro-apoptotic factors Bax and Bad. We also determined L-Glu-increased expression of FAS and p53 in HT-22 cells was significantly inhibited by LSZ, while the regulation of FAS and the Bcl-2 family by LSZ was blocked by FAS siRNA, indicating LSZ enhances neuron survival partly through the FAS/Bcl-2/p53 pathway. We do not know from the pretreatment mode *in vitro* how long LSZ can be given to continue to exert neuroprotective effects after the onset of neuron toxic. Further exploration is required.

Interestingly, *in vivo*, we noticed higher levels of Bcl-2, SOD, and GSH-PX expression in the brains of APP/PS1 mice treated with LSZ than in wild-type mice. As an anti-apoptotic protein, although the promotion of Bcl-2 has led us to consider an increase in the risk of cancer, its overexpression has been proven to resist Aβ-induced PC12 cell death (Song et al., 2004). Moreover, acting as barriers for cells and body against free radicals, the changes in antioxidant factors SOD and GSH-PX in AD were controversial (Markesbery, 1997). In our study, we observed increased Bcl-2 and antioxidant enzymes levels in LSZ-treated AD mice, even higher than untreated wild type levels. Whether such activation for the long term may cause detrimental effect or not remains unclear and warrants further investigation. However, clinical and basic studies have not reported any adverse events. In the future, the dose titration study should be completed to identify the optimal dose range of LSZ for AD treatment, which can demonstrate its therapeutic effects while keeping antioxidative stress and cell death under control.

Meanwhile, we observed accumulation of Aβ plaques and hyperphosphorylation of Tau were significantly increased in APP/PS1 mouse brains, while LSZ at different doses obviously reduced these two biomarkers. The reduction of Aβ plaques is associated with the inhibition of the amyloidogenic pathway. PSEN1, a subunit of γ-secretase, not only catalyzes the final γ-cleavage of APP but also mediates oxidative stress–induced expression of β-secretase. Thus, activation of PSEN1 results in excessive Aβ production/accumulation in the AD process (Cai et al., 2018). Our results show that PSEN1 expression in AD

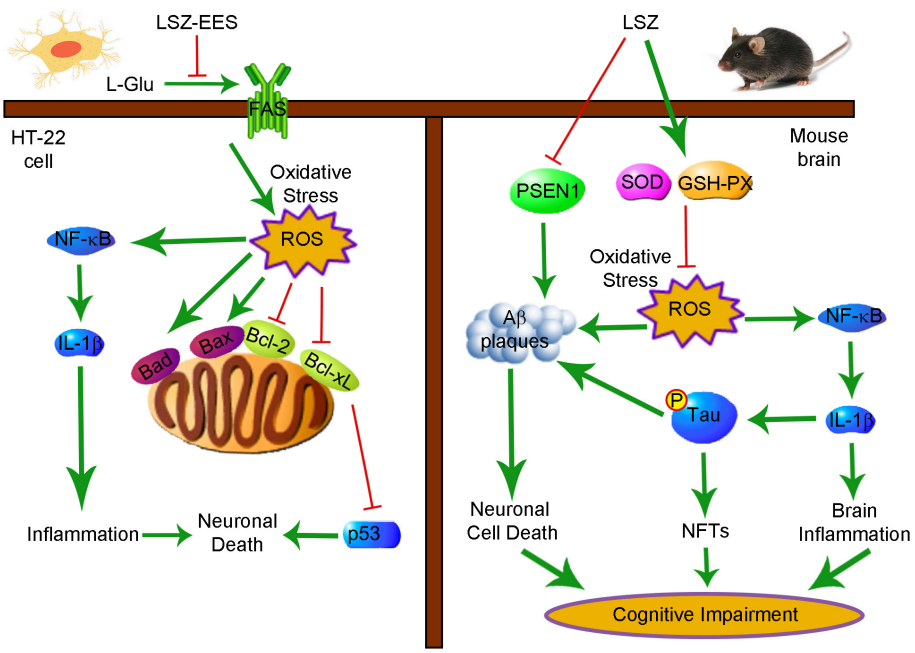

FIGURE 8 | Schematic Showing the Neuroprotection and Anti-AD-Like Pathology Properties of LSZ on HT-22 Cells and APP/PS1 Mice Are Associated with Reducing Oxidative Stress and Inflammation. Bcl-2, B-cell lymphoma 2; Bcl-xL, B-cell lymphoma-extra large; Bad, Bcl-2 associated agonist of cell death; Bax, Bcl-2 associated X protein; FAS, Fas cell surface death receptor; GSH-PX, glutathione peroxidase; IL-1β, interleukin-1β; LSZ, LongShengZhi capsule; LSZ-EES, LSZ ethanol extract solution; L-Glu, L-glutamic acid; NF-κB, nuclear factor kappa-B; NFTs, neurofibrillary tangles; ROS, reactive oxygen species; SOD, superoxide dismutase.

mice was upregulated compared with the WT group, which was reversed by LSZ treatment. In addition, LSZ reduced transcription of BACE1 and another two subunits of γ-secretase, APH1a and PEN2, suggesting that LSZ can inhibit β-secretase and γ-secretase function/expression to decrease Aβ processing. However, we need to determine the exact mechanism by which LSZ affects normal or mutated PSEN1 expression since these transgenic mice express both, which can be recognized by the antibody used in this study.

Expression of p-Tau, another critical biomarker for AD development, can be enhanced by the high level of glia inflammation in the brain, particularly by NF-κB (Barron et al., 2017). In this study, we observed the microglia was significantly activated in the brains of APP/PS1 mice, while LSZ markedly reduced the activation. In addition, increased NF-κB and IL-1β in both APP/PS1 mouse brains and HT-22 cells were substantially reduced by LSZ treatment, suggesting the anti-inflammatory effects of LSZ also play an important role in its functions of anti-AD-like pathology.

In summary, here we report that the protection of LSZ against AD-like pathology may be related to its antioxidant and anti-inflammation functions. Although our study was completed with the APP/PS1 double transgenic mouse model, LSZ inhibits Aβ aggregation and Tau hyperphosphorylation, the basis for AD development. Therefore, we speculate that LSZ may also offer protection against AD in other kinds of AD models with similar rationales, such as 5 × FAD, 3 × Tg mice, and aluminum-induced AD models, all of which have high levels of Aβ plaques, NFTs, and oxidative stress in the brain.

Despite some interesting findings we obtained in this study, there are a few limitations that should be improved in future studies. These limitations include the following: (1) the effect of LSZ on some molecule should be further confirmed by determination of protein expression since mRNA expression does not always mean protein expression; (2) the exact mechanisms of LSZ on AD-like pathology need be further investigated; only its association with oxidative stress/cell death in the brain were reported in this study; (3) the neuroprotective effects of LSZ *in vitro* were only completed in the pretreatment regime; the therapeutic effect of LSZ after AD onset remains to be explored; and (4) we should investigate whether LSZ can also function well with the AD mouse model induced by cholinergic antagonist injection since a different rationale is involved in this kind of model, and such study can further broaden the potential application of LSZ in AD treatment.

CONCLUSION

We demonstrated that LSZ can significantly improve cognitive functions of APP/PS1 mice. LSZ enhances neuron survival in HT-22 cells partly by regulating the FAS/Bcl-2/p53 pathway. LSZ can also decrease oxidative stress and reduce inflammatory cytokine expression *in vitro*. Pathologically, LSZ inhibits AD-induced accumulation of Aβ plaques, hyperphosphorylation of Tau, cell death, and NF-κB-mediated inflammation, and promotes antioxidative gene expression in the brains of APP/PS1 mice (**Figure 8**). Based on the finding that APP/PS1 mice can spontaneously develop AD pathology, our study clearly demonstrates the therapeutic properties of LSZ on AD and suggests its potential clinical application.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The animal study was reviewed and approved by the Institution Animal Ethics Committee of Hefei University of Technology.

AUTHOR CONTRIBUTIONS

JH and YD designed the study. ZY, XW, SHZ, PC, and YC performed the experiments. MY, CL, ZZ, and XY modified the file. SHZ and XY prepared the manuscript. All authors reviewed the results and approved the final version of the manuscript.

FUNDING

This work was supported by funding from the International Science & Technology Cooperation Programs of China 2017YFE0110100 to JH, YD, YC, and XY; NSFC grants 81973316 and 81773727 to JH; funding from the Key Research and Development Program of Anhui Province 201904a07020007 to JH; and Fundamental Research Funds for the Central Universities to YD, XY, and YC.

Hydrogen Sulfide Overproduction Is Involved in Acute Ischemic Cerebral Injury Under Hyperhomocysteinemia

Yan Ji, Yusheng Li*, Zichen Zhao, Panxing Li and Yi Xie*

Department of Neurology, The First Affiliated Hospital of Zhengzhou University, Zhengzhou, China

Objectives: This study aimed to identify the involvement of hydrogen sulfide overproduction in acute brain injury under ischemia/reperfusion and hyperhomocysteinemia.

Methods: *In vitro* and *in vivo* experiments were conducted to determine: the effect of sodium hydrosulfide treatment on the human neuroblastoma cell line (SH-SY5Y) under conditions of oxygen and glucose deprivation; the changes of hydrogen sulfide levels, inflammatory factors, energetic metabolism, and mitochondrial function in the brain tissue of rats under either ischemia/reperfusion alone or a combination of ischemia/reperfusion and hyperhomocysteinemia; and the potential mechanism underlying the relationship between homocysteine and these changes through the addition of the related inhibitors. Furthermore, experimental technologies, including western blot, enzyme-linked immunosorbent assay, immunofluorescence, reverse transcription polymerase chain reaction, and flow cytometry, were used.

Results: Our study found that high concentration of sodium hydrosulfide treatment aggravated the decrease in mitochondrial membrane potential, the increase in both mitochondrial permeability transition pore and translocation of cytochrome C, as well as the accumulation of reactive oxygen species in oxygen and glucose deprived SH-SY5Y cells. As a result, neurological deficit appeared in rats with ischemia/reperfusion or ischemia/reperfusion and hyperhomocysteinemia, and a higher water content and larger infarction size of cerebral tissue appeared in rats combined ischemia/reperfusion and hyperhomocysteinemia. Furthermore, alterations in hydrogen sulfide production, inflammatory factors, and mitochondria morphology and function were more evident under the combined ischemia/reperfusion and hyperhomocysteinemia. These changes were, however, alleviated by the addition of inhibitors for CBS, CSE, Hcy, H_2S, and NF-κB, although at different levels. Finally, we observed a negative relationship between the blockage of: (a) the nuclear factor kappa-B pathway and the levels of cystathionine β-synthase and hydrogen sulfide; and (b) the hydrogen sulfide pathway and the levels of inflammatory factors.

Conclusion: Hydrogen sulfide overproduction and reactive inflammatory response are involved in ischemic cerebral injury under hyperhomocysteinemia. Future studies in this direction are warranted to provide a scientific base for targeted medicine development.

Keywords: ischemia, homocysteine, hydrogen sulfide, inflammatory response, mitochondria

INTRODUCTION

Hydrogen sulfide (H_2S) is an established toxic gas that is characterized by an unpleasant odor of rotten eggs (Wang, 2012). Furthermore, physiological and pathological effects of H_2S as an endogenous signaling molecule have also been described (Fu et al., 2012; Zhang et al., 2015). Indeed, H_2S is identified as the third gaseous transmitter after nitric oxide (NO) and carbon monoxide (CO) (Wang, 2002). Endogenous H_2S is mainly synthesized from both cysteine (Cys) and homocysteine (Hcy), which are catalyzed by the cystathionine β-synthase (CBS) and cystathionine γ-lyase (CSE) enzymes. In fact, Hcy (i.e., an endogenous sulfur-containing amino acid and a metabolite of the essential amino acid methionine), is metabolized by two pathways, namely the methylation and transsulfuration pathways, and the latter is linked to endogenous H_2S formation.

H_2S plays several roles in mammals as a gaseous signal molecule. For example, the activity of the *N*-methyl-D-aspartate (NMDA) receptor, the induction of hippocampal long-term potentiation, the relaxation of vascular smooth muscles and the regulation of blood pressure have been reported to be associated with the physiological concentration of H_2S (Yang et al., 2008; Wang et al., 2015; Tu et al., 2016). Actually, the concentration of H_2S in the mammalian brain is challenging to measure and was reported to vary greatly in previous studies according to the assessment methods utilized (Ishigami et al., 2009; Levitt et al., 2011). In addition, a direct metabolic coupling between H_2S and oxygen (O2) has been described, i.e., while H_2S production is independent from O_2, its metabolism is O_2-dependent. Specifically, although the intracellular H_2S concentration is maintained at low levels through concomitant oxidation, it increases when its oxidation is outbalanced by its production during hypoxia. In fact, permanent occlusion of the middle cerebral artery (MCAO) was shown to increase the endogenous H_2S level in the ipsilateral cortex. This was especially valid for rat that received simultaneous intraperitoneal injection of Cys (Qu et al., 2006). Accumulated evidence also suggests a possible association between the concentration and the effects of H_2S. Specifically, high levels of H_2S are known to cause the generation of both reactive oxygen species (ROS) and reactive nitrogen species (RNS), whereas lower amounts react with hydrogen peroxides (H_2O_2), peroxynitrite ($ONOO^-$), and oxide ion (O^{2-}) (Mikami et al., 2011). In addition, some studies found H_2S to be involved in inflammatory responses (Bhatia, 2012). Specifically, biphasic effects of H_2S on inflammatory signals in murine lipopolysaccharide (LPS)-treated macrophages were reported (Whiteman et al., 2010). Therefore, future studies to better define this relationship are required given the contradictory findings in the literature, i.e., while the administration of sodium hydrosulfide (NaHS, an H_2S donor) significantly increases the infarct volume after MCAO in rats (Ishigami et al., 2009), beneficial effects of H_2S (e.g., decrease in I/R injury and localized inflammatory reaction) can also be observed (Huang et al., 2017). Indeed, the facticity and mechanism associated with the various H_2S effects remain to be defined and future studies should address these questions.

In a previous cohort study, we observed a prominent neurological deficit and poor prognosis in patients with both acute ischemic stroke and elevated levels of plasma Hcy (Ji et al., 2015). Given that these findings urged us to explore the possible pathological mechanism implicated, we performed the present study to observe the effects of different concentration of H_2S on SH-SY5Y cells under oxygen and glucose deprivation (OGD). Furthermore, the changes in H_2S levels, inflammatory factors, energetic metabolism, and cerebral mitochondrial function in rats under I/R alone or a combination of I/R and hyperhomocysteinemia (HHcy) were assessed. Finally, the possible pathologic association between H_2S levels and deteriorated ischemia/reperfusion (I/R) brain injury in patients with HHcy was discussed.

MATERIALS AND METHODS

The study was designed as two approaches: the *in vitro* and *in vivo* studies, and the related experimental process was demonstrated in **Figure 1**.

Antibodies and Reagents

L-methionine, Cys, DL–propargylglycine (PAG), aminooxyacetic acid (AOAA), NaHS, hydroxylamine (HA), *N*-anandamide, and pyrrolidine dithiocarboxylic acid ammonium salt (PDTC) were obtained from Sigma. In contrast, the anti-rabbit horseradish peroxidase (HRP)-conjugated secondary antibodies were purchased from Santa Cruz, whereas the anti-rabbit β-actin antibody and Cytochrome c oxidase IV (COXIV) were developed by Proteintech. In addition, the anti-mouse nuclear factor kappa-B (NF-κB) p65 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH), anti-rabbit histone H3 antibodies were purchased from Abcam, while the anti-rabbit cytochrome C, IkB-alpha (IκBa), P-IκBa and CBS antibodies were obtained from CST. Furthermore, while the primers were procured from Western Biotechnology, the JC-1 mitochondrial membrane potential (MMP), Fluo-3AM (calcium, Ca^{2+}), and ROS assay kits were purchased from BD Biotechnology. The enzyme-linked immunosorbent assay (ELISA) kits for interleukin (IL)-6, -1 and -8 were obtained from Like Beijing, whereas the assay kits for Cys, H_2S, adenosine triphosphate (ATP), and Hcy were acquired from Jiancheng Nanjing. Finally, while the kits for Nuclear and Cytoplasmic Protein Extraction and mitochondria isolation were purchased from Beyotime, those for the mitochondrial permeability transition pore (MPTP) were obtained from GENMED. All drugs were dissolved in saline and administered to rats through intraperitoneal injection.

Animals and Experimental Grouping

Total 135 Male Sprague-Dawley rats (230–260 g) from Chongqing Ensville Biotechnology Co., Ltd. were housed individually with the following conditions: natural light/dark (12/12 h) cycles, temperature of 22–24°C, either normal food or food with 1.7% methionine were provided, and water was available *ad libitum* for 4 weeks. All procedures were reviewed and approved by the Institutional Animal Care and Use

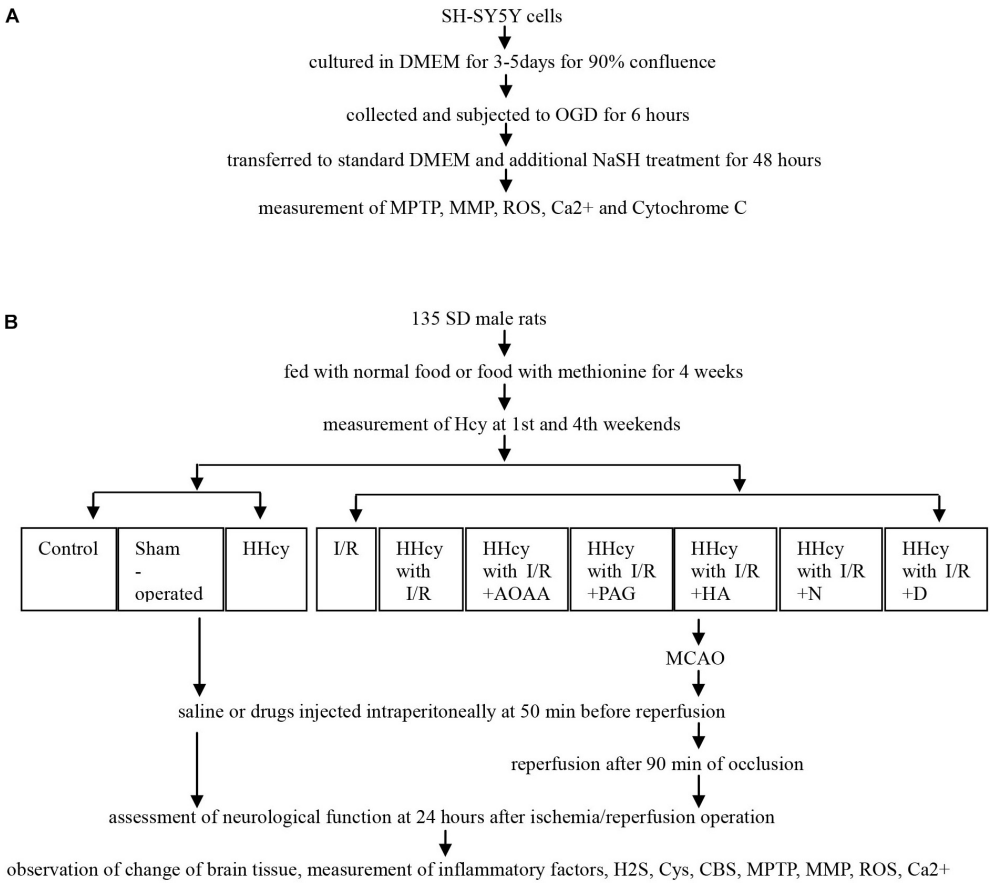

FIGURE 1 | Flowchart of experimental process. **(A)** SY5Y cells were cultured and subjected to OGD and different NaSH treatment, and then collected to measurement of MPTP, MMP, ROS, Ca^{2+} and Cytochorme C. **(B)** SD males fed using normal food or food with methionine were divided into ten groups, and received MCAO or not, saline or inhibitor injected intraperitoneally, and finally assessed for neurological function, morphological change and cytokines levels. *HHcy, hyperhomocysteinemia; I/R, ischemia/reperfusion; AOAA, aminooxyacetic acid; PAG, DL-propargylglycine; HA, hydroxylamine; N, N-anandamide; D, Pyrrolidine dithiocarboxylic acid ammonium salt.

Committee of the University of Zhengzhou, School of Medicine in accord with Animal Care and Use Program Guidelines of the National Institutes of Health. Rats were randomly assigned to the following groups in **Table 1**.

Cells Culture and Treatment

SH-SY5Y neuroblastoma cells were purchased from the Shanghai Cell Bank of the Chinese Academy of Sciences. Successively, they were cultured in high glucose Dulbecco's Modified Eagle Medium (DMEM), supplemented with 10% fetal bovine serum (FBS) and 1% of a penicillin-streptomycin stock, at 37°C in humidified air containing 5% carbon dioxide (CO_2). The serum- and glucose-free DMEM was bubbled with a mixture of 95% nitrogen (N_2) and 5% CO_2 for 30 min and an anaerobic acrylic jar was supplied with the same gas for 6 min. Thereafter, the cells were incubated in the DMEM and then were placed in the jar. The jar was sealed rapidly afterward and placed in an incubator at 37°C. Finally, following 6 h of OGD, the cells were transferred to standard culture conditions and subjected to either a 0, 100, 500, 1,000, or 1,500 μmol/L additional NaSH treatment for 48 h.

I/R Operation and Neurological Function Assessment

Transient brain ischemia was induced through MCAO, as previously described (Zan et al., 2014). In brief, rats were anesthetized with 7% chloral hydrate (0.5 ml/100 g), while their core temperature was maintained at 36.5–37.5°C through a temperature controller pad during the surgery. Following the separation of the right carotid artery from the surrounding tissue, a 3–0 monofilament nylon suture was advanced from the external into the internal carotid artery, until the origin of the middle cerebral artery was blocked. After 90 min of occlusion, the suture was withdrawn to restore blood flow, while either saline or drugs were injected intraperitoneally at 50 min before reperfusion. The wound was then sutured, and rats were allowed to recover from anesthesia before returning to their cages. While sham-operated rats underwent the same procedure, arterial occlusion was not conducted. Animals that died prematurely were excluded from the study. The Zea Longa scale was used for independently evaluating the neurological deficit of rats at 24 h after the operation by two researchers.

TABLE 1 | The detailed data of experiment groups of SDA rats.

Group	*n*	Food	Operation	Treatment
C (control group)	10	Normal	No	Saline (1 ml/kg)
S (sham-operated group)	10	Normal	Sham-operated	Saline (1 ml/kg)
I/R (ischemia/reperfusion group)	15	Normal	I/R operation	Saline (1 ml/kg)
H (HHcy group)	10	Methionine	No	Saline (1 ml/kg)
HI/R (HHcy with I/R)	15	Methionine	I/R operation	Saline (1 ml/kg)
A (HI/R + AOAA group)	15	Methionine	I/R operation	AOAA (1 ml/kg, 10 mg/1 ml)
P (HI/R + PAG group)	15	Methionine	I/R operation	PAG (1 ml/kg, 45 mg/1 ml)
O (HI/R + HA group)	15	Methionine	I/R operation	HA (1 ml/kg, 12.5 mg/1 ml)
N (HI/R + *N*-anandamide group)	15	Methionine	I/R operation	*N*-anandamide (1 ml/kg, 0.2 mg/1 ml)
D (HI/R + PDTC group)	15	Methionine	I/R operation	PDTC (1 ml/kg, 150 mg/1 ml)

Measurement of Water Content and Infarct Size of Brain Tissue

Rats were decapitated and the whole brain tissue was obtained 24 h after operation. Thereafter, the cerebral tissue was isolated from the olfactory bulb, cerebellum and brainstem, and weighed by an electronic analytical balance (i.e., wet weight). Successively, brain tissues were dried at 65°C for 36–72 h to a constant quality (i.e., the difference between two weighings is less than 1%) in an oven and weighed again (i.e., dry weight). Finally, the brain water content was calculated as the ratio of wet over dry weight.

Similarly, after obtaining the cerebral tissue, coronal sections (2 mm) were prepared. Briefly, they were stored for 5 min in a freezer at −80°C and were then stained with a 1% 2,3,5-triphenyltetrazolium chloride (TTC) solution at 37°C for 15 min. Thereafter, they were fixed using 4% formaldehyde for 24 h and photographed with a digital camera. While the infarct size was traced and quantified with the ImageJ software (National Institutes of Health, Bethesda, MD, United States), it was expressed as a percentage of the bilateral hemisphere.

Transmission Electron Microscope (TEM) Observation for Mitochondrial Morphology

Cerebral tissues were fixed using 2.5% glutaraldehyde for 24 h and then sliced into fragments of 1 mm^3 in size. Subsequently, they were fixed, dehydrated, embedded, cut into 1 μm-thick slices and further dried. Thereafter, they were sliced into ultraslices of 50 nm and finally stained with both uranyl acetate and lead citra to observe the changes in mitochondrial morphology using a transmission electron microscope (TEM) (PHILIPS Tecani-10).

Western Blot for Cytochrome C, IκBa, p-IκBa, NF-κB, and CBS Protein Levels

SH-SY5Y cells were cultured as abovementioned, and then were collected and washed in an ice-cold phosphate buffer saline (PBS). Cell mitochondria were isolated according to the manufacturer's protocol on the mitochondria isolation Kit for measuring cytochrome C protein level in both the mitochondria and cytoplasm separately.

Brain tissues were cut into tiny fragments and put into the homogenate tube, together with 1 ml of RIPA per 100 mg of tissue. The tissues were then homogenized for 20 times and transferred into a centrifuge tube (1.5 ml). Thereafter, the supernatant was collected after a 10 min-long centrifugation (12,000 rpm) at 4°C. To measure the NF-κB protein level, nuclear and cytoplasmic proteins were separately extracted, according to the manufacturer's protocol on the Nuclear and Cytoplasmic Protein Extraction Kit.

Protein concentration was measured using the Bradford assay. Briefly, equal amounts of protein (30 μg) per lane were separated through a 12% sodium dodecyl sulfate–polyacrylamide gel electrophoresis and then transferred onto polyvinylidene difluoride membranes. Thereafter, membranes were incubated with the rabbit anti-cytochrome C (1:2000), rabbit anti-IκBa (1:500), rabbit anti-p-IκBa (1:500), rabbit anti- NF-κB (1:500), rabbit anti-CBS (1:500), goat anti-GAPDH (1:1000), mouse anti-histone H3 (1:1000), rabbit anti-COXIV (1:1000) and rabbit anti-β-actin (1:2000) antibodies at 4°C overnight. This was followed by incubation with secondary antibodies for 2 h at room temperature. Finally, blots were scanned with a light/ultraviolet gel scanning system (Tannon-4200, China) and quantified with an analytic soft system (Labworks^{TM} Analysis Software, United States). Protein levels were normalized to GAPDH, β-actin, COXIV and histone H3.

Measurement of Hcy, IL-1,-6, -8, H_2S, Cys, and ATP Levels in Brain Tissue

Both a plasma sample from the angular vein and a cerebrospinal fluid sample were obtained from rats that received either normal food or food with methionine after 12 h of fasting at the 1st and the 4th weekends. While a capillary tube was rotated into rats' angular vein to obtain the blood samples, cerebrospinal fluid samples were drained from the foramen magnum (exposed through an operation) after rats were anesthetized. The Hcy levels were measured using Hcy assay kits, according to the manufacturer's instructions.

Brain tissue samples were kept in liquid nitrogen, thawed and then added to PBS in a 1:9 ratio. Thereafter, samples were homogenized and centrifuged at 2,000 rpm for 20 min. The

supernatant was then carefully collected and the IL-1, -6, and -8 levels were determined using ELISA analysis kits. Tissues were homogenized as mentioned above. To measure H_2S levels, samples were centrifuged (12,000 rpm) at 4°C for 10 min and the supernatant was collected. Thereafter, levels of H_2S were determined using the H_2S assay kit. In contrast, samples were centrifuged (8,000 rpm) at 4°C for 10 min to assess Cys levels. Subsequently, the supernatant was collected and Cys levels were determined using the Cys Assay Kit. Finally, ATP levels were measured. Samples were boiled in water for 10 min, they were then mixed and extracted for 1 min. This was followed by centrifugation at 3,500 rpm for 10 min and collection of the supernatant. ATP levels were assessed using the ATP Assay Kit (Colorimetric). All procedures followed the manufacturer's instructions on the reagent kits.

Real-Time Polymerase Chain Reaction (RT-PCR) for CBS mRNA

Brain tissues were cut into tiny fragments and mixed with 1 ml of TRIzol reagent (Beyotime) per 100 mg of tissue. They were then homogenized, dissolved and centrifuged (12,000 rpm) at 4°C for 10 min. Thereafter, the supernatant was collected and added to 0.2 ml of chloroform (Shanghai Chemical Reagent Company). Subsequently, the suspension was centrifuged at 10,000 rpm at 4°C for 10 min and the supernatant was then discarded, and the RNA pellet was washed in 75% ethanol and re-suspended in RNAase-free water. The RNA quantity and integrity were verified by agarose gel electrophoresis. In addition, RNA to cDNA reverse transcription was performed on 1 μg of total RNAs using the iScript Reverse Transcription reagent (Western Biotechnology). Successively, quantitative PCR was performed using the Funglyn Biotech Real Time PCR System (Funglyn Biotech, Canada). To determine the cycle threshold (CT) values for CBS and β-actin, SYBR green PCR reagents (Western Biotechnology) were used. Thereafter, a 35× amplification was performed for 4 min, 20 and 30 s at 94, 94, and 72°C, respectively. β-actin was used as an internal control to normalize mRNA abundance. The sequence of oligonucleotides used for RT-PCR was the following: (a) CBS, sense: CCCACCAACGCCAGATTC and antisense: TGCGGTGTCATCGTAGTGC; and (b) β-actin, sense: CCCATCTATGAGGGTTACGC and antisense: TTTAATGTCACGCACGATTTC. During PCR amplification, the amplified products were continuously measured through the determination of their fluorescence emission. All the gene expression data relative to the PCRs were analyzed using the $2^{-\Delta\Delta Ct}$ method and normalized to the β-actin RNA.

Assessment of MPTP, ROS, Ca^{2+} and MMP Levels

SH-SY5Y cells were cultured and treated as mentioned above, washed with cleaning solution, then added 500 μl of dying working solution and incubated for 20 min at 37°C according to the protocol on the MPTP assay kit. Finally, cells were observed using an inverted fluorescence microscope (BM, China).

Rats were decapitated and whole brain tissues were obtained 24 h after I/R operation. Following a PBS wash, a blot of cerebral tissue (100 mg) was cut into tiny fragments and mitochondria were obtained using the Tissue Mitochondria Isolation Kit, according to the manufacturer's protocol. Thereafter, mitochondria were washed with PBS (twice) and centrifuged at 1,500 rpm at 4°C for 5 min. After collecting the supernatant, 200 μl of dying working solution was added and mitochondria were incubated for 30 min at 37°C. Subsequently, they were again washed with PBS (twice) and re-suspended for measuring the mitochondrial permeability transition pore (MPTP) by flow cytometry (CytoFlex, United States).

SH-SY5Y cells and brain tissues were prepared as mentioned above. The cell suspension solution was poured into a centrifuge tube (1.5 ml) and centrifuged (1,500 rpm) at 4°C for 5 min. After collecting the supernatant, the solution was re-suspended in PBS and incubated with a fluorescent probe of DCFH-DA, according to the manufacturer's protocol on the ROS Assay Kit. Finally, the solution was measured using flow cytometry (BD, United States) to determine the ROS levels.

Similarly, the cell suspension solution were incubated with a fluorescent probe, Fluo-3, according to the manufacturer's protocol on the Fluo-3 AM kit, and measured using flow cytometry (BD, United States) to determine the Ca^{2+} levels.

Furthermore, cell suspension was prepared as previously mentioned, then incubated with the JC-1 working solution, washed with the JC-1 staining buffer and resuspended in the JC-1 staining buffer, according to the manufacturer's protocol on the JC-1 MMP Assay Kit. Finally, cells suspension was measured using flow cytometry (BD, United States) to determine the MMP levels.

Statistical Analysis

All experiments were independently performed in triplicates. Data were summarized by means and standard errors (standard error of the mean; SEM). A one-way ANOVA test, followed by Bonferroni *post hoc* testing, was used to compare groups of three or more. Independent *t*-tests were used for two-group comparisons. *P*-values less than 0.05 were considered statistically significant. All statistical analyses were conducted using SPSS 17.0 (SPSS Inc.).

RESULTS

Changes in SH-SY5Y Cells Under the OGD and NaSH Treatment

In vitro part, SH-SY5Y cells simultaneously were subjected to OGD and different concentrations of NaSH treatment. Next, they were collected for assessment of the related protein level, changes in mitochondria and energy metabolism.

Statistical analyses showed significant difference of MMP levels in SH-SY5Y cells among experimental groups [$F(4,10) = 581.68$, $P < 0.000$]. *Post hoc* testing showed obviously decreased MMP levels in cells subjected to OGD and 1,500 μM of NaSH as opposed to cells treated with OGD alone ($P < 0.01$) (**Figure 2A**).

Significant difference of Ca^{2+} levels existed among experimental groups [$F(4,10) = 30.370$, $P < 0.000$]. Compare to

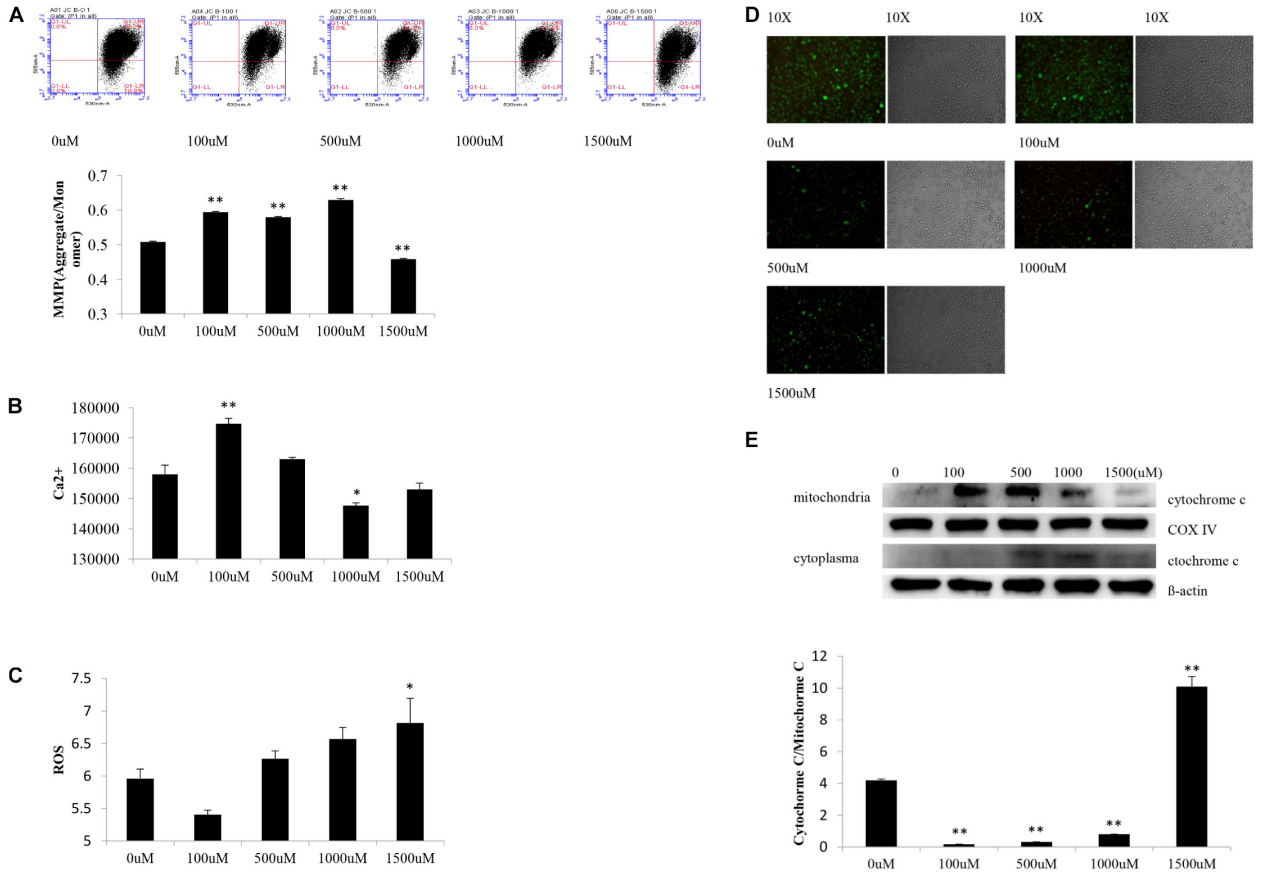

FIGURE 2 | Changes of SY5Y cells subjected to OGD and different concentration NaSH treatment. **(A)** Compared to OGD group, increased MMP levels appeared in cells subjected to OGD and 100, 500, and 1,000 μM NaSH treatment, and decreased MMP levels appeared in cells subjected to 1,500 μM treatment ($n = 3$, $P < 0.01$). **(B)** Compared to OGD group, increased Ca^{2+} levels appeared in OGD and 100 μM of NaSH treatment group ($P < 0.01$) while decreased Ca^{2+} levels appeared in OGD and 1,000 μM of NaSH treated ones ($n = 3$, $P < 0.05$). **(C)** Increased ROS levels appeared in cells subjected to OGD and 1,500 μM treatment compared to OGD group ($n = 3$, $P < 0.05$). **(D)** Compared to OGD group, immunofluorescence showed similar green fluorescence in cells subjected to OGD and 100 μM NaSH treatment, while lower green fluorescence in cells subjected to OGD and 500, 1,000, and 1,500 μM NaSH treatment. **(E)** Compared to OGD group, increased cytochrome C release appeared in cells subjected to OGD and 1,500 μM treatment but decreased in cells subjected to OGD and 100, 500, and 1,000 μM treatment as well ($n = 3$, $P < 0.01$). $^{**}P < 0.01$, $^{*}P < 0.05$, analyzed by one-way ANOVA and Bonferroni *post hoc* test.

cells subjected to OGD alone, increased Ca^{2+} levels appeared in OGD and 100 μM of NaSH treated cells ($P < 0.01$) while decreased Ca^{2+} levels appeared in OGD and 1,000 μM of NaSH treated ones ($P < 0.05$) (**Figure 2B**).

There were significant difference of ROS levels among experimental groups [$F(4,10) = 6.841$, $P < 0.01$]. As opposed to cells subjected to OGD alone, ROS levels increased in cells treated with both OGD and 1,500 μM of NaSH ($P < 0.05$) (**Figure 2C**).

Different appearance of green fluorescence existed among experimental groups. Compared to cells subjected to OGD alone, cells treated with OGD and 500, 1,000, or 1,500 μM of NaSH showed lower green fluorescence (higher MPTP level) while cells treated with OGD and 100 μM of NaSH showed similar green fluorescence (similar MPTP level) (**Figure 2D**).

There were significant difference of cytochrome C release in SH-SY5Y cells among experimental groups [$F(4,10) = 9.238$, $P < 0.01$]. Compared to cells treated with OGD alone, increased translocation of cytochrome C existed in cells subjected to OGD and 1,500 μM of NaSH ($P < 0.01$) but decreased translocation of cytochrome C in OGD and 100, 5,00, and 1,000 μM of NaSH treated cells ($P < 0.01$) (**Figure 2E**).

Neurological Function Change of Experimental Rats

Total 10 groups of rats were included in the *in vivo* part. Specifically, 105 rats were divided into 7 groups and all received I/R operation. Of these, 8 were excluded from our analysis due to a failure of I/R operation. Additional 10 rats were recruited for each of the other 3 groups. Only one group (i.e., 10 rats) received the sham-operation, and all rats survived. As a result, a total of 127 rats were considered for analysis.

The assessment of rats' neurological function according to Zea Longa scores was performed by 2 independent investigators 24 h after I/R operation. Zea Longa scores were identified under 5-scores grades. The detail was as following: zero point

means no neurological impairment, one point means a failure of complete stretch of leg, two points means leg bucking, three points means turning to one side slightly in walking, four points means turning to one side severely in walking, five points means falling to one side in walking. Statistical analyses showed significant difference of Zea Longa scores among experimental groups [$F(9,90) = 46.150$, $P < 0.000$], and *post hoc* testing showed significantly higher scores in both the I/R and HI/R groups compared to all other groups ($P < 0.01$), and decreased by all inhibitors ($P < 0.01$) (**Figure 3A**).

Comparison of Brain Water Content and Infarct Size in Experimental Rats

Significant difference of brain water content existed among experimental groups [$F(9,20) = 20.794$, $P < 0.000$], and *post hoc* testing showed a significantly higher water content in the I/R group and HI/R group compared to the C group, especially in the latter ($P < 0.01$). Furthermore, the water content decreased significantly in the A, P, O, and D groups, as opposed to the HI/R group ($P < 0.05$ or 0.01) (**Figure 3B**). TTC staining showed cerebral infarctions in rats that received I/R operation. Statistical analyses showed significant difference of infarction size among experimental groups [$F(6,14) = 358.431$, $P < 0.000$], and *post hoc* testing showed the first and second largest infarction size of cerebrum tissue in the HI/R and I/R groups, respectively ($P < 0.01$), whereas the A, P, O, N, and D groups was obviously lower ($P < 0.01$) (**Figure 3C**).

Changes in Mitochondrial Morphology of Brain Tissue

Transmission electron microscope were used to observe changes in mitochondrial morphology. As a result, the C and S groups presented a clear myelin sheath and nuclear membrane, as well as abundant round or oval mitochondria with clear crista in the cytoplasm of the cerebral tissue. In contrast, a partly impaired myelin sheath and irregular nuclear membrane were observed in the H group, even though the mitochondria remained unchanged. The morphological change was most evident in the HI/R group, which demonstrated severe edema, vague crista, partial vacuolization, a destroyed myelin sheath, the disappearance of the nuclear membrane and a decrease in organelles. Similar changes, even though to a lesser extent, were also seen in the I/R group. Finally, fewer changes were observed in the A, P, O, N, and D groups (**Figure 4**).

Change of Inflammatory Factors in Experimental Rats

Statistical analyses showed significant difference of IκBα levels among experimental groups [$F(9,20) = 134.199$, $P < 0.000$], and *post hoc* testing demonstrated significantly decreased IκBα levels in all other groups, compared to the C group ($P < 0.05$ or 0.01). Specifically, the first and second lowest IκBα levels were observed in the HI/R and I/R groups, respectively, and increased by all inhibitors ($P < 0.05$ or 0.01) (**Figure 5A**). With regards to the p-IκBα levels, significant difference existed among experimental groups [$F(9,20) = 113.955$, $P < 0.000$], and *post hoc* testing showed the first and second highest levels in the HI/R and I/R groups, respectively ($P < 0.01$). Significant decrease appeared in all inhibitor groups compared to the HI/R group, but only appeared in A, P, O, and D groups as opposed to the I/R group ($P < 0.05$ or 0.01) (**Figure 5B**). The western blot bands of IκBα and p-IκBα are displayed in **Figure 5C**. There were significant

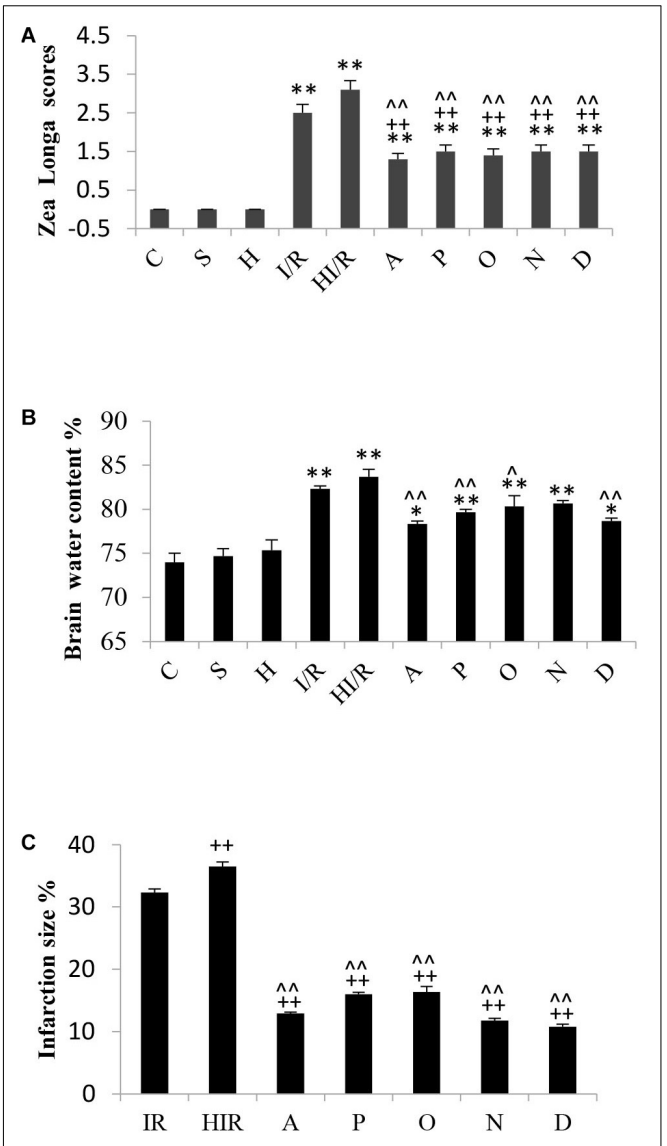

FIGURE 3 | Changes of brain tissue and neurological function in rats 24 h after I/R or not. **(A)** A significant increase of Zea Longa scores appeared in I/R and HI/R groups compared to control groups, especially in the latter, and decreased by all inhibitors ($n = 10$, $P < 0.01$). **(B)** The water content of brain tissue increased evidently in I/R and HI/R groups compared to control groups ($P < 0.01$), and decreased in A, P, O, and D groups when compared to HI/R group ($n = 3$, $P < 0.05$ or 0.01). **(C)** The infarction size of cerebrum tissue in HI/R or I/R group was the first and second largest, separately, and decreased by all inhibitors ($n = 3$, $P < 0.01$). ** or * means $P < 0.01$ or 0.05 versus control, $^{++}$or $^{+}$ means $P < 0.01$ or 0.05 versus I/R group, and ^^ or ^ means $P < 0.01$ or 0.05 versus HI/R group, analyzed by one-way ANOVA and Bonferroni *post hoc* test.

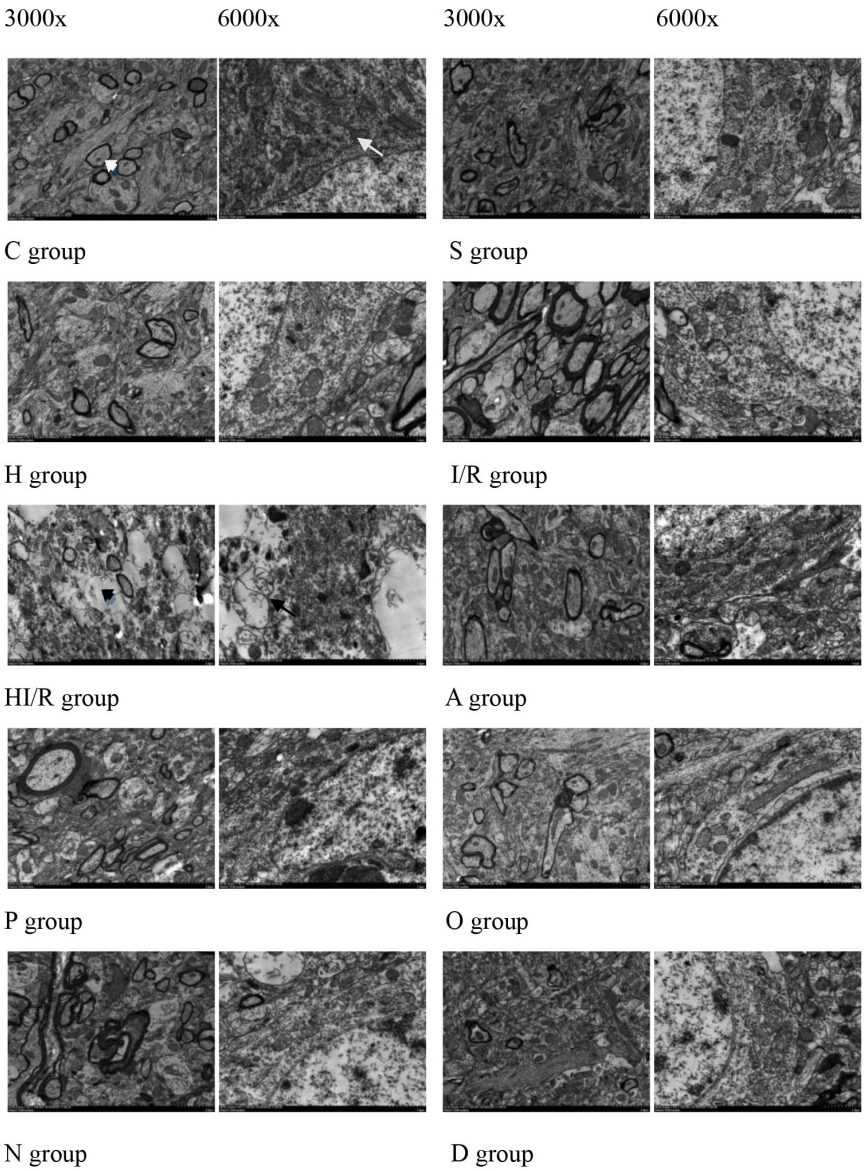

FIGURE 4 | Morphology of cell, myelin sheath, nuclear membrane and mitochondria of brain tissue of the rats 24 h after I/R or not. Abundant round or oval mitochondrial (arrowheads) and clear crista (arrows), myelin sheath and nuclear membrane appeared in the rats of control (C) and sham operated groups (S). Partly impairment of myelin sheath and irregularity of nuclear membrane appeared in H group (H). Myelin sheath destroyed, nuclear membrane disappeared (black arrows), and organelle (black arrowheads) decreased in the rats received I/R, especially I/R combined with HHcy (HI/R). Evident impaired but lesser morphological change in inhibitor groups (A, P, O, N, and D).

difference of NF-κB translocation among experimental groups [$F(9,20) = 1040.637$, $P < 0.000$], and *post hoc* testing showed higher translocation in the I/R and HI/R groups ($P < 0.01$), and decreased by all inhibitors ($P < 0.01$) (**Figure 5D**). The blot bands of NF-κB are demonstrated in **Figure 5D**. Finally, significant difference of the IL-1, IL-6, and IL-8 levels existed among experimental groups [$F(9,20) = 16900.86$, 17695.045, and 336.312, respectively, $P < 0.000$], and *post hoc* testing showed significant increase in the IL-1, IL-6, and IL-8 levels in all groups compared to C group ($P < 0.000$). The highest level was observed in the HI/R group, which was closely followed by the I/R group ($P < 0.000$), and evidently decreased in A, P, O, and D groups ($P < 0.01$) (**Figure 5E**).

Change of Hcy and H_2S Pathway in Experimental Rats

Significant difference of Hcy levels in plasma and cerebrospinal fluid existed among experimental groups [$F(3,16) = 527.566$ and 1563.3, respectively, $P < 0.000$], and *post hoc* testing showed significantly higher Hcy levels in the rats received food with methionine than those fed with normal food ($P < 0.01$)

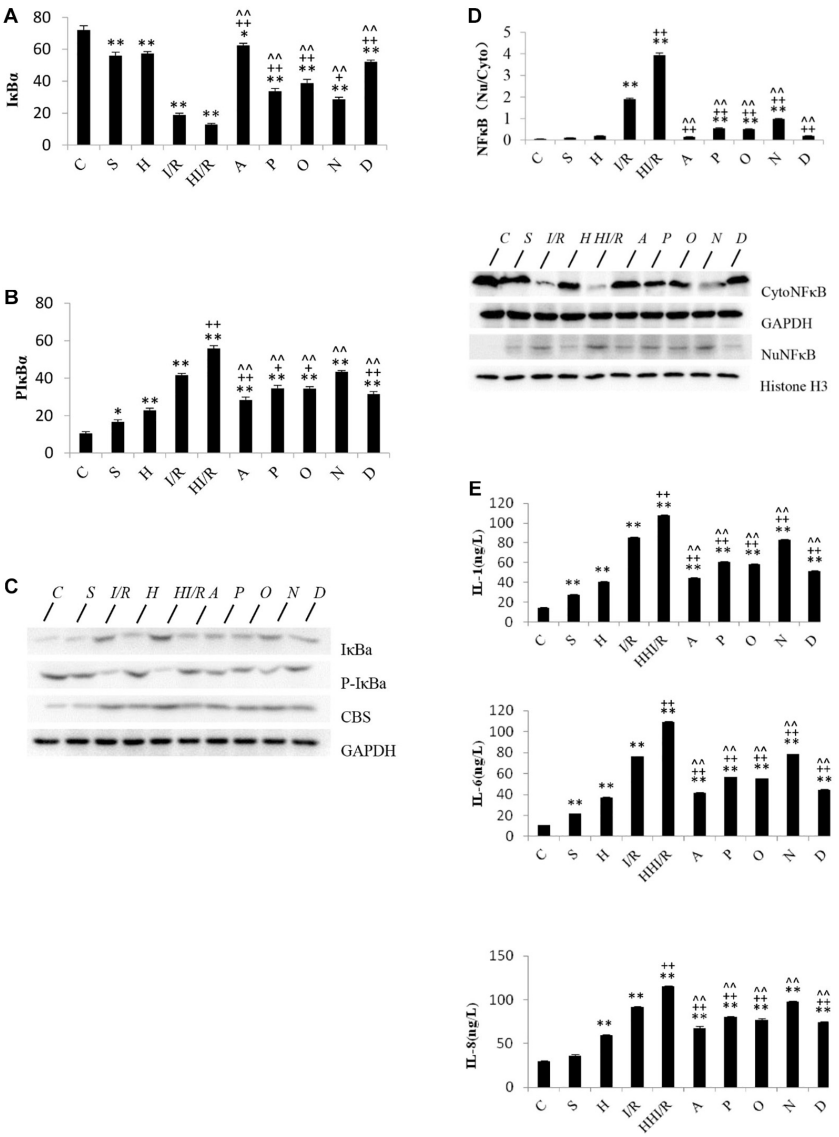

FIGURE 5 | Changes of IκBα, p-IκBα, and NFκB translocation, IL-1, IL-6, and IL-8 levels in cerebrum tissue in rats 24 h after I/R or not. **(A)** IκBα levels decreased significantly in all other groups, compared to the C group ($P < 0.05$ or 0.01). The first and second lowest IκBα levels appeared in the HI/R and I/R groups, respectively ($P < 0.01$), and increased by all inhibitors ($n = 3$, $P < 0.05$ or 0.01). **(B)** The first and second lowest P-IκBα levels appeared in the HI/R and I/R groups, respectively ($P < 0.01$). Significant decrease of p-IκBα levels appeared in all inhibitor groups than in the HI/R group, but appeared in A, P, O, and D groups when compared to the I/R group ($n = 3$, $P < 0.05$ or 0.01). **(C)** The blot band demonstrated changes of IκBα, p-IκBα, and CBS protein levels in each group. GAPDH was used as normalized protein. **(D)** Translocation of NFκB levels into nuclear evidently increased in I/R and HI/R groups compared to control group, and decreased by all inhibitors ($n = 3$, $P < 0.01$). The blot band showed changes of Cyto NFκB and Nu NFκB protein levels in each group. GAPDH and Histone H3 were used as normalized protein, separately. **(E)** The IL-1, IL-6, and IL-8 levels in I/R and HI/R groups significantly increased compared to control groups, especially in the latter, and evidently decreased in A, P, O, and D groups than that in HI/R group and I/R group ($n = 3$, $P < 0.01$). ** or * means $P < 0.01$ or 0.05 versus control, $^{++}$or $^{+}$ means $P < 0.01$ or 0.05 versus I/R group, and ^^ or ^ means $P < 0.01$ or 0.05 versus HI/R group, analyzed by one-way ANOVA and Bonferroni *post hoc* test.

(**Figure 6A**). As far as Cys levels, significant difference existed among experimental groups [$F(9,20) = 1017.961$, $P < 0.000$], and *post hoc* testing showed the lowest concentration in the C group, whereas the HI/R, I/R and H groups had the top three highest levels, respectively ($P < 0.000$). Compared to HI/R group and I/R group, Cys levels evidently decreased in all inhibitor groups ($P < 0.01$) (**Figure 6B**). There were significant difference of CBS levels among experimental groups [$F(9,20) = 183.349$, $P < 0.000$], and *post hoc* testing showed CBS levels in I/R and HI/R groups significantly increased compared to the control group, especially in the latter ($P < 0.01$), and evidently decreased in all inhibitors than in HI/R group but only in A, P, O, and D groups as opposed to I/R group ($P < 0.05$ or 0.01) (**Figure 6C**). Significant difference of CBS mRNA levels existed among experimental groups [$F(9,20) = 32.116$, $P < 0.000$], and *post hoc* testing demonstrated higher CBS mRNA levels appeared in I/R and HI/R

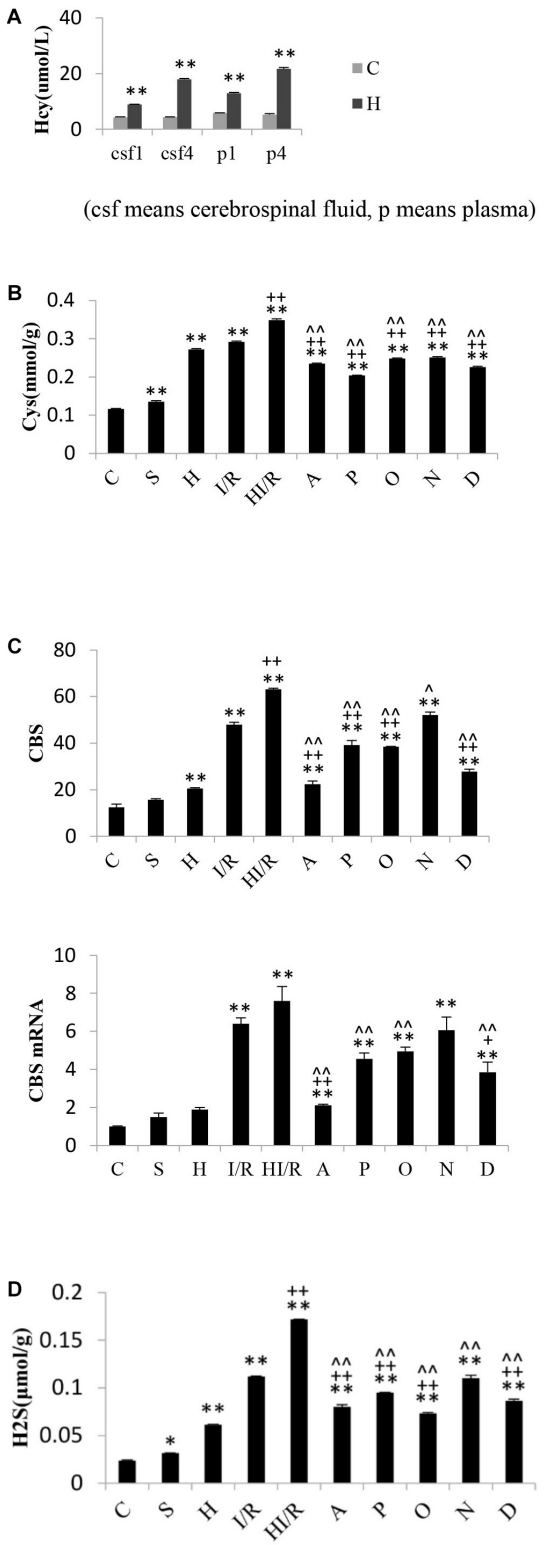

FIGURE 6 | Changes of Hcy levels in rats fed for one and 4 weeks, and Cys, CBS, and H_2S levels in rats 24 h after I/R or not. **(A)** Hcy levels in plasma and cerebrospinal fluid of rats received normal food or food added methionine for 1 week or 4 weeks. A higher Hcy level appeared in H group than that in C group ($n = 5$, $P < 0.01$). **(B)** Cys levels in I/R and HI/R groups significantly increased compared to C group, especially in the latter ($P < 0.01$), and evidently decreased in A, P, O, N, and D groups than that in HI/R group and I/R group ($n = 3$, $P < 0.01$). **(C)** CBS levels in I/R and HI/R groups significantly increased compared to control groups, especially in the latter ($P < 0.01$), and evidently decreased in A, P, O, and D groups than that in HI/R group and I/R group ($n = 3$, $P < 0.01$). CBS mRNA levels in I/R and HI/R groups significantly increased compared to control groups, especially in the latter ($P < 0.01$), and evidently decreased in A and D groups than that in HI/R group and I/R group ($n = 3$, $P < 0.01$). **(D)** H_2S levels in I/R and HI/R groups significantly increased compared to control groups, especially in the latter, and evidently decreased in A, P, O, and D groups than that in HI/R group and I/R group ($n = 3$, $P < 0.01$). ** or * means $P < 0.01$ or 0.05 versus control, $^{++}$or $^{+}$ means $P < 0.01$ or 0.05 versus I/R group, and ^^or ^ means $P < 0.01$ or 0.05 versus HI/R group, analyzed by one-way ANOVA and Bonferroni *post hoc* test.

groups compared to the control group, especially in the latter ($P < 0.01$), and decreased in A, P, O, and D groups compared to HI/R group but only in A and D groups as opposed to I/R group (**Figure 6C**). The blot band of CBS is listed in **Figure 5C**. Similarly, significant difference of H_2S levels existed among experimental groups [$F(9,20) = 919.121$, $P < 0.000$], and *post hoc* testing showed the first and second highest concentrations in the HI/R and I/R groups, and evidently decreased by all inhibitors than in HI/R group but only in A, P, O, and D groups compared to I/R group ($P < 0.01$) (**Figure 6D**).

Change of Mitochondria Function, ROS and Ca^{2+} Levels in Experimental Rats

Through flow cytometry, the decrease in Calcei-AM, the main component of the MPTP assay kit (i.e., a strong fluorescent agent), means the increase in MPTP can be assessed. As a result, significant difference of concentration of Calcei-AM existed among experimental groups [$F(9,20) = 36.066$, $P < 0.000$], and *post hoc* testing showed evidently lower concentration in the I/R and HI/R groups compared to the control group, and increased concentration in A, P, O, and D groups than in I/R group but only in P, O, and D groups compared to HI/R group ($P < 0.05$ or 0.01) (**Figure 7A**). As far as MMP levels, significant difference existed among experimental groups [$F(9,20) = 4488.385$, $P < 0.000$], and *post hoc* testing showed lower levels in I/R and HI/R groups compared to control groups, especially in the latter, and evidently increased in inhibitors groups than in HI/R group but in A, P, O, and D groups as opposed to I/R group ($P < 0.01$) (**Figure 7B**). Similar change of ATP levels existed among experimental groups [$F(9,20) = 123.192$, $P < 0.000$], and *post hoc* testing showed decreased levels in HI/R group and I/R group ($P < 0.01$) (**Figure 7C**). Significant difference of ROS levels existed among experimental groups [$F(9,20) = 13.75$, $P < 0.000$], and *post hoc* testing showed higher levels in the I/R and HI/R groups than in the C group ($P < 0.01$), and decreased in the A group compared to HI/R group ($P = 0.05$) (**Figure 7D**). With regards to the Ca^{2+} level, significant difference existed among experimental groups [$F(9,20) = 164.582$, $P < 0.000$], and *post hoc* testing found highest level in the HI/R group ($P < 0.01$), followed by the I/R group ($P < 0.01$), and evidently decreased in all inhibitor groups compared to HI/R group and I/R group ($P < 0.01$) (**Figure 7E**).

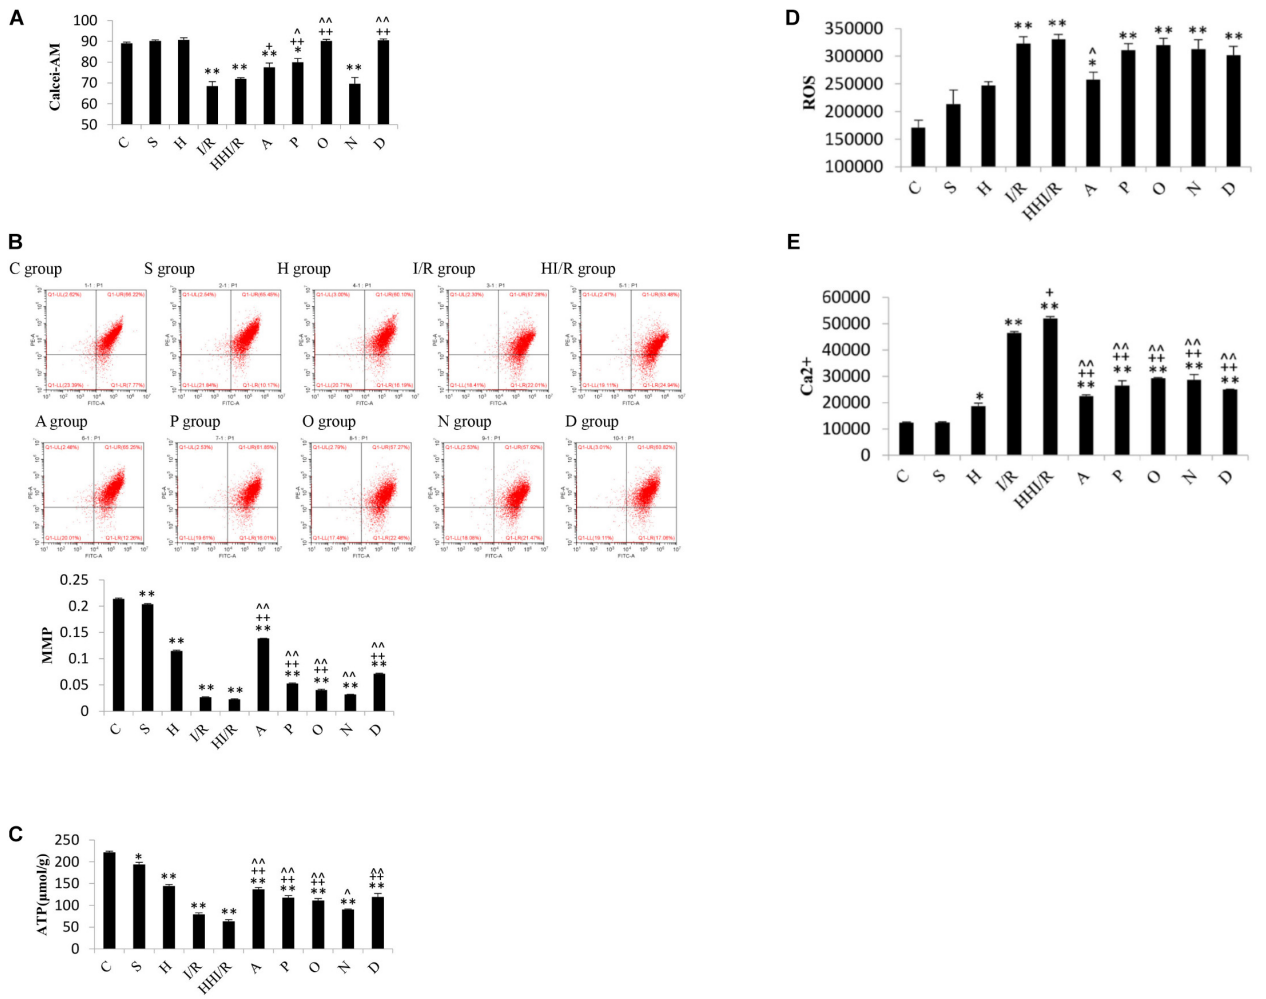

FIGURE 7 | Changes of MPTP, MMP, ATP, ROS, and Ca^{2+} levels in rats 24 h after I/R or not. **(A)** Calcei-AM levels evidently decreased in I/R and HI/R groups compared to control group, and increased significantly by P, O, and D groups (n = 3, $P < 0.05$ or 0.01). **(B)** MMP levels in I/R and HI/R groups significantly decreased compared to control groups, especially in the latter, and evidently increased in A, P, O, and D groups than that in HI/R group and I/R group (n = 3, $P < 0.01$). **(C)** The ATP levels in I/R and HI/R groups significantly decreased compared to control groups, especially in the latter, and evidently increased in A, P, O, and D groups than that in HI/R group and I/R group (n = 3, $P < 0.01$). **(D)** ROS levels increased significantly in I/R or HI/R than that in control groups ($P < 0.01$). **(E)** Ca^{2+} levels in I/R and HI/R groups significantly increased compared to control groups, especially in the latter, and evidently decreased in A, P, O, N, and D groups than that in HI/R group and I/R group (n = 3, $P < 0.01$). ** or * means $P < 0.01$ or 0.05 versus control, $^{++}$or $^{+}$ means $P < 0.01$ or 0.05 versus I/R group, and ^^or ^ means $P < 0.01$ or 0.05 versus HI/R group, analyzed by one-way ANOVA and Bonferroni *post hoc* test.

DISCUSSION

Multiple evidences suggested a definite relationship between elevated plasma Hcy levels and the risk of cardiocerebro-vascular diseases (McCully, 1969; Castro et al., 2006; Maron and Loscalzo, 2009; Ji et al., 2013; Zhao et al., 2017). In a previous study, we observed elevated Hcy levels to be associated with poor prognosis in acute ischemic cerebral infarction patients (Ji et al., 2015). Similarly, various experimental evidences indicated a pathogenic role for Hcy (Kim et al., 1987; Klancnik et al., 1992; Jellinger, 2013; Krishna et al., 2013; Currò et al., 2014; Pushpakumar et al., 2014). A close relationship between HHcy and multiple kinds of neurological diseases has been established. To further explore the effects of HHcy on acute ischemic brain injury and the underlying mechanisms, the present study was performed on OGD plus NaSH-treated SH-SY5Y cells and rat models of I/R and HHcy.

Hcy and Cys are substrates of the CBS and CSE and are thus involved in the endogenous production of H_2S (Griffith, 1987). Although H_2S is the third endogenously produced gasotransmitter and is considered as an important cell signaling molecule, its physiological levels in the body remain to be defined (Goodwin et al., 1989; Warenycia et al., 1989; Savage and Gould, 1990; Han et al., 2006; Ishigami et al., 2009; Levitt et al., 2011). Under the physiologic condition, catabolism of methionine causes an increased Hcy degradation to Cys via the transsulfuration pathway, which spontaneously decomposes and releases H_2S, and then H_2S is rapidly catabolized by the brain tissue (Furne et al., 2008). Therefore, the brain H_2S level

is generally very low at this time. However, the brain H_2S level may increase evidently under pathological condition. In a previous study, Julie et al. observed the anaerobic incubation of brain tissue yielded to higher H_2S release rates than the aerobic incubation at all L-cysteine concentrations (Furne et al., 2008). In the present study, H_2S levels in the brain tissue greatly increased to 110 and 171 nM in the rats under I/R and I/R combined with HHcy, respectively, as opposed to that in control group (24 nM). In concordance, the Cys levels also increased in rats that received either the I/R treatments alone or a combination of I/R and HHcy. To conclude, obvious increases in the H_2S concentration were identified in the brain tissue following an ischemic/reperfusion situation, especially when this was accompanied by an elevated HHcy level.

Several effects associated with H_2S have been reported in the pathophysiological realm. The physiological concentration of H_2S (i.e., low μM) was reported to play cytoprotective effects through the following processes: activation of sarcolemmal KATP channels, activation of the protein kinase C, anti-apoptotic effects and modulation of cellular respiration (Stipanuk et al., 2002). Lower levels of H_2S were identified to stimulate mitochondrial function, whereas higher level were associated with the inhibition of the cytochrome c oxidase, causing the mitochondrial respiration as a state of suspended animation in a dose-dependent manner (Furne et al., 2001; Calvert et al., 2010). Furthermore, supratherapeutic concentrations of H_2S were shown to irreversibly depress mitochondrial respiration, affecting ATP synthesis and further contributing to I/R injury. Previous study found H_2S played both stimulatory and inhibitory effects during the autophagy process (Wang et al., 2017). Its toxic effects are usually observed at relatively high concentrations, i.e., non-physiological levels (high μM to mM), which limits its clinical usefulness for treating patients (Stipanuk et al., 2002). As the dose-response curve of H_2S is bell-shaped, the effects of this compound switch from protective to deleterious based on both the environmental conditions and concentrations (Kumar and Sandhir, 2018). Specifically, while lower concentrations stimulate several physiological processes, including mitochondrial function and antioxidant effects, higher concentrations lead to cell death or other adverse effects.

In the *in vitro* phase of the present study, high concentrations of the NaSH treatment (1,500 μM) were found to cause an increase in the levels of intracellular ROS and MPTP, release of cytochrome C, as well as a decrease in the MMP of SH-SY5Y cells under OGD. In contrast, low concentrations of NaSH treatment (100 μM) appeared beneficial. These reveal high levels of H_2S exacerbate injury to cells under OGD although low levels demonstrate protective effects. *In vivo* phase of the study, the concentrations of H_2S greatly increased in the acute ischemia or when it was combined with HHcy, and the overproduction of H_2S produced a negative impact (Panagaki et al., 2019), such as a worsening in the brain tissue. Specifically, the infarction sizes of the cerebral tissues enlarged, while their water content increased. Furthermore, the energy metabolism of cells was impaired and ATP production decreased. This was followed by Ca^{2+} influx and ROS accumulation. The inflammatory reaction appeared and mitochondrial morphology and function were destroyed. Finally, cytochrome c was released from the mitochondria, which in turn induced cell apoptosis. Such pathological changes were especially obvious in rats that received the combination of I/R and HHcy, suggesting that acute ischemic brain tissue injury deteriorated when it encountered a high Hcy concentration. Higher levels of H_2S probably played a critical role during the pathological process supported by both *in vitro* and *in vivo* works of the study.

To further explore the possible mechanism underlying the involvement of H_2S and HHcy in the acute ischemic injury, we added several inhibitors of CBS, CSE, Hcy, H_2S, and NF-κB to the experimental groups. Specifically, both AOAA and HA were used as antagonists of CBS, whereas PAG was employed as an inhibitor of CSE. In contrast, the *N*-anandamide and PDTC antagonists were aimed for Hcy and NF-κB, respectively. Our results suggested that all inhibitors lessened the neurological function impairment, inflammatory reaction, mitochondria damage and decreased energy metabolism caused by acute ischemia and HHcy. While the AOAA, HA and PAG inhibitors showed obvious effects on the amelioration of the increased CBS, Cys, and H_2S levels in the HHI/R rats, PDTC was more effective on alleviating the release of inflammatory factors. Interestingly, inhibiting CBS, CSE, and Hcy was accompanied by a decrease in inflammatory factors, whereas inhibiting NF-κB was associated with a reduction in the CBS, Cys, and H_2S levels. Therefore, we here propose both the coexistence and interaction of H_2S overproduction and inflammatory factors to be one of the pathological mechanisms underlying the HHI/R process. Furthermore, the AOAA inhibitor was suggested to be extremely useful in modifying both the H_2S overproduction and the inflammatory reaction (Bento et al., 2016). In contrast, the *N*-anandamide inhibitor was less valuable, as it lessened the pathological changes in HHI/R rats only. In addition, mitochondrial function impairment was also involved in the pathological mechanism under HHI/R. In fact, inhibiting NF-κB resulted in a reduction of mitochondrial function impairment in HHI/R rats, whereas blocking either CBS or CSE only partly rectified the impairment. Therefore, it is reasonable to consider that H_2S may indirectly impair mitochondrial function by increasing the inflammatory reaction in the HHI/R condition.

CONCLUSION

To summarize, H_2S overproduction and inflammatory factors are involved in the pathological changes occurring after acute ischemic brain injury and HHcy. Furthermore, mitochondrial dysfunction is also involved in the pathological process. Future studies in this direction are warranted to provide instructive guidance for targeted medicine development.

Background: Neuroinflammation and cellular apoptosis caused by spinal cord ischemia/reperfusion (I/R) injury result in neurological dysfunction. MicroRNAs (miRs) have crucial functions in spinal cord I/R injury pathogenesis according to previous evidences. Herein, whether miR-128-3p contributes to spinal cord I/R injury by regulating specificity protein 1 (SP1) was assessed.

Methods: A rat model of spinal cord I/R injury was established by occluding the aortic arch for 14 min. Then, miR-128-3p's interaction with SP1 was detected by dual-luciferase reporter assays. Next, miR-128-3p mimic and inhibitor, as well as adenovirus-delivered shRNA specific for SP1 were injected intrathecally for assessing the effects of miR-128-3p and SP1 on rats with spinal cord I/R injury. SP1, Bax and Bcl-2 expression levels in I/R injured spinal cord tissues were evaluated by Western blotting, while IL-1β, TNF-α, and IL-6 were quantitated by ELISA. Tarlov scores were obtained to detect hind-limb motor function. Evans blue (EB) dye extravasation was utilized to examine blood–spinal cord barrier (BSCB) permeability. Terminal deoxynucleotidyl transferase mediated dUTP nick end labeling (TUNEL) staining was performed for neuronal apoptosis assessment.

Results: MiR-128-3p expression was decreased, while SP1 amounts were increased in rat spinal cord tissue specimens following I/R. SP1 was identified as a miR-128-3p target and downregulated by miR-128-3p. MiR-128-3p overexpression or SP1 silencing alleviated I/R-induced neuroinflammation and cell apoptosis, and improved Tarlov scores, whereas pretreatment with miR-128-3p inhibitor aggravated the above injuries.

Conclusion: Overexpression of miR-128-3p protects neurons from neuroinflammation and apoptosis during spinal cord I/R injury partially by downregulating SP1.

Keywords: spinal cord ischemia/reperfusion injury, miR-128-3p, SP1, neuroinflammation, apoptosis, rat

INTRODUCTION

Spinal cord I/R injury represents the most catastrophic complication generally ensuing multiple events, including thoracoabdominal aortic surgery and spinal cord injury (Wong et al., 2011; Etz et al., 2015). Spinal cord I/R injury may eventually lead to high incidence of paralysis or paraplegia (LeMaire et al., 2012; Coselli et al., 2016). Despite its improvement by clinical operative methods and perioperative approaches, spinal cord I/R injury cannot be prevented completely (Saito et al., 2013; Karatas et al., 2019). Owing to complicated pathogenic factors, such as oxygen free radical-associated lipid peroxidation, excessive calcium accumulation within the cell, leukocyte induction, inflammation, and neuronal apoptosis, which are rapidly induced and evoke serious complications (Li et al., 2014c). Therefore, it is essential to investigate the exact mechanism of spinal cord I/R injury and develop effective therapeutic measures.

SP1 belongs to the specificity protein/Kruppel-like factor family that also comprises SP2, SP3, and SP4 (Wierstra, 2008). Emerging evidences reveal SP1 as an important regulator of multiple cell events such as cell cycle, proliferation, and apoptosis (Nam et al., 2014; Beishline and Azizkhan-Clifford, 2015). Citron et al. suggested that SP1 was expressed in cerebral tissues, with elevated amounts decreasing neuronal survival (Citron et al., 2008). In addition, SP1 was shown to be upregulated in the development of neurological pathologies, including PD (Cai et al., 2020; Wang et al., 2020) and Alzheimer's diseases (Ramanan and Saykin, 2013). Furthermore, Qin et al. (2018) suggested that suppressing SP1 activation effectively inhibited OGD/R-induced inflammatory activation in microglia. Recent evidence indicated that the expression of SP1 under ischemia/hypoxic conditions was increased (Li et al., 2019). Jointly, the aforementioned data revealed the critical influence of SP1 in neurological pathologies.

MicroRNAs (miRNAs) represent a group of small non-coding RNAs with 21–23 nucleotides, which are able to interact with the 3′-UTRs of mRNAs and negatively modulate gene expression via cleavage or translational suppression at the posttranscriptional level (Kim et al., 2009). MiRNAs are highly expressed in the central nervous system, with crucial roles in neuron development, maintenance of neuronal phenotype, and neuroprotection (Saugstad, 2010). In addition, many miRNAs are dysregulated in the spinal cord during the pathogenesis of I/R injury (Song et al., 2016; Balsam, 2017). Meanwhile, synthetic miRNA mimics and anti-miRNA oligonucleotides powerfully mitigate neuroinflammation and neuroapoptosis, and elevate neurological functional recovery in rat models (He et al., 2015; Li et al., 2015; Liu et al., 2017; Li et al., 2018). Recently, miR-128-3p, which is best known as a tumor suppressor (Huang et al., 2015; Zhao et al., 2018), has been found to contribute to central nervous system disorders such as PD (Zhang et al., 2020) and glioma (Huo et al., 2019). Mao et al. (2017) demonstrated miR-128-3p prevented neuron apoptosis by regulating p38α in the initial stage of brain I/R. However, SP1's role in spinal cord I/R-associated injury and the mechanism by which miR-128-3p presents I/R remain unclear. Therefore, the current work aimed to assess the functions of miR-128-3p and SP1 in spinal cord I/R injury. We hypothesized that miR-128-3p relieves neurological damage in spinal cord I/R injury by depleting SP1 to decrease inflammatory reactions and apoptosis. This pathway could emerge as a possible target relieving spinal cord I/R injury -related nerve injury.

MATERIALS AND METHODS

Animals

In this study, male Sprague-Dawley rats (200–250 g) were provided by the Animal Center of China Medical University, Shenyang (China). All animals ($n = 136$) were housed for at least 1 week before the surgical operation, with freely available rodent chow and water at 22–24°C and 50–60% relative humidity, under a 12 h/12 h light-dark cycle. Animal experiments had approval from the Ethics Review Committee for Animal Experimentation of China Medical University, Shenyang (China) (CMU2020267/2020/03/02), and were carried out in conformity with the National Institutes of Health Guide for the Use and Care of Laboratory Animals (NIH Publications No.80-23, revised 1996).

Rat Model of Spinal Cord I/R Injury

Spinal cord I/R injury was induced in rats via a cross-clamped aortic arch (Li et al., 2014b,c). Briefly, upon anesthesia by intraperitoneally injecting 4% sodium pentobarbital (50 mg/kg; Beyotime Biotechnology, China), endotracheally intubated (24 g trocar sleeve) and lung ventilation was accomplished utilizing a small-animal ventilator (Harvard Apparatus, United States) (tidal 15 mL/kg, breathing frequency 80–100 times/min, breathing ratio 1:1). Body temperatures were kept at 37.5 ± 0.5°C as monitored with a rectal probe. Under aseptic conditions, the left common carotid artery was exposed in the middle of neck. Then, the aortic arch was uncovered through a cervicothoracic incision. Under direct vision, the aortic arch was cross-clamped for 14 min between the left carotid artery and the left subclavian artery to induce ischemia. A catheter (24 g trocar sleeve) was inserted into the femoral artery for blood pressure measurements. After ischemia confirmation [90% reduction of the flow assessed at the femoral artery using a laser Doppler blood flow monitor (Moor Instruments, Axminster, Devon, United Kingdom)], clamp removal was performed, followed by 12-h reperfusion. This procedure was performed in sham animals, except for blockade.

Experimental Protocol

Experimental groups and protocol were shown in **Figure 1**. We used 118 rats and 18 rats for modeling and sham operation, respectively. To measure expression of miR-128-3p and SP1 at various time points (6, 12, 24, 36, and 48 h) after reperfusion, 20 rats were killed at 6, 12, 24, 36, and 48 h after spinal cord I/R, respectively ($n = 4$, at each time point). Subsequently, eight groups were enrolled: (1) Sham group ($n = 14$): same procedure was performed on rats without blockade and 10 μL normal saline was injected inreathecally into each rat prior to sham-operation. (2) I/R group ($n = 14$): cross-clamping for 14 min on rats for ischemia induction. (3) miR-128-3p mimic group ($n = 14$): 10 μL synthetic miR-128-3p mimics were injected intrathecally into each rat prior to ischemia induction once a day for three consecutive days. (4) miR-128-3p negative control (NC) group ($n = 14$): 10 μL synthetic miR-128-3p NC was injected intrathecally into each rat prior to ischemia induction once a day for three consecutive days. (5) miR-128-3p inhibitor group ($n = 14$): 10 μL synthetic miR-128-3p inhibitors were injected intrathecally into each rat prior to ischemia induction once a day for three consecutive days. (6) Adenovirus (AV)-sh-SP1 group ($n = 14$): 20 μL shRNA-SP1 adenovirus at 5×10^{10} PFU/mL was carried out for 2 days before ischemia. (7) AV-sh-NC group ($n = 14$): 20 μL shRNA-NC adenovirus at 5×10^{10} PFU/mL was carried out for 2 days before ischemia. (8) AV-sh-SP1 + miR-128-3p inhibitor group ($n = 14$): 10 μL synthetic miR-128-3p inhibitor were injected intrathecally into each rat prior to ischemia induction once a day for three consecutive days and 2 days before ischemia 20 μL shRNA-SP1 adenovirus at 5×10^{10} PFU/mL was carried out.

Intrathecal Administration

Intrathecal administration of various substances followed a previously reported method (Mestre et al., 1994; Li et al., 2015; He et al., 2016; Li et al., 2018). In brief, upon anesthesia with isoflurane (RWD, Shenzhen, China), rats were placed in the prone position that flexed the rats' back. A 20-μL microsyringe (Gaoge Co., Ltd., Shanghai, China) was positioned in the subarachnoid space at the intervertebral space between L5 and L6 or L4 and L5. The spinal cord of rat terminated between the third and fourth lumbar vertebrae (Padmanabhan and Singh, 1979). This site was chosen so that the injection was restricted to the region where the spinal cord ends and the cauda equine begins in order to minimize the possibility of spinal damage and maximize intervertebral accessibility (Mestre et al., 1994). According to the anatomical structure of the rat, the horizontal position of the connection between the left and right hip joints corresponds to the spinous process space of L5–L6 or the spinous process of L5. When the needle entered the subarachnoid space, a sudden lateral tail-flick was used as a sign of successful puncture. Once correct needle placement was confirmed, the solutions were injected slowly and over the course of 1 min (Judas et al., 2014). Synthetic miR-128-3p mimic, inhibitor and negative control were purchased from Transheep (Shanghai China). A shRNA-SP1 adenovirus (AV-sh-SP1) and NC adenovirus (AV-sh-NC) were provided by IGE Bio. Ltd., (Guangzhou, China). Rats were intrathecally infused with 10 μL of synthetic miR-128-3p mimic, inhibitor and NC, respectively, at a concentration of 500 pmol/10 μL with Entranster^{TM}-*in vivo* transfection regent (Engreen, Beijing, China) to regulate miR-128-3p *in vivo* prior to ischemia induction once a day for three consecutive days. Meanwhile, 2 days before ischemia, intrathecal infusion of 20 μL of shRNA-SP1 or NC adenovirus at 5×10^{10} PFU/mL was carried out, as directed by the manufacturer. Transfection efficacy was assessed by qRT-PCR or Western blotting. Only animals with unaltered motor function after intrathecal injection underwent surgery. The sequences of miR-128-3p mimic, miR-128-3p inhibitor, miR-128-3p NC and AV-sh-SP1 were as follows: miR-128-3p mimic (5′-UCACAGUGAACCGGUCUCUUU-3′), miR-128-3p inhibitor (5′-AGUGUCACUUGGCCAGAGAAA-3′), miR-128-3p NC (5′-CAGUACUUUUGUGUAGUAAA-3′), AV-sh-SP1 (5′-CCGGCCAACTTACAGAACCAGCAAGTTCTCTCGAGAGAACTTGCTGGTTCTGTAAGTTGGTTTTTGAATT-3′).

Neurological Assessment

Hind-limb motor function was examined at 12 h post reperfusion ($n = 8$, at each group) by two investigators blinded to experimental design according to the Tarlov scoring system (Aslan et al., 2009; Li et al., 2014a): 0, Spastic paraplegia and no voluntary movement of lower limbs; 1, Spastic paraplegia and weak hind limb motor function of lower limbs; 2, good antigravity strength with some lower limb movement, but inability to stand; 3, abnormal standing but unable to walk normally; 4, normal motor function.

After neurological evaluation, the rats in all groups were anesthetized with 4% sodium pentobarbital 50mg/kg and perfused transcardially with normal saline. The spinal cords from L4 to L6 were harvested for molecular biology analysis because of their vulnerability to ischemic injury (Li et al., 2014a). There are two methods to identify the L4–L6 segments. On the one hand, in the rat, the sciatic nerve is composed of spinal segments L4, 5, and 6. The roots of these three spinal nerves originate in the spinal cord within the limits of the L1 vertebra, and then must descend distances of 2.7 cm (L4) to 4.5 cm (L6) within the vertebral canal before reaching the periphery (Gelderd and Chopin, 1977). Therefore, L4–L6 spinal segments were identified based on the ascending ends of the posterior fibers of the dorsal root ganglion of L4, 5, and 6. On the other hand, according to the anatomical morphology of the rat spinal cord, the lumbar enlargement of spinal cord in rat is located at the level of vertebrae T12-L1, which corresponds to spinal cord segments L1–L5 (Gilerovich et al., 2008). The L4–L6 segments lie at the upper border, middle and lower border of the L1 vertebra. Therefore, L4–L6 spinal cord segments were identified based on the position of L1 vertebra. At the end of these procedures, all rats were sacrificed under deep anesthesia.

Quantitative Real-Time Polymerase Chain Reaction (qRT-PCR)

After final neurological assessment, total RNA from L4–L6 spinal cord specimens ($n = 4$, at each group) was obtained with TRIzol

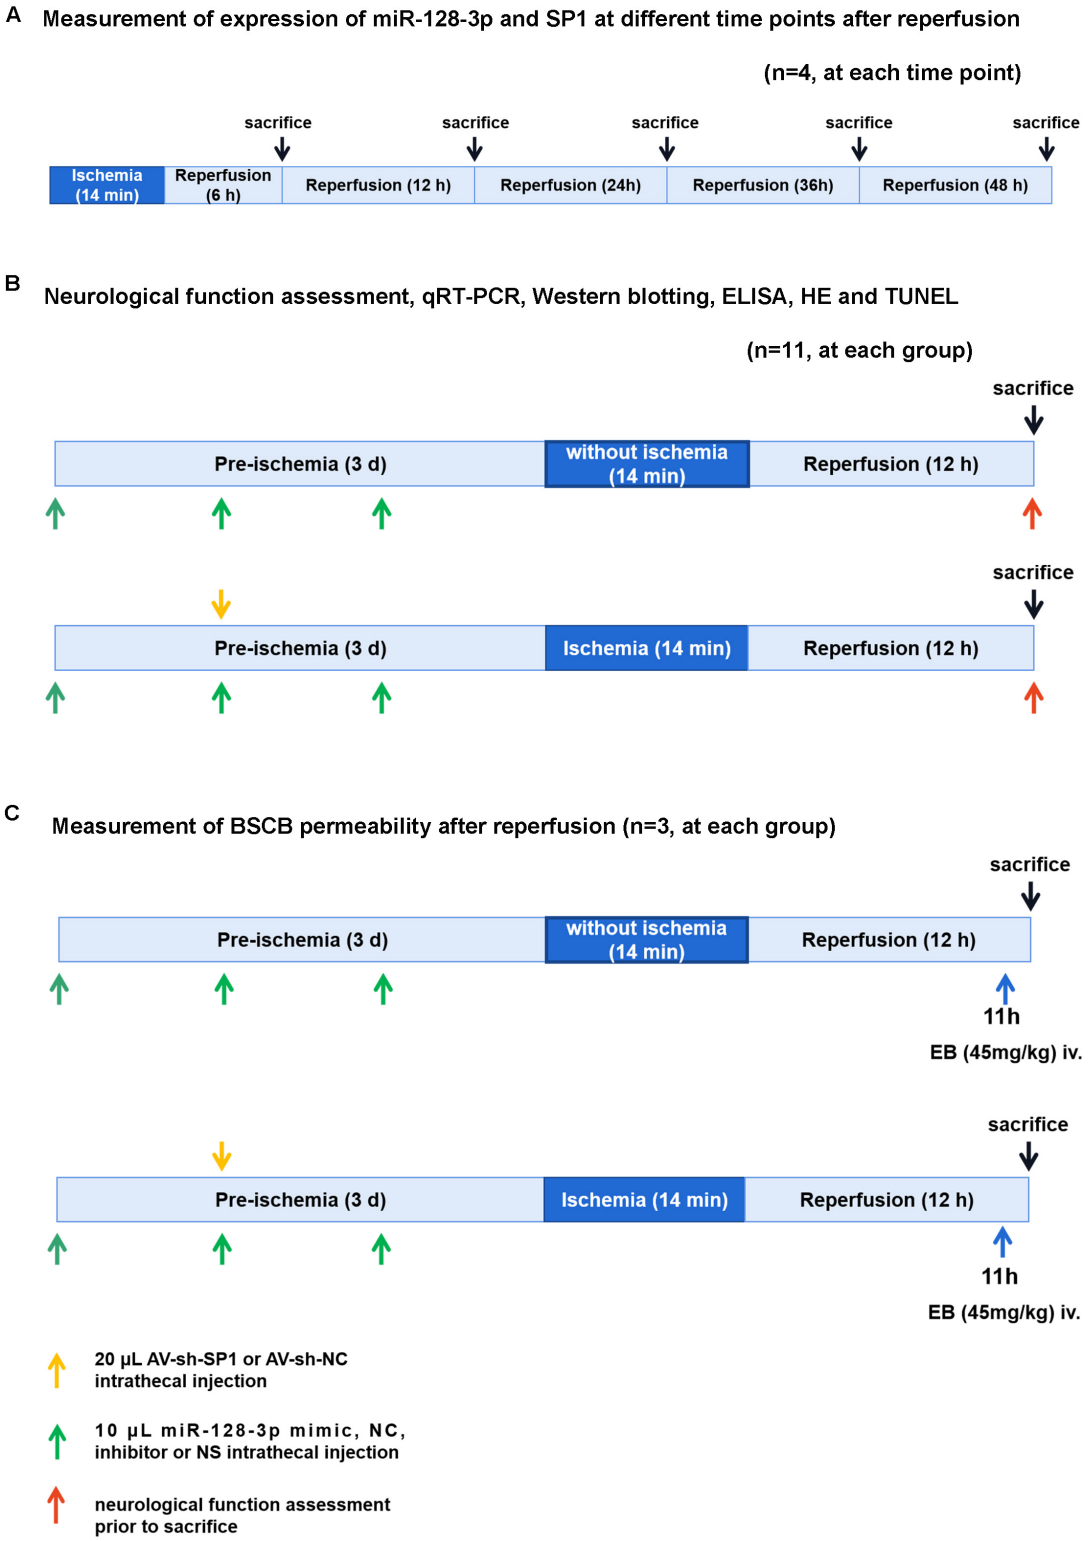

FIGURE 1 | Diagram of the experimental protocols. **(A)** Measurement of expression of miR-128-3p and SP1 at different time points (6, 12, 24, 36, and 48 h) after reperfusion. $n = 4$, at each time point. **(B)** Neurological function assessment ($n = 8$, at each group), qRT-PCR and Western blotting ($n = 4$, at each group), ELISA ($n = 4$, at each group), H&E and TUNEL ($n = 3$, at each group). Rats ($n = 8$, at each group) were euthanized after neurological function assessment. Then 4 rats' spinal cords were used for qRT-PCR and Western blotting and the other 4 rats' spinal cords were used for ELISA. **(C)** Measurement of BSCB permeability after reperfusion ($n = 3$, at each group).

reagent (Takara, Japan) as instructed by the manufacturer. Then, reverse transcription utilized Prime-Script RT reagent Kit with gDNA Eraser (TaKaRa) or MicroRNA Reverse Transcription Kit (Applied Biosystems, United States). Subsequently, qRT-PCR was performed with a SYBR PremixEx TaqII kit (Takara) on an ABI 7500 qRT-PCR instrument (Applied Biosystems) at 95°C (10 min), followed by 40 cycles at 95°C (20 s), 60°C (60 s), 62°C (30 s), and 72°C (30 s). Relative SP1 mRNA and miR-128-3p amounts were assessed by the $2^{-\Delta\Delta Ct}$ method, with GAPDH and U6 as internal references, respectively. The primers (Sangon Biotech, China) employed were as follows: miR-128-3p (forward: 5′-CGTCACAGTGAACCGGTCTCTTT-3′), SP1 (forward: 5′-CTGCAAGGGTCTGATTCTCTA-3′, reverse: 5′-AGCTTGTCCACCTTGAACTA-3′), GAPDH (forward: 5′-GGGGCTCTCTGCTCCTCCCTG-3′, reverse: 5′-AGGCGTCC GATCGGCCAAA-3′), U6 (forward: 5′-CTCGCTTCGGCAGC ACA-3′, reverse: 5′-AACGCTTCACGAATTTGCGT-3′).

Cell Culture

293T cell lines were purchased from cell bank center of Shanghai Institutes for Biological Sciences (SIBS) and were cultured in DMEM (Invitrogen, Thermo Fisher Scientific, Waltham, MA, United States) appended with 10% FBS and 2 Mm glutamine, and 100 μg/ml streotonucin and penicillin (Sangon Technology, Shanghai, China). All of the cells were incubated at 37°C with 5% CO_2 (Yang et al., 2019).

Dual Luciferase Reporter Gene Assay

MiR-128-3p target prediction was performed with TargetScan[1]. For constructing 3′-UTR-luciferase reporters, regions of SP1's 3′-UTR were introduced into pmirGLO (Promega). Then, two wild types named WT1-3′ UTR (binding sites at base pairs [bp] 1437–1443 and 1642–1649) and WT2-3′ UTR (binding site at bp 4373–4379) were constructed by Nanjing TsingKe Co., Ltd. (China). Mutant-type plasmids (MUT1-3′ UTR and MUT2-3′ UTR) were generated with the Directed Mutagenesis system (Invitrogen). Meanwhile, SP1 WT and MT plasmids, respectively, were co-transfected with miR-128-3p mimic or miR-128-3p -NC in 293 T cells with Lipofectamine 2000 (Invitrogen) as directed by the manufacturer. After transfection for 48 h, cell collection and homogenization in passive lysis buffer (Promega G182A) (100 μl) were carried out. Renilla and firefly luciferase activities in triplicate assays were assessed with Luciferase Assay Kit (Beyotime) on a multifunctional microplate reader (PerkinElmer EnSpire, United States).

Hematoxylin and Eosin (H&E) Staining

At 12 h post-modeling, rats (n = 3, at each group) were deeply anesthetized with 4% sodium pentobarbital (50 mg/kg, i.p.). Then, they were perfused transcardially with normal saline, followed by 4% buffered paraformaldehyde (Servicebio G1101, China), and until the right atrium flowed out clear paraformaldehyde and the lungs turned white (Li et al., 2019; Yin et al., 2019). The spinal cords from L4 to L6 were removed rapidly for analysis because of their vulnerability to ischemic injury (Li et al., 2014a). Tissue was fixed with 4% paraformaldehyde for 24 h and embedded in paraffin. Then, paraffin-embedded sections (4 μm) underwent staining with hematoxylin and eosin (H&E) staining kit (Servicebio G1005, China) as directed by the manufacture. Briefly, the 4 μm thick paraffin-embedded sections were firstly deparaffinized and hydrated to water. Second, the sections were stained in hematoxylin solution for 5 min and rinsed in water. Then, the sections were differentiated in 1% hydrochloric acid ethanol solution and restored blue in ammonia solution and washed in slowly running tap water. After then, the sections were dehydrated with 85 and 95% gradient alcohol III, Xylene I, and Xylene II for 5 min, respectively. Stained sections were examined under an optical microscope (Nikon Eclipse E100, Japan) by two blind investigators to judge the morphological appearance of neurons. Normal neurons were defined as viable by the existence of basophilic stippling, whereas necrotic or dead neurons were identified by the existence of diffusely eosinophilic cytoplasm with pyknotic homogenous nuclei (Ding et al., 2009; Li et al., 2014a). Gray matter injury was examined by counting normal motor neurons in its ventral region. Data were calculated as average numbers of intact neurons using ImageJ software (Download from the NIH website[2]) (Li et al., 2014a). Three sections for each rat were assessed in a blinded fashion.

Terminal Deoxynucleotidyl Transferase dUTP Nick End Labeling (TUNEL)

The TUNEL assay was extensively carried out for the detection and quantification of apoptosis in histological tissue sections (Duan et al., 2003). The above tissue sections (n = 3, at each group) underwent staining with TMR (red) TUNEL Cell Apoptosis Detection Kit (Servicebio, G1502, China) as directed by the manufacturer. Following TUNEL labeling, cell nuclei were stained with DAPI (Servicebio G1012, China) for 5 min. Cell apoptosis was assessed by two blinded investigators under a light microscope (Leica, Germany). The nuclei labeled with DAPI appear blue under a fluorescence microscope and the positive apoptotic nuclei were red. The TUNEL-positive cells were recognized as cells double labeled with TUNEL and DAPI and only TUNEL + DAPI were counted. (Li et al., 2018). Finally, the high power fields of spinal cord were randomly selected, and average percentage in three sections/rat of TUNEL-positive cells to total nuclei were calculated by two blind investigators using ImageJ software (Download from the NIH website[2]). The apoptotic rate was calculated as AR = (number of TUNEL-positive cells/total number of nuclei) × 100% (Fu et al., 2020).

Evans Blue (EB) Extravasation

Evans blue (EB) extravasation was carried out to quantitatively and qualitatively assess blood–spinal cord barrier (BSCB) integrity following I/R-associated injury (n = 3, at each group) (Li et al., 2015). After 12 h of reperfusion, Evans blue (EB, 1 mg/ml; Solarbio, China) was administered by intravenous (tail vein) injection (45 mg/kg) 60 min before euthanasia. The rats were anesthetized and perfused transcardially with 500 mL/kg normal

[1]http://www.targetscan.org

[2]https://imagej.nih.gov/ij/

saline, and the L4–L6 segments were removed and underwent fixation with 4% formalin and sectioning at 10 μm (Fang et al., 2013b). EB staining was evaluated under a fluorescence microscope (Olympus, Melville, NY, United States).

Enzyme Linked Immunosorbent Assay (ELISA)

Following 12 h of modeling, L4–L6 segments were obtained ($n = 4$, at each group), homogenized in chilled PBS and submitted to centrifugation (3,000 r/min, 15 min; 4°C). Then, interleukin (IL)-1β, IL-6 and TNF-α amounts were quantified on a microplate reader with ELISA kits (MultiSciences Biotech Co., Ltd., China), as described by the manufacturer. Triplicate experiments were assessed at 450 nm, and results were normalized to protein amounts.

Western Blotting

L4–L6 segments ($n = 4$, at each group) underwent lysis with radioimmunoprecipitation (RIPA) lysis buffer (R0010, Solarbio) supplemented with PMSF (P0100, Solarbio) as previously described (Li et al., 2018). Then, protein concentrations were quantified with a BCA protein assay kit (Beyotime Biotechnology). Equal amounts of protein were resolved by SDS-PAGE (KGP113K, KeyGen Biotech. Co. Ltd., Nanjing, China) and electro-transferred onto PVDF membranes (Millipore, Temecula, CA, United States). Upon blocking with 5% non-fat milk (1 h), the membranes underwent overnight incubation with anti-SP1 (Abcam, ab13370; 1:1000), anti-Bax (Cell Signaling Technology, 2772; 1:1000), anti-Bcl-2 (ProteinTech, 26593-1-AP; 1:1000) and β-actin (ZSGB-BIO, China; 1:5000) primary antibodies at 4°C. Next, the specimens were incubated with HRP-conjugated goat anti-rabbit (ProteinTech, SA00001-2) or anti-mouse (ProteinTech, SA00001-1) antibodies (1 h, 37°C). The membranes were further washed with TBST 3 times. An ECL kit (Bio-Rad, United States) was utilized for visualization, and bands were detected by the Quantity One software (Bio-Rad). ImageJ 1.6.0.24 (National Institutes of Health, United States) was used to quantify the band strength; β-actin served as a reference protein.

Statistical Analysis

SPSS 25.0 (SPSS, United States) was utilized for data analysis. Data are mean ± SD. The Student's *t*-test or Mann–Whitney test was performed for group pair comparisons, while multiple groups were assessed by one-way or two-way ANOVA, with *post hoc* Tukey test. $P < 0.05$ was deemed statistically significant.

RESULTS

Abnormal Expressions of miR-128-3p and SP1 After I/R

MiR-128-3p and SP1 amounts were assessed at 6, 12, 24, 36, and 48 h post-I/R, respectively. As shown in **Figure 2A**, qRT-PCR revealed that miR-128-3p expression was noticeably diminished over time and reached its minimum amounts at 12 h after I/R, in comparison with the sham group ($P < 0.05$). Additionally, qRT-PCR and Western blotting analysis revealed that SP1 mRNA and protein levels were elevated from 6 h post-I/R in comparison with the sham group, and peaked at 12 h (**Figures 2B–D**, $P < 0.05$).

SP1 Is a Direct miR-128-3p Arget

According to results from TargetScan database, a putative miR-128-3p binding site was found in the 3′ UTR of the SP1 gene (**Figure 3A**). This was confirmed by dual-luciferase reporter assays. Luciferase activities of WT1-3′ UTR and WT2-3′ UTR in 293T cells transfected with miR-128-3p mimic exhibited a remarkable decrease, while those of mutant-type (MUT)1-3′ UTR and MUT2-3′ UTR co-transfected with miR-128-3p mimic were unaltered (**Figure 3B**, $P < 0.05$). Furthermore, no disparities were recognized after transfection with NC mimic (**Figure 3B**, $P > 0.05$). The above findings suggested miR-128-3p directly targeted and downregulated SP1.

Intrathecal Administration of miR-128-3p Mimic and Inhibitor Strongly Regulates SP1 Expression *in vivo* After I/R

To investigate miR-128-3p's interaction with SP1 in the spinal cord tissue, miR-128-3p mimic, inhibitor and NC were administered by intrathecal injection for 3 days prior to ischemia. Then, qRT-PCR and Western blotting were carried out to assess miR-128-3p and SP1 mRNA and protein levels in the spinal cord, respectively. Compared with the I/R group, miR-128-3p was upregulated after administration of miR-128-3p mimic (**Figure 4A** $P < 0.05$) but showed no remarkable differences in the miR-128-3p NC group ($P > 0.05$). Significantly, pretreatment with miR-128-3p mimic remarkably reduced I/R-associated SP1 upregulation at the mRNA and protein levels at 12 h post-I/R; conversely, pretreatment with miR-128-3p inhibitor reversed the above effects (**Figures 4B–D**; $P < 0.05$). The above findings jointly suggested that the levels of SP1 were decreased due to overexpressed miR-128-3p and increased after miR-128-3p downregulation.

Intrathecal Pretreatment With miR-128-3p Mimic or AV-sh-SP1 Ameliorates Neurological Function and Histologic Evaluation After I/R

Neurological function in the eight groups according to the Tarlov scores post-I/R was presented in **Figure 5A** Tarlov scores in the I/R group were significantly reduced at 12 h post-I/R compared with the sham group ($P < 0.05$). In comparison with the I/R and miR-128-3p NC groups, the miR-128-3p mimic group showed markedly elevated scores, whereas administration of miR-128-3p inhibitor resulted in lower Tarlov scores ($P < 0.05$). Tarlov scores were comparable in the I/R and miR-128-3p NC groups. Knockdown of SP1 using AV increased Tarlov scores ($P < 0.05$). Meanwhile, Tarlov scores were similar in the I/R and AV-sh-NC groups. Additionally, the miR-128-3p inhibitor + AV-sh-SP1 showed higher Tarlov scores ($P < 0.05$ vs. IR group) indicating AV-sh-SP1 could eliminate the

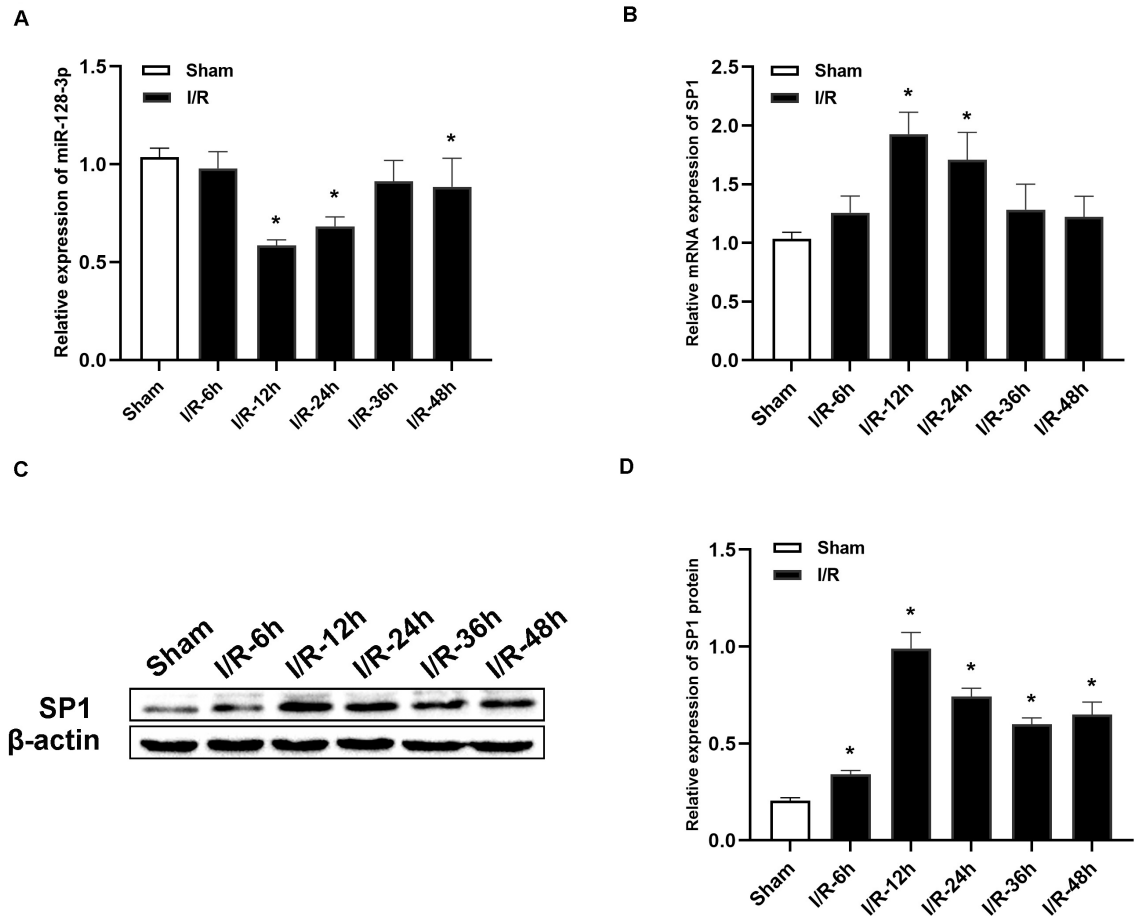

FIGURE 2 | Alterations in miR-128-3p and SP1 expression levels at various time points after spinal cord I/R injury. **(A)** Quantification of miR-128-3p expression in the L4–L6 segments of spinal cord specimens after spinal cord I/R injury. **(B)** Quantification of SP1 mRNA expression in the L4–L6 segments of spinal cord specimens after spinal cord I/R injury. **(C,D)** Western blotting analysis of SP1 protein levels in the L4–L6 segments of spinal cord specimens after spinal cord I/R injury. β-actin was used as a loading control. damage caused by miR-128-3p inhibitor. Consequently, spinal cord I/R injury induced severe neurological deficits of lower limbs; meanwhile, miR-128-3p mimic and AV-sh-SP1 relieved neurological damage, while miR-128-3p inhibitor aggravated neurological deterioration. Likewise, histological findings at 12 h post-I/R revealed that the numbers of intact neurons in the anterior horn were significantly decreased, as shown by the existence of diffusely eosinophilic cytoplasm without cell structure, extensive vacuolation and pkynotic nuclei of neurons. Whereas, more intact neurons with basophilic substance and multipolar structure were seen after treatment with miR-128-3p mimic and AV-sh-SP1; miR-128-3p inhibitor increased necrotic or dead neurons in the anterior horn, while treatment with miR-128-3p inhibitor + AV-sh-SP1 reversed this effect (**Figure 5B**). The numbers of neurons with normal morphology in the anterior horn of spinal cord at 12 h post-I/R was significantly decreased in the I/R group (9 ± 1.000) than in the sham group (25.33 ± 2.082), miR-128-3p mimic group (20.33 ± 2.517), AV-sh-SP1 group (20 ± 1.000) and AV-sh-SP1 + inhibitor group (13.67 ± 2.082) (**Figures 5C**; $P < 0.05$). In the miR-128-3p NC, miR-128-3p inhibitor and AV-sh-NC group the numbers of neurons with normal morphology in the anterior horn were 7.667 ± 2.517, 6.667 ± 1.155, and 8 ± 1.000, respectively and had no marked differences compared with I/R group ($P > 0.05$).

Intrathecal Pretreatment With miR-128-3p Mimic or AV-sh-SP1 Ameliorates BSCB Leakage and Proinflammatory Cytokine Release After I/R

I/R-induced BSCB leakage was evaluated by EB fluorescent dye as described in previous reports (Fang et al., 2013a; Li et al., 2014b,c). As shown in **Figures 6A,B**, I/R notably increased red fluorescence in the gray matter at 12 h after surgery in comparison with sham animals ($P < 0.05$). Intrathecal injection of miR-128-3p mimic or AV-sh-SP1 remarkably reduced fluorescence levels ($P < 0.05$), whereas miR-128-3p inhibitor aggravated BSCB leakage. Moreover, the degree and intensity of fluorescence in the miR-128-3p inhibitor + AV-sh-SP1 group

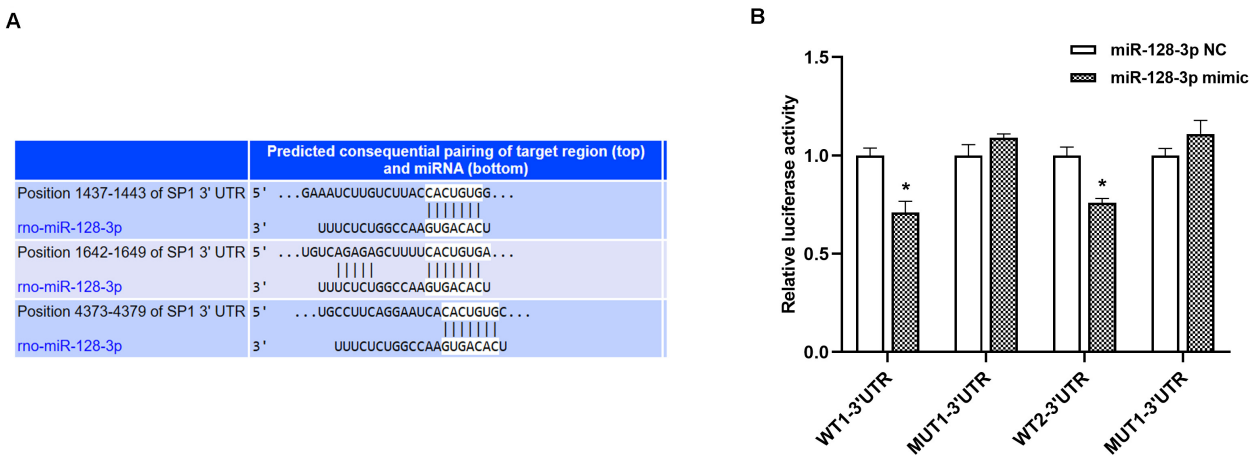

FIGURE 3 | SP1 is a direct miR-128-3p target. **(A)** Prediction of miR-128-3p and SP1 binding sites based on TargetScan. Three predicted conserved miR-128-3p target sites in the 3′UTR of SP1. **(B)** Suppression of SP1 expression by miR-128-3p. Luciferase activity was measured after 48 h of co-transfection of 293T cells with the miR-128-3p mimic and the WT or MUT reporter vector. Compare to the control, miR-128-3p significantly decreased the luciferase activity of the WT vector but not that of the MUT vector. 3′ UTR, 3′untranslated region; WT, wild-type; MUT, mutant-type, SP1, specificity protein 1; NC, negative control. *$P < 0.05$ vs. NC group.

were lower levels ($P < 0.05$). The I/R and NC groups also had no marked differences ($P > 0.05$).

Next, we assessed whether neuronal inflammation is an important response in spinal cord I/R injury development. As shown in **Figures 6C–E**, proinflammatory cytokines, including IL-6, TNF-α, and IL-1β, had remarkably increased amounts at 12 h post-I/R vs. sham group ($P < 0.05$). Interestingly, intrathecal injection of miR-128-3p mimic or AV-sh-SP1 reduced the release of IL-6, TNF-α and IL-1β (vs. I/R group; all $P < 0.05$). In contrast, miR-128-3p inhibitor increased IL-6, TNF-α, and IL-1β amounts (vs. I/R group; all $P < 0.05$), while, IL-6, TNF-α, and IL-1β amounts were reduced in the miR-128-3p inhibitor + AV-sh-SP1 group ($P < 0.05$ vs. inhibitor group), and were comparable in the I/R and miR-128-3P NC groups.

Intrathecal Pretreatment With miR-128-3p Mimic or AV-sh-SP1 Ameliorates Neuronal Apoptosis After I/R

Apoptotic cells in spinal cord samples were represented by TUNEL-positive signals. The results in **Figures 7A,B** showed that the rate of apoptosis was markedly elevated in the I/R group in comparison with sham animals ($P < 0.05$). Apoptosis rate increase was partially restored in the miR-128-p mimic and AV-sh-SP1 group, respectively (both $P < 0.05$), whereas miR-128-3p inhibitor promoted apoptosis. Interestingly, apoptosis rate in the miR-128-3p inhibitor group was restored by AV-sh-SP1 ($P < 0.05$). In addition, the I/R and NC groups showed comparable values ($P > 0.05$). Similarly, to assess the possible mechanism underlying the effects of miR-128-3p and SP1 on apoptosis post-I/R, SP1, Bcl-2 and Bax amounts were assessed by Western blotting upon transfection with miR-128-3p mimic, inhibitor and AV-sh-SP1, respectively. As shown in **Figures 7C–F**, SP1 expression levels were significantly upregulated in the I/R group in comparison with sham group ($P < 0.05$). Meanwhile, miR-128-3p mimic or AV-sh-SP1 remarkably downregulated SP1 ($P < 0.05$). Conversely, miR-128-3p inhibitor upregulated SP1. Interestingly, in the miR-128-3p + AV-sh-SP1 group, the expression of SP1 was inhibited ($P < 0.05$). Bax expression levels changed with the same trends observed for SP1. Bcl-2 was markedly downregulated in the I/R group in comparison with sham animals ($P < 0.05$), and miR-128-3p mimic or AV-sh-SP1 promoted Bcl-2 expression ($P < 0.05$), which was suppressed by miR-128-3p inhibitor. After administration of miR-128-3p inhibitor + AV-sh-SP1, Bcl-2 protein amounts were also elevated ($P > 0.05$). The I/R and NC groups were also comparable. Hence, upregulation of miR-128-3p suppressed apoptosis in rat spinal cord injury after I/R by suppressing SP1 expression.

DISCUSSION

Prominent findings unveiled by this work are that elevated miR-128-3p amounts downregulated the transcription factor SP1, thus ameliorating the impairment of neurons induced by I/R via regulating inflammation and apoptosis.

Cumulative evidences illustrate that miRs are novel molecular targets modulating the pathogenesis of I/R injury (Li et al., 2015, 2017; Liu et al., 2017; Li et al., 2018; Li et al., 2020). The associations of miR-128-3p with central nervous system diseases have been assessed previously. For example, Krichevsky et al. (2006) suggested that miR-128-3p is upregulated in the development of the central nervous system. Additionally, high miR-128-3p amounts in neurons alleviate motor deficits in a mouse model of PD (Tan et al., 2013), and it was recently confirmed that miR-128-3p overexpression in the 1-methyl-4-pheny-1,2,3,6-tetrahydropyridine (MPTP)-injured mouse model of PD reduced hippocampal neuron apoptosis (Zhang

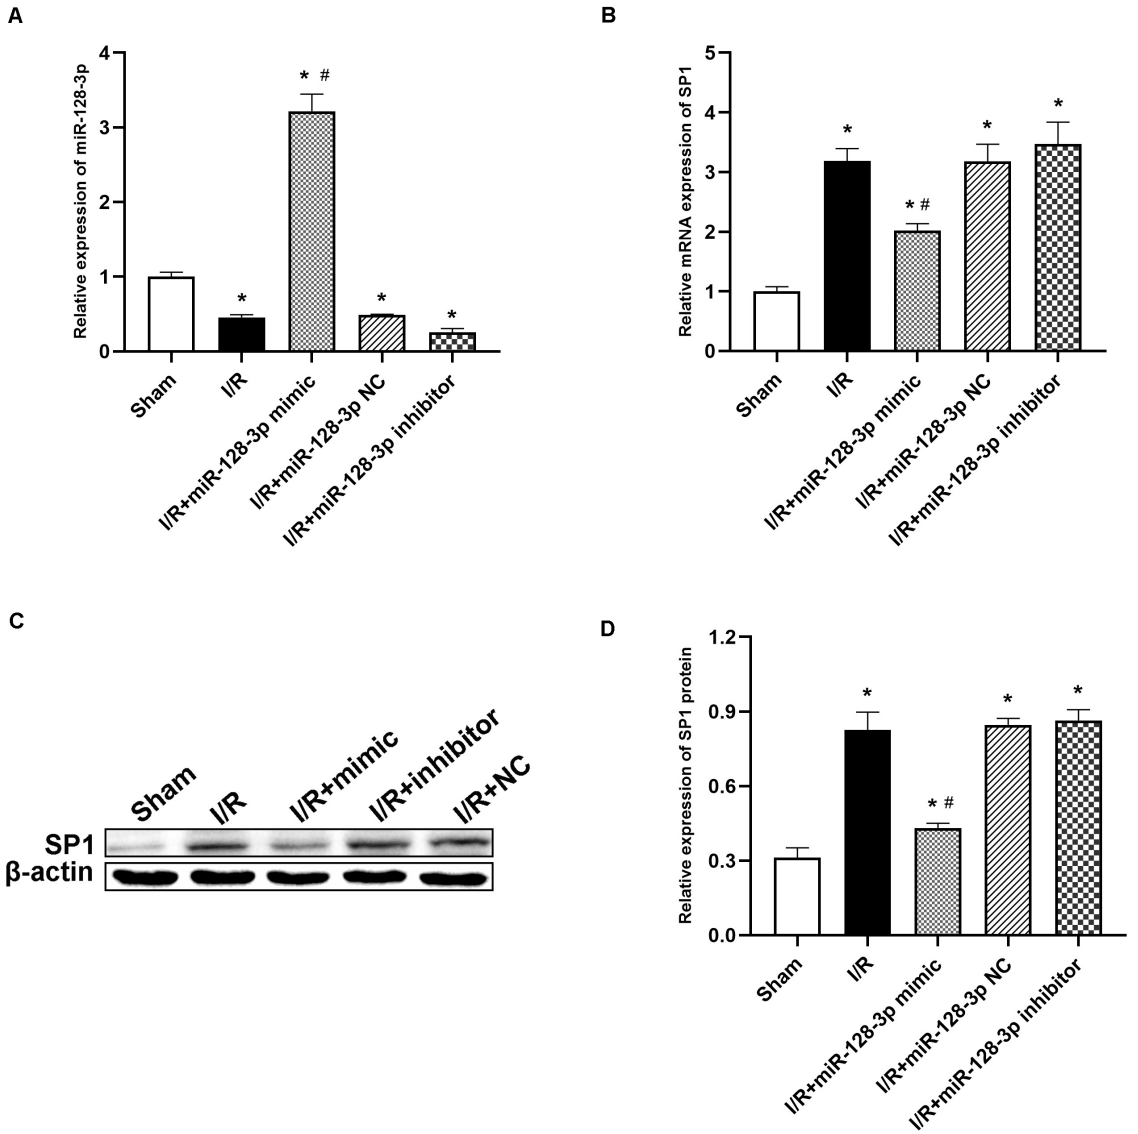

FIGURE 4 | Effects of miR-128-3p mimic and inhibitor on miR-128-3p and SP1 levels in the L4–L6 segments of spinal cord specimens. **(A)** miR-128-3p expression levels in various groups. **(B)** Quantification of SP1 mRNA expression in various groups by qRT-PCR. **(C,D)** Western blot analysis of SP1 protein levels in various groups. β-actin was used as a loading control. et al., 2020). Meanwhile, miR-128-3p protected neurons from apoptosis at the early stage of cerebral ischemia (Mao et al., 2017). The above data suggest miR-128-3p's regulatory role in neuroinflammation and neuroapoptosis post-injury. However, discrepant findings have been reported. While miR-128-3p is considered to enhance neuronal survival in ischemia-induced brain damage (Mao et al., 2017), its inhibition has been shown to induce the protection of cardiomyocytes from I/R injury (Chen et al., 2017). One miR can modulate many target genes, whereas one target gene could be modulated by multiple miRs (Brandenburger et al., 2012; Ksiazek-Winiarek et al., 2013), and functional target genes might depend on pathological conditions, treatments and the effector organ. Thus, it is very possible to encounter discrepancy in expression while examining the same miR in distinct conditions.

Given that neuroinflammation and neuroapoptosis have been shown to be critical phenotypes of spinal cord I/R injury (Li et al., 2015; Bao et al., 2018; Li et al., 2018), we further investigated whether miR-128-3p protected against spinal cord I/R injury by inhibiting inflammation and apoptosis. In this work, miR-128-3p was downregulated in the spinal cord at 6, 12, 24, 36, and 48 h, respectively, post-I/R in comparison with sham animals, and miR-128-3p content reached its lowest point at 12 h after I/R. We, therefore, selected 12 h post-I/R for subsequent assays. Consistently, distinct ameliorations in hind-limb motor function, preservation degrees of BSCB

permeability, reduction in inflammatory factors in ELISA (IL-1β, TNF-α, and IL-6) and numbers of complete neurons were obtained after miR-128-3p mimic administration, as reflected by increased Tarlov scores and reduced EB extravasation. Moreover, we performed TUNEL staining and measured protein levels of Bax and Bcl-2, to investigate the mechanisms by which miR-128-3p might attenuate the neuronal apoptosis after I/R (**Figures 7A,C**). The results showed that TUNEL-positive cells mainly presented a neuronal morphology and were distributed in the anterior horn with increased Bax and decreased Bcl-2 in Western blotting. Following miR-128-3p mimic administration, the TUNEL-positive cells decreased in the anterior horn with decreased Bax and increased Bcl-2. Based on these data, we hypothesized that miR-128-3p might induce neuroprotective effects in spinal cord I/R injury by ameliorating inflammatory cytokine production and apoptotic rate.

To explore the mechanism underlying the neuroprotective effects inducted by miR-128-3p overexpression on spinal cord I/R injury, potential mRNA targeting was examined. MiRs require complementary binding with ≥6 consecutive nucleotides in the 3′ UTR of an mRNA target (Li et al., 2015). Based on TargetScanHuman 7.1 (Li et al., 2018). SP1 mRNA had 8 complementary nucleotides in the 3′ UTR, and the temporal expression patterns of SP1 and miR-128-3p exhibited a negative

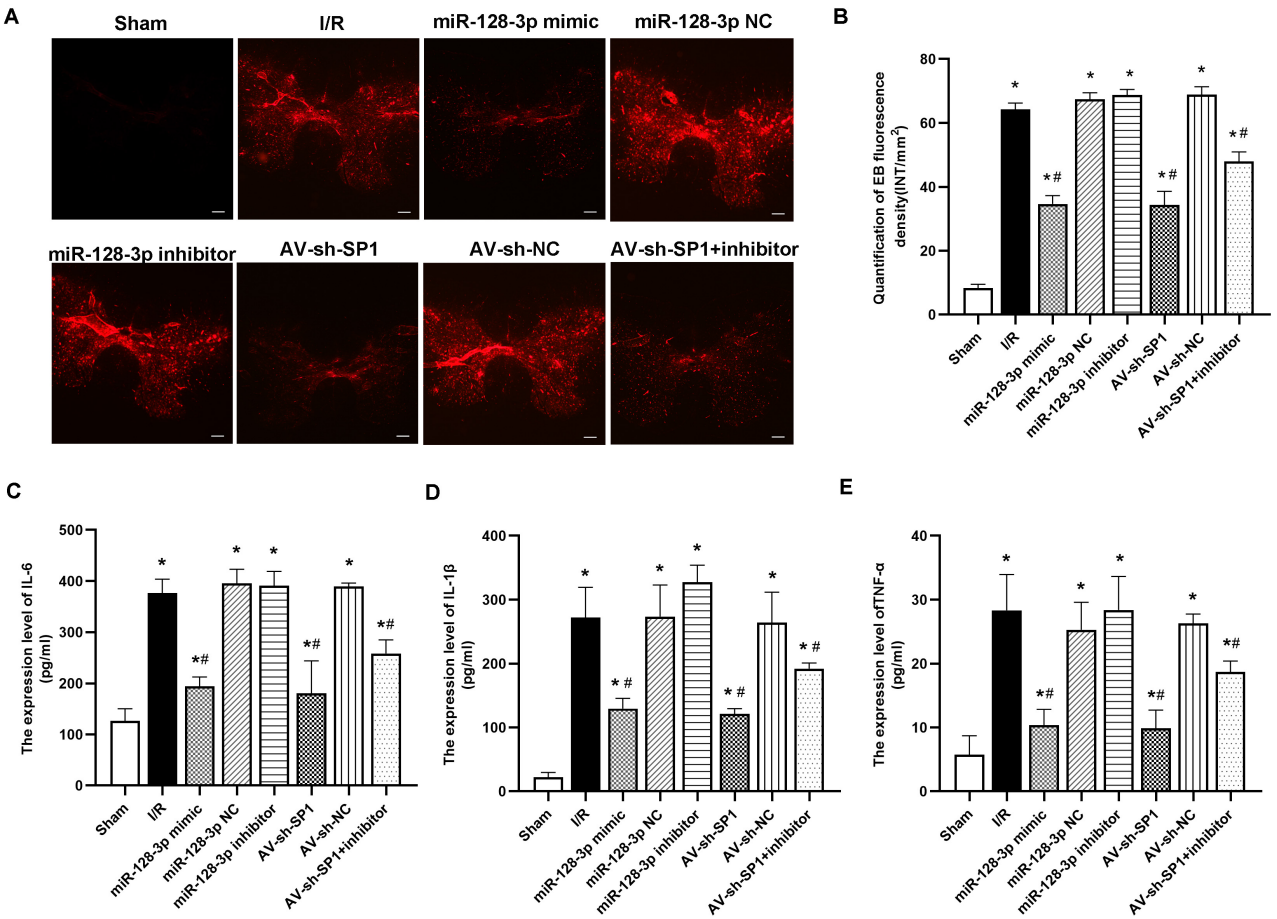

FIGURE 6 | Effects of miR-128-3p mimic and AV-sh-SP1 on blood–spinal cord barrier (BSCB) integrity and IL-6, IL-1β and TNF-α amounts after I/R. **(A)** EB extravasation visualized as red fluorescence by microscopy to evaluate the alterations in BSCB permeability in the eight groups. correlation at 12 h after reperfusion. In accordance with this result, reduced luciferase activity was found after co-transfection with a plasmid harboring the WT 3′ UTR of SP1 and miR-128-3p mimic. To avoid the cellular crosstalk and interactions *in vivo*, these effects were next assessed after pretreatment of rats with miR-128-3p mimic, control and inhibitor, respectively (Li et al., 2017). Administration of miR-128-3p mimic significantly reduced SP1 mRNA and protein amounts, while control and inhibitor miR showed no reductions, receptively (**Figures 4B–D**). Jointly, the above data suggest that miR-128-3p directly suppresses spinal cord SP1 following I/R.

SP1 is a frequently reported DNA-binding protein with a C2H2 zinc finger structure that controls gene transcription in multiple physiological and pathological processes (Chu, 2012). SP1 and related proteins contribute to multiple critical cellular events, including cell growth, differentiation, malignant transformation and apoptosis (Vizcaino et al., 2015). Based on previous literature, SP1 overexpression promotes apoptosis by itself, and malignant cells with SP1 overexpression can avoid SP1-associated apoptosis (Deniaud et al., 2006). In addition, some reports have found that SP1 was upregulated, and SP1 suppression exerted neuroprotection in experimental PD (Yao et al., 2018; Cai et al., 2020). SP1 also favors inflammation in many pathologies (Shin et al., 2015; Yang et al., 2018), and its absence reduces TNF-α, IL-1β, and IL-6 amounts in hypoxia-induced human umbilical vein endothelial cells (HUVECs) (Yang et al., 2018). These findings corroborate Qin et al. (2018), who revealed that suppressing the activation of SP1 effectively inhibits OGD/R-associated inflammation in microglia. Recently, emerging evidences indicate that expression of SP1 under ischemia/hypoxic conditions is increased (Eltzschig et al., 2009; Li et al., 2019). In addition, SP1 expression is upregulated following acute kidney damage associated with I/R (Chen et al., 2017). However, a report described anti-necroptosis effects for human-induced pluripotent stem cell-derived mesenchymal stromal cells-extracellular vesicles (hiPSC-MSCs-EVs) in renal I/R injury by delivering SP1 into target renal cells; meanwhile, SP1 knockout blunted renal protection by hiPSC-MSCs-EVs in rats with I/R injury (Yuan et al., 2017). Such discrepancy may be explained by distinct disease models and study time points for specific

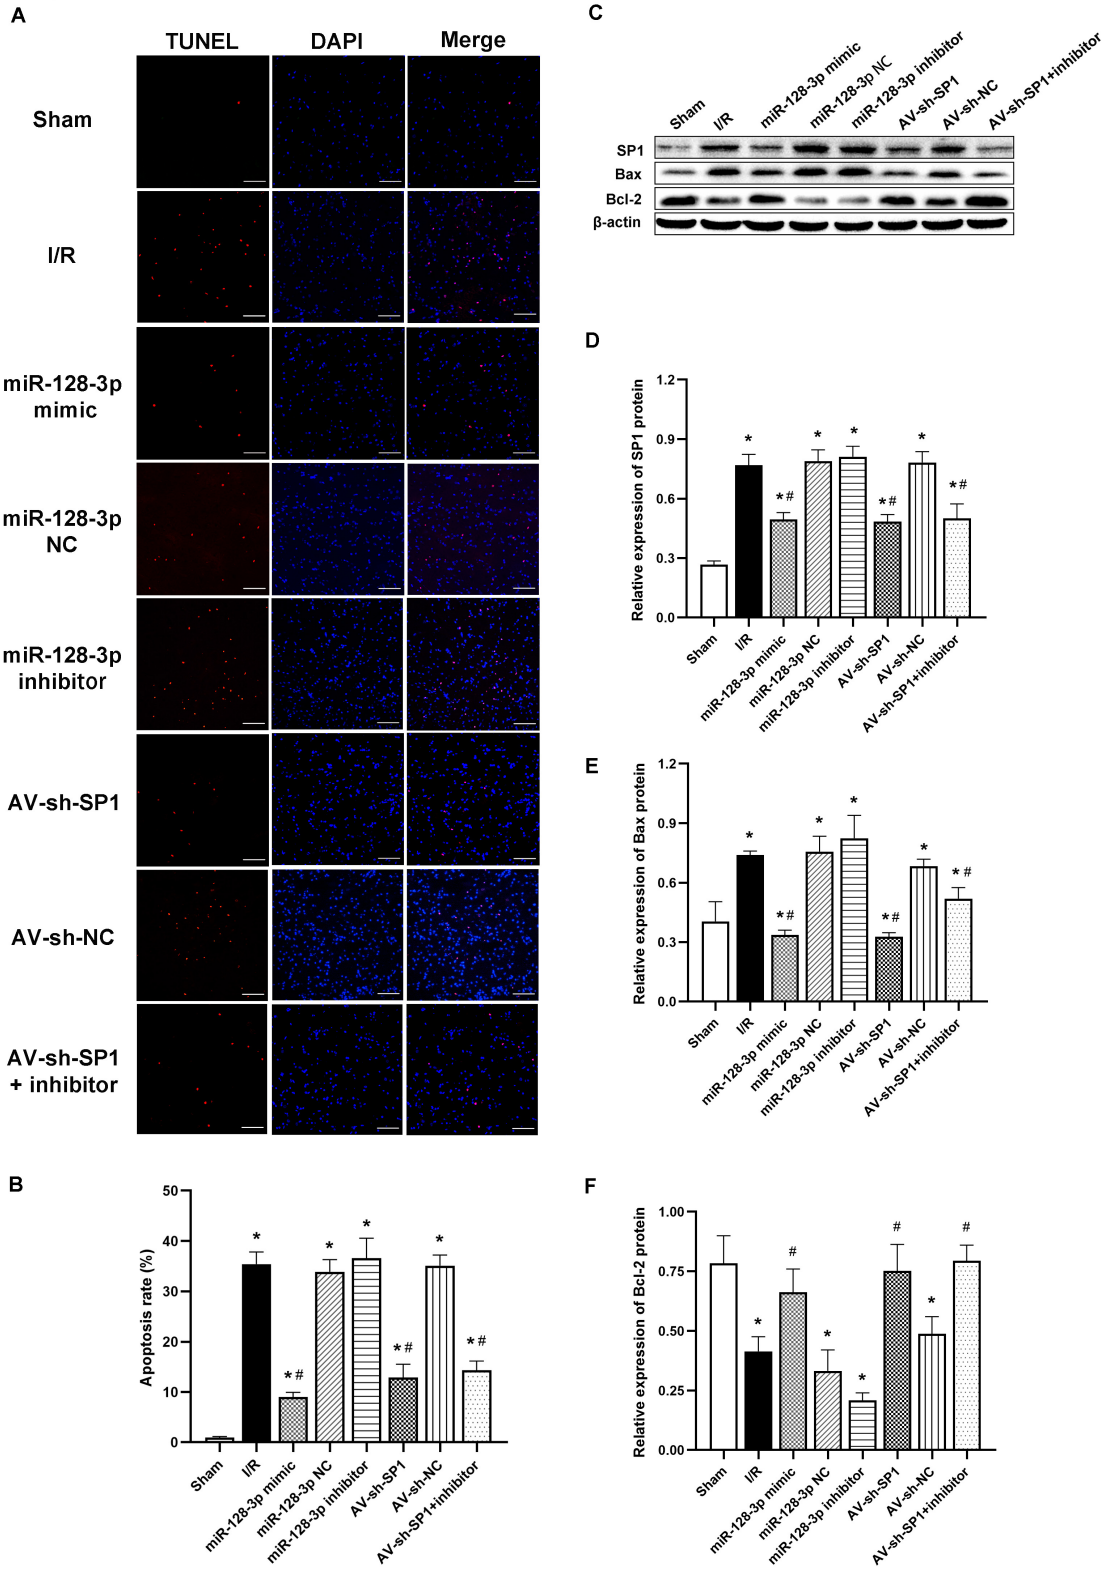

FIGURE 7 | Effects of miR-128-3p mimic and AV-sh-SP1 on neuronal apoptosis and SP1, Bax and Bcl-2 amounts after I/R. **(A)** Cell apoptosis in the ventral gray matter by TUNEL staining (green)and DAPI (blue). Scale bar = 100 μm. **(B)** Quantification of TUNEL-positive neurons in the ventral horn averaged across three independent experiments. **(C–F)** Representative Western blotting and quantitative protein analyses of SP1, Bax and Bcl-2 in the various groups. cell-type activation. A previous study also noted increased SP1 expression in the cortex after brain I/R damage and in primary neurons post-OGD/R (Sun et al., 2015), providing novel insights into the endogenous pathways that prevent ischemia-associated neuronal injury. Moreover, SP1 suppression delays neuronal loss and prolongs survival (Garcia-Morales et al., 2019). Additionally, in the current study, intrathecal injection of AV-sh-SP1 not only induced comparably lower levels of SP1 and resulted in poor production of IL-6, IL-1β, TNF-α, and Bax, but also upregulated Bcl-2, improved neurological function and histological findings, dwindled TUNEL-positive cells in anterior horn, and attenuated EB leakage, in comparison with the I/R group. The current findings suggest that SP1 might represent an inflammation and apoptosis-associated transcription factor, which promotes neuronal survival in spinal cord I/R injury. Moreover, we demonstrated that miR-128-3p targeted SP1, corroborating previous findings that miR-128 plays an essential role in glioma progression via SP1 suppression (Dong et al., 2014). Another report confirmed that high miR-128-3p expression suppresses cell proliferation and differentiation in bovine skeletal muscle satellite cells via SP1 downregulation (Dai et al., 2016).

CONCLUSION

Overall, miR-128-3p suppression provides remarkable protection of the spinal cord I/R injury, involving both anti-inflammatory and anti-apoptotic effects. Prophylactic approaches for spinal cord protection are essential, and this is the first report demonstrating that the miR-128-3p/SP1 axis has critical functions in neuroprotection upon spinal cord ischemia. This report further confirms that miRNAs are neuroprotective molecules affecting spinal cord I/R injury.

Pathophysiological Changes and the Role of Notch-1 Activation After Decompression in a Compressive Spinal Cord Injury Rat Model

Surgical decompression is the primary treatment for cervical spondylotic myelopathy (CSM) patients with compressive spinal cord injury (CSCI). However, the prognosis of patients with CSCI varies, and the pathophysiological changes following decompression remain poor. This study aimed to investigate the pathophysiological changes and the role of Notch-1 activation after decompression in a rat CSCI model. Surgical decompression was conducted at 1 week post-injury (wpi). DAPT was intraperitoneally injected to down-regulate Notch-1 expression. Basso, Beattie, and Bresnahan scores and an inclined plane test were used to evaluate the motor function recovery. Hematoxylin and eosin staining was performed to assess pathophysiological changes, while hypoxia-inducible factor 1 alpha, vascular endothelial growth factor (VEGF), von Willebrand factor (vWF), matrix metalloproteinase (MMP)-9, MMP-2, Notch-1, and Hes-1 expression in the spinal cord were examined by immunohistochemical analysis or quantitative PCR. The results show that early decompression can partially promote motor function recovery. Improvements in structural and cellular damage and hypoxic levels were also observed in the decompressed spinal cord. Moreover, decompression resulted in increased VEGF and vWF expression, but decreased MMP-9 and MMP-2 expression at 3 wpi. Expression levels of Notch-1 and its downstream gene Hes-1 were increased after decompression, and the inhibition of Notch-1 significantly reduced the decompression-induced motor function recovery. This exploratory study revealed preliminary pathophysiological changes in the compressed and decompressed rat spinal cord. Furthermore, we confirmed that early surgical decompression partially promotes motor function recovery may via activation of the Notch-1 signaling pathway after CSCI. These results could provide new insights for the development of drug therapy to enhance recovery following surgery.

INTRODUCTION

Cervical spondylotic myelopathy (CSM) is a degenerative condition of the spine that leads to static and dynamic compression of the spinal cord (Karadimas et al., 2013a). CSM in cases of compressive spinal cord injury (CSCI) results in various pathophysiological alterations, such as neuroinflammation, microvasculature changes, ischemic-hypoxic injury,

blood spinal cord barrier (BSCB) destruction, and neuronal cell death (Yu et al., 2011; Hirai et al., 2013; Tetreault et al., 2015; Vidal et al., 2019). Decades ago, it was reported that surgical decompression of the compressed spinal cord can partially recover neurological function in patients and halt CSM progression (Wiberg, 1986; Ishida et al., 1999; Li et al., 2019; Akter et al., 2020). However, our understanding of the physiological and pathological changes following decompression remains poor due to the lack of a reliable animal model of induced CSM. Thus, studies on the pathophysiological changes after decompression may contribute to improved prognoses of patients with CSCI.

In recent years, numerous attempts have been made to establish a CSCI model in different animals, employing methods such as tumor induction (Izumida, 1995), the use of penetrating hydrogels (Yang et al., 2015) or urethane polymers (Kurokawa et al., 2011), the use of spinal hyperostotic mice (twy/twy) (Hirai et al., 2013), and plastic screw implantation (Kanchiku et al., 2001). Among these approaches, hydrogels and polymers are expected be applicable materials that lead to a chronically progressive injury. However, neurological function changes after CSCI have not been reported for the application of polyurethane polymers. Previously, we successfully established a CSCI rat model using a water-absorbable polyurethane polymer sheet (Long et al., 2013), which provided a foundation for exploring pathophysiological changes in the decompressed spinal cord.

Thus far, only four studies have investigated the decompressed state of CSM in animal models (Harkey et al., 1995; Karadimas et al., 2015b; Dhillon et al., 2016; Haddas et al., 2018). Harkey et al. (1995) demonstrated that decompression can improve neurological function and can alter the necrosis and cavitation of spinal cord tissue in a dog model. Karadimas et al. (2015b) reported on an ischemia-reperfusion injury after decompression in a rat model, which could be prevented by treatment with riluzole. Dhillon et al. (2016) suggested that decompression may increase axon growth rates and promote axon sprouting in a rat model. In addition, (Vidal et al., 2017) found that early decompression is important for achieving better neurological outcomes and demonstrated that delayed decompression is associated with increased astrogliosis, microglia activation, and reduced spinal cord blood flow. As few studies have evaluated the decompression state of CSM, further investigations of pathophysiological changes in the decompressed spinal cord are vital to enable the development of comprehensive drug therapy in order to enhance recovery following surgery.

We have found that various changes, including alterations in microvascular density (Long et al., 2014; Cheng et al., 2015), varying degrees of ischemia-hypoxia (Long et al., 2012; Cheng et al., 2019), matrix metalloproteinase (MMP) expression (Cheng et al., 2019), BSCB disruption (Long et al., 2015), and neuron loss (Xu et al., 2017), occured at different time points after chronic CSCI. Structural and cellular changes after decompression, such as the expression of angiogenesis- and BSCB-related factors, have attracted substantial attention in acute and chronic SCI (Ng et al., 2011; Karadimas et al., 2015a; Randi and Laffan, 2017). Nevertheless, the pathophysiological changes occurring in the decompressed spinal cord have not been widely investigated. Increasing evidence suggests that Notch-1 signaling is involved in central nervous system (CNS) diseases and is associated with cell death, angiogenesis, and BSCB function (Fassbender et al., 2011; Cai et al., 2016). By elucidating the physiological and pathological changes and the role of the Notch-1 signaling pathway after decompression in CSCI, new perspectives may be provided for improving the prognosis of CSM patients with decompression. Therefore, based on our previous studies, we further investigated the physiological and pathological changes in the decompressed spinal cord and the effects of Notch-1 pathway inhibition in a rat CSCI model following decompression.

MATERIALS AND METHODS

Animal Studies

The procedures applied in these experiments were approved by the Research Ethics Committee of Sun Yat-sen University and conformed to all relevant regulatory standards (Animal protocol number: 2020458). A total of 73 adult female Sprague–Dawley rats (weighing 250–300 g; aged 28–30 weeks) were included in this study. Ten of these rats were used to evaluate the extent of expansion of the compression material at 1 day post-injury (dpi) ($n = 3$), 1 week post-injury (wpi) ($n = 3$), or 3 wpi ($n = 4$). Thirty-one rats were randomly allocated to the sham ($n = 10$), CSCI ($n = 10$), or CSCI with decompression (CSCI + decompression; $n = 11$) group. Finally, Thirty-two rats were randomly allocated to the CSCI ($n = 10$), CSCI with decompression and control (CSCI + decompression + NC; $n = 11$), or CSCI with decompression and DAPT (CSCI + decompression + DAPT; $n = 11$) group. One rat died in the Sham group and CSCI group respectively, after the initial surgery due to anesthetic accident, One rat in the CSCI group died on the next day after compression surgery. We performed compression surgeries for 76 rats and three of them died. The mortality rate was 3.9%. The rats were housed in groups of 4–5 per cage on a 12/12-h light/dark cycle with free access to food and water.

Intraperitoneal Injection

DAPT solution (1 μg/μL) was prepared by dissolving DAPT powder (MCE, United States) in 0.01 M phosphate-buffered saline (PBS) containing 5% dimethyl sulfoxide. The DAPT solution (1 mg/kg per rat) and a negative control were intraperitoneally injected using a microinjection syringe (Cheng et al., 2020).

Compressive Spinal Cord Injury

Rats in the sham and CSCI groups were anesthetized with a cocktail (3 mg/kg) (Guangzhou FISCLAB Environ. Sci-Tech. Co., Ltd., Guangzhou, China) containing ketamine (31.25 mg/kg), xylazine (1.58 mg/kg), and acepromazine (0.31 mg/kg). Following exposure of the C4–C6 spinal process and laminas from the posterior, C5 laminectomy was conducted to access the epidural space. In the CSCI group, a sheet (1 mm × 3 mm × 1 mm) of water-absorbable polyurethane polymer, (1→4)-3,6-anhydro-a-l-galactopyranosyl-(1→3)-β-D-galactopyranan), was implanted into the C6 epidural space

in the dorsal region of the spinal cord (Hu et al., 2011). A modified polyurethane membrane (synthesized by isocyanates and polyols) was coated on the surface of the polymer sheet to reduce the expansion speed. Spinal cord compression was gradually achieved through slow expansion of the polymer sheet. In contrast, animals in the sham groups received only the C5 laminectomy, without insertion of the polymer. For surgical decompression, the same anesthesia methods were applied, and all animals were reopened. In this step, the polymer was removed in the decompression group. After surgery, the paravertebral muscle was sutured in layers, and the skin incision was stapled. Animals received a subcutaneous injection of lactated Ringer's solution (200 μL) immediately after compression or decompression to prevent dehydration. Penicillin G (80 U/g) was intramuscularly injected to prevent infection during surgery, and carprofen (4–5 mg/kg, Rimadyl, Pfizer) was injected subcutaneously 2 days post-surgery for further pain relief as needed. Both compression and decompression surgeries were performed by the same experienced investigator.

Motor Function Evaluation

To evaluate the motor function recovery after CSCI, the Basso, Beattie, and Bresnahan (BBB) locomotor scale (Basso et al., 1995) and an inclined plane test (IPT) (Rivlin and Tator, 1977) were conducted at 1 dpi and 1, 2, and 3 wpi. BBB scores range between 0 and 21, where a score of 0 reflects complete paralysis and a score of 21 indicates normal locomotion. Lower scores (0–7) denote isolated joint movements with little or no hindlimb movement; intermediate scores (8–13) express intervals of uncoordinated stepping; and higher scores (14–21) express forelimb and hindlimb coordination. For the IPT, rats were placed horizontally on a smooth tilt board. The board was initially placed in a horizontal orientation (0°), and the angle was increased by 5–10° after each attempt. The maximum angle at which the rats remained on the board for 10 s was recorded. Raw BBB score data for the group of CSCI with decompression were used to evaluate the recovery of animals at 3 wpi in comparison with 1 wpi [Recovery BBB score (CSCI): BBB score (3 wpi) – BBB score (1 wpi)]. If the recovery BBB score $\geq$ standard deviation (S.D.) of the recovery BBB score (CSCI), then the case was determined to have significant recovery. If the recovery BBB score $<$ S.D. of the recovery BBB score (CSCI), then the case was determined to have no recovery. This evaluation was conducted by two investigators blinded to the group assignments.

Micro-Computed Tomography

To assess the extent of expansion of the compression material after implantation, the cervical spinal cords of rats in different groups were assessed by micro-computed tomography (micro-CT) (ZKKS-MCT-Sharp-II, Guangzhou Zhongkekaisheng Medical Technology Co., Ltd., Guangzhou, China). Animals were anesthetized with an overdose of 80–120 mg/kg intravenous sodium pentobarbital (Guangzhou Fischer Chemical Co., Ltd.) and transcardially perfused with 0.9% saline followed by 4% paraformaldehyde in 0.1 M phosphate buffer. The whole cervical spinal cord was then carefully harvested and fixed overnight with 4% formaldehyde in phosphate-buffered solution. Prior to micro-CT scanning, the tissues surrounding the spine were carefully removed under a microscope. The compression material of each specimen was presented using 3D-Med 4.3 software (Guangzhou ZhongkeKaisheng Medical Technology Co., Ltd., Guangzhou, China).

Immunohistochemistry

After perfusion, the C5–C7 spinal cord segment was harvested, fixed overnight with 4% formaldehyde in phosphate-buffered solution at 4°C, and then embedded in paraffin. A series of 25-μm-thick spinal cord sections was used for immunohistochemical (IHC) staining. Microwave epitope retrieval was performed before staining. Sections were incubated overnight at 4°C with a mouse monoclonal antibody against hypoxia-inducible factor 1 alpha (HIF-1α) (1:150; ab1, Abcam, Cambridge, United Kingdom), a rabbit polyclonal antibody against Notch-1 (1:200; ab8925, Abcam, Cambridge, United Kingdom), a mouse monoclonal antibody against Hes-1 (1:50; sc-166410, Santa Cruz Biotechnology, Inc., United States), a mouse monoclonal antibody against vascular endothelial growth factor A (VEGFA) (1:200; ab1316, Abcam, Cambridge, United Kingdom), a rabbit polyclonal against von Willebrand factor (vWF) (1:200; ab6994, Abcam, Cambridge, United Kingdom), a rabbit polyclonal against MMP-9 (1:100; ab38898, Abcam, Cambridge, United Kingdom), and a mouse monoclonal antibody against MMP-2 (1:300; ab86607, Abcam, Cambridge, United Kingdom). Subsequently, the sections were sequentially incubated with a ready-to-use DAKO ChemMate EnVision^{TM} kit (K500711; Dako; Agilent Technologies, Inc., Santa Clara, CA, United States) for 30 min at room temperature. Images of each section of the perilesional spinal cord were acquired at 200× or 400× magnification using an XC30 camera mounted on an Olympus microscope (Olympus Corporation, Tokyo, Japan). Three random images at 200× or 400× magnification were also captured for semi-quantitative analysis. The brown area in the sham spinal cord was analyzed, and the background density was excluded to create the standard. Subsequently, the integrated optical density (IOD) was calculated using Image-Pro Plus 6.0 software (Media Cybernetics, Inc., Rockville, MD, United States). Omission of the primary antibody only controls for unspecific staining of the secondary antibodies.

Hematoxylin and Eosin Staining

Briefly, slides were placed in xylene in a 37°C incubator. The slides were hydrated by passing through the following alcohol concentrations (100, 100, 95, 95, 75, 75%). Hematoxylin staining (Guangzhou Fischer Chemical Co., Ltd.) was applied for 2–5 min. The slides were then washed in ddH_2O for 5 min or less, until they turned "blue." The slides were differentiated in 1% acid alcohol (1% HCL in 70% alcohol) for 5 min. After a washing step, the slides were stained in 1% eosin Y (Guangzhou Fischer Chemical Co., Ltd.) for 10 min. Subsequently, the slides were again washed in ddH_2O for 2–5 min. The samples were dehydrated in alcohol solutions of increasing concentration (75, 75, 95, 95, 100, 100%) and were cleared of xylene. Finally, the

slides were mounted with mounting media, and images (20×, 200×, and 400× magnification) were acquired under a light microscope.

Real-Time Quantitative Polymerase Chain Reaction

Total RNA was extracted from the compressed or decompressed spinal cord. The purity of the RNA was determined, and reverse transcription PCR (PrimeScript^{TM} RT reagent kit) and real-time quantitative PCR (RT-qPCR) (SYBR Premix Ex Taq II) were performed following the manufacturer's instructions (Takara Biotechnology Co., Ltd., China). The detailed primer sequences used in RT-qPCR are given in **Supplementary Table S1**. Cycle threshold (CT) values were recorded, and the relative expression of target genes was calculated using the expression $2^{-\Delta\Delta Ct}$ (Hu et al., 2019).

Statistical Analysis

All data are expressed as the mean with 95% confidence intervals (CI) or Medians with interquartile ranges. Statistical tests were performed using GraphPad Prism 7.0 software (San Diego, CA, United States). The motor function recovery results were analyzed by repeated-measures analysis of variance (ANOVA) to reveal overall group differences and significant changes over time. One-way analysis of variance followed by Tukey's *post hoc* test was used for comparisons among multiple groups. Statistical significance was set at $p < 0.05$.

RESULTS

Expansion of Water-Absorbable Compression Material After Implantation

These experiments were designed to evaluate the extent of expansion of polyurethane polymer sheets under the study conditions (**Figure 1A**). As shown in **Figure 1B**, this modified water-absorbable material gradually swelled after implantation and reached a maximal size at 3 wpi. Micro-CT scanning also clearly revealed the extent of expansion at 1 dpi, 1, and 3 wpi (**Figure 1C**).

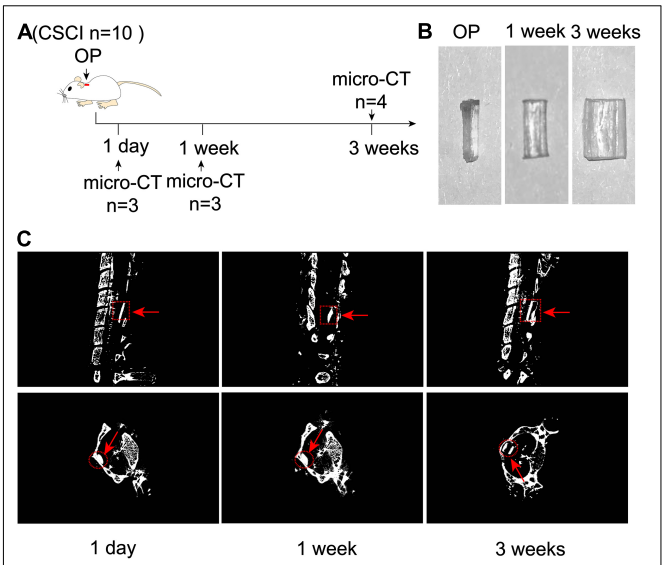

FIGURE 1 | Expansion of compression material after implantation. **(A)** Experimental design. **(B)** Alteration in the water-absorbable polyurethane polymer before and after surgery at 1 and 3 weeks. **(C)** Three-dimensional reconstruction and representative sagittal and transverse micro-CT images of the compressive segment. The red arrow indicates the compression site and material. 1 day post-injury: $n = 3$; 1 week post-injury: $n = 3$; 3 weeks post-injury: $n = 4$.

Early Decompression Partially Promoted Motor Function Recovery After CSCI

Surgical decompression has been regarded as a safe treatment for incomplete CSCI (Bakhsheshian et al., 2017; Sakaura et al., 2019), which results in improved functional status and quality of life for patients with various diseases, including CSM, ossification of the posterior longitudinal ligament (OPLL), and spinal stenosis. Here, we used the BBB score and IPT to evaluate changes in motor function after surgical decompression in a rat model of CSCI (**Figure 2A**). The results showed that the motor function gradually decreased from 1 to 3 wpi after CSCI. However, rats with surgical decompression at 1 wpi exhibited significantly improved motor function compared to rats without decompression (**Figures 2B,C**). Moreover, two of eleven CSCI rats did not recover at 3 wpi in comparison with 1 wpi in terms of BBB score and over 80% of rats exhibited a significant recovery after early decompression in our model (**Figure 2D**).

Structural and Cellular Changes and Hypoxic Level in the Decompressed Spinal Cord

Hematoxylin and eosin (HE) staining revealed histological changes at the injury epicenter under different levels of magnification (**Figure 3A**). The spinal cord was intact in the sham group. In the CSCI without decompression group, the compressed spinal cord exhibited structural damage, including fragmentation of neuronal nuclei, pyknosis, neuropil damage, degradation of the extracellular matrix, interstitial edema, cytoplasmic reduction, and cavity formation. Cellular changes were also observed at 3 wpi following CSCI, including neuron loss and axon degradation. Interestingly, differences were observed in the structural and cellular changes between the groups with and without decompression. After decompression, fragmentation of neuronal nuclei, degradation of the extracellular matrix, pyknosis, neuropil damage, interstitial edema, cytoplasmic reduction, cavity formation, neuron loss, and axon degradation were clearly alleviated.

HIF-1α IHC staining and RT-qPCR were performed to evaluate the hypoxic levels after CSCI (**Figure 3B**). As shown in **Figures 3C,D**, the quantitative analysis results indicate that HIF-1α expression in the spinal cord lesion site was increased after 3 weeks of compression. Preliminary data suggest that surgical compression at 1 wpi may improve the hypoxia environment and

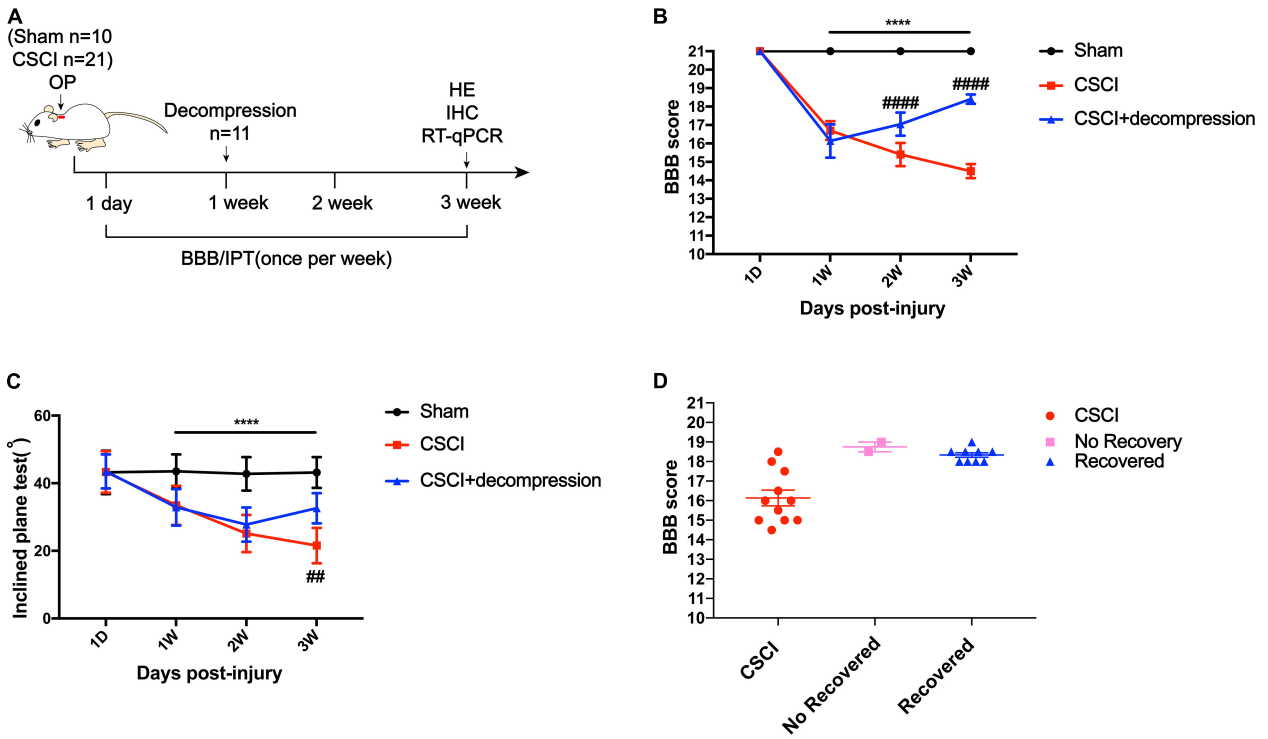

FIGURE 2 | Early decompression promoted motor function recovery after CSCI. **(A)** Experimental design. **(B)** Animals were tested weekly starting from 1 dpi in an open field, and motor function recovery was evaluated according to the BBB score [Two-way ANOVA, $F(1,8) = 66.13$, $p = 0.0043$; $^{****}p < 0.0001$: sham group vs. CSCI group; $^{\#\#\#\#}p < 0.0001$: CSCI group vs. CSCI with decompression group]. **(C)** Animals were tested weekly starting from 1 dpi using the IPT, and the angle (°) was recorded to reveal motor function recovery [Two-way ANOVA, $F(6,112) = 4.861$, $p < 0.001$; $^{****}p < 0.0001$: sham group vs. CSCI group; $^{\#\#}p = 0.0052$: CSCI group vs. CSCI with decompression group]. **(D)** BBB scores for recovered and non-recovery rats after decompression at 3 wpi. decrease HIF-1α expression compared with no decompression. However, further experiments are needed to confirm this notion.

Expression of VEGF, vWF, MMP-9, and MMP-2 in the Decompressed Spinal Cord

Vascular endothelial growth factor (DuBois and Demetri, 2007) and vWF (Randi and Laffan, 2017) have been reported as angiogenesis markers in many diseases, while MMPs such as MMP-9 and MMP-2 are related to inflammation and the BSCB (Na et al., 2015; Yao et al., 2018). Recently, many researchers have suggested that axonal degeneration, vascular dysfunction, and BSCB disruption may be key processes in neurological function recovery following decompression (Badhiwala et al., 2018; Blume et al., 2020). We previously reported on vascular and BSCB alterations as well as a correlation between MMP-9 and motor function recovery after CSCI, which indicated that angiogenesis and MMP may play critical roles in the process of motor function recovery (Long et al., 2014; Cheng et al., 2015, 2019; Xu et al., 2017). Therefore, we further investigated VEGF and vWF expression in spinal cord by using IHC to evaluate the potential effects of surgical decompression on angiogenesis. We also explored the effects of decompression on MMP-9 and MMP-2 (**Figure 4**). The results revealed that VEGF expression level in spinal cord gray matter and vWF expression level in spinal cord white matter were decreased, while MMP-9 and MMP-2 levels were increased in endothelial cells, neurons, and glia of the spinal cord after CSCI. Interestingly, VEGF and vWF levels were dramatically increased after decompression. Moreover, preliminary results suggest that decompression resulted in decreased MMP-9 and MMP-2 expression at 3 wpi (**Figures 4B–E** and **Supplementary Figures S1A,B**). However, further experiments are needed to confirm this notion. These data reveal that decompression may influence angiogenesis and BSCB function in the lesional spinal cord.

Notch-1 Expression Was Up-Regulated and Positively Associated With Motor Function Recovery After Decompression

To investigate whether Notch-1 signaling is activated after decompression, IHC and RT-qPCR were applied to detect the expression of Notch-1 and its downstream gene Hes-1. Preliminary data indicates that decompression lead to an upregulation of Notch-1 and Hes-1 expression levels (**Figure 5** and **Supplementary Figures S1C,D**). However, further studies need to confirm these findings. These preliminary results indicate that the Notch-1 signaling pathway may play a role in motor function recovery after CSCI. Furthermore,

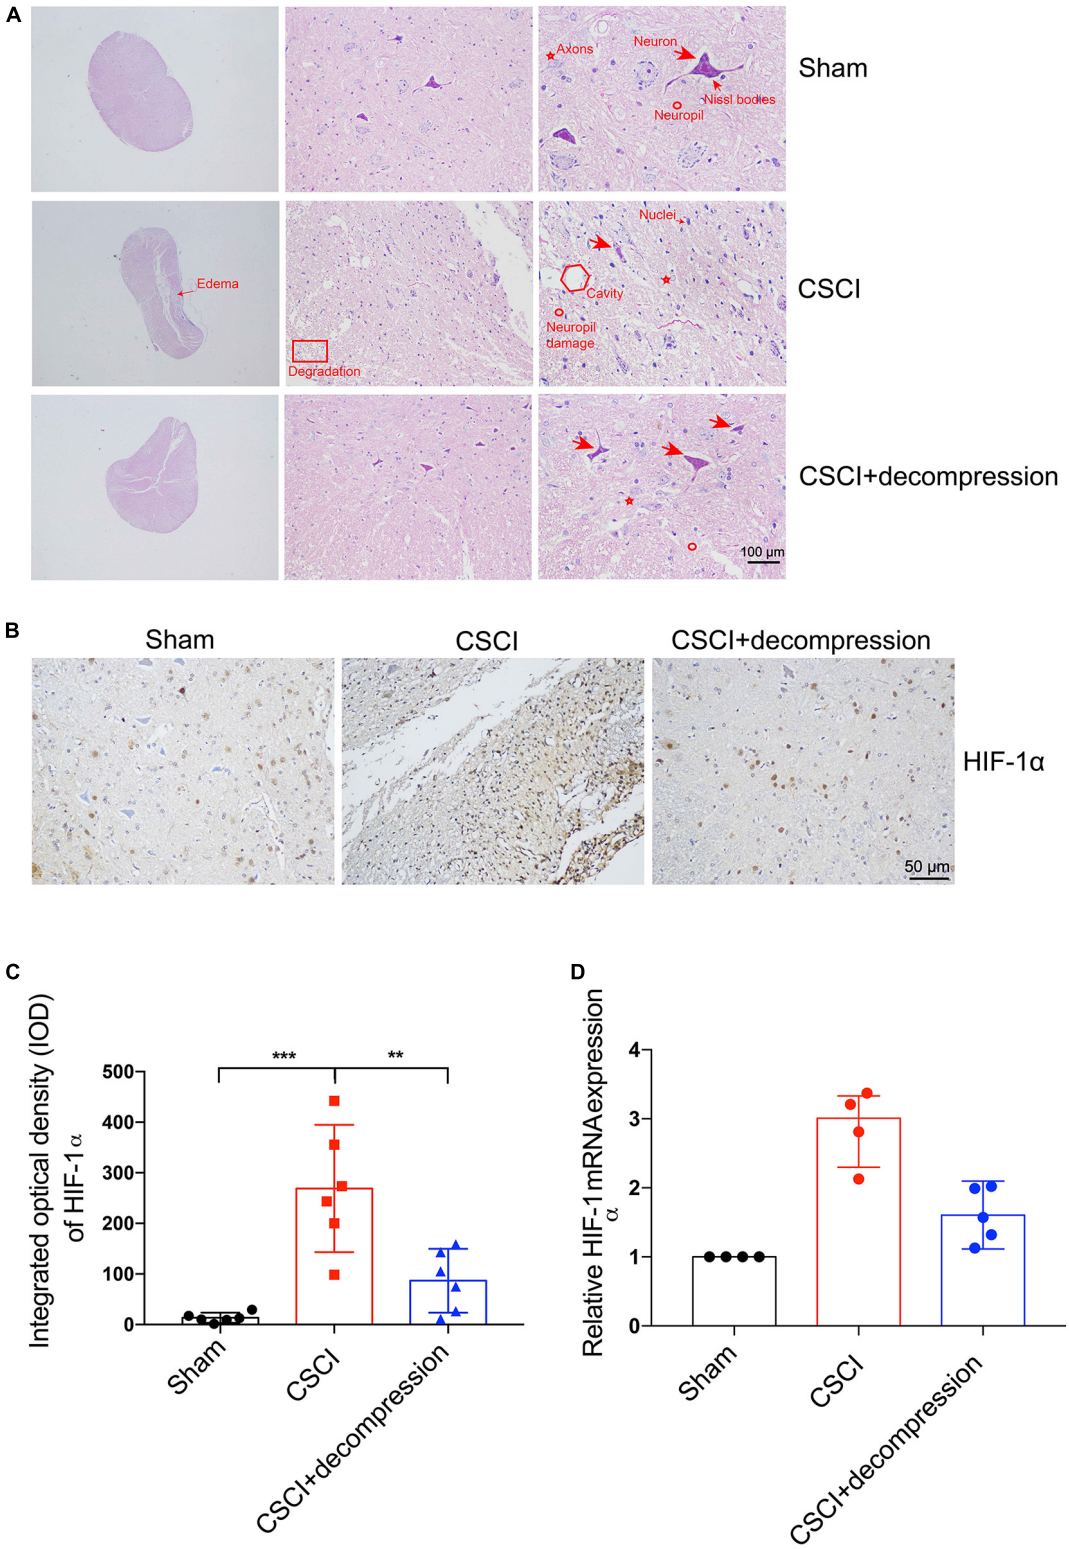

FIGURE 3 | Decompression-protected neurons and improved hypoxia environment after CSCI. **(A)** HE staining of lesion sites from the sham, CSCI, and CSCI with decompression groups (20× , 200× , and 400× magnification; scale bar, 100 μm). **(B)** HIF-1α expression, as assessed by IHC (200× magnification; scale bar, 50 μm). **(C)** HIF-1α IHC staining, as quantitated by the IOD [One-way ANOVA, $F(2,15) = 17.18$, $p < 0.001$; Tukey *post hoc*: ***$p < 0.001$, **$p = 0.003$]. **(D)** Relative HIF-1α expression, as determined by RT-qPCR. HE staining and IHC: $n = 6$ each group; Mean ± 95% CI. Relative expression of **(D)** MMP-9 and **(E)** MMP-2 as assessed by RT-qPCR. IHC: $n = 6$ each group. Mean ± 95% CI; RT-qPCR: the Sham group: $n = 4$; CSCI group: $n = 4$; CSCI with decompression group: $n = 5$; Medians ± interquartile ranges, the sample size was too low to perform statistics for these data.

we down-regulated Notch-1 expression by applying DAPT, a γ-secretase inhibitor, to deactivate the Notch-1/Hes-1 signaling pathway (**Figure 6A**). **Figures 6B,C** clearly show that the motor function recovery was inhibited following down-regulation of Notch-1 after decompression, as the motor function recovery differed from that of the control group at 3 wpi. These results reveal that Notch-1 up-regulation after decompression plays a critical role for motor function recovery in a rat CSCI model.

Effects of Notch-1 Down-Regulation on Pathophysiological Changes in the Decompressed Spinal Cord

As previously described, HE and IHC staining were used to investigate pathological changes in our study. After the down-regulation of Notch-1, the fragmentation of neuronal nuclei, neuropil damage, interstitial edema, cytoplasmic reduction, cavity formation, degradation of the extracellular matrix, neuron loss, and axon degradation were more pronounced than in the group of CSCI without decompression (**Figure 7A**). However, the down-regulation of Notch-1 did not have any effect on the compression-induced hypoxia condition (**Figure 7B** and **Supplementary Figure S2A**). We were not able to detect any difference in our preliminary analysis of HIF-1α expression between the animals with or without DAPT treatment after decompression (**Figure 7C**). Further experiments are needed to confirm this result.

It was previously reported that activation of the Notch-1 signaling pathway can up-regulate VEGF, MMP-2, and MMP-9 by triggering the activation of NF-κB (Li et al., 2016). To further elucidate whether Notch-1 activation is associated with VEGF, vWF, MMP-9, and MMP-2 expression after decompression in the CSCI model, the expression of these factors was detected after Notch-1 down-regulation (**Figure 8**). Interestingly, following the inhibition of Notch-1, VEGF, and vWF expression levels were significantly lower compared with the control group (**Figures 8G,H**). In addition, preliminary data suggest that the down-regulation of Notch-1 increased MMP-9 and MMP-2 expression (**Figures 8I,J** and **Supplementary Figures S2B,C**), however, further experiments are needed to confirm these findings. The correlation among the expression of VEGF, vWF, MMP-9, MMP-2, and Notch-1 is presented in **Figures 8K–N**. The results demonstrate a significant correlation between the expression of Notch-1 and VEGF, vWF, and MMP-9.

Overall, the results indicate that early surgical decompression promoted motor function recovery may through protecting neurons and influencing the expression of angiogenesis-related markers and MMPs. Moreover, activation of the Notch-1 signaling pathway was shown to play an important role in motor function recovery following decompression.

DISCUSSION

Our study clarified the pathophysiological changes that occur in the spinal cord after decompression and demonstrated that early surgical decompression partially promoted motor function recovery in a water-absorbable polyurethane polymer compressive SCI. The motor function improvement achieved by surgical decompression was paralleled by improvements in structural and cellular damage, increased angiogenesis markers

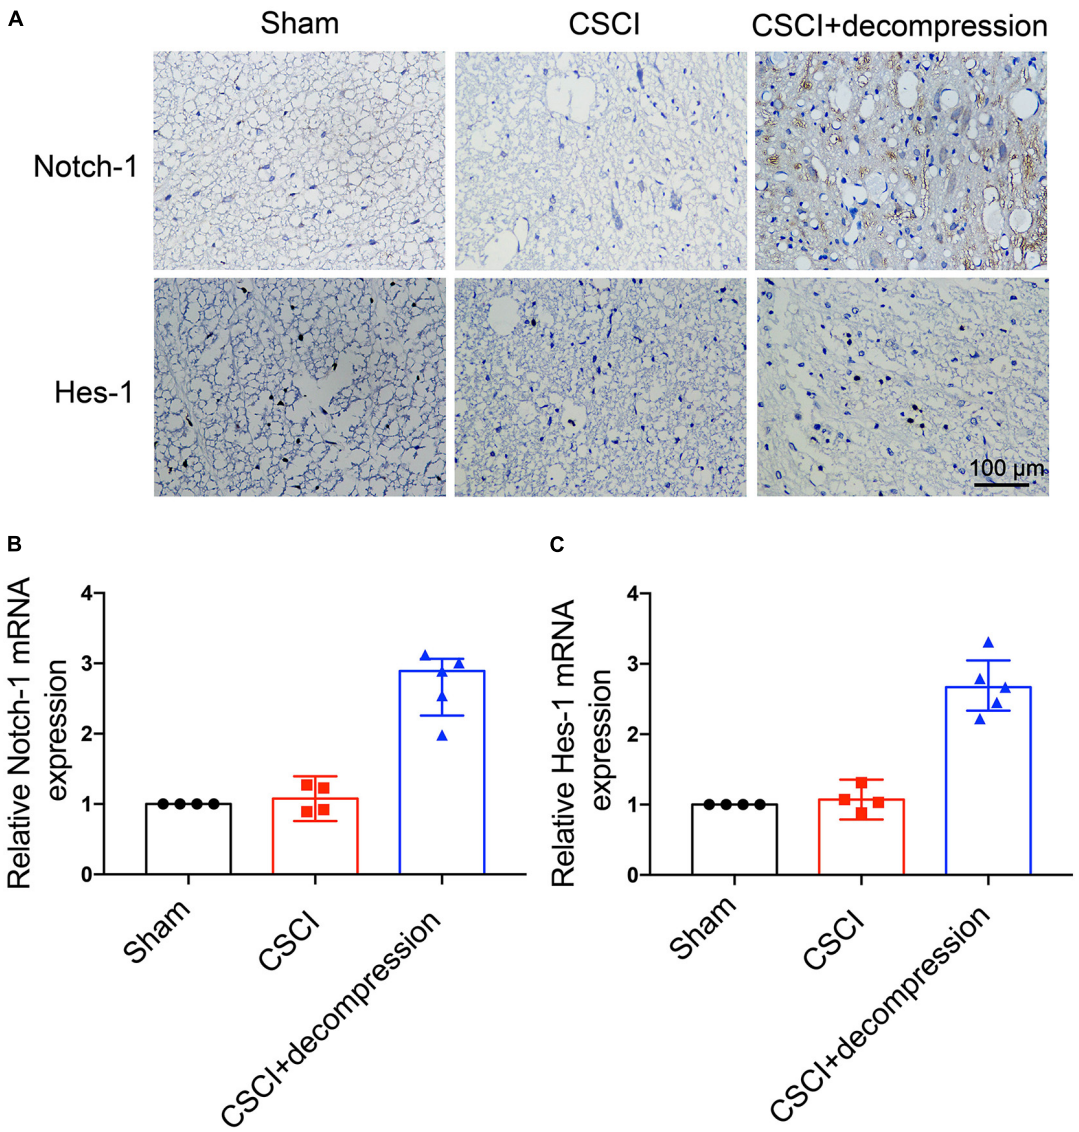

FIGURE 5 | Decompression-induced up-regulated Notch-1 expression. **(A)** Notch-1 and Hes-1 expression was assessed by IHC (400× magnification; scale bar, 100 μm). **(B)** Relative Notch-1 expression and **(C)** relative Hes-1 expression, as assessed by RT-qPCR. (VEGF and vWF), and reduced MMPs (MMP-9 and MMP-2) in the decompressed spinal cord. Moreover, the Notch-1/Hes-1 signal pathway was found to play an important role in the prognosis following decompression.

Due to the lack of a proper spinal cord compression model, pathophysiological changes following decompression are difficult to assess in rodent CSCI models (Akter et al., 2020). A stable, reusable material should also be considered. We therefore characterized rats with a chronic C6 compressive injury by performing IPTs and assessing BBB scores in an open field. The material used in this work gradually expanded after implantation, and therefore, the injured animals developed significant motor dysfunction after 1 wpi. The behavior outcomes in our cervical CSCI model are in line with growing evidence that rats begin to develop motor dysfunction after 1 week post-compression (Wang et al., 2012; Dhillon et al., 2016). Therefore, our study can partially reflect the sub-acute injury process of CSCI. These results indicate that water-absorbable polyurethane polymer may be a suitable material for imitating the occurrence and development of CSM in patients.

In the current study, surgical decompression was able to partially improve the motor function recovery. The pathophysiological mechanisms governing the effects of decompression are complicated. In clinical practice, outcomes are also influenced by the compression degree and symptom duration of each patient. Improvements in structural and cellular changes in the decompressed spinal cord may play a role in the progress of motor function recovery. It has been

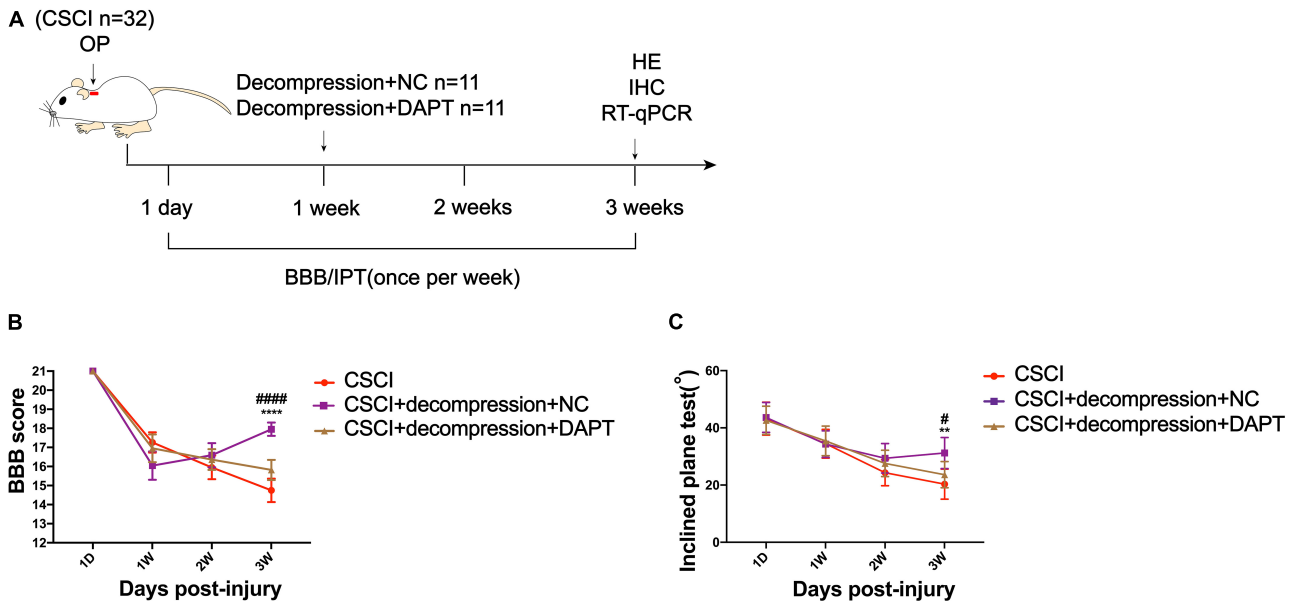

FIGURE 6 | Inhibition of Notch-1 attenuated motor function recovery after decompression. **(A)** Experimental design. **(B)** Animals were tested weekly starting from 1 dpi in an open field, and motor function recovery was evaluated according to the BBB score [Two-way ANOVA, $F(6,116) = 16.85$, $p < 0.0001$; $^{****}p < 0.0001$: CSCI group vs. CSCI with decompression and NC group; $^{\#\#\#\#}p < 0.0001$: CSCI with decompression and NC group vs. CSCI with decompression and DAPT group]. **(C)** Animals were tested weekly starting from 1 dpi using the IPT, and the angle (°) was recorded to reveal the motor function recovery [Two-way ANOVA, $F(6,116) = 3.279$, $p = 0.0412$; $^{**}p = 0.0052$: CSCI group vs. CSCI with decompression and NC group; $^{\#}p = 0.0431$: CSCI with decompression and NC group vs. CSCI with decompression and DAPT group]. well-documented that compression-induced neuron loss is paralleled by motor dysfunction (Ogino et al., 1983; Yu et al., 2009). Many factors such as cell death, inflammation, and ischemia can lead to neuron loss (Akter et al., 2020). Tanabe et al. (2011) suggested that HIF-1α may be increased in the twy/twy model and that hypoxic stress may promote neuronal cell death. However, ischemic-hypoxic changes in CSCI have not been widely investigated (Akter et al., 2020). Our data show that hypoxia conditions, which are also associated with motor function recovery, were improved after surgical decompression.

In addition, we observed that angiogenesis markers, i.e., VEGF and vWF, were increased following decompression. It has been reported that vascular dysfunction and angiogenesis may affect myelin damage, glial fibrosis, and necrosis after cervical spinal cord compression (Gooding et al., 1975; Ng and Lee, 2019). Furthermore, reduced blood flow to the spinal cord is associated with vascular dysfunction after compression (Franklin and Ffrench-Constant, 2008; Kurokawa et al., 2011). The molecular mechanisms of angiogenesis in decompression remain unclear. We also found that decompression can significantly decrease MMP-9 and MMP-2 expression. MMPs are associated with BSCB dysfunction (Zhang et al., 2017), and a similar expression pattern in CSM was described by Karadimas et al. (2013b). We previously found that the BSCB is disrupted after long-term spinal cord compression (Xu et al., 2017). Therefore, the high expression levels of MMP-9 and MMP-2 in the lesional spinal cord suggest these factors may play a role in BSCB disruption and that decompression may improve the BSCB by decreasing MMP-9 and MMP-2 expression. However, further research is needed to confirm this interpretation.

Notch signaling in CNS diseases is associated with cell death, angiogenesis, and BSCB function (Fassbender et al., 2011; Cai et al., 2016). Recently, studies have indicated that Notch-1 signaling can modulate VEGF, MMP-9, and MMP-2 expression *in vitro* and *in vivo* (Li et al., 2016). In our study, Notch-1 and its downstream gene Hes-1 were decreased under compression and increased after decompression. More interestingly, the down-regulation of Notch-1 can inhibit angiogenesis marker expression and promote MMP-9 and MMP-2 expression. The role of Notch-1 in angiogenesis is still unclear. Tang et al. (2018) reported that inhibition of the Notch-1/DLL4 pathway promotes angiogenesis in rats, while (Gao et al., 2012) demonstrated that Notch-1/HIF-1α interactions mediate hypoxia-induced angiogenesis in inflammatory arthritis. More investigations are needed to clarify these findings. In our study, HIF-1α expression in the decompressed spinal cord was not influenced by the inhibition of Notch-1. Nevertheless, the improvements in structure and cellular changes were weakened after Notch-1 inhibition. Thus, the underlying mechanisms require further investigation.

The dipeptidic compound DAPT (N-[N- (3,5-difluorophenacetyl) -L-alanyl] -S-phenylglycine t-butyl ester), a γ−secretase inhibitor was tested *in vivo* in Dovey et al. (2001). γ-Secretase displays poor substrate specificity (Panza et al., 2010) and (Takeshita et al., 2007) suggested that γ-secretase can mediate Notch1 cleavage and activation

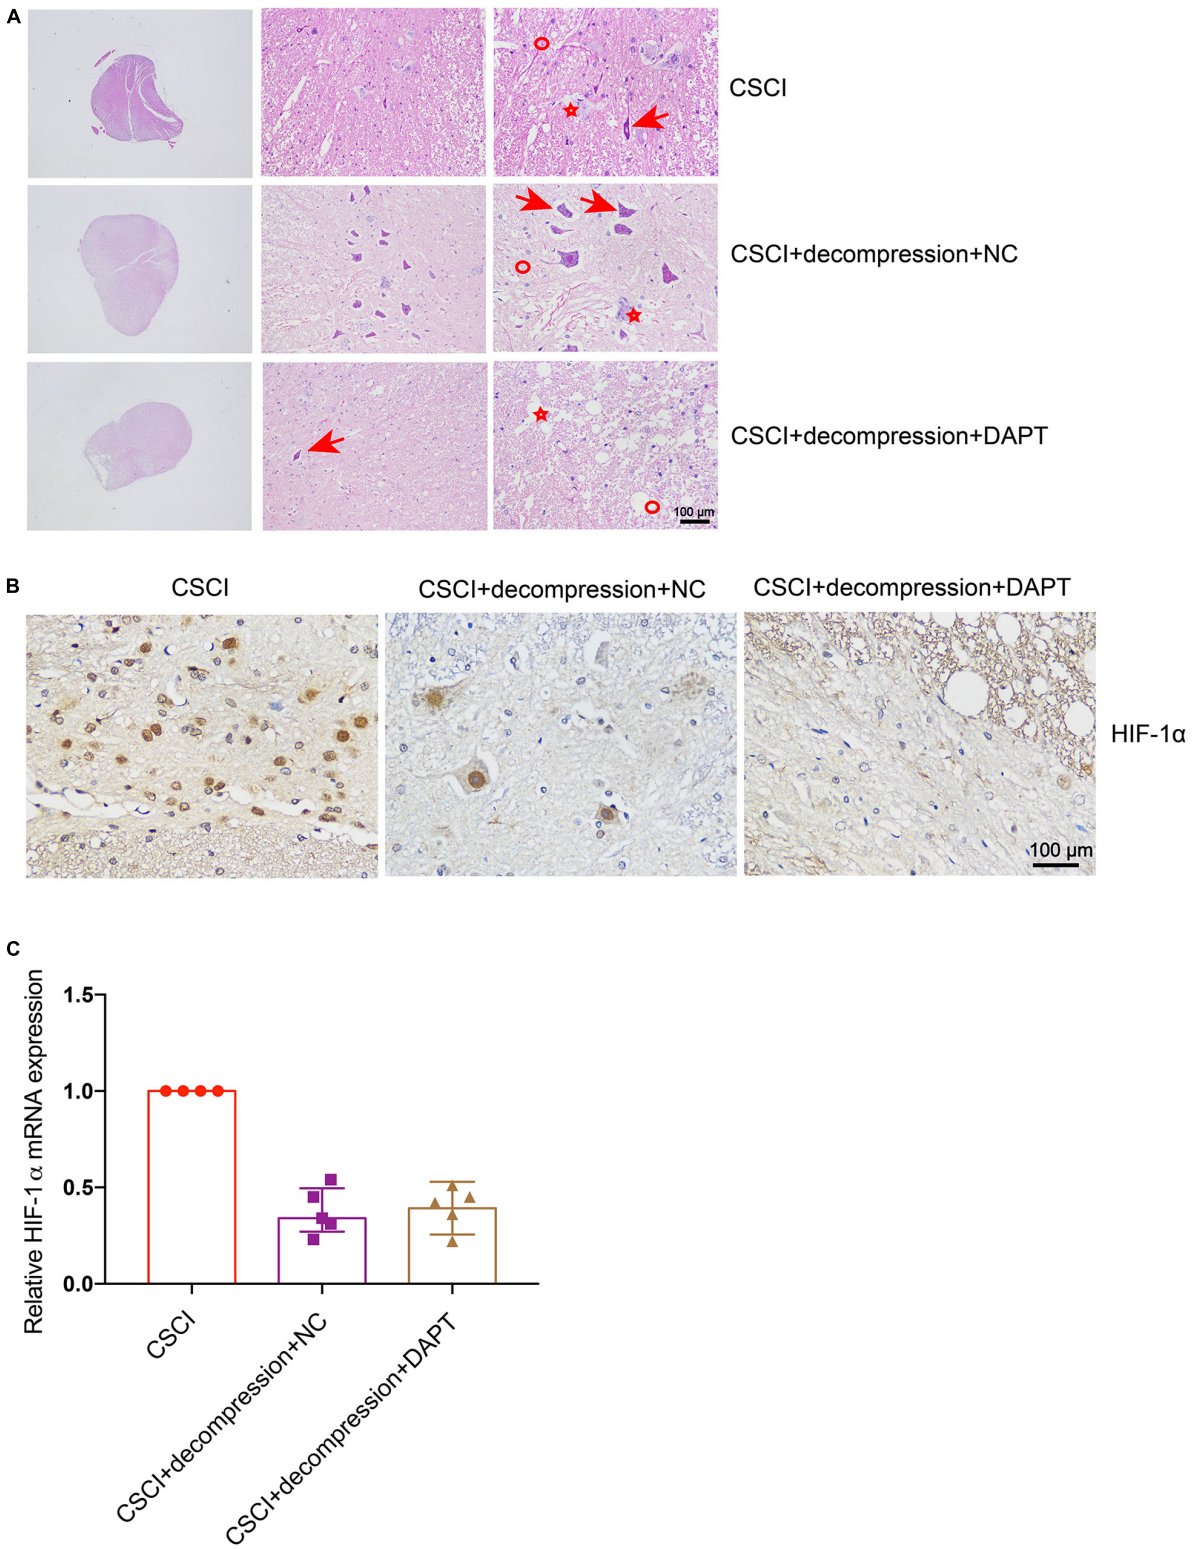

FIGURE 7 | Inhibition of Notch-1 does not have neuron-protective effects on CSCI after decompression. **(A)** HE staining of lesion sites from the CSCI, CSCI with decompression and NC, and CSCI with decompression and DAPT groups (20×, 200×, and 400× magnification; scale bar, 100 μm). **(B)** HIF-1α expression was assessed by IHC (400× magnification; scale bar, 100 μm). **(C)** The relative HIF-1α expression was assessed by RT-qPCR. RT-qPCR: the CSCI group: $n = 4$; CSCI with decompression and NC group: $n = 5$; CSCI with decompression and DAPT group: $n = 5$; Medians ± interquartile ranges, the sample size was too low to perform statistics for these data.

by phosphatidylinositol 3-kinase/Akt pathway in postnatal angiogenesis. However, it still needs to be explored whether other signaling molecules/pathways besides Notch-1 may be affected in our CSCI model. In a transgenic mouse model of Alzheimer's Disease, it was demonstrated that DAPT could reverse contextual memory deficit through targeting beta-amyloid (Comery et al., 2005). It has also been reported that DAPT could inhibit all four Notch receptors and is a promising option for cancer

therapy (Shih and Wang, 2007). Moreover, the γ-secretase inhibitor DAPT could decrease angiogenesis and inhibit VEGF-induced endothelial cell proliferation, migration, and survival as well (Takeshita et al., 2007).

To the best of our knowledge, this study is the first to focus on the influence of early surgical decompression on motor function recovery and physiological and pathological changes in CSCI rats. Our findings can serve as a basis for future studies in rodents to explore the molecular and cellular changes underlying motor dysfunction after CSM and decompression-induced improvements.

Nevertheless, our study has several limits. It has been reported that surgical decompression for the treatment of CSM is associated with not only motor function recovery, but also sensory function recovery (Fehlings et al., 2013; Zaveri and Jaiswal, 2019). However, the sensory function was not evaluated in this study. In addition, we found that the inhibition of Notch-1 was associated with the expression of angiogenesis markers and MMPs, but the underlying mechanisms governing these changes were not pursued. Thus, the manner in which Notch-1 modulates the expression of these factors after decompression remains unclear. The NF-κB signaling pathway can be triggered by the activation of Notch-1; therefore, this pathway can be initiated by up-regulated expression of NF-κB target genes, including VEGF, MMP-9, and MMP-2 (Karadimas et al., 2013b). Hence, it would be valuable to explore whether the NF-κB signaling pathway is activated by Notch-1 after decompression in a rat CSCI model. Further research is also needed to demonstrate that activation of Notch-1 is sufficient to induce the protection. Furthermore, although we demonstrated the changes in angiogenesis markers and MMPs in the decompressed spinal cord via histological approaches, the detection of angiogenesis and BSCB disruption via morphological and functional approaches is needed in future work. Given that the sample size in different groups of this exploratory study is not large enough, therefore it is necessary to increase the sample size to further explore the underlying mechanisms of our preliminary findings.

In summary, our study illustrated the preliminary physiological and pathological changes occurring in the compressed and decompressed spinal cord in the sub-acute injury process of CSCI rats. In addition, we confirmed that early surgical decompression can partially improve motor function recovery. Our data indicate that activation of the Notch-1 signaling pathway may play a role in the prognosis of CSCI after decompression, which may provide a new drug approach in order to enhance recovery following surgery.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The animal study was reviewed and approved by The first affiliated hospital of Sun Yat-sen University.

AUTHOR CONTRIBUTIONS

XC analyzed the data, wrote the manuscript, and created the figures. ZY performed the experiments and analyzed the data. JX performed the experiments. DQ revised the manuscript and designed the experiments. HL designed the experiments, contributed to manuscript writing, and gave final approval of the manuscript. All authors contributed to the article and approved the submitted version.

FUNDING

This study was supported by the National Natural Science Foundation of China (81450020 to HL).

ACKNOWLEDGMENTS

We thank Prof. Yong Hu (Hong Kong University) for providing the polymer.

Improved Functional Outcome After Peripheral Nerve Stimulation of the Impaired Forelimb Post-stroke

Lack of blood flow to the brain, i.e., ischemic stroke, results in loss of nerve cells and therefore loss of function in the effected brain regions. There is no effective treatment to improve lost function except restoring blood flow within the first several hours. Rehabilitation strategies are widely used with limited success. The purpose of this study was to examine the effect of electrical stimulation on the impaired upper extremity to improve functional recovery after stroke. We developed a rodent model using an electrode cuff implant onto a single peripheral nerve (median nerve) of the paretic forelimb and applied daily electrical stimulation. The skilled forelimb reaching test was used to evaluate functional outcome after stroke and electrical stimulation. Anterograde axonal tracing from layer V pyramidal neurons with biotinylated dextran amine was done to evaluate the formation of new neuronal connections from the contralesional cortex to the deafferented spinal cord. Rats receiving electrical stimulation on the median nerve showed significant improvement in the skilled forelimb reaching test in comparison with stroke only and stroke with sham stimulation. Rats that received electrical stimulation also exhibited significant improvement in the latency to initiate adhesive removal from the impaired forelimb, indicating better sensory recovery. Furthermore, axonal tracing analysis showed a significant higher midline fiber crossing index in the cervical spinal cord of rats receiving electrical stimulation. Our results indicate that direct peripheral nerve stimulation leads to improved sensorimotor recovery in the stroke-impaired forelimb, and may be a useful approach to improve post-stroke deficits in human patients.

INTRODUCTION

Stroke is the fifth leading cause of death in the U.S. and is the most common cause of adult disability. Nearly 4 million stroke survivors live with permanent neurological damage effecting their function and quality of life. Among them, 87% of strokes are ischemic in nature (1). Currently, the only approved treatments for acute ischemic stroke (tissue plasminogen activator and embolectomy) must be administered or performed in the early post-stroke period, which, unfortunately accounts for only 10% of all stroke patients as the rest do not reach a hospital

early enough to receive such interventions (2–4). This leaves roughly 90% of ischemic stroke survivors to rely on rehabilitative therapies which show real but limited success in functional restoration. Among the many complications and sequelae of stroke, more than 75% of patients have upper extremity paresis (5) which includes the inability to properly use the thumb and fingers, as in a grasping motion (6, 7). Thus, improving upper extremity and hand function is of great importance in post-stroke rehabilitation and it is necessary to develop therapeutic approaches for this debilitating aspect of stroke recovery (8).

Neuromuscular electrical stimulation (NMES) has been used to facilitate rehabilitation post-stroke by improving and/or replacing volitional movement to enhance neural motor control, and hence reduce disability (9–11). NMES stimulates nerves to activate paretic muscles, and can be applied as either a supplementary tool combined with other rehabilitation strategies or used alone to improve functional recovery beyond the time of stimulation (12). The actual benefits of NMES are unclear as contradictory results from various clinical studies have emerged (11), and therefore more experimental studies are needed.

NMES can be used via invasive (implanted, percutaneous) or non-invasive (transcutaneous) devices (13, 14). For upper extremity rehabilitation, non-invasive approaches have been applied with conventional therapy in a cyclic pattern, EMG-triggered, or switch-triggered manner to facilitate activation of specific muscles to enhance task performance (15). However, the major issue of transcutaneous devices is that while a specific nerve of interest can be targeted, these devices also activate non-targeted nerves. Moreover, deeper nerves and muscles are more difficult to target using non-invasive techniques. Implanted devices (such as cuff electrodes) target specific nerves and reduce the current required to discharge the nerve while reducing non-targeted nerve activation (10, 16). While some implantable devices have been approved in Europe for use in aiding foot drop in stroke patients, none are currently FDA approved.

Previous studies have suggested that NMES may improve function by inducing neuroplastic changes in the spared motor cortex post-stroke (11, 14, 17). However, this possible cellular mechanism has not been fully investigated. Since changes in cortical efferent circuitry have been reported by our lab and others to play an important role in sensorimotor functional improvement after stroke (18–21), we sought to determine whether post-stroke NMES modulated neuroplasticity and improved function. In this report, we used a rat model of ischemic stroke to produce upper extremity paresis to assess whether peripheral nerve stimulation (*via* nerve cuff electrode) increased functional and volitional recovery in the effected forelimb.

METHODS

Animal Subjects

All animal studies were approved by the Institutional Animal Care and Use Committee of the Edward Hines Jr. Veterans Affairs Hospital. A total of 24 male Long Evans black-hooded rats (2 months of age, HsdBLU:LE, Harlan Laboratories IN, Barrier 217) were used at the beginning of the study. Rats were housed in standard cages (2 rats per cage) with a 12-h light/dark cycle in a fully accredited animal care facility. Rats had access to fresh water and were fed standard laboratory chow (Harlan 2018 Rodent Diet). All rats were number coded by a laboratory member not participating in the study, and investigators conducting behavioral testing and neuroanatomical analyses were blinded to the treatment conditions throughout the experiments.

Experimental Timeline and Overview

The experimental timeline is shown in **Figure 1**.

Behavioral Procedures

When the initial training period began, rats were reduced to 95% of their total body weight by food restriction; water was freely available. Behavioral tests were conducted at approximately the same time of day. Each animal was video recorded separately after the daily tests at baseline, 3 days following stroke, and at the end (8 weeks post-stroke) of the behavioral study. The recorded data was used to calibrate inter-rater variability and reaching error analysis.

Skilled Forelimb Reaching Test

This test was first performed as designed by Whishaw and our laboratory (22, 23) and used as described in our previous work (18, 20, 21, 24). It is well-established that the sensorimotor circuitry controlling motor control and related reaching and grasping of skilled reaching behavior is highly conserved in mammals (25). In brief, animals were placed in a transparent Plexiglas chamber (30 × 36 × 30 cm) with a rectangular opening (1.5 × 3 cm) in one wall. Small round food pellets (45 mg; Bilaney Consultants, Frenchtown, NJ) were placed one after the other onto the shelf at a distance of 1.5 cm from the opening. Rats were placed in the testing chamber daily until they learned to reach through the opening for the pellet, grasp the pellet and bring it to their mouth (a success). Rats were free to use either limb to reach through the opening and limb preference was determined and recorded for each animal. Rats reaching a baseline score with at least 16 successes out of 20 pellets per day for three consecutive days were enrolled in the study for stroke surgery. A maximum time limit of 5 min per session was given. Each rat resumed testing 3 days after stroke, and then daily (Mon-Fri) until the end of the study. The parameters recorded for the skilled forelimb reaching test included (1) the amount of time needed to obtain all 20 pellets, and (2) the success score, i.e., the number of pellets grasped with the preferred limb and placed into the mouth.

Reaching Error Analysis

Each animal was video recorded after the daily tests at baseline, 3 days following stroke, and at the end (8 weeks post-op). Reaching video files were analyzed frame by frame using QuickTime Player. Each reach error was recorded during analysis as described (**Table 1**). Descriptions included (a) the outcome (success or failure) and (b) description of event (short reach, inaccurate aim, bad grasp, etc.). From the described attempts four overarching categories emerged (miss, touch, drop, and success) with two subtypes per category. Categories were assigned a numerical value based on a progression of a reach (1–8). Therefore, rats that

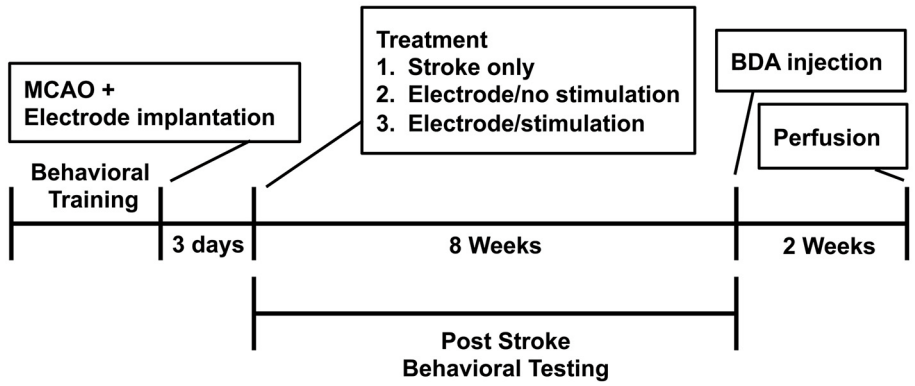

FIGURE 1 | Experimental design and timeline.

were able to grasp received a higher numeric value than rats that could not extend their limb.

Bilateral Tactile Adhesive Removal Task

This task has been shown to be sensitive for the detection of somatosensory deficits following sensorimotor cortex injury (26, 27). Small round adhesive stickers (Creatology adhesive foam sheet, 0.7 mm diameter, Michaels, Irving, TX) were placed onto the plantar surface of both forepaws. The order of contact, contact latency, and removal latency for each paw was recorded independently for each limb. Each rat was given maximal 120 s to complete initiation and removal of the adhesive. One hundred twenty seconds was recorded if the rat did not complete the task in time.

Stroke Surgery

A focal ischemic stroke was induced via middle cerebral artery occlusion (MCAO) modified from Chen et al. (28) and as in our previous work (18, 20, 21, 24). Rats were anesthetized with isoflurane (2–3% in oxygen) and core body temperature was maintained between 36.5 and 37.5°C during the entire procedure. The bilateral common carotid arteries (CCA) were first isolated from a ventral longitudinal cervical incision and the common carotid artery ipsilateral to the hemisphere corresponding to the preferred forelimb was permanently ligated. Rats were then placed in a stereotaxic frame and a vertical incision was made between the eye and ear. The temporalis muscle was retracted, and a burr hole was made to expose the middle cerebral artery (MCA) on the opposite side of the preferred limb, which was subsequently ligated with a 10-0 suture and then transected with microscissors. The contralateral CCA was temporarily occluded for 45 min using an aneurysm clip. After removal of the aneurysm clip, all wounds were closed and rats were either kept warm until awake or were kept anesthetized for nerve electrode cuff implantation. Rats were monitored during the post-op period until fully awake and able to eat and drink.

Nerve Cuff Electrode Placement

Placement of the electrode cuff (MicroProbes for Life Science, Gaithersburg, MD) was performed immediately after completion of MCAO under the same anesthesia (**Figure 2**). The procedure was adapted from Cho et al. (29) as shown in **Figures 2A,B**. Skin incisions were made on the top of the head and at the interscapular region. Additionally, an incision was made along the upper medial aspect of the impaired extremity and extended into the axilla to expose the pectoralis major muscle. The muscle was then retracted to expose the brachial plexus and the median nerve was isolated. A tunnel under the skin was created from the top of the head to the interscapular incision and to the axilla, and the electrode wire was guided into the axilla opening. The median nerve was placed in the electrode cuff and stabilized by sutures (**Figure 2B**). The cuff was custom made with the following specifications: 0.75 mm inner diameter, two 100 μm platinum contacts were situated 1 mm longitudinally apart and 2 mm to the edge of the cuff, an ultra fine lead leaving the cuff at a 45 degree angle with a total silicone encapsulation running for 100 mm, and connected to an *in vivo* 1 MS303-120 right-angled two channel connector (PI Technology, Roanoke, VA). Partial loops of the lead were left in the neck wound to allow for movement and to prevent strain on the electrode/nerve. A small guide hole was placed in the skull frontal bone followed by a stainless steel screw placement. The connector and screw were then covered with a fast-setting dental cement to form a connector cap. The electrical continuity of the electrode leads was tested using an ohmmeter. The head incision was sutured while leaving the top part of the connector cap above the skin and exposed to allow for connection to the stimulator.

Peripheral Neuromuscular Electrical Stimulation

A schematic of the electrical stimulation circuitry is shown in **Figure 2C**. Charge balanced stimulation was used to prevent corrosion of the electrodes and deleterious effects on the nerve.

TABLE 1 | Reaching Error Analysis.

Miss	Touch	Drop	Success
1 – No Extension • Limb contracted • Limb did not extend past window or just past • Curled wrist and digits	*3 – No grasp* • Limb extended past window • Paw and digits are flat or curved toward body • Paw planted flat on pellet – digits do not curl around pellet • Pellet pulled through window or paw lifted up and back	*5 – Early Drop* • Limb extended past window • Paw and digits slightly angled toward pellet • Digits are planted and curled around pellet • Pellet is in paw as limb is retracted • Paw is not brought to mouth but placed on ground near starting position • Pellet falls out of paw while the limb is on the ground or while another reach is attempted	*7 – Partial Success* • Limb extended past window • Paw and digits slightly angled toward pellet • Digits are planted and curled around pellet • Pellet is in paw as limb is retracted • Paw is brought to mouth • Digits are straightened as paw is brought to mouth. Removing pellet from grasp requires multiple licks.
2 – Poor aim • Limb extended past window • Digits curled in grasp motion in air above pellet • Limb/paw ended on either side of pellet and grasps	*4 – Inaccurate grasp* • Limb extended past window • Paw and digits are flat or curved • Digits planted on and curled around pellet • During limb retraction, pellet is either dragged or immediately propelled away from between digits	*6 – Late Drop* • Limb extended past window • Paw and digits slightly angled toward pellet • Digits are planted and curled around pellet • Pellet is in paw as limb is retracted • Paw is brought to mouth • Pellet falls while attempting to remove from grasp	*8 – Complete success* • Limb extended past window • Paw and digits slightly angled toward pellet • Digits are planted and curled around pellet • Pellet is in paw as limb is retracted • Paw is brought to mouth • Digits are straightened as pellet is placed in mouth

The capacitor coupled stimulation balanced the stimulation current during the pulse with an equal and opposite discharge during the inter-pulse period. Rats undergoing stimulation were individually placed into a repurposed forelimb reaching box after their electrode was connected to the stimulator. The leads from the electrode to the stimulator were attached to the roof of the box so the rat could move freely. Using a Grass S11 constant voltage stimulator, stimulation voltage was gradually increased until muscle contraction was felt (deemed threshold level). A 1.5-fold increase over the threshold voltage was applied to induce muscle contraction throughout the 30 min stimulation sessions. Threshold current was determined by measuring the voltage across a 1 K Ohm resistor in series with the stimulating electrode and using Ohm's law to solve for current. Threshold currents were recorded after completion of the electrode cuff implantation. The stimulation parameters were adapted from our previous work on a spinal cord injury model with modifications (30). Other parameters included 1.0 ms in duration of stimulation, delivered every 2 s in 1-s trains of 5 Hz (**Figure 2D**). Daily 30 min stimulation sessions began 3 days after MCAO surgery and continued (Monday–Friday) for a total of 8 weeks. Rats in the Stroke/No E-stim group had the exact same placement of the electrode post-stroke, were placed in the stimulation boxes for the same time period, but did not receive any electrical stimulation. Each stimulation session occurred at least 2 h after the behavioral tests. The staff applying stimulation was different from the staff testing animals.

Biotin Dextran Amine Tracing

When behavioral testing was complete, rats were re-anesthetized with isoflurane (2–3% in oxygen) and secured in a stereotaxic frame. A 2 mm burr hole was made to expose the sensorimotor cortex of the hemisphere opposite to the stroke lesion site. Two 1 μl aliquots of 10% BDA solution in 0.01 M phosphate buffer (pH 7.2) were injected into the caudal forelimb motor cortex (coordinates: 0.5 mm caudal/2.5 mm lateral, 1.0 mm caudal/3.0 mm lateral to bregma, and both at 1.5 mm ventral from the brain surface), as defined electrophysiologically by Neafsey et al. (31).

BDA Histochemistry

BDA histochemistry was performed as previously described by our laboratory (18, 20, 32). Two weeks after BDA injections, rats were euthanized with sodium pentobarbital (100 mg/kg; i.p.) and perfused transcardially with heparinized PBS solution followed by fixative [4% paraformaldehyde (PFA) in 0.1 M phosphate buffer]. The brains and spinal cords were removed, post-fixed, cryoprotected, and frozen sectioned coronally at 40 μm. Sections were collected every 200 μm in one series. Endogenous peroxidases were blocked via incubation with 0.1% hydrogen peroxide solution. Sections were then washed and incubated overnight with an avidin-biotin-peroxidase complex (ABC elite, Vector Labs). The sections were washed again and pre-incubated with 0.4% ammonium nickel sulfate followed by 0.015% 3.3-diaminobenzidine (DAB), and finally reacted with 0.004% hydrogen peroxide. The reaction was stopped by washing with tris buffer and the sections were left to air dry before being lightly counterstained with Nissl stain and coverslipped.

Stroke Size Analysis

Nissl-stained coronal brain sections were quantitatively analyzed every 400 μm between +4.7 to −5.2 mm from bregma according to Paxinos and Watson (33) using a computer-interfaced imaging system (Image J, NIH, Bethesda, MD) as described

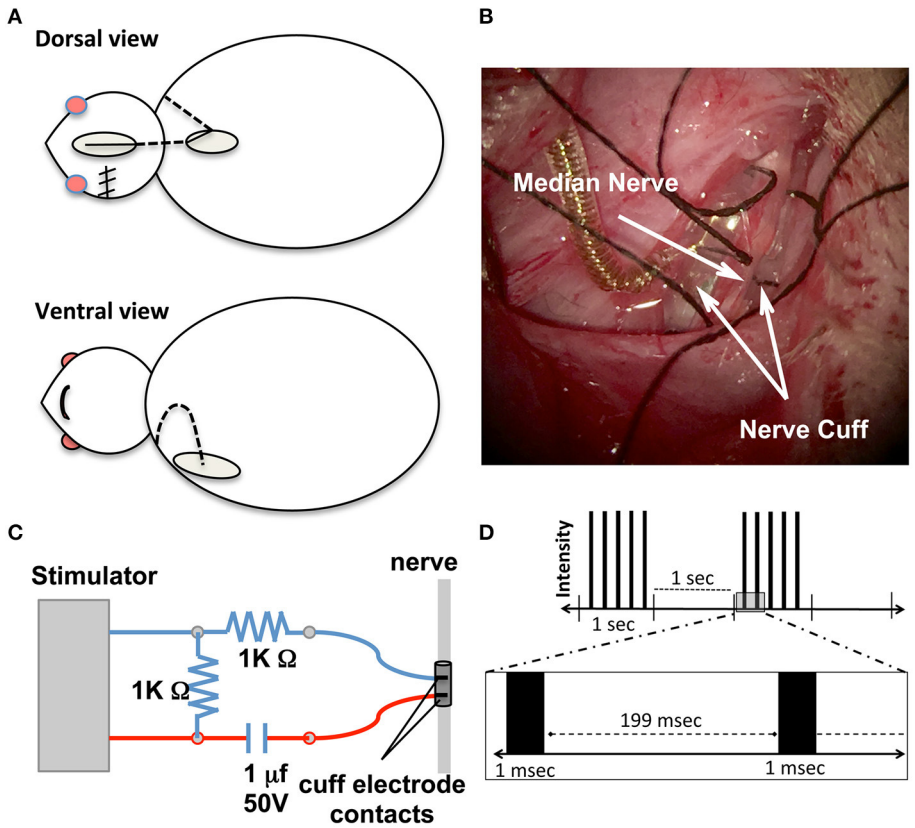

FIGURE 2 | Nerve cuff placement. **(A)** Schematic of surgical procedures for nerve cuff placement. Dotted lines represent the lead wire and ovals represent surgical incision sites. **(B)** Intraoperative photographs of the cuff enclosing the nerve according to the experimental design. previously (18, 20, 21, 34). Stroke size was expressed as a percent of the intact contralateral hemispheric area (total area of the intact contralateral hemisphere minus total area of the ipsilesional hemisphere divided by the total area of the intact contralateral hemisphere).

Neuroanatomical Analysis

The analyses for corticospinal plasticity described in this section were performed as previously reported (18, 35). All analyses were done on coded slides so that the investigator was blinded as to the experimental group. Anatomical structures were identified with the atlas of Paxinos and Watson (33).

Quantification of Corticospinal Tract Labeling Crossing the Midline and in the Dorsal Column

BDA-labeled fibers in the dorsal column were counted using stereological methods (StereoInvestigator, MBF Bioscience, Williston, VT) on the first two C5 sections analyzed for midline fiber crossing. In brief, dorsal column outline tracings were performed under a 2.5X objective. Both the sampling grid size (75 × 75 μm) and the sampling ratio (20%) were optimized to provide adequate sampling of the entire dorsal column. The estimated total BDA-labeled CST fibers of both sections were averaged as an internal reference for BDA injections and staining. This was done in order to standardize the total number of labeled midline crossing fibers in the spinal cord (18).

On sections analyzed, all BDA-positive fibers crossing the midline were counted under a 40X objective. Twenty alternate sections (400 μm apart) at the cervical spinal cord levels C5–C8 were totaled. To correct for inter-animal tracing variability, the total number of crossing fibers was divided by the number of labeled corticospinal fibers in the dorsal column (as determined above) multiplied × 10^4 and expressed as fibers crossing the midline per ten thousand labeled corticospinal axons.

Inclusion/Exclusion Criteria

Skilled Forelimb Reaching Test

Prior to surgery, animals were excluded from the study if they were unable to successfully reach for 16 out of 20 pellets within 5 min after 3 weeks of training on the task. Three days post-stroke, all rats were tested. Animals showing severe deficits were excluded from the study. Severe deficits were defined as the inability of a rat to reach using his impaired forelimb through the open window for at least one out of 20 attempts.

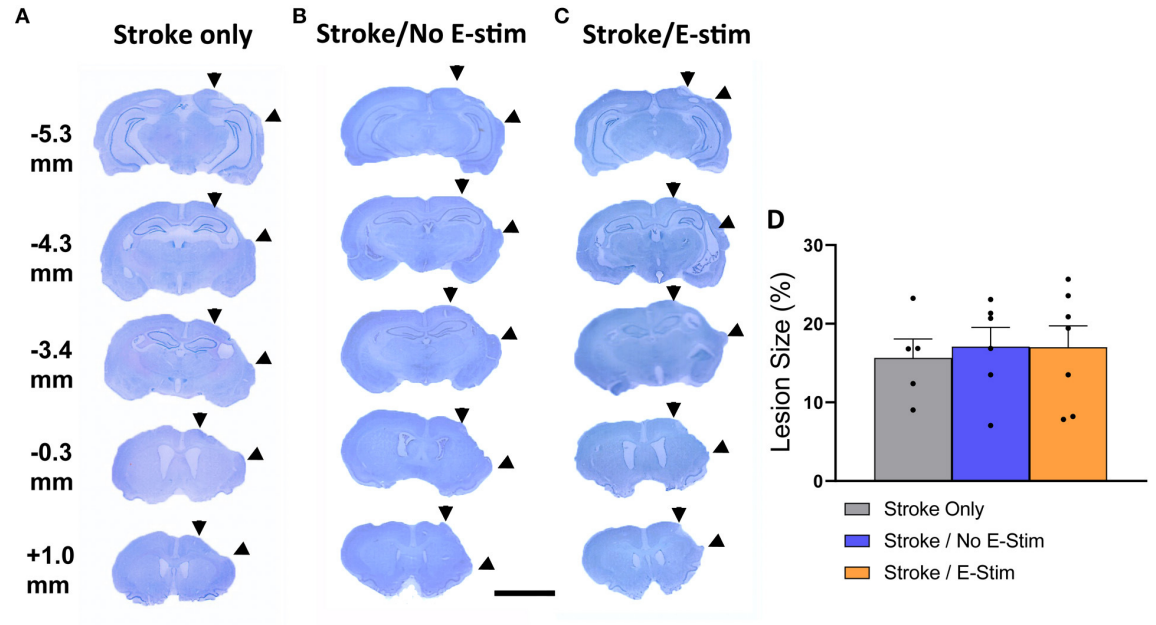

FIGURE 3 | Lesion analysis. Nissl stain sections and their relative distance from bregma showing typical ischemic lesion of all three groups of rats **(A–C)**. Area between two arrowheads on each brain section indicates stroke-induced necrotic regions. The numbers indicate relative distance to bregma. The scale bar indicates 0.5 cm. **(D)** Lesion analysis showed no difference in the lesion size between groups (Stroke only vs. Stroke/No e-stim vs. Stroke/E-stim ANOVA, $p > 0.05$).

Conversely, if a rat showed only a mild deficit 3 days post-stroke, which we defined as reaching successfully for 10 or more pellets out of the 20 attempts, they were excluded from the entire study (21).

Bilateral Tactile Adhesive Removal Task

In order for the handling of the animal to not interfere with the subcutaneous leads and the electrode cuff, animals which struggled excessively during the adhesive removal task at post-op day three were excluded only from this analysis.

Stroke Lesion

Following our previous reports (18, 21), rats were excluded from the study if lesion analysis did not show sensorimotor cortex involvement and/or showed extensive dorsal lateral (DL) striatum involvement.

BDA Labeling

For this analysis, rats demonstrating dorsal column BDA-labeled corticospinal fiber counts of <500 were excluded from crossing fiber analysis due to poor BDA transport or insufficient injection site uptake.

Statistical Analysis

Analyses of all data were performed with SPSS version 13.0 (SPSS Inc., Chicago, IL). A 2-WAY repeated measure ANOVA (time × treatment) was used to analyze differences in the forelimb reaching test between three experimental groups, followed by Tukey *post-hoc* to compare weekly mean values between the three experimental groups. The adhesive removal test was analyzed using Non-parametric Mann-Whitney test. Spinal cord midline crossing index were analyzed using a Student's *T*-test. Forelimb reaching results were correlated with spinal cord midline crossing index. A p value ≤ 0.05 was considered significant. All error bars shown are ±SEM. All bar graphs show individual data points (n value).

RESULTS

At the beginning of the study, 26 animals received skilled forelimb reaching task training. Three animals were removed (n = three) from the study prior to surgery due to failing to reach baseline, i.e., they were not successful at grasping at least 16 out of 20 pellets within 5 min. A total of five animals ($n = 5$) were further excluded from the study 3 days after stroke. Of those, three were removed due to the inability to reach for the pellets (severe deficit), and two were removed because they showed only a mild reaching deficit.

At the completion of electrode cuff implantation, the average threshold currents (mean ± SEM) were 0.11 ± 0.01 mA.

Stroke Lesion in the Sensorimotor Cortex

Stroke lesions in all rats showed ipsilateral sensorimotor cortex necrosis with no or minimal anterior striatum involvement and without other anatomical structure damage (**Figures 3A–C**). There was no statistical difference in stroke size between groups (Stroke only, 15.67% ± 2.4 SEM; Stroke/No E-stim, 17.09%

± 2.45 SEM; Stroke/E-stim, 17.02% ± 2.73 SEM) (one-way ANOVA, $p > 0.05$) (**Figure 3D**).

Functional Improvement After Direct Peripheral Nerve Electrical Stimulation

Skilled Forelimb Reaching

After training on the skilled reaching task, baseline success scores showed no significant difference between the three groups (**Figure 4**). Three days post-MCAO, all rats exhibited a marked deficit in reaching success using their preferred limb with no difference between groups. However, rats receiving electrical stimulation showed significant overall improvement of the skilled forelimb reaching test when compared to stroke only and stroke with sham stimulation (two way repeated-measure ANOVA, main effect time $p < 0.0001$, main effect treatment $p < 0.0001$, interaction $p < 0.001$). Differences in reaching success scores were first apparent 3 weeks post-MCAO between stroke only animals and those receiving electrical stimulation (Tukey, $p < 0.05$). This significant difference between electrical stimulation and stroke only groups continued throughout the remaining weeks ($p < 0.05$ at week 3, 4, and 5, $p < 0.01$ at week 6, $p < 0.001$ at week 7 and week 8). Six weeks after MCAO, those rats receiving stimulation showed significant increases in reaching success compared to those with sham stimulation ($p < 0.01$). This significant increase persisted throughout the remainder of the behavioral testing ($p < 0.001$ at week 7, $p < 0.01$ at week 8). Additionally, the reaching success score of animals receiving electrical stimulation was not significantly different from baseline scores at 8 weeks, with stimulated animals receiving, on average, 83% of the baseline score.

Reaching Error Analysis

Qualitative analysis of the forelimb reaching errors showed a decrease in deficit severity across time that was particularly obvious in rats receiving E-Stim (**Figure 5**). Reaching behaviors were analyzed at pre-stroke baseline, 3 days post-stroke before stimulation, and at the end of 8 weeks just prior to BDA injection. Recordings of three animals in the Stroke only group were dropped from the analysis due to poor recording quality. At 3 days post-stroke, errors were comprised mainly of missed pellets or failure to grasp the pellets. Rats receiving either no stimulation or sham stimulation remained similar in the error types at the end of the study. On the contrary, rats receiving E-stim showed similar errors as the other two control groups at 3 days post-stroke, but improved to less severe categories by the end of the study (**Figures 5A,B**), indicating that not only did electrical stimulation improve overall success in obtaining pellets, but also lessened the impact of the stroke by decreasing the severity of the errors that did persist.

Bilateral Tactile Adhesive Removal Task

In order to examine whether electrical stimulation to the median nerve in the forelimb affected sensory perception, we performed the adhesive removal test on rats that received implantation of an electrode (**Figure 6**). As this test required a longer duration of handling, animals that showed excessive struggle/agitation were excluded from this analysis in order to preserve and not disturb electrode placement. Sensory perception was analyzed using the difference in time it took for the rat to initiate removal of the adhesive sticker from its stroke-affected forepaw compared to its other forepaw. At baseline testing prior to stroke (**Figure 6A**), no difference in latency to initiate removal was observed between the Stroke/no E-stim group ($n = 5$) and the Stroke/E-stim group ($n = 4$). One week post-stroke (**Figure 6B**), the difference in latency to initiate removal between dominant and non-dominant forepaws was increased in both Stroke/no E-stim (mean = 35.7 s) and Stroke/E-stim (mean = 37.8 s) group, indicating a sensory deficit caused by the stroke. However, at 8 weeks post-stroke (**Figure 6C**), rats that received the E-stim therapy showed a significant decrease in latency to initiate between impaired and non-impaired forepaws (mean = 8.1 s) compared to the rats that only received sham stimulation (mean = 30 s) (nonparametric Mann-Whitney test, $p < 0.05$), suggesting that electrical stimulation contributed to improved sensory perception in the stroke-affected limb.

Quantification of Neuronal Plasticity

Compensatory sprouting and neuroanatomical plasticity were analyzed for corticospinal midline crossing fibers originating from the contralesional forelimb cortex using the anterograde neuroanatomical tracer BDA (**Figures 7A,B**). Due to exclusion criteria requiring at least a count of 500 dorsal column BDA-labeled corticospinal fibers, a total of 8 rats (Stroke Only = 3, Stroke/No E-stim = 2, and Stroke/E-stim = 3) were removed from this analysis due to poor BDA transport or insufficient injection site uptake. Since the two control groups showed no statistical difference in crossing fibers, they were pooled as Stroke Control for analysis (**Figure 7C**).

Rats receiving E-stim therapy (**Figure 7D**) exhibited nearly three times the midline crossing index (104.97 ± 19.22 SEM) in the cervical spinal cord as compared to the combined Stroke control group (32.52 ± 5.73 SEM) (**Figure 7E**, $p < 0.05$, Student's t-test). Further analysis (**Figure 7F**) showed that there was a direct correlation between the corticospinal fiber midline crossing index and the final forelimb reaching score for each rat ($r = 0.44$, $p < 0.05$), suggesting a positive relationship between the number of fibers that crossed the midline and functional recovery.

DISCUSSION

Our results show that daily, direct median nerve stimulation to the stroke-impaired forelimb in the adult rat led to significant improvement in the skilled forelimb reaching test, and also reduced the time to initiate adhesive removal on the stroke-impaired limb, indicating significant sensorimotor recovery. Furthermore, this therapy enhanced cortico-efferent plasticity from the contralesional cortex to the deafferented spinal cord, which may be the underlying substrate for the observed improvement in function.

One of the main goals for stroke survivors is improving hand and finger use of the paretic upper extremity, such as flexion/extension and adduction/abduction motion. The median

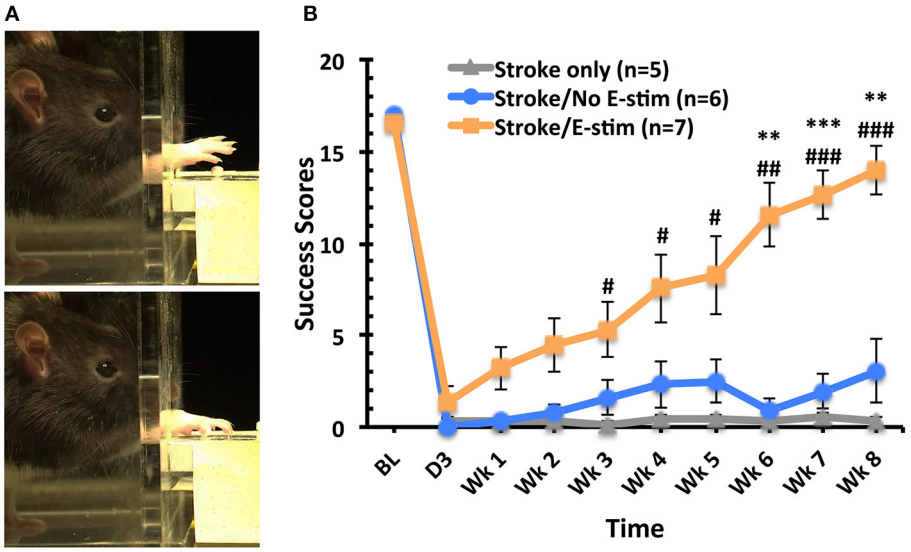

FIGURE 4 | Skilled forelimb reaching task analysis. **(A)** Sequential frames of the skilled forelimb reaching task performed by an adult rat grasping a sugar pellet. **(B)** Success scores for reaching task (out of 20 reaches) across time. No difference between groups at baseline. Marked deficits in successfully obtaining pellets with the stroke-impaired limb were apparent 3 days post-op (before treatment) with no significant difference between groups. Rats receiving electrical stimulation showed significant overall improvement of the skilled forelimb reaching test when compared to stroke only and stroke with sham stimulation (two way repeated-measure ANOVA, main effect time $p < 0.0001$, main effect treatment $p < 0.0001$, interaction $p < 0.001$). Weekly comparison showed that animals receiving electrical stimulation exhibited significant improvement in the success scores than the Stroke only group (#$p < 0.05$ at week 3, 4, and 5, ##$p < 0.01$ at week 6, ###$p < 0.001$ at week 7 and week 8) and Stroke/No e-stim group (**$p < 0.01$ at week 6 and 8, ***$p < 0.001$ at week 7) and the improvement persisted until the end of the study. There was no difference between two control groups at any time point (Tukey's *post hoc* analysis, error bars indicates ±SEM).

nerve was directly targeted in this study as it innervates muscles of the forearm and digits one through four. Furthermore, there are great similarities between humans and rats in performing reaching movements that largely involve the flexion movements that are controlled by the median nerve (37–39). As a mixed nerve, the median nerve also transmits sensory information from the palm and some of the digits (39). Our results showed that direct median nerve stimulation improved performance in a sensorimotor based (skilled reaching task) and a sensory (adhesive removal) task. In the skilled forelimb reaching task, we observed that rats receiving E-stim improved up to 80% or better performance of their baseline values, compared to those who did not receive E-stim. Further analysis of errors leading to non-successful reaches showed that in all three groups rats demonstrated similar types of errors at baseline, which is to be expected since they were essentially "normal" rats. At 3 days post-stroke, and before E-stim was started, the same types of errors were demonstrated across all groups. These errors largely were categorized in the more severe error categories, i.e., inability to aim properly or grasp with their digits. However, there was an exception to this pattern. One rat in the E-stim group did not make as severe of errors. This rat was not excluded from the study as its lesion size and performance on the daily reaching task post-stroke did not differ significantly from the rest of the group.

At the end of the 8 weeks, rats receiving E-stim showed a marked shift in their errors toward categories considered less severe, compared to the stroke/No E-stim group whose errors were predominantly still classified in the more severe categories. This indicated not only an improvement in the total success scores from the reaching task, but a decrease in the overall severity of the stroke impact on forelimb function. Several reports have shown that peripheral electrical stimulation induced neuroplastic changes in the motor cortex (see Chipchase et al. for review) (40), in particular when the stimulation intensity was above the motor threshold (41, 42). Peripheral stimulation of 1.5–2 times the motor threshold (as was used in this study) not only induced a response in the corresponding cortex, but also the contralesional cortex (43–45). This bilateral activation of the cortex may play important roles for cortical reorganization, as the homotopic contralesional cortex is a major site for cortical plasticity leading to functional recovery (20, 46–50).

Our laboratory and others have reported that improved functional outcomes after CNS injury can be induced through a variety of approaches (i.e., neurite inhibitors, pharmacologic interventions, environmental enrichment, stem cells) (18, 51–55). Furthermore, it has been shown that peripheral nerve stimulation induced neuroplastic changes (40), therefore, we sought to determine if E-stim therapy led to new corticospinal connections from the contralesional cortex (47, 56). BDA analysis in the present study revealed that rats which received E-stim had increased spinal cord midline crossings of corticospinal tract axons originating in the contralesional motor cortex and

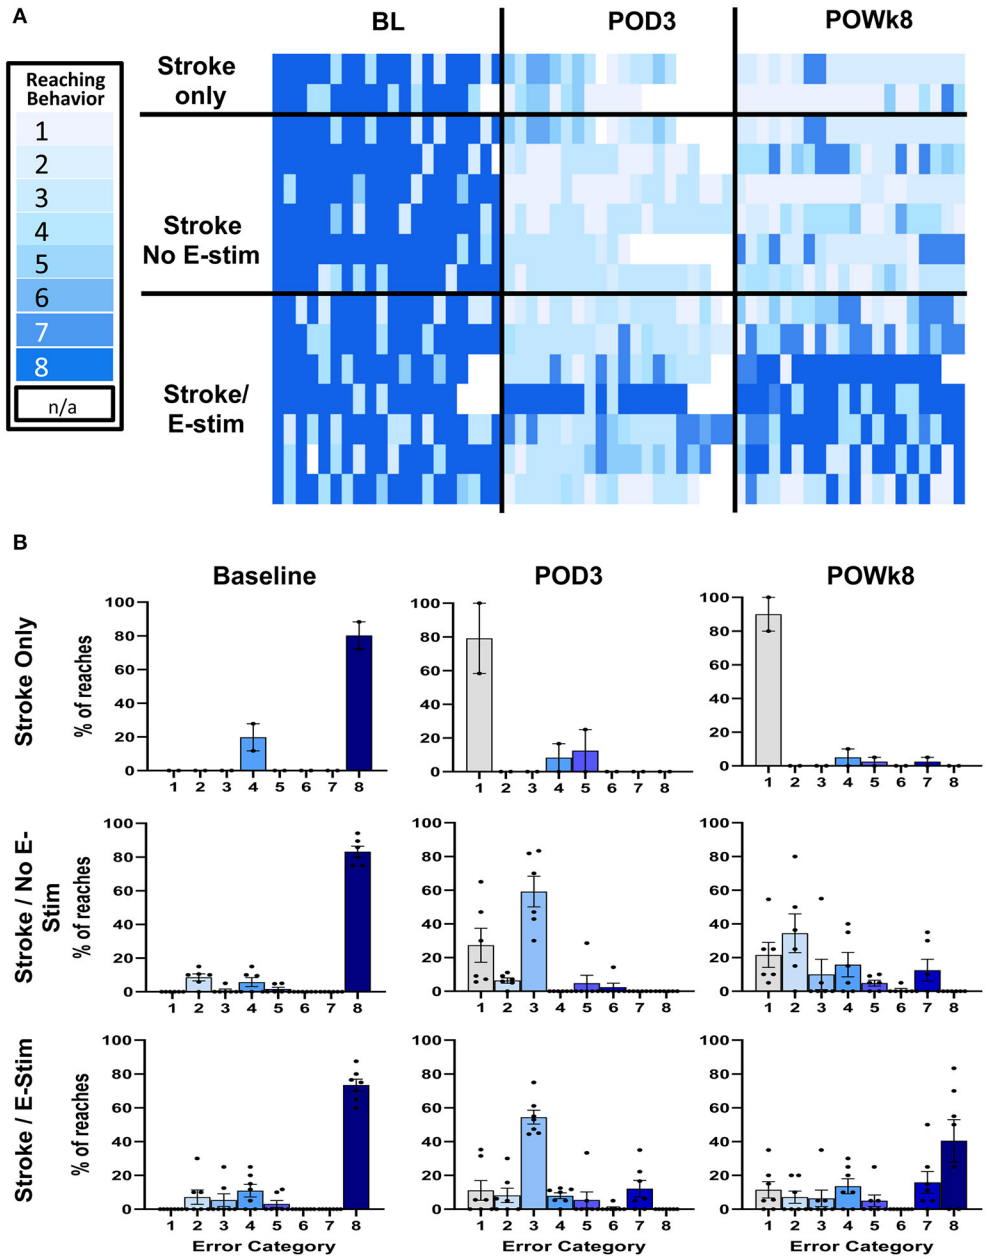

FIGURE 5 | Reaching error analysis. **(A)** Reaching error analysis of individual animals in each experimental group. All animals' reaching behaviors were recorded and analyzed at pre-stroke baseline, 3 days post-op before stimulation, and at the end of 8 weeks before BDA injection. The errors were categorized based on reaching error type. Each trial was composed of 20 different reaches where each reach was categorized independently. Reaching behaviors are categorized as follows and range from the lightest blue to the darkest blue: (1) Miss – no extension, (2) Miss – poor aim, (3) Touch –no grasp, (4) Touch – inaccurate grasp, (5) Grasp – dropped early, (6) Grasp – dropped during eating, (7) Success – arm motions not smooth, and (8) Total Success. White boxes represent missing data points (N/A). **(B)** Bar graph plots of reaching errors. At baseline, most reaches were successes across groups. However, of the unsuccessful reaches, most were in the moderate severity categories. At 3 days post-op (POD3), animals across experimental groups committed errors in the more severe error categories (i.e., 1–3) with less complete success. At the end of behavioral studies (POWk8), animals receiving E-stim not only improved in the number of successful reaches but also committed less errors in the more severe categories. In the non-stimulated groups, animals either showed no improvement (Stroke only) or there was a slightly right shift toward the less severe error categories without increasing success (Stroke/No E-stim).

terminating in deafferented cervical spinal areas. Moreover, by plotting both reaching score and fiber crossing index, two distinct treatment-based populations were evident (**Figure 7F**), which supports the significance of neuroplasticity in functional recovery. This finding is consistent with our previous studies demonstrating that remodeled motor pathways at the spinal cord

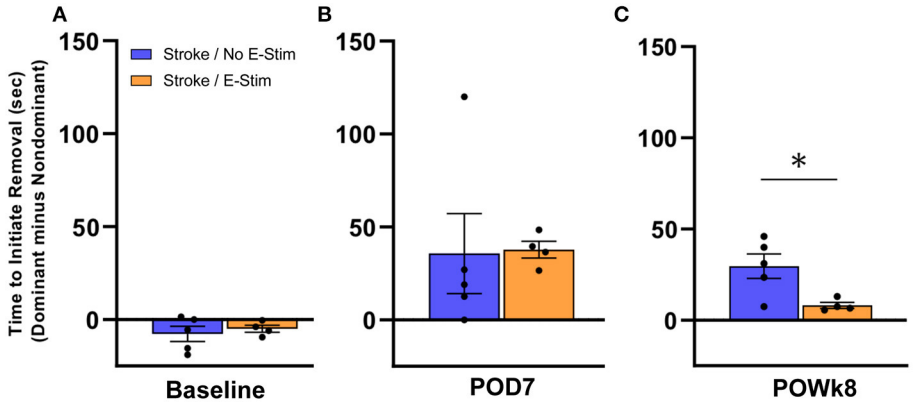

FIGURE 6 | Adhesive removal analysis. Both Stroke/No E-stim and Stroke/E-stim groups showed similar time in the initiation difference between two forelimbs for adhesive removal at pre-stroke baseline **(A)** and such initiation difference increased greatly at 7 days post-stroke **(B)** ($p > 0.05$). **(C)** At the end of behavioral tests, i.e., 8 weeks after stroke, animals receiving direct electrical stimulation on median nerve showed significant less time difference between two limbs to initiate adhesive removal (mean ± SEM, Non-parametric Mann-Whitney test, $^*p < 0.05$).

level correlated with improved function after cortical lesions (18, 35). Although plastic changes in the contralesional cortex may serve as the origin of improved functional outcomes, the role of the perilesional cortex cannot be ignored (57–59). Studies have shown that enhanced synaptic efficacy and either an increase or reorganization of axodendritic synaptic density of the perilesional cortex is also closely associated with spontaneous functional improvement after stroke (60). However, larger stroke size in our model may lessen the availability of intact perilesional cortex in the forelimb area. Further studies will be needed to examine whether anatomical plasticity occurs in response to peripheral electrical stimulation in the perilesional region.

Only young adult animals were examined in the current study (2 months of age at the start of the study). Our previous studies in aged rats showed that improvement in sensorimotor performance (19) and spatial memory (61) can still be achieved post-stroke with the same interventions utilized in young adult rats (18, 24, 32). Therefore, we expect the same approach in this study will lead to similar outcomes in the aged rats. However, we may observe a different recovery pattern, such as delayed recovery (19).

Due to the lack of standard parameters, such as time to start stimulation after stroke and stimulation frequency/intensity, the beneficial effects of NMES on stroke patients cannot be verified easily. The stimulation parameters chosen in the present study were based on our previous report on spinal cord injury in the rat (30). Several clinical studies applying NMES alone suggested sensorimotor function improvement in stroke patients (62, 63) although with stimulation frequencies between 10 and 50 Hz. Further, a report showed that activation at 5 Hz on the cortex did improve stroke patients' motor function (64). Our present study using a lower frequency at 5 Hz is supportive of those clinical studies showing that NMES has great potential to be used alone as an option to promote functional improvement in stroke patients. More importantly, our model can be used to further systemically explore the therapeutic effects of various parameter combinations.

To our knowledge, there is no known research on cellular mechanisms involved in implanted NMES in stroke animals. However, we have considered several possible mechanisms that may contribute to the corticospinal plasticity presented here. (1) Peripheral nerve stimulation could recruit contralesional and surviving ipsilesional cortical neurons to undergo axonal remodeling and motor map reorganization (14, 65–67). (2) Peripheral nerve stimulation could affect all types of neural pathways including sensory, motor, proprioceptive, as well as polysynaptic transmission (44, 45, 63). In this way, future studies should investigate whether median nerve E-stim in this stroke model leads to plastic changes or modulation of structures along the ascending pathway, such as neural modulation in the periaqueductal gray (68). (3) In addition to the plasticity enhancing trophic factors brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and cytokines (tumor necrosis factor-alpha, interleukin-6) induced in the spinal cord after stroke (69), plasticity at the spinal cord level may be further enhanced through stimulation-induced changes of the micro-environment such as release of signaling molecules, BDNF (70) and/or insulin-like growth father (IGF) in muscle and spinal cord (71). These trophic factors are known to promote neural growth and enhance neuronal plasticity. Using this model, these trophic factors, and others, should be assayed to determine if changes in their levels could potentially correlate with both function and midline crossing. (4) Peripheral nerve stimulation has recently been shown to lead to subventricular zone (SVZ) neurogenesis (72), which has been implicated as a source of migrating neural progenitors to the lesioned motor cortex (73). Taken together, these possible mechanisms suggest that the neuroplastic effects promoted by peripheral nerve stimulation may not

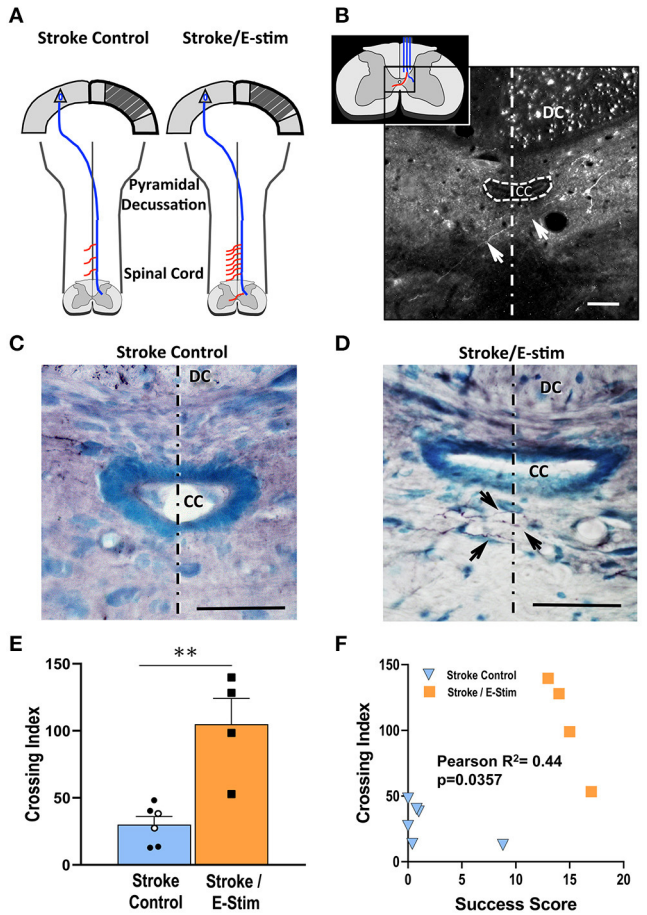

FIGURE 7 | Neuroanatomical analysis. **(A)** Schematic diagram showing corticospinal plasticity presented as more midline crossing fibers (red lines) along the cervical enlargement after stroke and E-stim treatment. Diagram adapted from Wahl et al. (36). **(B)** An enlarged schematic midline fiber crossing diagram (inset) and a representative fluorescent photomicrograph shows an alexa fluor 488 streptavidin-labeled BDA-positive midline-crossing corticospinal fiber (arrows) at C6 level. The fluorescent dots in the right dorsal column are BDA-positive corticospinal fibers. **(C,D)** Photomicrographs of BDA-reacted C6 spinal level sections show differences of corticospinal midline crossing fibers (arrows) between a Stroke Control **(C)** and Stroke/E-stim animals **(D)**. **(E)** Stroke/E-stim treated animals exhibited a significant higher midline crossing corticospinal fiber index in comparison with Stroke control (pooled Stroke Only and Stroke/No E-stim animals) (mean ± SEM, $^{**}p < 0.01$, Student's *t*-test). Black circles represent Stroke/No E-stim and white circles represent Stroke Only animals. **(F)**. Midline crossing corticospinal fibers showed positive correlation with the final forelimb reaching success score across 3 groups of animals ($P < 0.05$). The dotted lines indicate the midline. The scale bar indicates 50 μm. DC, dorsal column; CC, central canal.

only act locally, but also likely involve multiple pathways and cellular mechanisms.

This study provides a reliable animal model to examine the effects of NMES on stroke recovery and to study the underlying mechanisms. There are several points worth mentioning for our model. (1) The nerve cuff electrode reduced animal discomfort during stimulation, allowed for a lower current amplitude (0.11 mA on average) to induce muscle contraction and targeted a specific nerve (median nerve in this study). (2) Utilization of a nerve cuff also allowed for the targeting of a specific nerve (median nerve in this study) and prevented current leakage into the adjacent nerves and tissues, thereby lessening activation of non-targeted nerves (74). (3) Our stimulation paradigm utilized a sub-tetany frequency (5 Hz) compared to other paradigms that utilize higher frequencies that may lead to muscle tetanus (75). Furthermore, a clinical study showed that low frequency stimulation led to activation of bilateral thalami (76) which connect to the sensorimotor cortex and may play an important role in neuroplastic changes. (4) We applied electrical stimulation for only 30 min each day and did not add any additional therapies, yet still yielded improvement in volitional function. Once it is translated for clinical use, the simplicity of this therapy promotes continued patient compliance. (5) Stimulation was delayed until 3 days after stroke, and therefore this intervention may be used in patients that are stabilizing post-stroke and/or missing the time window to receive tPA or thrombectomy. It is believed that most recovery from impairment in humans resulting from enhanced plasticity occurs in the first 1–3 months after stroke (25, 77). The cortical plastic responses to stroke are particularly active within days or weeks after stroke in rodents (78–80). Our reports showed that such plasticity could be enhanced when interventions were given ranging from within a week (18, 19, 32, 52, 53) to months post-stroke in rodents (20, 21). Therefore, the time window to deliver NMES to promote neuronal plasticity and improve functional outcome may be extended beyond the acute stage after stroke in both rodent models and human patients. However, as it is not known for certain, more studies are needed to determine the best time window for clinical use.

In conclusion, median nerve stimulation post-ischemic stroke led to functional recovery on sensorimotor tasks that can potentially be attributed to plastic changes at the cervical spinal cord level. This study has provided an important model for both the cellular mechanisms by which peripheral E-stim promotes functional recovery, and its stimulation paradigm which has high translation potential to the stroke population at large.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

ETHICS STATEMENT

The animal study was reviewed and approved by Hines VA/Lovell IACUC.

AUTHOR CONTRIBUTIONS

S-YT contributed to the concept and design, acquisition/analysis and interpretation of data, and drafted the major part of the article. JS contributed to acquisition/analysis and interpretation of data, and drafted part of the article.

NA, JWu, and ST contributed to the acquisition/analysis of data. RH contributed to the design and experimental method refinement. JWa contributed to the design and refinement of experimental methods. TO'B contributed to data analysis/interpretation. GK contributed to the concept and design, interpretation of data, and revised the article for important intellectual content. RN originated the concept and design, interpretation of data, revised the article for important intellectual content. All the authors read and approved the final version.

FUNDING

This project was supported by the Paul Kalmanovitz Central Nervous System Repair Research Program, the Department of Veterans Affairs and NIH Grant NS115759.

Advantages of publishing in Frontiers

OPEN ACCESS
Articles are free to read for greatest visibility and readership

FAST PUBLICATION
Around 90 days from submission to decision

HIGH QUALITY PEER-REVIEW
Rigorous, collaborative, and constructive peer-review

TRANSPARENT PEER-REVIEW
Editors and reviewers acknowledged by name on published articles

Frontiers
Avenue du Tribunal-Fédéral 34
1005 Lausanne | Switzerland

Visit us: www.frontiersin.org
Contact us: frontiersin.org/about/contact

REPRODUCIBILITY OF RESEARCH
Support open data and methods to enhance research reproducibility

DIGITAL PUBLISHING
Articles designed for optimal readership across devices

FOLLOW US
@frontiersin

IMPACT METRICS
Advanced article metrics track visibility across digital media

EXTENSIVE PROMOTION
Marketing and promotion of impactful research

LOOP RESEARCH NETWORK
Our network increases your article's readership
