Frontiers eBook Copyright Statement

The copyright in the text of individual articles in this eBook is the property of their respective authors or their respective institutions or funders. The copyright in graphics and images within each article may be subject to copyright of other parties. In both cases this is subject to a license granted to Frontiers.

The compilation of articles constituting this eBook is the property of Frontiers.

Each article within this eBook, and the eBook itself, are published under the most recent version of the Creative Commons CC-BY licence. The version current at the date of publication of this eBook is CC-BY 4.0. If the CC-BY licence is updated, the licence granted by Frontiers is automatically updated to the new version.

When exercising any right under the CC-BY licence, Frontiers must be attributed as the original publisher of the article or eBook, as applicable.

Authors have the responsibility of ensuring that any graphics or other materials which are the property of others may be included in the CC-BY licence, but this should be checked before relying on the CC-BY licence to reproduce those materials. Any copyright notices relating to those materials must be complied with.

Copyright and source acknowledgement notices may not be removed and must be displayed in any copy, derivative work or partial copy which includes the elements in question.

All copyright, and all rights therein, are protected by national and international copyright laws. The above represents a summary only. For further information please read Frontiers' Conditions for Website Use and Copyright Statement, and the applicable CC-BY licence.

About Frontiers

Frontiers is more than just an open-access publisher of scholarly articles: it is a pioneering approach to the world of academia, radically improving the way scholarly research is managed. The grand vision of Frontiers is a world where all people have an equal opportunity to seek, share and generate knowledge. Frontiers provides immediate and permanent online open access to all its publications, but this alone is not enough to realize our grand goals.

Frontiers Journal Series

The Frontiers Journal Series is a multi-tier and interdisciplinary set of open-access, online journals, promising a paradigm shift from the current review, selection and dissemination processes in academic publishing. All Frontiers journals are driven by researchers for researchers; therefore, they constitute a service to the scholarly community. At the same time, the Frontiers Journal Series operates on a revolutionary invention, the tiered publishing system, initially addressing specific communities of scholars, and gradually climbing up to broader public understanding, thus serving the interests of the lay society, too.

Dedication to Quality

Each Frontiers article is a landmark of the highest quality, thanks to genuinely collaborative interactions between authors and review editors, who include some of the world's best academicians. Research must be certified by peers before entering a stream of knowledge that may eventually reach the public - and shape society; therefore, Frontiers only applies the most rigorous and unbiased reviews.
Frontiers revolutionizes research publishing by freely delivering the most outstanding research, evaluated with no bias from both the academic and social point of view. By applying the most advanced information technologies, Frontiers is catapulting scholarly publishing into a new generation.

What are Frontiers Research Topics?

Frontiers Research Topics are very popular trademarks of the Frontiers Journals Series: they are collections of at least ten articles, all centered on a particular subject. With their unique mix of varied contributions from Original Research to Review Articles, Frontiers Research Topics unify the most influential researchers, the latest key findings and historical advances in a hot research area! Find out more on how to host your own Frontiers Research Topic or contribute to one as an author by contacting the Frontiers Editorial Office: frontiersin.org/about/contact

CUTTING-EDGE APPROACHES FOR CNS PROTECTION AND REPAIR: FOCUS ON VASCULAR AND DEGENERATIVE DISORDERS

Topic Editors:
Johannes Boltze, University of Warwick, United Kingdom
Marietta Zille, University of Lübeck, Germany
Stephan Schilling, Fraunhofer Society (FHG), Germany
Mathias Gelderblom, University Medical Center Hamburg-Eppendorf, Germany
Gregory Jaye Bix, Tulane University, United States
Piotr Walczak, University of Maryland, Baltimore, United States
Christoph Harms, Charité – Universitätsmedizin Berlin, Germany
Paulo Henrique Rosado-de-Castro, D'Or Institute for Research and Education (IDOR), Brazil
Emmanuel Pinteaux, The University of Manchester, United Kingdom

Citation: Boltze, J., Zille, M., Schilling, S., Gelderblom, M., Bix, G. J., Walczak, P., Harms, C., Rosado-de-Castro, P. H., Pinteaux, E., eds. (2021). Cutting-Edge Approaches for CNS Protection and Repair: Focus on Vascular and Degenerative Disorders. Lausanne: Frontiers Media SA. doi: 10.3389/978-2-88971-177-2

Table of Contents

11 ***New Mechanistic Insights, Novel Treatment Paradigms, and Clinical Progress in Cerebrovascular Diseases***

Johannes Boltze, Jaroslaw A. Aronowski, Jerome Badaut, Marion S. Buckwalter, Mateo Caleo, Michael Chopp, Kunjan R. Dave, Nadine Didwischus, Rick M. Dijkhuizen, Thorsten R. Doeppner, Jens P. Dreier, Karim Fouad, Mathias Gelderblom, Karen Gertz, Dominika Golubczyk, Barbara A. Gregson, Edith Hamel, Daniel F. Hanley, Wolfgang Härtig, Friedhelm C. Hummel, Maulana Ikhsan, Miroslaw Janowski, Jukka Jolkkonen, Saravanan S. Karuppagounder, Richard F. Keep, Inga K. Koerte, Zaal Kokaia, Peiying Li, Fudong Liu, Ignacio Lizasoain, Peter Ludewig, Gerlinde A. S. Metz, Axel Montagne, Andre Obenaus, Alex Palumbo, Monica Pearl, Miguel Perez-Pinzon, Anna M. Planas, Nikolaus Plesnila, Ami P. Raval, Maria A. Rueger, Lauren H. Sansing, Farida Sohrabji, Charlotte J. Stagg, R. Anne Stetler, Ann M. Stowe, Dandan Sun, Akihiko Taguchi, Mickael Tanter, Sabine U. Vay, Raghu Vemuganti, Denis Vivien, Piotr Walczak, Jian Wang, Ye Xiong and Marietta Zille

26 ***Extracellular Vesicles Secreted in Response to Cytokine Exposure Increase Mitochondrial Oxygen Consumption in Recipient Cells***

Ashley E. Russell, Sujung Jun, Saumyendra Sarkar, Werner J. Geldenhuys, Sara E. Lewis, Stephanie L. Rellick and James W. Simpkins

38 ***Cell Type-Specific Human APP Transgene Expression by Hippocampal Interneurons in the Tg2576 Mouse Model of Alzheimer's Disease***

Corinna Höfling, Emira Shehabi, Peer-Hendrik Kuhn, Stefan F. Lichtenthaler, Maike Hartlage-Rübsamen and Steffen Roßner

50 ***Early Dyskinesias in Parkinson's Disease Patients With Parkin Mutation: A Primary Corticostriatal Synaptopathy?***

Jenny Sassone, Flavia Valtorta and Andrea Ciammola

57 ***Propensity Score-Matched Analysis of Lesion Patterns in Stroke Patients With Patent Foramen Ovale and Patients With Spontaneous Intracranial Artery Dissection***

Yangyang Huang, Yifan Cheng, Bei Shao, Xuanyou Zhou, Huazheng Liang, Jianhua Zhuang and Yong Bi

65 ***Correlates of Spreading Depolarization, Spreading Depression, and Negative Ultraslow Potential in Epidural Versus Subdural Electrocorticography***

Jens P. Dreier, Sebastian Major, Coline L. Lemale, Vasilis Kola, Clemens Reiffurth, Karl Schoknecht, Nils Hecht, Jed A. Hartings and Johannes Woitzik

85 ***Clinical Improvement Following Stroke Promptly Reverses Post-stroke Cellular Immune Alterations***

Antje Vogelgesang, Carl Witt, Christin Heuer, Juliane Schulze, Juliane Gellrich, Bettina von Sarnowski, Sönke Langner, Alexander Dressel and Johanna Ruhnau

94 ***Overexpression of CX3CR1 in Adipose-Derived Stem Cells Promotes Cell Migration and Functional Recovery After Experimental Intracerebral Hemorrhage***

Gaigai Li, Haihan Yu, Na Liu, Ping Zhang, Yingxin Tang, Yang Hu, Ye Zhang, Chao Pan, Hong Deng, Jiahui Wang, Qi Li and Zhouping Tang

106 ***Dipeptidyl Peptidase-4 Inhibitors for the Potential Treatment of Brain Disorders; A Mini-Review With Special Focus on Linagliptin and Stroke***

Vladimer Darsalia, Odd Erik Johansen, Grazyna Lietzau, Thomas Nyström, Thomas Klein and Cesare Patrone

115 ***Cross-Reactivity as a Mechanism Linking Infections to Stroke***

Guglielmo Lucchese, Agnes Flöel and Benjamin Stahl

123 ***MicroRNA-210-3p Targets RGMA to Enhance the Angiogenic Functions of Endothelial Progenitor Cells Under Hypoxic Conditions***

Wen-Jing Lu, Huai-Bin Liang, Yong-Fang Li, Xuan-Qiang Tu, Ji-Rong He, Kai-Qi Ding, Guo-Yuan Yang, Xiao-Yu Xin and Li-Li Zeng

134 ***Dysfunction of 67-kDa Laminin Receptor Disrupts BBB Integrity via Impaired Dystrophin/AQP4 Complex and p38 MAPK/VEGF Activation Following Status Epilepticus***

Hana Park, Seo-Hyeon Choi, Min-Jeong Kong and Tae-Cheon Kang

149 ***The Inflammatory Response After Ischemic Stroke: Targeting β_2 and β_1 Integrins***

Danielle N. Edwards and Gregory J. Bix

159 ***Fibrinogen Chains Intrinsic to the Brain***

Eugene V. Golanov, Martyn A. Sharpe, Angelique S. Regnier-Golanov, Gregory J. Del Zoppo, David S. Baskin and Gavin W. Britz

171 ***Generation of Oligodendrocyte Progenitor Cells From Mouse Bone Marrow Cells***

Yuan Zhang, Xin-Yu Lu, Giacomo Casella, Jing Tian, Ze-Qing Ye, Ting Yang, Juan-Juan Han, Ling-Yu Jia, Abdolmohamad Rostami and Xing Li

181 ***Canine Cognitive Dysfunction and Alzheimer's Disease – Two Facets of the Same Disease?***

Sonja Prpar Mihevc and Gregor Majdič

199 ***Telomere Length: A Potential Biomarker for the Risk and Prognosis of Stroke***

Yanjun Tian, Shuai Wang, Fengjuan Jiao, Qingsheng Kong, Chuanxin Liu and Yili Wu

207 ***Non-pulsed Sinusoidal Electromagnetic Field Rescues Animals From Severe Ischemic Stroke via NO Activation***

Lena P. Font, Miriam M. Cardonne, Hannelore Kemps, Raf Meesen, Oneida F. Salmon, Fidel G. González, Ivo Lambrichts, Jean-Michel Rigo, Bert Brône and Annelies Bronckaers

214 ***Proteostasis During Cerebral Ischemia***

Audrey M. Thiebaut, Elodie Hedou, Stefan J. Marciniak, Denis Vivien and Benoit D. Roussel

228 ***Old Dog New Tricks; Revisiting How Stroke Modulates the Systemic Immune Landscape***

Siddharth Krishnan and Catherine B. Lawrence

239 ***NK1-r Antagonist Treatment Comparable to Decompressive Craniectomy in Reducing Intracranial Pressure Following Stroke***
Annabel J. Sorby-Adams, Anna V. Leonard, Jan W. Hoving, Nawaf Yassi, Robert Vink, Adam J. Wells and Renée J. Turner

251 ***Determining the Temporal Profile of Intracranial Pressure Changes Following Transient Stroke in an Ovine Model***
Annabel J. Sorby-Adams, Anna V. Leonard, Levi E. Elms, Oana C. Marian, Jan W. Hoving, Nawaf Yassi, Robert Vink, Emma Thornton an Renée J. Turner

267 ***Intravenous Administration of Human Adipose Derived-Mesenchymal Stem Cells Is Not Efficient in Diabetic or Hypertensive Mice Subjected to Focal Cerebral Ischemia***
Gabrielle Mangin, Adrien Cogo, Anaïck Moisan, Philippe Bonnin, Benjamin Maïer and Nathalie Kubis on behalf of the RESSTORE Consortium

283 ***Delayed Effects of Acute Reperfusion on Vascular Remodeling and Late-Phase Functional Recovery After Stroke***
Violeta Durán-Laforet, David Fernández-López, Alicia García-Culebras, Juan González-Hijón, Ana Moraga, Sara Palma-Tortosa, Isaac García-Yébenes, Adrián Vega-Pérez, Ignacio Lizasoain and María Ángeles Moro

295 ***Re-thinking the Etiological Framework of Neurodegeneration***
Ximena Castillo, Susana Castro-Obregón, Benjamin Gutiérrez-Becker, Gabriel Gutiérrez-Ospina, Nikolaos Karalis, Ahmed A. Khalil, José Sócrates Lopez-Noguerola, Liliana Lozano Rodríguez, Eduardo Martínez-Martínez, Claudia Perez-Cruz, Judith Pérez-Velázquez, Ana Luisa Piña, Karla Rubio, Héctor Pedro Salazar García, Tauqeerunnisa Syeda, America Vanoye-Carlo, Arno Villringer, Katarzyna Winek and Marietta Zille

320 ***Dental Pulp Stem Cells: An Attractive Alternative for Cell Therapy in Ischemic Stroke***
Xiaoyan Lan, Zhengwu Sun, Chengyan Chu, Johannes Boltze and Shen Li

330 ***Therapeutic Potential of Neurotrophins for Repair After Brain Injury: A Helping Hand From Biomaterials***
Josh Houlton, Nashat Abumaria, Simon F. R. Hinkley and Andrew N. Clarkson

353 ***Pluripotent Stem Cells for Brain Repair: Protocols and Preclinical Applications in Cortical and Hippocampal Pathologies***
Claudia Alia, Marco Terrigno, Irene Busti, Federico Cremisi and Matteo Caleo

368 ***Acute Subcortical Infarcts Cause Secondary Degeneration in the Remote Non-involved Cortex and Connecting Fiber Tracts***
Xiao-Er Wei, Kai Shang, Jia Zhou, Ya-Jun Zhou and Yue-Hua Li

377 ***Topical Administration of a Soluble TNF Inhibitor Reduces Infarct Volume After Focal Cerebral Ischemia in Mice***
Minna Yli-Karjanmaa, Bettina Hjelm Clausen, Matilda Degn, Hans Gram Novrup, Ditte Gry Ellman, Peter Toft-Jensen, David E. Szymkowski, Allan Stensballe, Morten Meyer, Roberta Brambilla and Kate Lykke Lambertsen

395 ***Aging Neurovascular Unit and Potential Role of DNA Damage and Repair in Combating Vascular and Neurodegenerative Disorders***
Yan Li, Lv Xie, Tingting Huang, Yueman Zhang, Jie Zhou, Bo Qi, Xin Wang, Zengai Chen and Peiying Li

410 ***Potential Immunotherapeutic Targets on Myeloid Cells for Neurovascular Repair After Ischemic Stroke***
Ziyu Zhu, Li Zheng, Yan Li, Tingting Huang, Yu-Chieh Chao, Lijun Pan, Hui Zhu, Yanhua Zhao, Weifeng Yu and Peiying Li

425 ***Small Vessels are a Big Problem in Neurodegeneration and Neuroprotection***
Şefik Evren Erdener and Turgay Dalkara

445 ***Involvement of Epigenetic Mechanisms and Non-coding RNAs in Blood-Brain Barrier and Neurovascular Unit Injury and Recovery After Stroke***
Svetlana M. Stamatovic, Chelsea M. Phillips, Gabriela Martinez-Revollar, Richard F. Keep and Anuska V. Andjelkovic

460 ***Serial Metabolic Evaluation of Perihematomal Tissues in the Intracerebral Hemorrhage Pig Model***
Muhammad E. Haque, Refaat E. Gabr, Sarah D. George, Xiurong Zhao, Seth B. Boren, Xu Zhang, Shun-Ming Ting, Gunghua Sun, Khader M. Hasan, Sean Savitz and Jaroslaw Aronowski

468 ***The Potential of Biomaterial-Based Approaches as Therapies for Ischemic Stroke: A Systematic Review and Meta-Analysis of Pre-clinical Studies***
Faye Bolan, Irene Louca, Calvin Heal and Catriona J. Cunningham

480 ***New Perspective for Non-invasive Brain Stimulation Site Selection in Mild Cognitive Impairment: Based on Meta- and Functional Connectivity Analyses***
Jiao Liu, Binlong Zhang, Georgia Wilson, Jian Kong and the Alzheimer's Disease Neuroimaging Initiative

488 ***Stem Cell-Derived Exosomes Protect Astrocyte Cultures From* in vitro *Ischemia and Decrease Injury as Post-stroke Intravenous Therapy***
Xiaoyun Sun, Ji-Hye Jung, Oiva Arvola, Michelle R. Santoso, Rona G. Giffard, Phillip C. Yang and Creed M. Stary

497 ***Neurons Induced From Fibroblasts of c9ALS/FTD Patients Reproduce the Pathology Seen in the Central Nervous System***
Peter O. Bauer, Judith H. Dunmore, Hiroki Sasaguri and Vaclav Matoska

507 ***Small Vessel Disease***
Antoine M. Hakim

513 ***Enzymatic Digestion of Hyaluronan-Based Brain Extracellular Matrix* in vivo *Can Induce Seizures in Neonatal Mice***
Alena Balashova, Vladimir Pershin, Olga Zaborskaya, Natalia Tkachenko, Andrey Mironov, Evgeny Guryev, Leonid Kurbatov, Murat Gainullin and Irina Mukhina

525 ***Visualization and Quantification of Post-stroke Neural Connectivity and Neuroinflammation Using Serial Two-Photon Tomography in the Whole Mouse Brain***
Katherine Poinsatte, Dene Betz, Vanessa O. Torres, Apoorva D. Ajay, Shazia Mirza, Uma M. Selvaraj, Erik J. Plautz, Xiangmei Kong, Sankalp Gokhale, Julian P. Meeks, Denise M. O. Ramirez, Mark P. Goldberg and Ann M. Stowe

539 ***A Safe and Effective Magnetic Labeling Protocol for MRI-Based Tracking of Human Adult Neural Stem Cells***
Albrecht Stroh, Jenny Kressel, Roland Coras, Antje Y. Dreyer, Wenke Fröhlich, Annette Förschler, Donald Lobsien, Ingmar Blümcke, Saida Zoubaa, Jürgen Schlegel, Claus Zimmer and Johannes Boltze

549 ***Thyroid Hormones in the Brain and Their Impact in Recovery Mechanisms After Stroke***
Daniela Talhada, Cecília Reis Alves Santos, Isabel Gonçalves and Karsten Ruscher

565 ***Behcet's Disease With Cerebral Artery Infarction Caused by Cerebral Arteritis as an Early Symptom Only With Elevated Interleukin-8***
Hao Yin, Yun Song, Meimei Zheng, Ju Han and Jiyou Tang

572 ***Metabolic Changes in Focal Brain Ischemia in Rats Treated With Human Induced Pluripotent Stem Cell-Derived Neural Precursors Confirm the Beneficial Effect of Transplanted Cells***
Daniel Jirak, Natalia Ziolkowska, Karolina Turnovcova, Kristyna Karova, Eva Sykova, Pavla Jendelova and Nataliya Romanyuk

587 ***ApoA-I Mimetic Peptide Reduces Vascular and White Matter Damage After Stroke in Type-2 Diabetic Mice***
Xiaohui Wang, Rongwen Li, Alex Zacharek, Julie Landschoot-Ward, Michael Chopp, Jieli Chen and Xu Cui

600 ***Transcranial Current Stimulation Alters the Expression of Immune-Mediating Genes***
Monika Rabenstein, Marcus Unverricht-Yeboah, Meike Hedwig Keuters, Anton Pikhovych, Joerg Hucklenbroich, Sabine Ulrike Vay, Stefan Blaschke, Anne Ladwig, Helene Luise Walter, Magdalena Beiderbeck, Gereon Rudolf Fink, Michael Schroeter, Ralf Kriehuber and Maria Adele Rueger

608 ***The Delta-Subunit Selective $GABA_A$ Receptor Modulator, DS2, Improves Stroke Recovery via an Anti-inflammatory Mechanism***
Silke Neumann, Lily Boothman-Burrell, Emma K. Gowing, Thomas A. Jacobsen, Philip K. Ahring, Sarah L. Young, Karin Sandager-Nielsen and Andrew N. Clarkson

621 ***Opposite Effects of Neuroprotective Cannabinoids, Palmitoylethanolamide, and 2-Arachidonoylglycerol on Function and Morphology of Microglia***
Urszula Hohmann, Markus Pelzer, Joshua Kleine, Tim Hohmann, Chalid Ghadban and Faramarz Dehghani

636 ***Bioscaffold-Induced Brain Tissue Regeneration***
Michel Modo

662 ***Brain–Immune Interactions and Neuroinflammation After Traumatic Brain Injury***
Virginie Dinet, Klaus G. Petry and Jerome Badaut

674 ***Development of a Routinely Applicable Imaging Protocol for Fast and Precise Middle Cerebral Artery Occlusion Assessment and Perfusion Deficit Measure in an Ovine Stroke Model: A Case Study***
Andrea Maria Herrmann, Giorgio Franco Maria Cattaneo, Sebastian Alexander Eiden, Manuela Wieser, Elias Kellner, Christoph Maurer, Jörg Haberstroh, Christoph Mülling, Wolf-Dirk Niesen, Horst Urbach, Johannes Boltze, Stephan Meckel and Mukesch Johannes Shah

685 ***Proteostasis in Cerebral Small Vessel Disease***
Christof Haffner

695 ***Successes and Hurdles in Stem Cells Application and Production for Brain Transplantation***
Daniel Henriques, Ricardo Moreira, Jens Schwamborn, Luís Pereira de Almeida and Liliana S. Mendonça

710 ***Pericytes in Cerebrovascular Diseases: An Emerging Therapeutic Target***
Xiaojuan Su, Lingyi Huang, Yi Qu, Dongqiong Xiao and Dezhi Mu

722 ***A Pilot Study Investigating Changes in Capillary Hemodynamics and Its Modulation by Exercise in the APP-PS1 Alzheimer Mouse Model***
Xuecong Lu, Mohammad Moeini, Baoqiang Li, Yuankang Lu, Rafat Damseh, Philippe Pouliot, Éric Thorin and Frédéric Lesage

734 ***Viability and Contractility of Rat Brain Pericytes in Conditions That Mimic Stroke; an* in vitro *Study***
Mohammed Heyba, Lulwa Al-Abdullah, Andreas W. Henkel, Zeinab Sayed, Slava A. Malatiali and Zoran B. Redzic

744 ***Mean Platelet Volume-To-Lymphocyte Ratio Predicts Poor Functional Outcomes Among Ischemic Stroke Patients Treated With Intravenous Thrombolysis***
Si-Yan Chen, Yuan-Shao Lin, Yi-Fan Cheng, Hong Wang, Xiao-Ting Niu and Wan-Li Zhang

752 ***Effects of Transcranial Direct Current Stimulation (tDCS) and Exercises Treadmill on Autonomic Modulation of Hemiparetic Patients Due To Stroke—Clinic Test, Controlled, Randomized, Double-Blind***
Glauber Heinz, Katia De Angelis, Simone Dal Corso, Maria Helena Gomes De Sousa, Ariane Viana, Fernando Dos Santos, João Carlos Ferrari Corrêa and Fernanda Ishida Corrêa

764 ***Acute Treatment With Gleevec Does Not Promote Early Vascular Recovery Following Intracerebral Hemorrhage in Adult Male Rats***
Mohammed Abbas, Elizabeth Haddad, Mary Hamer, Derek Nowrangi, John Zhang, William J. Pearce, Jiping Tang and Andre Obenaus

781 ***Hierarchical Clustering Analyses of Plasma Proteins in Subjects With Cardiovascular Risk Factors Identify Informative Subsets Based on Differential Levels of Angiogenic and Inflammatory Biomarkers***
Zachary Winder, Tiffany L. Sudduth, David Fardo, Qiang Cheng, Larry B. Goldstein, Peter T. Nelson, Frederick A. Schmitt, Gregory A. Jicha and Donna M. Wilcock

791 ***Subarachnoid Hemorrhage Induces Dynamic Immune Cell Reactions in the Choroid Plexus***
Peter Solár, Ilona Klusáková, Radim Jančálek, Petr Dubový and Marek Joukal

804 ***Platelets in Amyloidogenic Mice are Activated and Invade the Brain***
Kathrin M. Kniewallner, Diana M. Bessa de Sousa, Michael S. Unger, Heike Mrowetz and Ludwig Aigner

818 ***Influence of Age-Related Complications on Clinical Outcome in Patients With Small Ruptured Cerebral Aneurysms***
Jianfeng Zheng, Xiaochuan Sun and Xiaodong Zhang

825 **In vivo *Two-Photon Imaging Reveals Acute Cerebral Vascular Spasm and Microthrombosis After Mild Traumatic Brain Injury in Mice***
Xinjia Han, Zhi Chai, Xingjie Ping, Li-Juan Song, Cungen Ma, Yiwen Ruan and Xiaoming Jin

837 ***Hypoxia-Inducible Factor 1α and 2α Have Beneficial Effects in Remote Ischemic Preconditioning Against Stroke by Modulating Inflammatory Responses in Aged Rats***
Xiangnan Du, Jian Yang, Cuiying Liu, Sainan Wang, Chencheng Zhang, Heng Zhao, Huishan Du and Xiaokun Geng

848 ***Gene Expression Dynamics at the Neurovascular Unit During Early Regeneration After Cerebral Ischemia/Reperfusion Injury in Mice***
Roxane-Isabelle Kestner, Franziska Mayser, Rajkumar Vutukuri, Lena Hansen, Stefan Günther, Robert Brunkhorst, Kavi Devraj and Waltraud Pfeilschifter

860 ***Isolation of Mouse Cerebral Microvasculature for Molecular and Single-Cell Analysis***
Hallel C. Paraiso, Xueqian Wang, Ping-Chang Kuo, Destin Furnas, Barbara A. Scofield, Fen-Lei Chang, Jui-Hung Yen and I-Chen Yu

873 ***Effects of Periprocedural Tirofiban vs. Oral Antiplatelet Drug Therapy on Posterior Circulation Infarction in Patients With Acute Intracranial Atherosclerosis-Related Vertebrobasilar Artery Occlusion***
Xuan Sun, Huijun Zhang, Xu Tong, Feng Gao, Gaoting Ma and Zhongrong Miao

880 ***Hypothesis and Theory: A Pathophysiological Concept of Stroke-Induced Acute Phase Response and Increased Intestinal Permeability Leading to Secondary Brain Damage***
Fabienne Ferrara, Vilia Zeisig, Sören Pietsch, Rita Rütten, Antje Y. Dreyer, Laura Pieper, Ann-Kathrin Schatzl, Damian D. McLeod, Henryk Barthel, Johannes Boltze, Wieland Schrödl and Björn Nitzsche

888 ***Reduced Post-ischemic Brain Injury in Transient Receptor* Potential Vanilloid 4 *Knockout Mice***
Koji Tanaka, Shoji Matsumoto, Takeshi Yamada, Ryo Yamasaki, Makoto Suzuki, Mizuho A. Kido and Jun-Ichi Kira

896 ***Serum-Based Proteomics Reveals Lipid Metabolic and Immunoregulatory Dysregulation in Cervical Artery Dissection With Stroke***
Yongtao Yang, Jing Peng, Suxia Wang, Jialu Huang, Hong Ran, Kangning Chen and Zhenhua Zhou

905 ***New PAR1 Agonist Peptide Demonstrates Protective Action in a Mouse Model of Photothrombosis-Induced Brain Ischemia***
Maksim Galkov, Ekaterina Kiseleva, Mikhail Gulyaev, Maria Sidorova and Liubov Gorbacheva

917 ***NEK7 Coordinates Rapid Neuroinflammation After Subarachnoid Hemorrhage in Mice***
Gen Li, Yushu Dong, Dongdong Liu, Zheng Zou, Guangzhi Hao, Xu Gao, Pengyu Pan and Guobiao Liang

931 ***A Semiquantitative Non-invasive Measurement of PcomA Patency in C57BL/6 Mice Explains Variance in Ischemic Brain Damage in Filament MCAo***
Samuel Knauss, Carolin Albrecht, Ulrich Dirnagl, Susanne Mueller, Christoph Harms, Christian Johannes Hoffmann, Stefan Paul Koch, Matthias Endres and Philipp Boehm-Sturm

942 ***Beta-Hydroxybutyrate Enhances BDNF Expression by Increasing H3K4me3 and Decreasing H2AK119ub in Hippocampal Neurons***
Erling Hu, Huan Du, Sen Shang, Yali Zhang and Xiaoyun Lu

955 ***Disrupted Regional Cerebral Blood Flow and Functional Connectivity in Pontine Infarction: A Longitudinal MRI Study***
Ying Wei, Luobing Wu, Yingying Wang, Jingchun Liu, Peifang Miao, Kaiyu Wang, Caihong Wang and Jingliang Cheng

968 ***LongShengZhi Capsule Attenuates Alzheimer-Like Pathology in APP/PS1 Double Transgenic Mice by Reducing Neuronal Oxidative Stress and Inflammation***
Zequn Yin, Xuerui Wang, Shihong Zheng, Peichang Cao, Yuanli Chen, Maoyun Yu, Chenzhong Liao, Zhongyuan Zhang, Jihong Han, Yajun Duan, Xiaoxiao Yang and Shuang Zhang

986 ***Hydrogen Sulfide Overproduction is Involved in Acute Ischemic Cerebral Injury Under Hyperhomocysteinemia***
Yan Ji, Yusheng Li, Zichen Zhao, Panxing Li and Yi Xie

1000 ***MiR-128-3p Alleviates Spinal Cord Ischemia/Reperfusion Injury Associated Neuroinflammation and Cellular Apoptosis via SP1 Suppression in Rat***
Dan Wang, Fengshou Chen, Bo Fang, Zaili Zhang, Yan Dong, Xiangyi Tong and Hong Ma

1015 ***Pathophysiological Changes and the Role of Notch-1 Activation After Decompression in a Compressive Spinal Cord Injury Rat Model***
Xing Cheng, Zhengran Yu, Jinghui Xu, Daping Quan and Houqing Long

1029 ***Improved Functional Outcome After Peripheral Nerve Stimulation of the Impaired Forelimb Post-stroke***
Shih-Yen Tsai, Jennifer A. Schreiber, Natalie S. Adamczyk, Joanna Y. Wu, Son T. Ton, Ryan C. Hofler, James S. Walter, Timothy E. O'Brien, Gwendolyn L. Kartje and Russ P. Nockels

The past decade has brought tremendous progress in diagnostic and therapeutic options for cerebrovascular diseases as exemplified by the advent of thrombectomy in ischemic stroke, benefitting a steeply increasing number of stroke patients and potentially paving the way for a renaissance of neuroprotectants. Progress in basic science has been equally impressive. Based on a deeper understanding of pathomechanisms underlying cerebrovascular diseases, new therapeutic targets have been identified and novel treatment strategies such as pre- and post-conditioning methods were developed. Moreover, translationally relevant aspects are increasingly recognized in basic science studies, which is believed to increase their predictive value and the relevance of obtained findings for clinical application.This review reports key results from some of the most remarkable and encouraging achievements in neurovascular research that have been reported at the 10th International Symposium on Neuroprotection and Neurorepair. Basic science topics discussed herein focus on aspects such as neuroinflammation, extracellular vesicles, and the role of sex and age on stroke recovery. Translational reports highlighted endovascular techniques and targeted delivery methods, neurorehabilitation, advanced functional testing approaches for experimental studies, pre-and post-conditioning approaches as well as novel imaging and treatment strategies. Beyond ischemic stroke, particular emphasis was given on activities in the fields of traumatic brain injury and cerebral hemorrhage in which promising preclinical and clinical results have been reported. Although the number of neutral outcomes in clinical trials is still remarkably high when targeting cerebrovascular diseases, we begin to evidence stepwise but continuous progress towards novel treatment options. Advances in preclinical and translational research as reported herein are believed to have formed a solid foundation for this progress.

Keywords: cell therapies, dementia, experimental therapy, hemorrhage, neuroprotection, neurorehabilitation, stroke, translational research

INTRODUCTION

Overcoming more than two decades of translational standstill and providing options to treat selected stroke patients in extended time windows, the advent of recanalization approaches has sparked a new dynamic in preclinical and clinical stroke research. With a catheter in place, i.e., in a reopened cerebral artery, we now have the opportunity to apply neuroprotective treatments exactly when and where they may exert their optimal benefit (Savitz et al., 2019). These new options have the potential to initiate a "renaissance of neuroprotectants." Neuroprotectants may also play an increasingly important role in the treatment of cerebral hemorrhages. Minimally invasive techniques for hematoma evacuation relying on specialized, catheter-based intervention strategies have been developed and were assessed in first clinical trials (Hanley et al., 2019). Neuroprotective agents may be delivered *via* those catheters once the hematoma was removed, and novel targets for neuroprotective interventions have been identified (Zille et al., 2017).

Nevertheless, the majority of patients still cannot benefit from the recent advances in acute interventions for cerebrovascular diseases. Among others, reasons comprise strict inclusion/exclusion and eligibility criteria, uncertainties regarding the optimal way to deliver such treatments as well as logistical challenges and limited availability of required infrastructure. Therefore, the need for new treatments being effective within therapeutic time windows beyond the range of hours as well as supporting long-term recovery and recuperation continues to exist. The development of these new treatments should take into account advances in basic science areas such as neuroimmunology, neurobiochemistry, and molecular biology, as well as cell-based approaches. Moreover, translational research shall reflect advances in imaging technologies and rehabilitation research and must consider aspects such as the influence of sex and age on therapeutic outcome.

The International Symposium on Neuroprotection and Neurorepair (ISN&N) discussed these aspects in the light of current therapeutic advances in cerebrovascular diseases. The ISN&N is a biennial meeting series on fundamental and translational neuroscience with a scope on cerebrovascular diseases and dementia (Boltze et al., 2011, 2012; Demuth et al., 2017). Attracting leading neuroscientists and clinicians from around the world, the meeting is characterized by intensive scientific exchange and discussions of new insights into neurovascular and neurodegenerative diseases. To share some of the most exciting reports with a wider academic community in a concise format, this review summarizes cross-selected, outstanding sessions from the 10th ISN&N that took place from October 9th to 11th 2018 in Radebeul near Dresden, Germany. It covers the main topics of the meeting, and puts a particular scope on translational and clinical aspects, as such providing a good overview of the field.

Conditioning Medicine: Basic Mechanisms and Clinical Potential

It is now well accepted that ischemic pre- and post-conditioning promotes ischemic neuroprotection in different modalities (e.g., pharmacological, remote, and ischemic) and in many different animal models (Wang et al., 2015). Novel mechanisms involved in conditioning were discussed and clinical views of how to apply conditioning strategies to thrombectomy were provided.

IL (Madrid, Spain) presented that toll-like receptor 4 (TLR4) has both protective (ischemic tolerance) and damaging (acute ischemia) roles in cerebral ischemia, including hemorrhagic transformation (Pradillo et al., 2009; Vartanian et al., 2011; García-Culebras et al., 2017). TLR4 deficiency increased the levels of alternative neutrophils (N2), which may be involved in the resolution of inflammation and in the neuroprotective effect observed after stroke (García-Culebras et al., 2019). New drugs blocking TLR4 (Fernández et al., 2018) may be useful for the treatment of patients with stroke.

RAS (Pittsburgh, PA, USA) demonstrated that ischemic neuroprotection can be achieved by dietary restriction, improving both gray and white matter outcomes and functional recovery (Zhang et al., 2018). Although the activation of sirtuins may be a potential contributor to ischemic neuroprotection (Haigis and Guarente, 2006; Guarente, 2008; Stetler et al., 2014), dietary restriction is also well known to affect the release of a variety of humoral factors, particularly from adipose tissue. Adiponectin release into the plasma occurs acutely after dietary restriction and increased levels in the serum. This was associated with beneficial outcomes, as global knockout of adiponectin negated the effects of dietary restriction on the subsequent ischemic injury. The effects may be due to penetration of adiponectin into the brain parenchyma and the subsequent binding to its receptors on neural cells in the context of the opening of the blood-brain barrier (BBB) after ischemic injury (Brochu-Gaudreau et al., 2010; Zhang et al., 2018). Whether this scenario or the alternative situation—wherein adiponectin acts directly on endothelial barrier function to exert protection—underlies the neuroprotective effects remains under investigation.

MP-P (Miami, FL, USA) reported a novel window for ischemic tolerance for preconditioning mimetics, which was previously limited to 48–72 h after cerebral ischemia (Narayanan et al., 2015). Resveratrol preconditioning yielded gene expression changes in 136 genes at 14 days after single administration: many of the 116 downregulated genes were related to transcription, synaptic signaling, and neurotransmission, resembling the metabolic depression observed in hibernating species. This downregulation of gene expression fits well with the hippocampal synaptic and electrophysiological depression observed with pre-conditioning mimetics (DeFazio et al., 2009; Neumann et al., 2015; Cohan et al., 2017). Also, glycolysis and mitochondrial respiration efficiency were increased upon resveratrol preconditioning (Koronowski et al., 2017; Khoury et al., 2019), indicating an increased reliance on energy-producing pathways.

PL (Shanghai, China) discussed anesthetic postconditioning as a valuable neuroprotection candidate (Cohan et al., 2017) as fast onset and short-acting anesthetics allow smooth anesthesia induction and faster anesthetic emergence to overcome the clinical limitation that neurological assessment during anesthesia or sedation is not possible. New technology-based anesthetic

drug delivery systems, such as target-controlled infusion, close loop infusion, and computer-assisted sedation systems allow better control of anesthesia (Struys et al., 2016; Zaouter et al., 2016). Dr. Li further reported about a planned clinical study in stroke patients undergoing endovascular thrombectomy to compare general anesthesia with and without anesthetic postconditioning for countering reperfusion injury after endovascular thrombectomy.

Overall, conditioning represents a clinically available therapeutic strategy for ischemic stroke, and the presented findings put forward our understanding of the underlying mechanisms and provided novel insights into its clinical application. However, to utilize its full potential, relevant aspects of heterogeneous patient populations such as age and sex have to be considered. Their relevance has already been shown in numerous studies.

Effect of Sex and Age on Post-ischemic Outcome and Therapy

Sex and age are known to affect stroke outcomes (Kim and Vemuganti, 2015). Their contribution concerning mechanisms of ionic imbalance, inflammation, microRNAs, and the interaction of long noncoding RNAs with epigenetics was discussed.

As the expression of the chloride influx transporter, Na-K-Cl cotransporter 1 (NKCC1) in male rodent brains starts earlier during development compared to female brains, targeting NKCC1 during post-injury in adulthood may be sex-dependent. Indeed, DS (Pittsburgh, PA, USA) showed that pharmacological blockade of NKCC1 protein has higher sensitivity in adult male mice than female mice for reducing post-ischemic brain injury (Huang et al., 2019).

FL (Houston, TX, USA) presented that post-stroke inflammation and microglial activation are sex- and age-dependent and that these differences exist throughout the lifespan (Zhao et al., 2017b; Ritzel et al., 2018). He also showed that sex-chromosomal effects in addition to sex hormones contribute to the differential outcomes between males and females after focal ischemia (McCullough et al., 2016).

AR (Miami, FL, USA) reported that the depletion of endogenous estrogen at reproductive senescence increases inflammasome proteins in the brain of females, but not in age-matched male rats (de Rivero Vaccari et al., 2016). In reproductively senescent females, extracellular vesicles (EVs) from reproductive organs carry inflammasome proteins to the brain leading to an exacerbated innate immune response that may be responsible for the increased severity of ischemic damage in senescent females (D'Adesky et al., 2018).

FS (Bryan, TX, USA) showed that stroke neuroprotectants may act in a sex-specific manner. Post-stroke administration of IGF-1 is neuroprotective after stroke. Preventing microRNA let-7f, thus upregulating IGF-1 which is reduced in aging animals and humans, is protective in young female rats. However, it is not neuroprotective in young males and even worsens outcomes in senescent females post-stroke (Selvamani et al., 2012; Sohrabji et al., 2019). Let7f also regulates caspase 3, and treatment with miR-363–3p mimic (repressing caspase-3) protects young and senescent females, but not males, after focal ischemia (Selvamani and Sohrabji, 2017). Thus, the neurotoxic effect seen in older females may be related to an increase in caspase-3 and its cell death pathways caused by the blocking of let7f (Sohrabji and Selvamani, 2019). These findings also illustrate the complexity of sex-specific neuroprotective actions that must be taken into consideration.

RV (Madison, WI, USA) presented that the long noncoding RNAs Fos downstream transcript (FosDT) is induced after stroke and that knockdown of FosDT with a siRNA cocktail protects the brain in both males and females and also aged animals (Mehta et al., 2015). The epigenetic modification hydroxymethylation that converts 5-methylcytosine to 5-hydroxymethylcytosine induced after stroke is neuroprotective in both sexes (Morris-Blanco et al., 2019).

In summary, the contribution of age and sex to the outcome of cerebrovascular diseases should be carefully considered in the development of novel therapeutic strategies.

Long-Term Neuroinflammation During Functional Recovery From Stroke

Inflammation has been regarded as a target to reduce brain damage in acute stroke. While dampening innate immune responses and addressing complement or danger signaling effectively reduces acute brain damage (Muhammad et al., 2008; Alawieh et al., 2018), certain inflammatory responses are necessary for repair as they induce cell migration, proliferation, matrix deposition, and tissue remodeling. This suggests that initial inflammatory reactions trigger a set of responses that may improve functional outcome in the long term.

AMP (Barcelona, Spain) reported that although monocytes and macrophages reach the brain within the first 4 days after stroke (Miró-Mur et al., 2016), macrophages persist for weeks in the damaged brain tissue (Wattananit et al., 2016; Mantovani, 2017). While they may have detrimental functions acutely, macrophages also play critical roles in long-term functional recovery (Wattananit et al., 2016). Besides, lymphocytes, which promote acute thromboinflammation through mechanisms that do not involve adaptive immune responses (Kleinschnitz et al., 2010), also infiltrate the brain in higher numbers during chronic phases, when adaptive immune responses may play a role in functional impairment (Selvaraj and Stowe, 2017).

AMS (Lexington, KY, USA) discussed that $CD8^+$ T cells (i.e., cytotoxic T cells) move into several regions interconnected to the infarct within 4 days after transient middle cerebral artery occlusion (tMCAO) in mice, where they remain and support recovery (Poinsatte et al., 2019). Antibody-mediated depletion of $CD8^+$ T cells improved motor recovery and reduced diapedesis of other leukocyte populations, including macrophages, neutrophils, and $CD4^+$ T cells (Selvaraj and Stowe, 2017).

MSB (Stanford, CA, USA) described that in a model of post-stroke cognitive impairment, mice have normal cognition and hippocampal long-term potentiation 1 week after a cortical stroke adjacent to the hippocampus, while within 7 weeks, cognitive impairment and progressive loss of long-term potentiation begin (Doyle et al., 2015). In parallel, antibody-producing B-lymphocytes accumulate in the infarct

core. Antibody levels increase in both the core and the surrounding brain parenchyma but the specificity of these antibodies could not (yet) be revealed. However, ablating B-lymphocytes prevents delayed cognitive impairment. Dr. Buckwalter further presented that B-lymphocytes are involved in this process in humans, suggesting that B cells may be critical targets for the development of post-stroke immunotherapies.

FS (Bryan, TX, USA) showed that anti-inflammatory miRNA therapy improves long-term affective dysfunction after ischemic stroke (Panta et al., 2019). Intravenous injection of mir363-3p mimics reduced infarct volume in the acute phase of stroke, ameliorated sensory-motor impairment, and attenuated transient increases of IL-6 and TNF-α. Depressive behaviors, assessed over 30–100 days after stroke, were also attenuated in mir363-3p treated animals (Panta et al., 2019). This indicates that a neuroprotectant that has anti-inflammatory properties may also improve affective dysfunction after stroke.

Taken together, these studies highlight the complex role of inflammation in the chronic phase after stroke and that modulating inflammation may require targeting a specific subset of inflammatory cells and proteins.

Targeting the Interplay Between Stem Cells and Neuroinflammation in Stroke Regeneration

Sustained neuroinflammation is also required to eliminate degenerating tissue, supplying a restorative milieu for stem cell-mediated repair. However, immune responses are often dysregulated and lead to detrimental effects on regeneration. Recent work aims to elucidate the complex and interwoven processes of neuroinflammation and stem cell-mediated regeneration after a stroke that may form the basis for novel therapeutic approaches to modulate these processes and their interactions.

SUV (Cologne, Germany) reported that differentially polarized microglia differ in their effects on the fate of neural stem cells (NSC) *in vitro* and *in vivo*, with pro-inflammatory microglia promoting the generation of astrocytes, while anti-inflammatory microglia support neurogenesis. Regardless of their polarization, the secretome of activated microglia inhibits NSC proliferation, increases NSC migration, and accelerates NSC differentiation (Vay et al., 2018). These combined effects suggest that activated microglia induce NSC to exit the cell cycle, to migrate towards a putative lesion site, and to attempt cell replacement by differentiation. Besides, NSC promotes functional restoration after stroke not only by cell replacement but also by modulating surrounding cells and inflammatory processes.

ZK (Lund, Sweden) discussed the significance of monocyte-derived macrophages (MDM) in supporting regenerative processes after ischemic stroke. MDM are recruited to the ischemic lesion site exhibiting a high degree of functional plasticity, changing from a pro- to an anti-inflammatory phenotype during the first weeks after stroke. Blockage of MDM recruitment worsens functional and structural outcomes after stroke (Wattananit et al., 2016; Kronenberg et al., 2018). Dr. Kokaia's work suggests that immune cells affect the regenerative capacity of the brain, most likely by modulating stem-cell-derived neuronal plasticity in the subventricular zone and the adjacent striatum (Laterza et al., 2017).

KG (Berlin, Germany) emphasized the beneficial role of anti-inflammatory MDM activated in the early phase after stroke. However, not only stroke-invading MDM but also brain-resident microglia are activated, and both MDM and microglia often display a mixture of phenotypic markers ("intermediate states") during the first weeks after stroke (Kronenberg et al., 2018).

Overall, the cross-talk between inflammatory cells acting as key regulators and endogenous or grafted neural stem cells acting as key effectors is highly relevant during post-stroke regeneration. Thus, therapeutic strategies based on modulating these cell entities and their interactions could be exploited to facilitate functional recovery after stroke.

Extracellular Vesicles: Therapy and Imaging

Although there is growing evidence that long-term benefits are produced by stem cells, particularly in sudden onset diseases, these cells are often short-lived after transplantation (Kim et al., 2012; Jablonska et al., 2016). Stem cells release EVs including exosomes that mediate therapeutic effects (Xin et al., 2012, 2013a; Zhang et al., 2015) and in certain conditions, they can achieve the same efficacy obtained by the administration of the stem cells themselves (Doeppner et al., 2015).

TD (Göttingen, Germany) explained the positive effects of mesenchymal stem cell-derived EVs (Doeppner et al., 2015). Interestingly, similar effects have recently been described for EVs derived from neural progenitor cells (Zheng et al., 2021). This suggests that EV-derived modes of action could be a general mechanism related to beneficial stem and progenitor cell effects. Apart from this, Dr. Doeppner also reported innovative therapeutic approaches such as the application of remote ischemic post-conditioning (for review and current clinical application please see Ji et al., 2019), defined as a transient and subcritical period of peripheral organ ischemia following cerebral ischemia, to exert beneficial but transient effects on recovery. Interestingly, post-conditioning also facilitated intracerebral transplantation of neural progenitor cells resulting in persistent protection and improved functional recovery (Doeppner et al., 2017).

YX (Detroit, MI, USA) discussed that exosomes elicit potent cellular responses *in vitro* and *in vivo* by delivering their cargos, including lipids, proteins, RNAs (miRNAs and mRNAs), and other macromolecules, to recipient cells (Xin et al., 2013a; Zhang et al., 2019). In turn, microRNAs regulate numerous genes that mediate beneficial therapeutic effects (Zhang et al., 2019) and exosomes with select miRNAs can be designed to provide further improved therapeutic efficacy (Xin et al., 2013b, 2017).

MJ (Baltimore, MD, USA) explained strategies for EV labeling and imaging to assess direct routes of EV delivery that are potentially more beneficial and to monitor EV biodistribution in the body. Iron oxide-based labeling is comparably easy as it is sufficient to apply a standard labeling protocol to

stem cells, from which EVs are subsequently derived (Busato et al., 2017; Dabrowska et al., 2018). While the signal is strong, its specificity is quite low due to other sources of hypointensities in tissues related to pathology. However, this approach may be particularly compelling to monitor EV delivery in real-time as the signal of the label can be subtracted from the background image obtained before the procedure (Walczak et al., 2017). Further labeling techniques based on radioisotopes are very attractive to assess EV biodistribution even in clinical settings, while other modalities such as fluorescence or bioluminescence labeling are limited to preclinical studies (Choi and Lee, 2016).

Summing up, cell-free exosome-based approaches may replace stem cells and become a major driving force for therapeutic interventions with the aid of engineering and imaging.

Traumatic Brain Injury Can Lead to Cerebrovascular Disease

A provocative question discussed was whether traumatic brain injury can serve as a model to study neurovascular unit dysfunction in cerebrovascular disease as their relationship has been proposed in recent studies (Pop and Badaut, 2011; Sandsmark et al., 2019).

NP (Munich, Germany) showed that controlled cortical impact in adult mice induces progressive cognitive decline (Mao et al., 2020). While motor function recovered partially after TBI, depression-like behavior and the loss of memory function were progressive. Increasing tissue loss in the corpus callosum, hippocampus, and hydrocephalus formation was also observed over time. Hence, experimental TBI in mice replicates the long-term sequelae post-trauma including dementia and depression that are observed in humans. It needs to be determined whether these changes are triggered by concomitant vascular injury or other, so far unknown mechanisms.

JB (Bordeaux, France) discussed the alteration of the NVU months after mild pediatric TBI in which changes of water channel expression on astrocytic endfeet adjacent to blood vessels have been observed (Fukuda et al., 2013). These changes are related to diffusion tensor imaging modifications in different brain structures at 12 months post-injury after a single impact.

Linked with NVU remodeling, AO (Irvine, CA, USA) presented the importance of the activation of the Wnt-Beta-catenin pathway in cerebral blood vessels after TBI (Salehi et al., 2018). After acute vascular loss post-TBI, new immature vessels occurred at the injury site 7 days after the injury. This coincided with decreased levels of β-catenin protein in the injury site but dramatically increased β-catenin protein expression in vessels. β-catenin and Wnt expression were particularly increased in perilesional vessels and are thought to promote new vessel formation into the injury site.

Overall, most of the pre-clinical models of TBI from mild to severe severities reproduce the long-term clinical changes described in the literature in terms of neuroimaging. IKK (Boston, MA, USA) reviewed noninvasive neuroimaging techniques that can help to bridge clinical and preclinical studies.

In summary, the presented data impressively showed that assessing long-term outcomes after TBI in preclinical models may be a suitable approach for a better understanding of the molecular and cellular processes in cerebrovascular diseases.

Targeting Acute Pathomechanisms Following Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) is a devastating type of stroke with a high mortality rate, especially during the acute phase after the ictus. Therefore, current strategies focus on minimizing early brain injury to reduce SAH-induced mortality and disability (Lantigua et al., 2015).

NP (Munich, Germany) reported that SAH causes acute and long-lasting constrictions of pial arterioles (microvascular spasm): the CO_2-reactivity is lost within the first 3 h, followed by an impairment of neurovascular coupling within 24 h after SAH. Within 1 month, CO_2-reactivity reestablishes, while neurovascular coupling does not recover (Balbi et al., 2017, 2020). Loss of neurovascular coupling may result in further brain damage after SAH due to an uncoupling of blood flow and metabolism, e.g., during cortical spreading depolarizations or even during normal brain activity.

SAH also induces acute spreading depolarizations as shown by JPD (Berlin, Germany) both in animal models and in patients (Dreier et al., 2018). These lead to severe hypoperfusion in tissue at risk for progressive injury, which may directly initiate infarction (Lückl et al., 2018).

RK (Ann Arbor, MI, USA) demonstrated that SAH induces BBB disruption (Egashira et al., 2016) and white matter injury acutely after the ictus (Guo et al., 2017). Dr. Keep further discussed the importance of clot-derived factors and the significance of hemorrhage extension into the ventricular system leading to injury and hydrocephalus. In particular, epiplexus cell activation was associated with hydrocephalus development and may occur in response to thrombin production after SAH (Wan et al., 2019).

BAG (Newcastle, Newcastle upon Tyne, UK) presented the ongoing Treatment of Poor-grade SubArachnoid Hemorrhage Trial 2 (TOPSAT2; ISRCTN15960635) that investigates whether early treatment compared to conventional treatment after neurological recovery improves functional outcome after 12 months in poor-grade aneurysmal SAH patients.

In summary, these reports demonstrated several acute pathomechanisms after SAH that present promising therapeutic targets that need to be further assessed in clinical trials of SAH.

Targeting the Hematoma and the Search for Protective Strategies in Intracerebral Hemorrhage

Another hemorrhagic subtype of stroke is intracerebral hemorrhage (ICH), which remains a major cause of mortality and permanent disability (Poon et al., 2014; van Asch et al., 2010). Recent studies targeting both primary and secondary injury components (Keep et al., 2012) were discussed in two mini-symposia of the 10th ISN&N.

As targeting primary injury by surgical evacuation using craniotomy does not improve functional outcome in large

surgical trials of ICH (STICH I and II; Potts and Riina, 2014), recent efforts focused on Minimally Invasive Surgery with Thrombolysis in ICH Evacuation (MISTIE). MISTIE featured the administration of alteplase (initially 1.0 mg in ml followed by up to nine 3 ml flushes every 8 h) *via* a soft catheter directly into a residual hematoma that was primarily addressed by clot aspiration (Hanley et al., 2019). DFH (Baltimore, MD, USA) reported no overall efficacy of the MISTIE procedure in phase III clinical trial. However, a subgroup analysis on the surgical performance showed that a hematoma reduction below 15 ml increases the chances of having a good outcome by 10% for each additional ml of hematoma removed (Awad et al., 2019). Furthermore, KRD (Miami, FL, USA) demonstrated that a novel hemostatic agent, red blood cell-derived microparticles (RMPs), which display negatively charged phosphatidylserines to induce coagulation, limited hematoma growth in a collagenase-induced model of ICH in rats. According to the pharmacokinetic and safety profile of RMPs, this agent is applicable in the clinics (Jy et al., 2018; Rehni et al., 2019). Since a complete evacuation of the hematoma is unlikely to be achieved in every patient, additional strategies targeting clot-derived factors are needed for ICH therapy.

Addressing neuroinflammation as a secondary injury component, LHS (Yale, New Haven, CT, USA) described the properties of leukocytes in the peripheral blood and hematoma evacuates from the MISTIE III clinical trial using RNA sequencing and provided evidence for the importance of efferocytosis in reducing inflammation in human macrophages (Chang et al., 2018). Furthermore, macrophages and microglia undergo acute activation during the first week after ICH, with microglia producing inflammatory cytokines and chemokines, and a decreasing expression of microglia-specific genes (Taylor et al., 2017). Other immune cells such as neutrophils are another source of damage and secondary injury as they infiltrate the brain in response to sterile inflammation triggered by ischemic stroke or ICH. JA (Houston, TX, USA) presented that neutrophils are plastic regarding their phenotype and the cytokine IL-27 can alter their gene expression during maturation in the bone marrow (Zhao et al., 2017a). After ICH, IL-27-modified neutrophils can deliver to the hematoma site more beneficial haptoglobin and lactoferrin to neutralize the toxicity of hemoglobin and iron and to limit the brain exposure to pro-oxidative and pro-inflammatory mediators normally transported by the infiltrating neutrophils.

As hemolysis leads to the release of blood breakdown products that induce cell death, targeting cell death is another strategy for secondary intervention. MZ (Lübeck, Germany) demonstrated that primary cortical neurons in culture die by a mixture of ferroptotic and necroptotic cell death when exposed to blood breakdown products (Zille et al., 2017). In contrast, cell death mechanisms underlying brain endothelial cell death after hemorrhagic stroke remain poorly understood (Zille et al., 2019). JW (Baltimore, MD, USA) demonstrated the co-existence of ultrastructural characteristics of ferroptosis, autophagy, and necroptosis after experimental ICH *in vivo* (Li et al., 2018). The inhibition of ferroptosis using the small molecule ferrostatin-1 improved neurological function and conferred protection after ICH (Li et al., 2017). Moreover, SSK (White Plains, NY, USA) showed that the ferroptosis inhibitor N-acetylcysteine improved functional recovery after ICH in mice by inhibiting toxic lipid products (Karuppagounder et al., 2018).

Taken together, the presented studies put forward the idea that targeting the hematoma is an important strategy in ICH therapy and that there should be a combinatorial approach consisting of primary intervention (to evacuate the hematoma) together with a secondary intervention (immunomodulatory and neuroprotective; **Figure 1**).

Next-Generation Functional Testing in Experimental Brain Research

The reliable assessment of functional improvement after cerebrovascular injury and potential treatment remains challenging. The recent development of new assessment strategies in experimental brain research considers several conceptual and methodological aspects.

GASM (Lethbridge, AB, Canada) showed that compensation after brain injury represents the primary process of functional improvement, i.e., the development of alternate behavioral strategies rather than the recovery of the original functions (Metz et al., 2005; Fouad et al., 2013). Compensatory behaviors are clearly recognizable and acquired through repetitive training in a task-specific manner (Girgis et al., 2007; Kirkland et al., 2012).

KF (Edmonton, AB, Canada) discussed recent advances that have exploited automated test apparatus solutions to enhance the efficacy of animal training and assessment (Fenrich et al., 2015; Bova et al., 2019) along with machine learning algorithms to identify discrete aspects of compensatory movement patterns (Ryait et al., 2019).

EH (Montreal, QC, Canada) showed that exercise-based rehabilitation and pharmacotherapy influence white matter inflammation and the degree of cognitive and cerebrovascular improvement, including neurovascular coupling, in a mouse model of vascular cognitive impairment and dementia (Trigiani and Hamel, 2017; Trigiani et al., 2019).

These observations open new avenues for the discovery of biomarkers that aid in the stratification of patients to personalized rehabilitation programs. The overarching goal of combined multi-level functional and molecular analysis is the improved translation of experimental innovations to clinical practice.

Cutting-Edge Brain Imaging in Disease and Regeneration

Magnetic resonance imaging (MRI) has been decisive in understanding cerebrovascular disease over the past decades. Besides MRI, functional ultrasound has recently evolved as an analog to functional MRI. Cutting-edge imaging-based findings were reported at the 10th ISN&N.

AM (Los Angeles, CA, USA) reported on brain imaging of vascular dysfunction to understand BBB breakdown and how this may contribute to cerebrovascular diseases, with a particular focus on dementia. Measuring BBB alterations *in vivo* can be challenging. Examples of how brain imaging (i.e., dynamic contrast-enhanced MRI) may contribute to a better

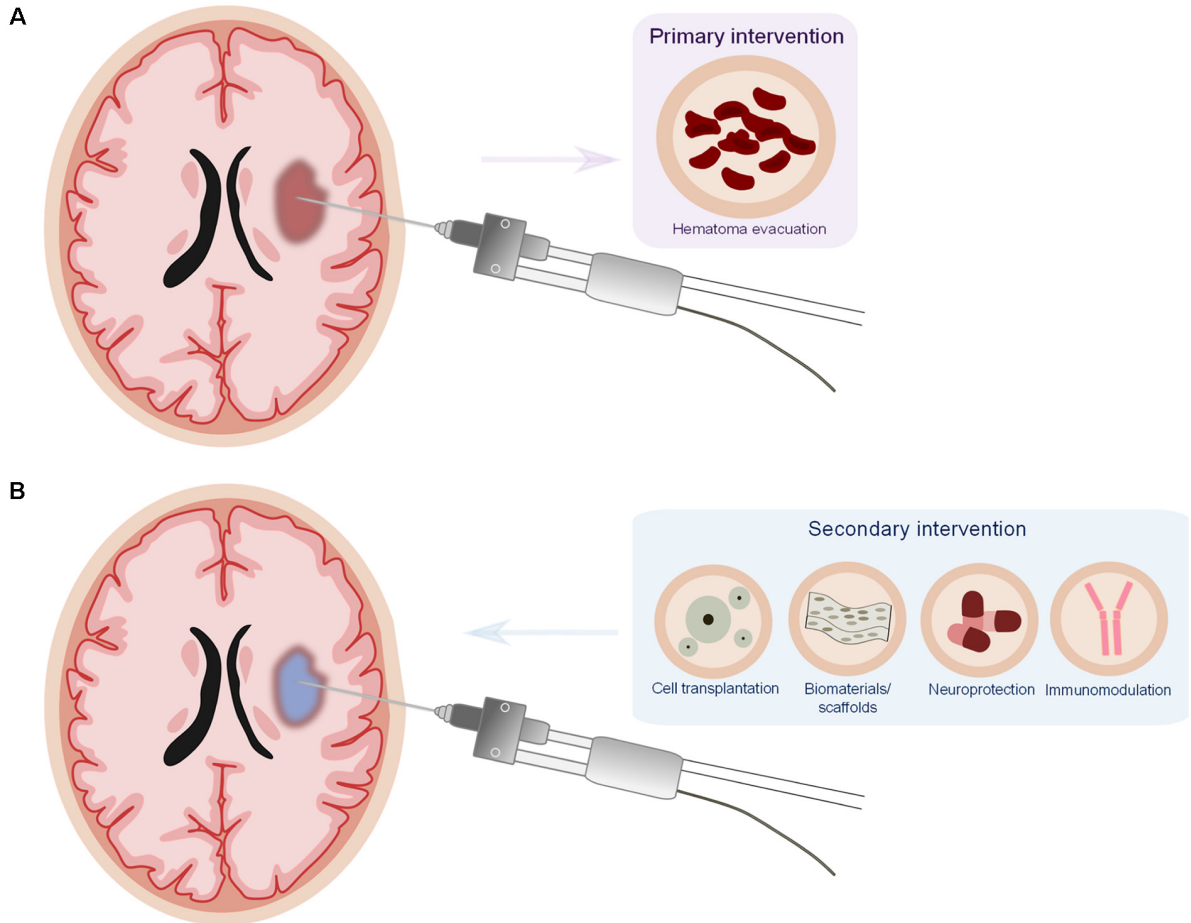

FIGURE 1 | Proposed model for a combinatorial therapy in intracerebral hemorrhage (ICH). **(A)** Minimally invasive surgery for the evacuation of the hematoma (primary intervention). **(B)** Minimally invasive surgery offers the particular opportunity to deliver potential therapeutics (cell transplantation, biomaterials/scaffolds, neuroprotective, and/or immunomodulatory drugs) as secondary intervention directly into the lesion site, reducing drug delivery issues and potential systemic side effects of the drugs.

diagnosis and prognosis of BBB alterations and how targeting the BBB can influence the course of neurological disorders have been discussed. Finally, an outlook on future approaches to better understand the cellular and molecular events underlying mechanisms between BBB breakdown and neurodegeneration was given (Montagne et al., 2017).

DV (Caen Cedex, France) focused on molecular MRI of neuroinflammation, including targeting vascular cell adhesion molecule 1 and P-selectin. The perspectives for the clinical application of this technology were discussed and he showed that molecular MRI of adhesion molecules, using micro-sized particles of iron oxide complexed with specific antibodies of adhesion molecules, may be useful for the diagnosis and prognosis of brain disorders (Gauberti et al., 2018).

RMD (Utrecht, The Netherlands) presented recent data that inform on correspondences between quantitative functional and structural connectivity measures in the mammalian brain from resting-state functional MRI, diffusion-weighted MRI, and neuronal tract tracing. Overall, despite methodological differences between studies, the current literature supports the hypothesis that structural connectivity provides the hardware from which functional connectivity emerges (Straathof et al., 2019). However, strong structural connections are not necessarily strong functional connections.

MT (Paris, France) spoke on recent progress in ultrafast ultrasound imaging. Neurologists and neuroradiologists warrant an imaging technique that can be performed at the bedside (as transcranial Doppler ultrasound), is repeatable (as arterial spin labeling MRI), provides quantitative measurement (as positron emission tomography), and measures multiple perfusion parameters (as perfusion computed tomography). The recent development of ultrafast ultrasound sequences and advances in high-frequency probes technologies combines all these criteria in a unique system. Specifically, it allows detecting subtle cerebral blood volume changes due to neurovascular coupling, which has led to the development of the ultrasound analog to functional MRI, functional ultrasound providing a high spatiotemporal resolution of cerebral blood flow and brain functioning in animals and humans (Rabut et al., 2019).

The presented imaging tools promise to further enhance our understanding of cerebrovascular disease in the future that will form the basis for the development of novel therapeutic strategies. Moreover, these new imaging techniques might develop into invaluable diagnostic tools augmenting current diagnostic procedures and leading to better clinical treatment by identifying patients with specific dysfunctions that would benefit from targeted interventions. They may also provide opportunities to use imaging biomarkers of vascular dysfunction in patients with TBI or cerebral small vessel disease.

Endovascular Approaches to Image and Treat Stroke: Beyond Thrombectomy

Modern mechanical thrombectomy techniques are highly efficient and have revolutionized the treatment of acute stroke patients with large vessel occlusion. However, the restoration of blood flow is insufficient to completely reverse the ischemic insult. The next phase of stroke intervention should therefore focus on reparative mechanisms that can be delivered with image-guidance (Chu et al., 2018) in the same setting after thrombectomy to further improve patient outcomes, as outlined by MP (Baltimore, MD, USA).

PW (Baltimore, MD, USA) stressed that the brain remains to be a challenging target for drug delivery with systemic injection frequently resulting in less than 1% of injected dose reaching the brain parenchyma. Due to compromised perfusion, drug accumulation in the stroke lesion is related to even higher uncertainty and unpredictability. Dr. Walczak presented approaches for spatially selective, intra-arterial drug and cell delivery guided with interventional MRI (**Figure 2**; **Supplementary Video 1**). High precision and reproducibility are achieved by visualization of trans-catheter pre-injections of a contrast agent using dynamic MRI. Imaging the trans-catheter perfusion territory facilitates optimization of that territory by modulating the infusion rate or the position of the catheter tip. Once the targeted volume is optimized, the drug (or any other therapeutic agent) is infused. This procedure improves the precision and efficiency of targeting (Walczak et al., 2017). In case BBB opening is desired or required, it can be implemented in the procedure by an additional step such as infusion of hyperosmotic mannitol (Chu et al., 2018).

As a new tomographic imaging method, PL (Hamburg, Germany) reported on magnetic particle imaging, which is a useful tool for the rapid assessment of the cerebral vasculature and perfusion in stroke due to its temporal resolution. Magnetic particle imaging provides great innovation potential to improve stroke imaging and treatment in the future (Ludewig et al., 2017).

DG (Olsztyn, Poland) presented a recently developed endovascular method for inducing ischemic stroke in swine (Golubczyk et al., 2020). To overcome the long-standing drawback due to the vascular rete preventing the navigation of endovascular catheters into the brain, her approach is to inject thrombin solution *via* the pharyngeal ascendant artery to occlude cerebral vessels. The entire procedure including the injection of a clot-forming solution, the blockage of vasculature and the evolution of stroke was visualized with MRI. This new model offers several important advantages including a minimally invasive approach in a species with large, gyrencephalic brain and overall high clinical relevance (Herrmann et al., 2019).

A potential treatment option, as outlined above, is targeting neuroinflammation. MG (Hamburg, Germany) reported on the influence of the post-ischemic inflammatory reaction on the fate of the ischemic brain (Gülke et al., 2018). He presented novel data on conserved proinflammatory pathways, which are crucial for the initiation of the damaging inflammatory reaction in the ischemic brain. Finally, he correlated the available experimental data with human clinical studies.

Taken together, the described tools and strategies are particularly relevant at the time of growing use of endovascular mechanical thrombectomy as the placement of intra-arterial catheters introduces the opportunity to implement intra-arterial adjuvant therapies.

Recent Advances in Neurorehabilitation Strategies in Stroke

As a result of improved acute stroke care, more and more patients survive, but many are left with permanent disabilities, making stroke a major cause of adult disability. Although neurorehabilitation is the only established stroke therapy being effective beyond acute stages of the disease, combinatorial approaches may strengthen the beneficial effects of neurorehabilitation strategies.

MC (Pisa, Italy) described rehabilitation of motor function in a mouse model of focal cortical stroke induced by photothrombosis. A robotic device (M-platform) was used for the daily training of the affected forelimb in combination with pharmacological contralesional silencing to dampen excessive transcallosal inhibition. Mice receiving this combined therapy displayed motor improvements that persisted beyond the treatment period and these were even generalized to non-trained tasks (Spalletti et al., 2017).

JJ (Kuopio, Finland) presented on combined cell therapy and rehabilitative training in experimental stroke. The transplantation of subventricular zone or human embryonic stem cells into the perilesional cortex was characterized by low cell survival (Hicks et al., 2009). Nonetheless, some improvement was observed in behavioral outcomes both when cells were transplanted alone or together with housing the experimental animals in an enriched environment i.e., mimicking rehabilitation. Likewise, the intravenous delivery of human adipose tissue-derived mesenchymal stem cells and exposure to the enriched environment improved forelimb function in the cylinder test and sticky label test (Mu et al., 2019).

CJS (Oxford, UK) discussed the role of non-invasive brain stimulation in recovery, which is a promising tool as it is relatively cheap, very well tolerated, and easy to use. However, the functional improvements demonstrated are highly variable across people. Various MRI approaches have been applied to predict the response to transcranial direct current stimulation in the motor system, indicating that a reduction of inhibition

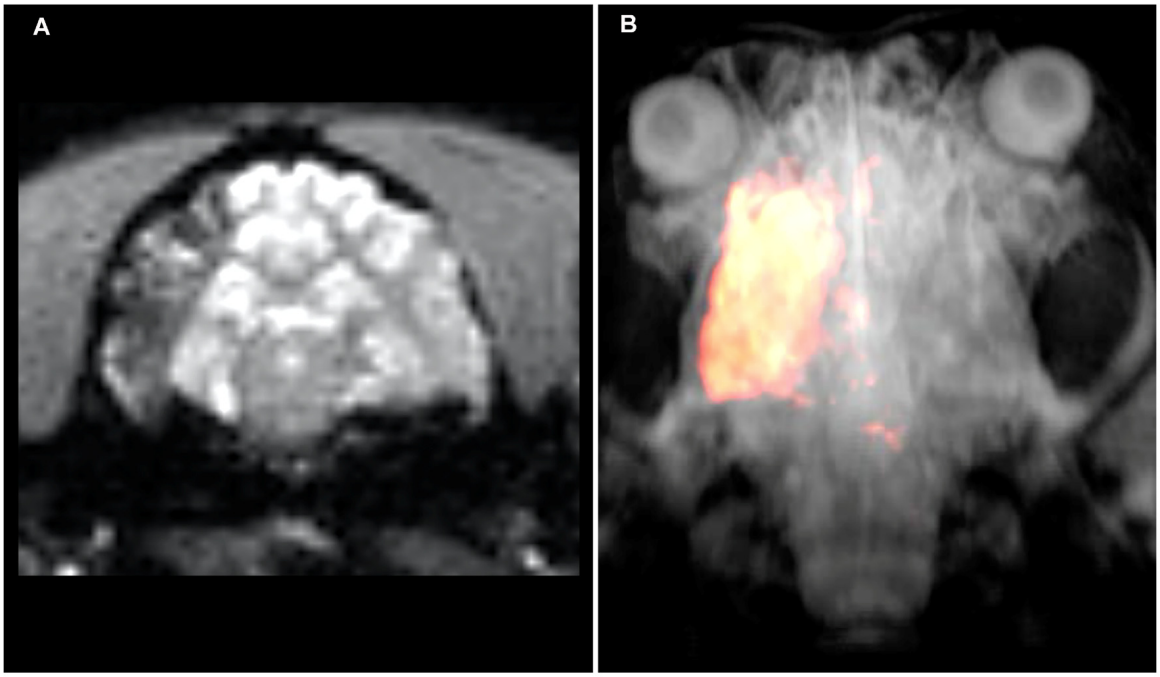

FIGURE 2 | Intraarterial magnetic resonance imaging (MRI)-guided injection of mesenchymal stem cells into the canine brain. **(A)** Raw T2*w MRI after intraarterial injection of superparamagnetic iron oxide particle-labeled mesenchymal stem cells showing cell accumulation throughout the ipsilateral middle cerebral artery territory. **(B)** Segmentation of hypo-intense pixels and 3D visualization of stem cell biodistribution. Please see the **Supplementary Video 1** for a dynamic visualization of stem cell injection.

in the primary motor cortex (M1) is a central mechanism for motor plasticity in humans, both in health and in recovery after stroke (Stagg et al., 2011; Blicher et al., 2015; Kolasinski et al., 2019). Indeed, GABA levels in the ipsilateral M1 cortex can predict the response to transcranial direct current stimulation (O'Shea et al., 2014).

FCH (Geneva, Switzerland) summarized the reasons for heterogeneous results of neurorehabilitative interventions, such as non-invasive brain stimulation, and discussed a paradigm shift from imprecision of "one treatment suits all" strategies towards personalized medicine approaches delivered in a manner tailored to the demands of the individual patient (Raffin and Hummel, 2018; Coscia et al., 2019). Structural MRI imaging and connectome analyses can be used to determine the functional outcome of patients to stratify patients towards specific brain stimulation protocols (Koch and Hummel, 2017; Schulz et al., 2017).

Taken together, these studies support the use of rehabilitation and neuromodulatory approaches for promoting post-stroke recovery. Although combination therapy and early delivery may be more effective, further studies with greater statistical power to cope with these complex experimental designs will be needed to determine the optimal treatment protocol, the effect of co-morbidities, and to explore underlying therapeutic mechanisms (Boltze et al., 2017). Moreover, novel imaging approaches as discussed in the section "Cutting-Edge Brain Imaging in Disease and Regeneration" (above) might be helpful to identify patients that may benefit from brain stimulation interventions.

OUTLOOK AND CONCLUSIONS

Based on the setbacks seen in the past decades of cerebrovascular disease research, the field has clearly consolidated and recognized the reasons for previous translational failure as exemplified in the field of cell therapies (Cui et al., 2019). Recent guidelines for translational research in that field stress, for instance, the importance of considering comorbidities, the use of highly predictive animal models and experimental settings as well as a closer interaction between preclinical and clinical research activities for more integrated study designs being able to inform each other (Boltze et al., 2019). Moreover, with the refinement of our research tools, some of which have been discussed herein, and increasing study quality (Ramirez et al., 2017), it seems that the translational roadblock is slowly overcome as new therapeutic concepts start to arise (Liebeskind et al., 2018). For instance, new combinations of recanalization and neuroprotecive approaches are believed to emerge for stroke (Savitz et al., 2019) and potentially ICH.

Encouraging progress is also witnessed in related fields such as vascular dementia or even Alzheimer's disease. For instance, significant progress has been made in understanding the vascular contribution to various form of dementia (Iadecola and Gottesman, 2018; Royea et al., 2020). While the role of

the frequent but treatable risk factors of dementia such as hypertension and hypercholesterinemia is better understood (Kaiser et al., 2014; Trigiani et al., 2019), new animal models of vascular cognitive impairment may facilitate translational research programs (Hainsworth et al., 2017). In parallel, new targets for pharmacological interventions have been identified (Loera-Valencia et al., 2019) and are expected to lead to future clinical trials (Howard et al., 2019). Although there will likely be setbacks on the way forward and we shall avoid premature enthusiasm as seen in the past, the "therapeutic nihilism" still observed in translational cerebrovascular research just 5 years ago has turned into new optimism.

The 11th ISN&N will continue to monitor the progress in the fields of basic translational and clinical cerebrovascular disease research. Moreover, it will extend its scope by partnering with the 18th International Conference on Brain Edema and Cellular Injury (BEM) for a single combined meeting in October 2022 in Berlin, Germany.

AUTHOR CONTRIBUTIONS

All authors listed have made a substantial, direct and intellectual contribution to the work, and approved it for publication.

FUNDING

We wish to express our gratitude to all institutions and people who supported the 10th ISN&N. First and foremost, we want to thank all meeting participants for their outstanding academic contributions. Moreover, we are particularly grateful to the Deutsche Forschungsgemeinschaft (grant number: BO 3518/2-1) and the International Society of Cerebral Blood Flow and Metabolism, both of which supported the meeting with generous grants. We further acknowledge all industrial sponsors and exhibitors for their academic and invaluable financial support.

ACKNOWLEDGMENTS

The Eventlab congress organizing team deserves special thanks for tireless and professional support that was not only crucial for carefully preparing the meeting, but also for running it successfully and smoothly.

Extracellular vesicles (EVs) are small, membrane-bound nanoparticles released from most, if not all cells, and can carry functionally active cargo (proteins, nucleic acids) which can be taken up by neighboring cells and mediate physiologically relevant effects. In this capacity, EVs are being regarded as novel cell-to-cell communicators, which may play important roles in the progression of neurodegenerative diseases, like Alzheimer's disease (AD). Aside from the canonical physical hallmarks of this disease [amyloid β (Aβ) plaques, neurofibrillary tangles, and widespread cell death], AD is characterized by chronic neuroinflammation and mitochondrial dysfunction. In the current study, we sought to better understand the role of tumor necrosis factor-alpha (TNF-α), known to be involved in inflammation, in mediating alterations in mitochondrial function and EV secretion. Using an immortalized hippocampal cell line, we observed significant reductions in several parameters of mitochondrial oxygen consumption after a 24-h exposure period to TNF-α. In addition, after TNF-α exposure we also observed significant upregulation of two microRNAs (miRNAs; miR-34a and miR-146a) associated with mitochondrial dysfunction in secreted EVs. Despite this, when naïve cells are exposed to EVs isolated from TNF-α treated cells, mitochondrial respiration, proton leak, and reactive oxygen species (ROS) production are all significantly increased. Collectively these data indicate that a potent proinflammatory cytokine, TNF-α, induces significant mitochondrial dysfunction in a neuronal cell type, in part *via* the secretion of EVs, which significantly alter mitochondrial activity in recipient cells.

INTRODUCTION

Alzheimer's disease (AD) is a chronic neurodegenerative disease characterized by amyloid β (Aβ) plaques, neurofibrillary tangles, neuroinflammation, and mitochondrial dysfunction (Wyss-Coray and Rogers, 2012). Extracellular Aβ plaques activate microglia, prompting secretion of immunomodulatory molecules, including tumor necrosis factor-alpha (TNF-α; Hanisch, 2002). Elevated levels of this cytokine have been detected in the plasma (Fillit et al., 1991; Zuliani et al., 2007), cerebrospinal fluid (CSF; Tarkowski et al., 2003), and brains (Sharma et al., 2012) of AD patients when compared to healthy, age matched controls (AMCs). Further, several studies have implicated TNF-α as a key player in the formation of Aβ plaques (Blasko et al., 2000; Liao et al., 2004; Yamamoto et al., 2007), suggesting that this cytokine may participate in a vicious cycle of AD progression. TNF-α activates the transcription factor NF-κB (Schütze et al., 1995), which induces the transcription of many genes, including microRNAs (miRNAs); these small, non-coding RNAs function as gene repressors by base-pairing with complementary mRNAs and inhibiting protein translation, or accelerating the de-adenylation of the poly-A tail (Krek et al., 2005; Huntzinger and Izaurralde, 2011). Changes in expression of various miRNAs have been associated with inflammation and may influence AD progression.

Previous work from our laboratory assessed brain region-specific changes in miRNA expression, and observed significant upregulation of miR-34a and miR-146a in AD patients' temporal cortices, when compared to AMCs (Sarkar et al., 2016). Promotor analysis revealed that various components of the NF-κB family bind to the promotor region of both miR-34a (Sarkar et al., 2016) and miR-146a (Taganov et al., 2006), suggesting that the activation of pro-inflammatory pathways could lead to increased transcription of these miRNAs. Interestingly, these miRNAs target several mRNAs, which encode for proteins of the mitochondrial electron transport chain (ETC; Dasgupta et al., 2015; Sarkar et al., 2016). Indeed, overexpression of miR-146a in primary microglial cells (Jun et al., unpublished observation) or miR-34a in primary neurons (Sarkar et al., 2016) significantly reduced mitochondrial function, and repressed expression of all of the associated mitochondrial proteins that were assessed (Sarkar et al., 2016). Inflammation-induced upregulation of NF-κB may lead to aberrant expression of miR-34a and -146a and lead to translational repression of ETC proteins, thus contributing to the widespread reductions in glucose metabolism and dysregulated mitochondrial function observed in AD brains.

Intercellular communication allows for the transfer of information from one cell to another. The secretion of extracellular vesicles (EVs) affords the opportunity for cells to send important signaling molecules out into the extracellular environment to convey vital messages to neighboring cells (Harding et al., 1983; Pan et al., 1985; Valadi et al., 2007; Tkach and Théry, 2016). As EVs are encapsulated by a lipid bilayer, their contents (including proteins, DNA, and RNA) are protected from degrading enzymes, allowing for delivery of functional cargo. During periods of neuroinflammation, concentrations of circulating EVs have been shown to be significantly upregulated, and within the context of AD, EVs have been shown to confer noxious molecules, including Aβ (Rajendran et al., 2006; Sardar Sinha et al., 2018), to recipient cells and thereby participate in the spreading of AD pathology and neuroinflammation.

Inasmuch as neuroinflammation clearly occurs in affected individuals, and likely occurs years prior to onset of clinical symptoms, it is difficult to model *in vitro*, the effects of long-term inflammation. In the current study, we sought to characterize the role of acute TNF-α exposure on phenotypes seen in AD, including mitochondrial dysfunction, increased miRNA expression (e.g., miR-34a and miR-146a; Sarkar et al., 2016), and altered EV secretion in an immortalized hippocampal cell line (HT-22). Here we demonstrate that direct exposure to TNF-α for 24-h significantly reduces mitochondrial oxygen consumption, induces cellular death, and induces differential expression of miR-34a and miR-146a both within cells, and in secreted EVs. We also assessed the functional outcomes of exposing TNF-α naïve cells to TNF-α-induced EVs and found significant increases in mitochondrial oxygen consumption, proton leak, and reactive oxygen species (ROS) production.

MATERIALS AND METHODS

Cell Culture

The HT-22 immortalized mouse hippocampal cells were obtained from the Salk Institute for Biological Research (La Jolla, CA, USA). HT-22 cells were cultured in Hyclone Dulbecco's modified Eagle's medium (DMEM)/high glucose (Fisher Scientific, Waltham, MA, USA) with 10% fetal bovine serum (FBS; Atlanta Biologicals, Flowery Branch, GA, USA) and 1% penicillin/streptomycin (Fisher Scientific). When cells were at least 80% confluent, they were trypsinized and spun down at 325.5× *g* for 3 min. Cells were counted with a Nexcelom Bioscience Cellometer AutoT4 (Lawrence, MA, USA). Cell passages 5–18 were used for all experiments.

Cytokine Reconstitution and Exposure

Recombinant mouse TNF-α was purchased from R&D Systems (Minneapolis, MN, USA) and reconstituted at 100 μg/ml in phosphate-buffered saline (PBS) containing 0.1% bovine serum albumin. Dilutions were made in Hyclone DMEM/high glucose with 10% exosome-depleted FBS (Fisher Scientific), and 1% penicillin/streptomycin to obtain concentrations of 0.1, 1, and 10 ng/ml. The 24-h time point for TNF-α exposure was chosen as preliminary data suggested that shorter exposure period did not result in mitochondrial dysfunction (data not shown). Longer exposure periods were not tested due to the potential complication of TNF-α-induced neurotoxicity on cell number, which could affect readouts of all of the assessed parameters in this study.

EV Isolation From Cell Culture Media

Conditioned media was collected after a 24-h exposure to TNF-α and filtered through a Millex-AA Syringe Filter Unit, 0.80 μm (Millipore Sigma, Burlington, MA, USA) to remove cellular debris. EV isolation was performed as per the manufacturer's instructions using either the ExoRNeasy Serum Plasma Maxi Kit

(Qiagen, Germantown, MD, USA) utilized for RNA purification from EVs, or the ExoEasy Maxi Kit (Qiagen) for all other EV applications.

Briefly, 1 volume of filtered media was mixed with 1 volume of buffer XBP and then placed on a spin column and centrifuged at 500× *g* for 1 min. The flow-through was discarded and the column was washed with 10 ml buffer XWP and centrifuged at >3,000× *g* for 5 min. The column was then transferred to a new collection tube and the EVs were eluted with 700 μl QIAzol for downstream RNA purification, or 400 μl buffer XE for all other EV applications.

Particle Size Distributions and Concentrations

To determine if changes in EV concentrations after exposure to TNF-α could account for alterations in mitochondrial function, EVs were isolated from HT-22 cell conditioned media using the ExoEasy Maxi Kit (as described above) and profiled with the NanoSight NS300 (Malvern, Westborough MA, USA). In the final isolation step using the ExoEasy Maxi Kit, EVs were eluted from the spin column membrane in 400 μl XE Buffer. Suspended EVs were diluted 1:200 in sterile filtered PBS for injection into the NanoSignt NS300 unit. Capture and analysis settings were manually set according to the manufacturer's instructions. Particles were visualized using laser light scattering to quantify nanoparticles (10–1,000 nm) moving under Brownian motion as they pass through the flow chamber. The Nanoparticle Tracking Analysis (NTA) software generates particle size distributions and concentrations based on an analysis of both Brownian motion and light scattering observed from tracked particles.

EV Marker Dot Blot

The presence of several EV markers was assessed to ensure that isolated particles from control or TNF-α exposure groups were indeed EVs. Protein concentration was measured using a microBCA kit (Fisher). BSA standards were prepared in the same solution EVs were eluted in (XE Buffer). EVs were diluted in 2% sodium dodecyl sulfide (SDS) at a ratio of 1:10 to a final volume of 150 μl, and transferred to a 96 well clear bottom assay plate. The standard curve was prepared using 150 μl of each, in duplicate. Working reagent was prepared in a 25:24:1 ratio of reagents A, B, and C, respectfully. One-hundred and fifty microliter working reagent was added to each of the standards and diluted EV samples, and incubated at room temperature for 2 h on a shaker. The plate was read using a BioTek Synergy H1 Hybrid reader at 562 nm absorbance.

The Exo-Check Exosome Antibody Array (System Biosciences) was used to detect the presence of several EV markers as per the manufacturer's instructions. Briefly, from either control or TNF-α induced EVs, 200 μg protein was incubated with 600 μl Exosome Lysis buffer and vortexed. Next, the lysate mixture was combined with 9.4 mL Exosome Array Binding buffer and was then added to a pre-wet antibody array membrane and incubated overnight at 4°C on a shaker. The following day the membrane was washed and 10 mL Detection buffer was added to the membrane and incubated for 2 h on a shaker. Next, the membrane was washed 3× and 2 mL SuperSignal West Femto Chemi-luminescent Substrate (Fisher) developer solution was added and the membrane was imaged.

Mitochondrial Functional Assessment

HT-22 cells were seeded at 5 k per well in an XF^{e}96 cell culture microplate (Agilent, Santa Clara, CA, USA) for 24 h. Media was gently aspirated from the cells and replaced with 100 μl Hyclone DMEM/high glucose, supplemented with 10% exosome-depleted FBS and 1% penicillin/streptomycin, the various concentrations of TNF-α, or isolated TNF-α-induced EVs. For EV exposure, EVs were isolated from the media of HT-22 cells exposed to varying concentrations of TNF-α (0, 0.1, 1, and 10 ng/ml) for 24 h. As described above, EVs were isolated from 20 ml media of cytokine-exposed HT-22 cells and eluted from spin columns in 400 μl buffer XE. Assuming a high yield of recovery from a starting volume of 20 ml conditioned cell culture media, EVs eluted in 400 μl buffer XE would be concentrated 50×. To mimic *in vitro* EV concentrations from each cytokine exposure condition, EVs were diluted 50× in DMEM/high glucose, supplemented with 10% exosome-depleted FBS and 1% penicillin/streptomycin (i.e., 2 μl EVs suspended in buffer XE were diluted into 98 μl media per well). Various parameters of mitochondrial function were assessed using a Mito Stress kit, with the XF^{e}96 Analyzer. Using Wave 2.4.0 Desktop software, all mitochondrial assessments were calculated with the Agilent Seahorse XF Cell Mito Stress Test Report Generator. Non-mitochondrial oxygen consumption rate (OCR) was calculated as the minimum rate measurement after rotenone/antimycin A injection. Basal respiration was calculated by subtracting non-mitochondrial OCR from the last rate measurement before oligomycin injection. Maximal respiration was calculated by subtracting non-mitochondrial OCR from the maximum rate measurement after trifluorocarbonylcyanide phenylhydrazone (FCCP) injection. Proton leak was calculated by subtracting non-mitochondrial OCR from the minimum rate measurement after Oligomycin injection. ATP production was calculated by subtracting the minimum rate measurement after Oligomycin injection from the last rate measurement before Oligomycin injection. Lastly, spare respiratory capacity was calculating by subtracting basal respiration from maximal respiration. All measurements are displayed percent changes from control. All wells with a basal respiratory rate below 40 pmol/min were excluded from analysis.

While glycolysis was not directly measured, data on the extracellular acidification rate (ECAR) is an additional measurement collected while completing the Mito Stress test. From these measurements, basal levels of glycolytic activity can be determined. To determine basal glycolysis, the third measurement, prior to the injection of oligomycin, was used. For cells treated with TNF-α, the average ECAR reading was calculated, and was used to calculate percent of control for each of the TNF-α treatment groups (0, 0.1, 1, and 10 ng/ml). For cells treated with EVs derived from TNF-α exposed cells, the cells treated with the XE buffer served as the control, and percent of control was calculated in the same way in each of the treatment groups (0, 0.1, 1, and 10 ng/ml).

Lactate Dehydrogenase Assay

Cell death after cytokine or EV exposure was assessed using the Pierce™ lactate dehydrogenase (LDH) Cytotoxicity Assay (Fisher Scientific) kit. Reaction substrates were prepared as per the manufacturer's instructions. LDH assay was performed with the media from the XF^{e}96 cell culture microplate. Forty-five minutes prior to the end of the 24-h exposure period, 10 μl 10× lysis buffer was added to one control well, and the plate was placed back in the incubator. At the conclusion of the exposure period, 50 μl of media was carefully removed from each well and transferred to a new 96 well clear bottom assay plate. The well exposed to 10× lysis buffer was excluded from the mitochondrial functional assessment. Next, 50 μl of the LDH reaction mixture was added to each well, and the plate was incubated for 30 min at room temperature, protected from light. The reaction was stopped by adding 50 μl of LDH stop solution to each sample. The plate was read using the BioTek Synergy H1 Hybrid reader (BioTek, Winooski, VT, USA) at absorbance of 490 nm and 680 nm. Cell death was calculated as a percentage of total death, relative to maximal cell death induced by treatment with the 10× lysis buffer.

Intracellular and EV miRNA Analysis

Cells were seeded at 250 k per 10 cm cell culture dish and left to reach ∼80% confluency over the course of 48 h. Media was gently aspirated from cells, and replaced by 10 ml of Hyclone DMEM/high glucose, supplemented with 10% exosome-depleted FBS and 1% penicillin/streptomycin, or the various concentrations of TNF-α. After a 24-h exposure period the media was collected for EV isolation, and cell lysates were collected using a Cell Lifter (Corning, Corning, NY, USA), washed with PBS, and pelleted by centrifugation at 325.5× *g* for 3 min, followed by the addition of 700 μl QIAzol Lysis Reagent for RNA purification (Qiagen).

RNA was purified from EVs eluted in 700 μl QIAzol by using the exoRNeasy Serum Plasma Maxi Kit (Qiagen). For all EV samples, 3.5 μl miRNeasy Serum/Plasma Spike-In Control (*C. elegans* miR-39; at a concentration of 1.6 × 10^8 copies/μl) was added to each sample, followed by the addition of 90 μl chloroform and a 3 min incubation. Next the samples were centrifuged for 15 min at 12,000× *g* at 4°C. The upper aqueous phase (300 μl) was transferred to a new collection tube and mixed with 600 μl 100% ethanol. The solution was then placed on a RNeasy MinElute spin column and centrifuged at 12,000× *g* for 15 s. The flow through was discarded and 700 μl buffer RWT was added to the spin column and centrifuged at 12,000× *g* for 15 s. Two washes of 500 μl buffer RPE were then performed, the first lasting 15 s and the second lasting 2 min. The RNeasy MinElute spin column was then placed in a new collection tube and spun at 12,000× *g* for 5 min to dry the column membrane. Lastly, the column was placed in another collection tube and 28 μl RNase-free water was added to the center of the membrane and incubated for 1 min, and then centrifuged at 12,000× *g* for 1 min ending with the purified RNA eluted in the collection tube. Cellular RNA was purified using the miRNeasy Mini Kit (Qiagen) as per the manufacturer's instructions, similar to the purification process for EVs, as described above.

RNA concentrations for each sample were measured using Nano drop 2,000 spectrophotometer (Thermo Scientific). For cDNA synthesis, 0.75 μg total RNA containing miRNAs was reverse transcribed using the miScript II RT kit (Qiagen). A 10 μl total volume reaction mix was made using 2 μl 5× miScript HiSpec Buffer, 1 μl 10× miScript Nucleics Mix, 1 μl miScript Reverse Transcriptase Mix, and 6 μl Template RNA/nuclease-free water. Prior to use for quantitative real-time PCR (qRT-PCR), cDNA was diluted in nuclease-free water, at a ratio of 1:10.

Previous work from our laboratory indicates that of a panel of miRNAs assessed, only miR-34a and miR-146a showed disease-stage related increases in expression in both human AD and triple transgenic AD mouse (3xTgAD) brains. Therefore, expression of miR-34a and miR-146a were profiled for both EV and intracellular levels using target specific miScript primer assays and the miScript SYBR® Green PCR kit (Qiagen; 5 μl SYBR® Green; 1 μl Universal Primer; 1 μl Target Primer; 3 μl diluted cDNA). qRT-PCR reactions were performed in triplicate for each sample, using the CFX384 Touch™ RT PCR Detection System (Bio-Rad, Hercules, CA, USA) for 45 cycles as follows: 15 s at 94°C, 30 s at 55°C, 30 s at 70°C. Negative control reactions were included as wells containing only master mix and nuclease-free water (no template cDNA). All miRNA specific primers were miScript Primer Assays (Qiagen); Hs_RNU6-2_11 (MS00033740), Ce_miR-39_1 (219610), Hs_miR-34a (MS00003318), and Hs_miR-146a (MS00003535). The expression levels of target genes in EVs were standardized against those of the spike-in control, *C. elegans* miR-39 gene, detected in identical cDNA samples, while the expression levels of target genes in cell lysates was standardized against RNU6. Quantification of PCR amplified miRNA specific cDNA was done by comparative cycle threshold CT method ($2^{-\Delta\Delta CT}$).

EV Uptake *via* Naïve Cells

To determine if naïve HT-22 cells have the capacity to take up cytokine-induced EVs, cells were incubated with EVs labeled with Exo-Red Exosome RNA Fluorescent Label (System Biosciences, Palo Alto, CA, USA). EVs isolated from all TNF-α exposure groups were labeled as per the manufacturer's protocol. Briefly, ∼100 μg protein of isolated EVs were incubated with 50 μl Exo-Red for 10 min at 37°C. ExoQuick-TC reagent (100 μl) was then added to the labeled EV suspension and mixed by gentle inversion. This solution was incubated on ice for 30 min, followed by centrifugation at 14,000 rpm for 3 min. The supernatant was removed and the EV pellet was resuspended in 500 μl PBS. Next, 100 μl labeled EVs were added to naïve HT-22 cells in a 6-well dish (∼80% confluent), and imaged with the Nikon Swept Field Confocal microscope (Nikon, Melville, NY, USA) approximately 10 min after addition to naïve cells.

Mitochondrial Membrane Potential Assay

Mitochondrial membrane potential (Ψm) was measured using the tetramethylrhodamine, ethyl ester (TMRE; Abcam, Cambridge, United Kingdom) reagent. Cells were grown in a 96-well clear bottom black plate and exposed to TNF-α induced vesicles as described for the Seahorse assay. At the end of the

experiment, media was gently aspirated from the wells and replaced by 100 μl of 60 nM TMRE in cell culture media, and incubated at 37°C for 20 min, protected from light. Cells were gently washed three times with warmed HBSS and fluorescence was measured on a Synergy HT multimodal plate reader with excitation 549 nm and emission 575 nm.

Mitochondrial Superoxide Assay

The levels of mitochondrial superoxide in cells were determined using the MitoSOX^{TM} reagent (Fisher). Cells were grown in a 96-well clear bottom black plate and exposed to TNF-α induced vesicles as described for the Seahorse assay. At the end of the experiment, media was gently aspirated from the wells and replaced by 100 μl of 5 μm MitoSox in cell culture media and incubated for 10 min at 37°C, protected from light. Cells were gently washed three times with warmed HBSS and fluorescence was measured on a Synergy HT multimodal plate reader with excitation 510 nm and emission 580 nm.

Hydrogen Peroxide Assay

The hydrogen peroxide (H_2O_2) assay was performed using the Amplex Red Kit (Invitrogen). Cells were grown in a 96-well clear bottom black plate, and exposed to TNF-α induced vesicles as described for the Seahorse assay. At the end of the experiment, 50 μL of the Amplex Red reagent was added to the media in the plate without washing, and incubated for 30 min at room temperature. The fluorescence of the Amplex Red reagent was measured on a Synergy HT multimodal plate reader with excitation 530 nm and emission 590 nm.

Statistical Analyses

All biological experiments were repeated at least three times with $n = 3$–16 plates/wells per treatment. Results from the experiments are reported as means ± SEM. All quantitative data were assessed for significance using a one-way ANOVA with Dunnett's *post hoc* test. All results were analyzed by GraphPad Prism 8.0 software (GraphPad Software, La Jolla, CA, USA). A p value < 0.05 was used to establish significance; significance presented as $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, and $^{****}p < 0.0001$.

RESULTS

TNF-α Induces Mitochondrial Dysfunction and Cellular Death

A Seahorse mitochondrial stress test was conducted to assess mitochondrial function in HT-22 cells exposed to TNF-α for 24 h. Results indicate that TNF-α exposure reduced basal and maximal respiration, ATP production, and spare capacity in a dose-dependent manner, with significant reductions occurring at the two highest concentrations (1 and 10 ng/ml) compared to unexposed control cells (**Figures 1A–D**). These same concentrations of TNF-α induced significant proton leak (**Figure 1E**), which can reduce the Ψm, and uncouple oxidative phosphorylation (Terada, 1990; Jastroch et al., 2010). Significant, dose-dependent decreases in basal glycolysis were also detected as a result of TNF-α exposure (**Figure 1F**). Exposure to all concentrations of TNF-α lead to cell death as shown by significant increases in LDH present in the conditioned culture media (**Figure 1G**). In view of the apparent cell death induced by increasing doses of TNF-α (**Figure 1G**), the observed decline in oxidative phosphorylation (**Figures 1A–D**) and glycolysis (**Figure 1F**) may be caused by the loss of cells in the assay.

TNF-α Exposure Induces EV Secretion, but Not in a Dose-Dependent Fashion

We next assessed the ability of TNF-α exposure to induce EV secretion in this hippocampal cell line. Vesicles isolated from the conditioned media of TNF-α exposed cells were profiled using the NanoSight NS300. Interestingly, TNF-α exposure lead to increased EV particle number, however this effect does not appear to be dose-dependent (**Figures 2A,B**). Exposure to low (0.1 ng/ml) and high (10 ng/ml) concentrations of TNF-α significantly increased particle concentration, whereas exposure to 1 ng/ml TNF-α did not lead to particle concentrations above control. Additionally, TNF-α exposure did not alter vesicle size, as all EV size distributions were between ∼80 and 300 nm in diameter, consistent with what has been shown in the literature (van Niel et al., 2018).

As recommended by the International Society for EVs (Lötvall et al., 2014), we probed for the presence of several canonical EV markers, including ALIX, CD81, CD63, and TSG101. Vesicles isolated from both the control and TNF-α exposure groups expressed all of the expected markers (**Figure 2C**) indicating that EVs were indeed being isolated in the vesicle preparation.

TNF-α Alters miRNA Expression Intracellularly and in Secreted EVs

In order to determine the impact of acute TNF-α exposure on miRNA expression, we assayed miR-34a and miR-146a expression within cells and their secreted EVs 24-h after exposure. Interestingly, intracellular expression levels of miR-34a were not changed after exposure to TNF-α (**Figure 3A**), yet a dose-dependent significant upregulation of this miRNA was observed in the secreted EVs (**Figure 3B**). Intracellular miR-146a expression was significantly increased after TNF-α exposure with an apparent ceiling effect (**Figure 3C**), and was significantly increased in a dose-dependent fashion in secreted EVs (**Figure 3D**).

EVs Are Taken Up by, and Enhance Mitochondrial Function in Recipient Cells

Because the secreted EVs contained TNF-α dose-dependent increased expression of both miR-34a and miR-146a, we were interested in determining whether EV cargo could be delivered to TNF-α naïve recipient cells, and how this may affect their mitochondrial function. We exposed TNF-α naïve cells to EVs isolated from the media of TNF-α exposed cells whose RNA was fluorescently labeled; EVs delivered this RNA to naïve recipient cells (**Figure 4**). We then assessed mitochondrial function, using the XF^{e}96 Mito Stress kit, in EV-recipient cells at 24 h after exposure. To our surprise, we observed significant, dose-dependent increases in mitochondrial oxygen consumption after EV exposure (**Figures 5A–D**). Interestingly, we also observed significant increases in proton leak (**Figure 5E**)

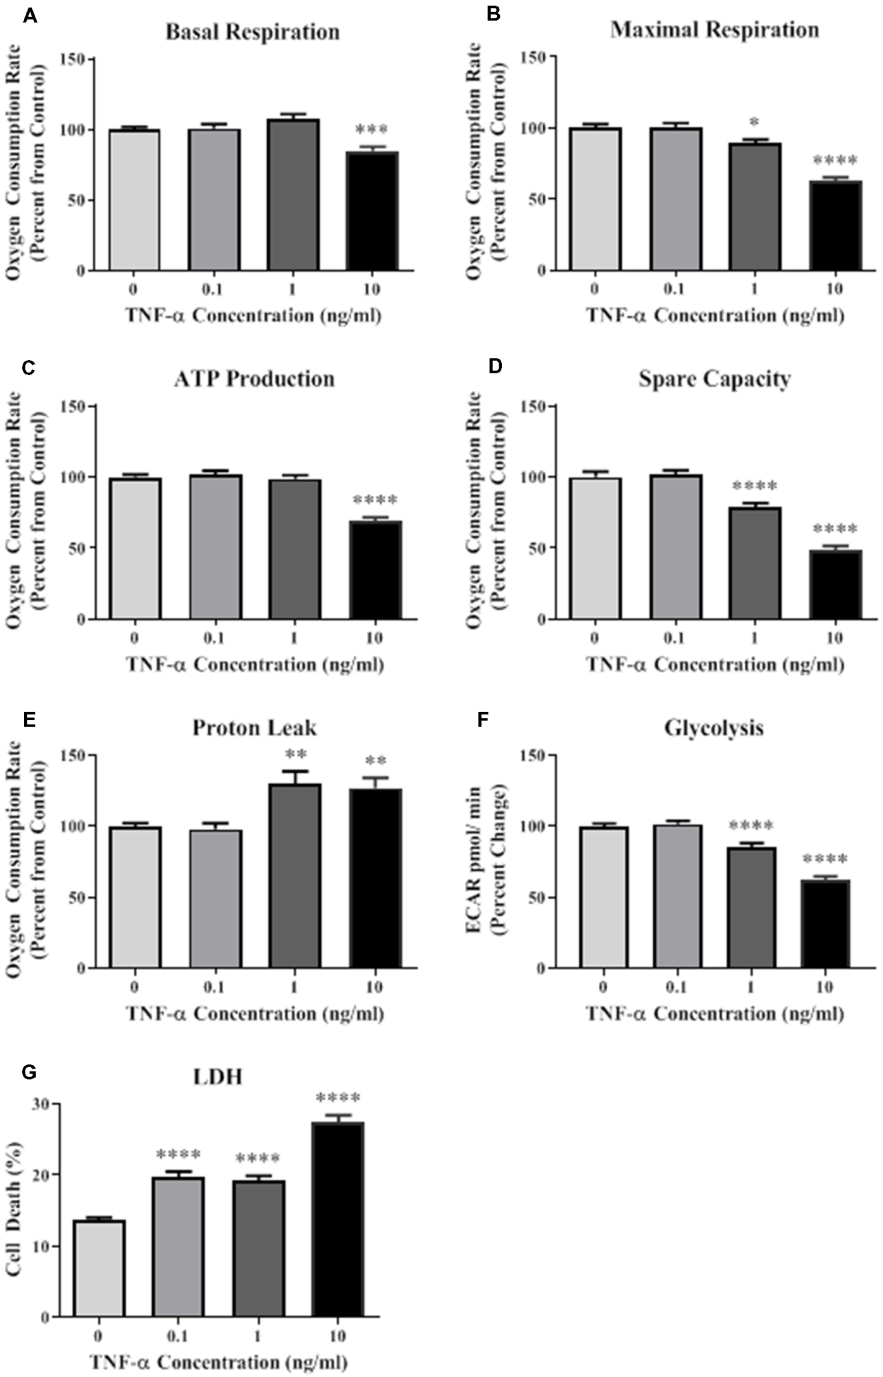

FIGURE 1 | Tumor necrosis factor-alpha (TNF-α) exposure significantly reduces cellular bioenergetic function and increases cell death. After 24 h exposure to TNF-α, basal respiration (**A**; $F_{(3,292)} = 11.90$, $p < 0.001$), maximal respiration (**B**; $F_{(3,292)} = 42.31$, $p < 0.0001$), ATP production (**C**; $F_{(3,292)} = 39.80$, $p < 0.0001$), and spare capacity (**D**; $F_{(3,292)} = 50.10$, $p < 0.0001$) were significantly reduced at the highest two concentrations. Proton leak (**E**; $F_{(3,202)} = 10.62$, $p < 0.0001$) was significantly increased. Glycolysis was also significantly reduced after TNF-α exposure (**F**; $F_{(3,164)} = 59.42$, $p < 0.0001$). Lactate dehydrogenase (LDH) data indicate that significant cell death occurred at all concentrations of TNF-α exposure (**G**; $F_{(3,223)} = 65.31$, $p < 0.0001$). $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, and $^{****}p < 0.0001$.

suggesting that although oxidative phosphorylation is increased, mitochondria are likely not functioning optimally, as protons are leaking across the membrane. We also observed a significant dose-dependent upregulation of basal glycolysis after exposure to EVs (**Figure 5F**). Unlike direct exposure to TNF-α, only EVs induced from the highest concentration of TNF-α (10 ng/ml) caused significant cell death in naïve cells (**Figure 5G**). The enhanced oxidative phosphorylation (**Figures 5A–D**) and

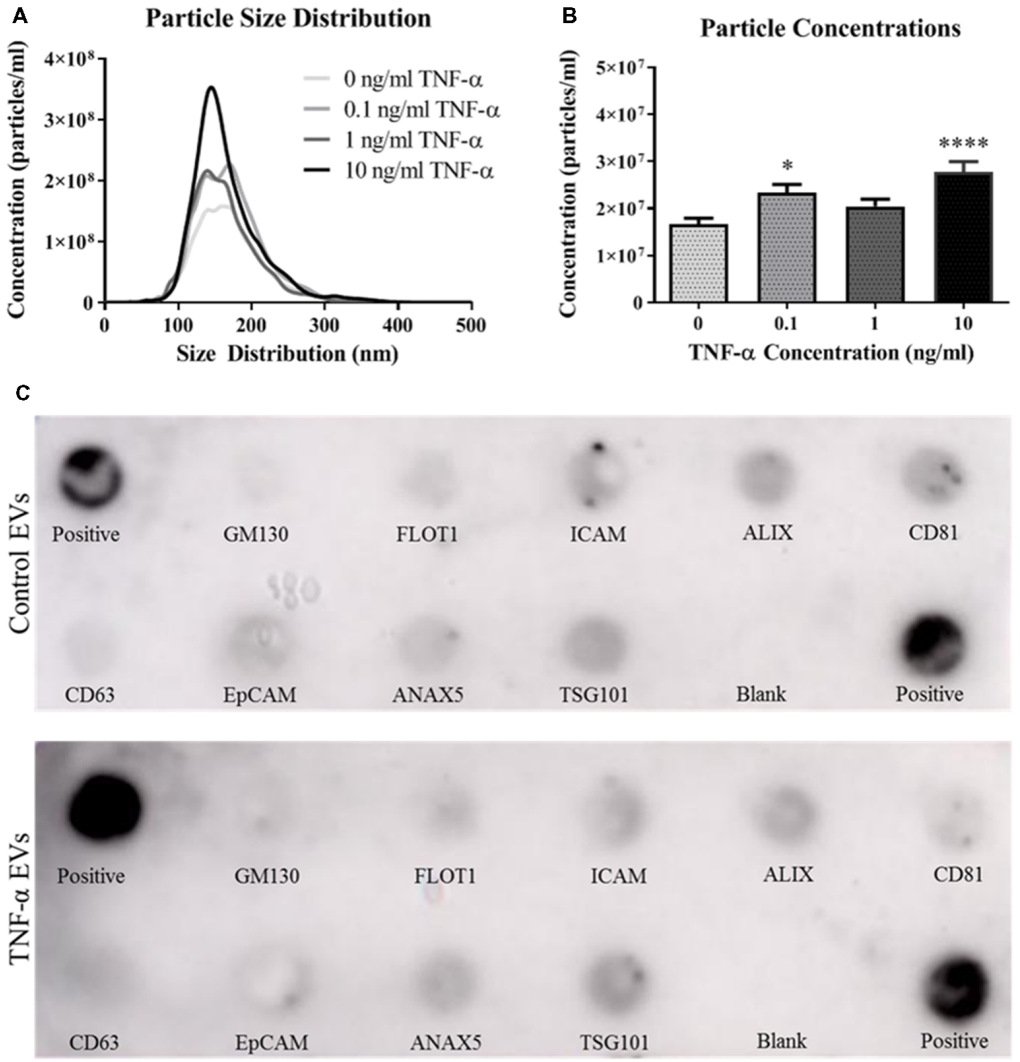

FIGURE 2 | TNF-α exposure induces secretion of extracellular vesicles (EVs). Particle size distributions calculated from the NanoSight NS300 show expected size ranges for EVs (**A**; $F_{(3,3,996)} = 7.06$, $p < 0.0001$). Overall particle concentrations for each TNF-α exposure group indicate that TNF-α exposure induces vesicle secretion **(B)**. TNF-α induces EVs expressing canonical markers and are appropriately sized. Canonical EV proteins and their locations on a dot blot are shown **(C)**. Presence of proteins expressed for control vesicles (**C**, top panel) and TNF-α (10 ng/ml) induced vesicles (**C**, bottom panel) are shown. $^{*}p < 0.05$, $^{****}p < 0.0001$.

glycolysis (**Figure 5F**) seen after exposure to TNF-α-induced EVs is likely an underestimate of the bioenergetic function of the cells exposed to 10 ng/ml TNF-α-induced EVs, as this group experienced significant cell death (**Figure 5G**).

EVs Increase ROS Production in Recipient Cells

Due to the increased proton leak observed in the Seahorse assay following EV exposure, we next assessed mitochondrial Ψm. We did not observe any significant changes in potential (**Figure 6A**) after a 24-h exposure period to TNF-α induced EVs.

We next assessed ROS production in cells exposed to TNF-α induced EVs. We observed a statistically significant increase in mitochondrial superoxide production when cells were incubated with EVs induced by 0, 0.1, and 1 ng/ml TNF-α, but not 10 ng/ml (**Figure 6B**); however, this result may be attributed to the significant amount of cell death observed in this group (**Figure 5G**). Additionally, we observed significant increases in H_2O_2 after exposure to EVs, with the highest amount generated in the 10 ng/ml TNF-α induced EV group (**Figure 6C**). As H_2O_2 has the capacity to induce neuronal cell death (Ricart and Fiszman, 2001), this may explain why we observed significant cellular death in this group (**Figure 5G**).

DISCUSSION

AD is characterized by neuroinflammation (Wyss-Coray and Rogers, 2012) and mitochondrial dysfunction (Swerdlow, 2018). In the present study, we observed that physiologically relevant levels of the proinflammatory cytokine TNF-α are capable of

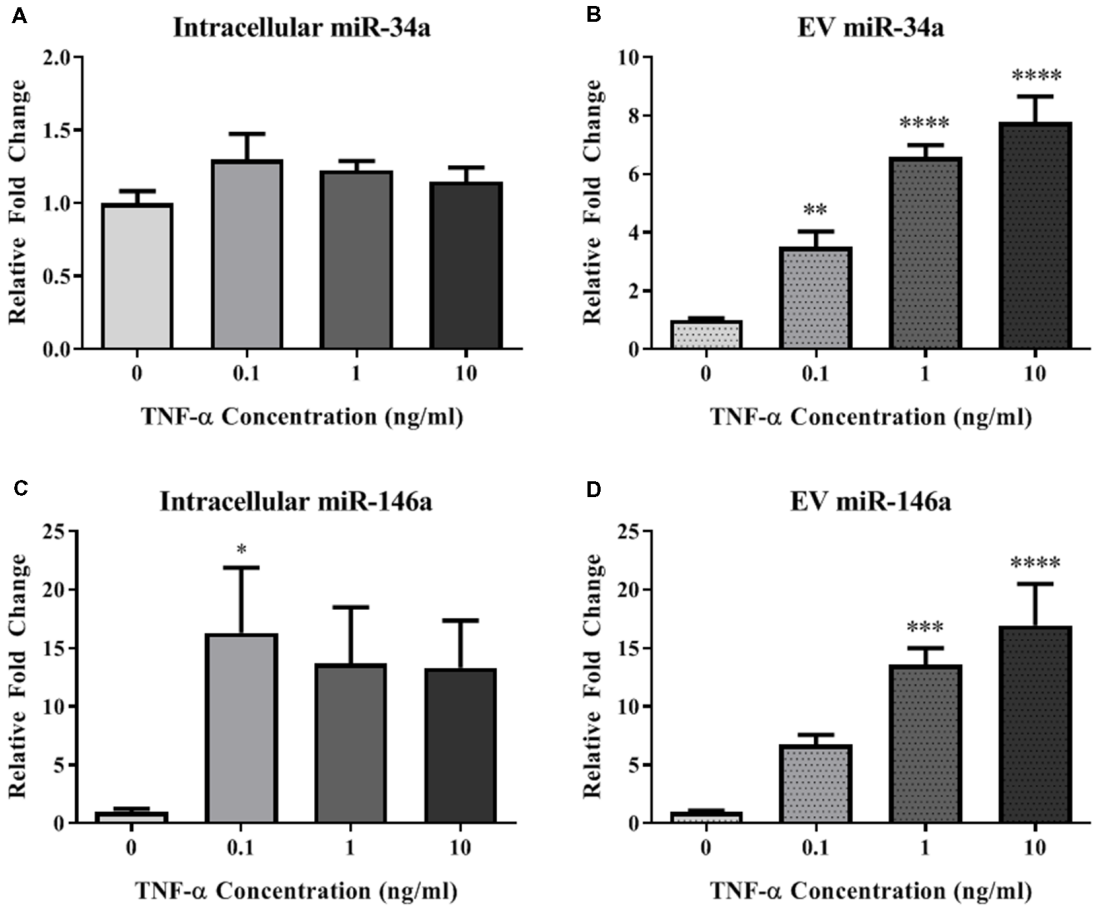

FIGURE 3 | TNF-α significantly alters microRNA (miRNA) expression profiles. TNF-α exposure did not significantly alter intracellular expression of miR-34a (**A**; $F_{(3,32)} = 1.29$, $p = 0.2951$), but did induce a dose-dependent increase in miR-34a expression within EVs (**B**; $F_{(3,31)} = 30.00$, $p < 0.0001$). Conversely, TNF-α exposure induced intracellular upregulation of miR-146a which trended towards significance (**C**; $F_{(3,32)} = 2.92$, $p = 0.0643$), as well as a significant, dose-dependent increases within EVs (**D**; $F_{(3,31)} = 13.15$, $p < 0.0001$). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$, and ****$p < 0.0001$.

causing significant cellular death and mitochondrial dysfunction in hippocampal neurons after a 24-h exposure period. We also demonstrate that TNF-α induced EVs are taken up by naïve cells, and significantly alter mitochondrial activity in recipient cells. Specifically, we observed increases in mitochondrial respiration, glycolysis, proton leak, and ROS production in recipient cells after 24 h of EV exposure. Together, these data suggest that direct exposure of TNF-α to a neuronal cell type is highly toxic, and the vesicles secreted in response to this exposure are capable of inducing a stress response in neighboring cells.

We observed significant downregulation of mitochondrial oxidative phosphorylation and glycolysis in HT-22 cells exposed to TNF-α for 24 h. Under some conditions, when oxidative phosphorylation is inhibited or reduced, neurons can increase glycolysis as a protective, compensatory mechanism (Bas-Orth et al., 2017). However, with the decline in oxidative phosphorylation observed in this study, there is no compensatory increase in glycolysis. We additionally assessed expression of several ETC proteins involved in oxidative phosphorylation (including NDUFC2 of complex I, SHDC of complex II, UQCRB of complex III, and Cytochrome C oxidase of complex IV) after TNF-α exposure, and observed no significant changes in expression (data not shown). High concentrations of LDH in the media, along with reductions in bioenergetic measurements indicate that these observations are likely a result of cell death due to exposure to the cytotoxic protein, TNF-α.

We have previously shown that overexpression of miR-34a significantly reduces mitochondrial function in neuronal cells (Sarkar et al., 2016). In view of our evidence that miR-146a, but not miR-34a, was increased intracellularly in HT-22 cells, miR-146a may be responsible for the TNF-α induced mitochondrial impairment observed in these cells. Indeed, overexpression of miR-146a significantly reduces cellular bioenergetics (Jun et al., unpublished observation). Additionally, TNF-α exposure caused a dose-dependent increase in both miR-34a and miR-146a in secreted EVs. In line with other reports, these results suggest differential packaging and secretion mechanisms which are dependent on specific miRNAs (Abels and Breakefield, 2016). The results from the current study support the concept that some miRNAs (e.g., miR-34a) may be

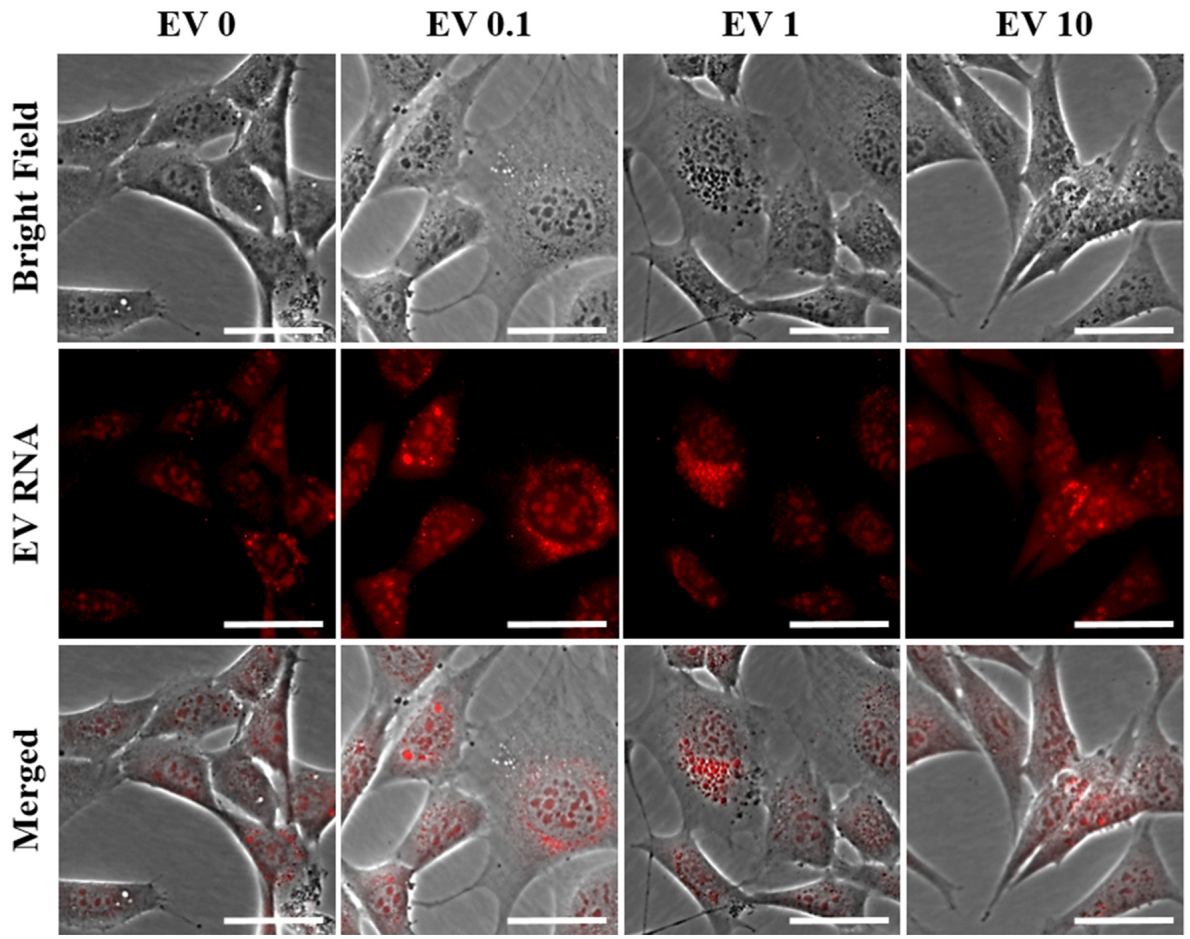

FIGURE 4 | Naïve cell EV uptake and functional consequences. EVs derived from control and all concentrations of TNF-α (0, 0.1, 1, and 10 ng/ml) are taken up by naïve cells as evidenced by punctate staining of red-labeled EV RNA present within naïve cells. Scale bar = 40 μm.

preferentially sorted out of cells (Jovicic and Gitler, 2017; Wei et al., 2017), however this interpretation is strictly speculative and requires further investigation.

As TNF-α exposure significantly elevated miR-34a and miR-146a expression within secreted EVs, we hypothesized that exposing naïve cells to TNF-α induced EVs would result in significant reduction of mitochondrial respiration due to miRNA-mediated repression of ETC protein translation. Interestingly, we observed significant increases in mitochondrial oxygen consumption in naïve cells exposed to these vesicles. In this study, only relative changes in miRNA expression were assessed, not definitive quantities. It has been postulated that there is fewer than one copy of an individual miRNA per EV (Chevillet et al., 2014; Wei et al., 2017), so it is likely that the absolute concentrations of miR-34a and miR-146a were not high enough to induce physiologically relevant repression of ETC proteins in recipient cells and cause reductions in oxygen consumption.

Several groups have also shown that exposure to EVs significantly increases mitochondrial respiration in recipient cells (Phinney et al., 2015; Sansone et al., 2017; Bland et al., 2018), and others have described that in response to stimulation, neurons are able to increase their rate of glycolysis (Yellen, 2018). This unexpected increase in mitochondrial activity may actually be a signal of mitochondrial stress, as we concomitantly observed dose-dependent increases in proton leak, suggesting that although oxidative phosphorylation is increased, the mitochondria are not actually functioning optimally. Indeed, a disproportionately large rate of mitochondrial oxygen consumption likely indicates an attempt to maintain Ψm as proton leak across occurs (Jastroch et al., 2010). Spare respiratory capacity is an indicator of mitochondria's ability to respond to stress (Hill et al., 2009). Here we observe significant elevation of spare capacity in cells exposed to EVs, which is likely the mechanism by which mitochondria were able to maintain Ψm, despite undergoing significant proton leak. As mitochondria are the main generators of ROS, it is likely that the increased oxygen consumption incurred by maintaining Ψm is responsible for significant ROS generation. Superoxide anions are quickly converted to less reactive H_2O_2 by superoxide dismutases (Lennicke et al., 2015), which may explain why we saw significantly more H_2O_2 than superoxide after EV exposure.

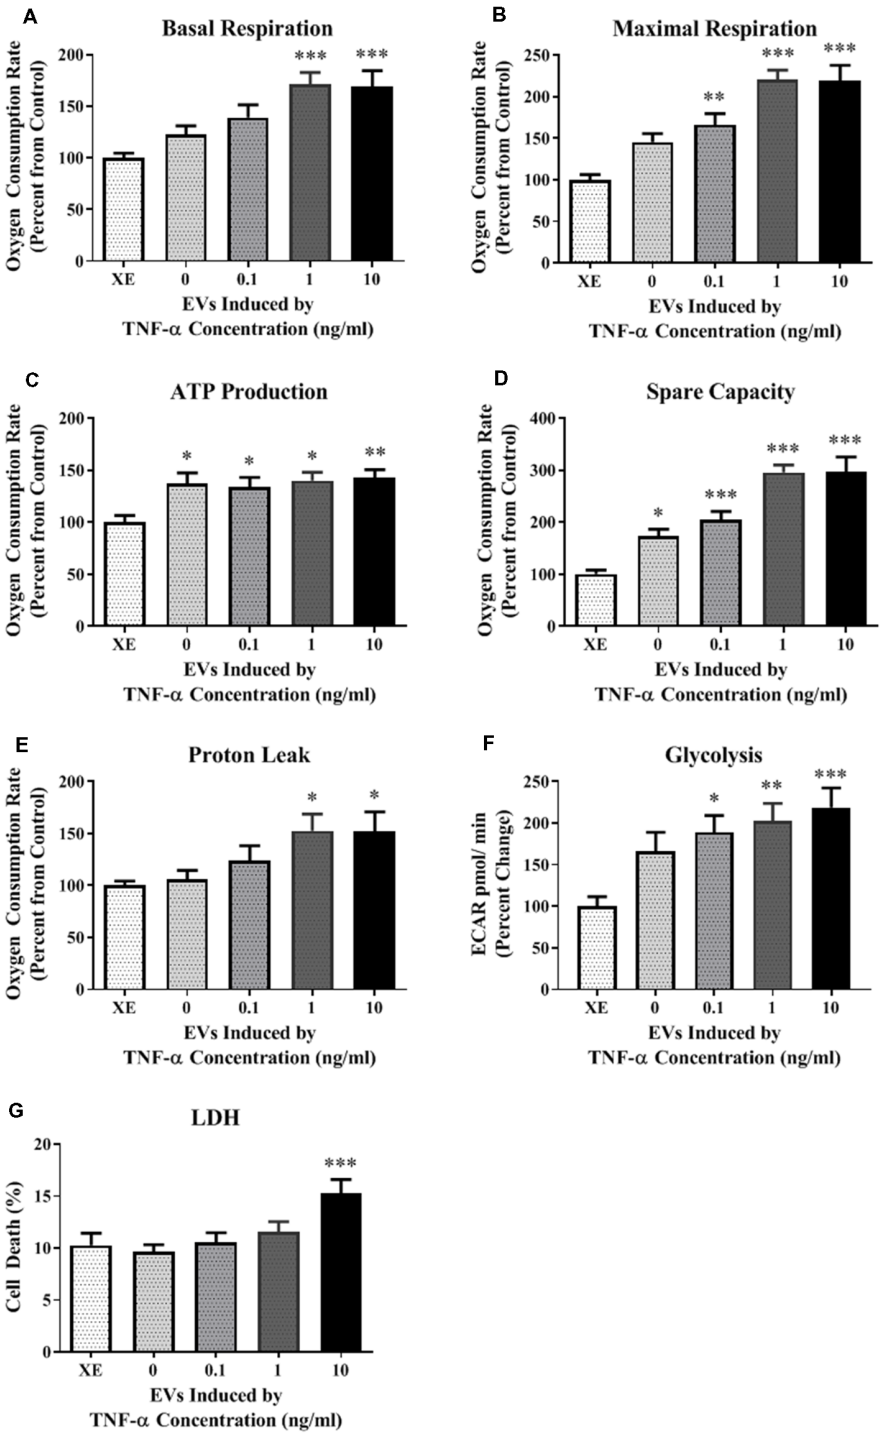

FIGURE 5 | TNF-α induced EVs significantly alter energy metabolism. Data are depicted as significant differences related to XE buffer as the control. TNF-α induced EVs significantly increased basal respiration (**A**; $F_{(4,67)} = 6.72$, $p = 0.0001$) and maximal respiration (**B**; $F_{(4,67)} = 15.05$, $p < 0.0001$), while exposure to all vesicles significantly increased ATP production (**C**; $F_{(4,67)} = 3.64$, $p = 0.0096$) and spare capacity (**D**; $F_{(4,67)} = 21.50$, $p < 0.0001$). Proton leak was also significantly increased at the highest TNF-α concentrations (**E**; $F_{(4,67)} = 3.07$, $p = 0.0221$). Exposure to these vesicles significantly increased glycolysis as well (**F**; $F_{(4,84)} = 5.024$, $p < 0.0011$). Significant cell death only occurred at the highest concentration (**G**; $F_{(4,44)} = 4.717$, $p = 0.003$). Additional analyses using 0 ng/ml TNF-α exposed EVs as control were also conducted. When 0 EVs were used as the control, the effects of TNF-α-induced EVs remained significant for basal respiration ($F_{(3,55)} = 3.614$, $p = 0.0187$), maximal respiration ($F_{(3,55)} = 7.607$, $p = 0.0002$), spare capacity ($F_{(3,55)} = 11.09$, $p < 0.0001$), and LDH ($F_{(3,35)} = 6.174$, $p = 0.0018$). There were no significant responses to TNF-α-induced EVs for ATP production ($F_{(3,55)} = 0.1857$, $p = 0.9057$), proton leak ($F_{(3,55)} = 2.266$, $p = 0.0909$), or glycolysis ($F_{(3,68)} = 1.039$, $p = 0.3809$). $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

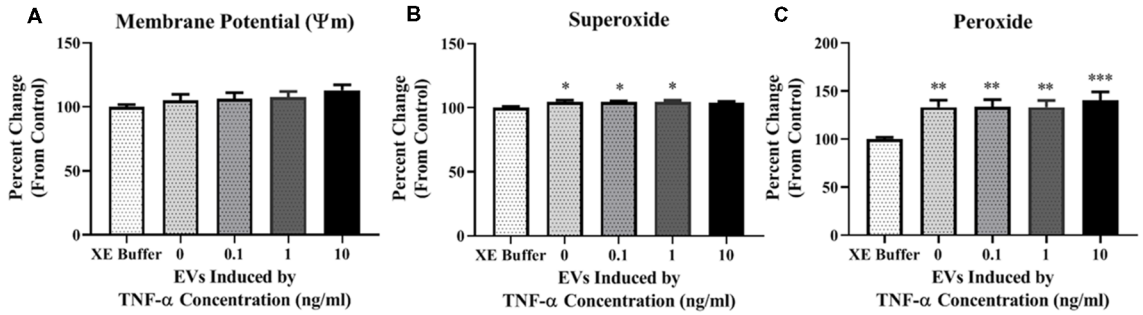

FIGURE 6 | TNF-α induced EVs alter reactive oxygen species (ROS) production in recipient cells. Data are depicted as significant differences related to XE buffer as the control. EVs do not have a significant impact on the inner mitochondrial membrane potential (Ψm; **A**; $F_{(4,115)} = 1.287$, $p = 0.2794$). Exposure of naïve cells to EVs significantly increases ROS production in the form of mitochondrial superoxide (**B**; $F_{(4,113)} = 2.787$, $p = 0.0298$), and hydrogen peroxide (H_2O_2; **C**; $F_{(4,85)} = 5.329$, $p = 0.0007$). Additional analyses using 0 ng/ml TNF-α exposed EVs as control were also conducted. There were no significant responses to TNF-α-induced EVs for membrane potential ($F_{(3,92)} = 0.5786$, $p = 0.6305$), mitochondrial superoxide ($F_{(3,90)} = 0.07873$, $p = 0.9714$), or H_2O_2 ($F_{(3,68)} = 0.2021$, $p = 0.8946$). $^*p < 0.5$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

Our observation of altered mitochondrial function after a single exposure to TNF-α, or TNF-α induced EVs does not recapitulate the *in vivo* conditions of AD, as there is constant crosstalk between different cell types, and persistent, dynamic EV-cell interactions. However, the current findings suggest that neuronal, inflammation-derived EVs may acutely alter mitochondrial activity in recipient cells. The mitochondrial cascade hypothesis of AD posits that increased ROS induces mitochondrial DNA damage and reduces mitochondrial function; with time this initiates a "reset response" in which Aβ production is increased, leading to further generation of ROS in a vicious, positive feedback cycle (Swerdlow and Khan, 2004). While we have not identified the cargo within EVs that initiates this mitochondrial response, future studies will address this issue, as any component of EV-associated cargo may be responsible for these effects, e.g., direct transfer of specific proteins, mRNAs, or other miRNAs not assessed here.

Importantly, the current study provides novel insights on the role of inflammation-induced EVs in the inflamed and aging brain. The results underscore the importance of TNF-α, a canonical proinflammatory cytokine in the brain, as a regulator of mitochondrial function, miRNA expression, and EV secretion in neurons. Thus, TNF-α induced EVs may be drivers of the bioenergetic function and dysfunction throughout the brain in AD and other neuroinflammatory disorders.

Amyloid precursor protein (APP) transgenic animal models of Alzheimer's disease have become versatile tools for basic and translational research. However, there is great heterogeneity of histological, biochemical, and functional data between transgenic mouse lines, which might be due to different transgene expression patterns. Here, the expression of human APP (hAPP) by GABAergic hippocampal interneurons immunoreactive for the calcium binding proteins parvalbumin, calbindin, calretinin, and for the peptide hormone somatostatin was analyzed in Tg2576 mice by double immunofluorescent microscopy. Overall, there was no GABAergic interneuron subpopulation that did not express the transgene. On the other hand, in no case all neurons of such a subpopulation expressed hAPP. In dentate gyrus molecular layer and in stratum lacunosum moleculare less than 10% of hAPP-positive interneurons co-express any of these interneuron markers, whereas in *stratum oriens* hAPP-expressing neurons frequently co-express these interneuron markers to different proportions. We conclude that these neurons differentially contribute to deficits in young Tg2576 mice before the onset of Abeta plaque pathology. The detailed analysis of distinct brain region and neuron type-specific APP transgene expression patterns is indispensable to understand particular pathological features and mouse line-specific differences in neuronal and systemic functions.

INTRODUCTION

Alzheimer's disease (AD) is histopathologically characterized by the formation of intracellular neurofibrillary tangles, principally made of tau protein and extracellular amyloid deposits composed of Abeta peptides that deposit in the parenchyma and in the vessel walls. These Abeta peptides are cleavage products generated by proteolytical processing of the amyloid precursor

protein (APP) by the β-secretase BACE1 (Lichtenthaler et al., 2011; Vassar et al., 2014) and the γ-secretase complex composed of presenilin-1 or -2, nicastrin, APH-1, and PEN-2 (Kimberly et al., 2003). Abeta plaques represent a final aggregation state of Abeta peptides and are used for *post mortem* AD diagnosis but can be also detected by positron emission tomography imaging in patients (Barthel and Sabri, 2017; Salloway et al., 2017).

A substantial gain of knowledge on mechanisms of amyloid pathology in AD was achieved by the analyses of transgenic mouse models overexpressing human APP (hAPP) with disease-promoting mutations that lead to early-onset AD in humans (Ameen-Ali et al., 2017; Sasaguri et al., 2017). However, these animal models differ significantly regarding the onset of pathology, spatial appearance of Abeta deposits, neuronal loss and deficits in learning and memory tasks as reviewed by Höfling et al. (2016) which hampers drawing general conclusions on defined pathogenic functions of Abeta peptides. Thus, a detailed analysis of the brain region and cell type-specific transgene expression patterns is indispensable to understand pathogenic mechanisms in each animal model. A very well characterized and frequently used transgenic model is the Tg2576 mouse established by Hsiao et al. (1996). These mice overexpress hAPP harboring the Swedish double mutation KM670/671NL and develop Abeta deposits starting in entorhinal cortex followed by hippocampus at around 11 months of age (Hsiao et al., 1996; Kawarabayashi et al., 2001; Hartlage-Rübsamen et al., 2011).

Interestingly, these mice display impaired hippocampus-dependent spatial learning, working memory, and contextual fear conditioning already at 6 months of age (King and Arendash, 2002), which is well before extracellular plaques appear in the brains of these mice. The deficiencies in spatial learning and memory consolidation are of particular interest since they resemble clinical aspects of AD patients such as disturbed spatial orientation (Kumar et al., 2015) and altered neuronal network activity (Allen et al., 2007; Brier et al., 2012; Sheline and Raichle, 2013). In that regard dendritic spine loss in the Tg2576 CA1 region (Lanz et al., 2003) and a decline in long-term potentiation (LTP) in dentate gyrus (DG) after performant path stimulation (Jacobsen et al., 2006) already detectable at 5 months of age point towards a pathogenic role of soluble, oligomeric Abeta prior to Abeta plaque formation. Additionally, using resting-state functional Magnetic Resonance Imaging (MRI), a hypersynchrony of functional connectivity in the hippocampus of 5-month-old Tg2576 mice was demonstrated (Shah et al., 2016) suggesting increased excitatory and/or reduced inhibitory neuronal activity. These pathogenic aspects have been frequently related to Abeta oligomer formation. However, a series of recent studies from different laboratories demonstrates that such disturbances may occur independently of Abeta formation. In particular, there appears to be a causal link between early pathogenic events including lysosomal autophagic pathology, hyperactivity in lateral entorhinal cortex, early brain network alterations in the CA1/subiculum and the generation of intracellular APP C-terminal fragments not cleaved by γ-secretase (Lauritzen et al., 2012, 2016; Xu et al., 2015; Mondragón-Rodríguez et al., 2018). In addition, the AD-related endosome dysfunction in Down syndrome was demonstrated to be independent of Abeta generation but to rely on the BACE1-catalyzed formation of the APP C-terminal fragment C99 (Jiang et al., 2010).

However, both the generation of soluble human Abeta and of C-terminal hAPP fragments require transgenic hAPP expression. In that regard, it is a still unaddressed question which specific neuronal populations are affected by hAPP overexpression in Tg2576 hippocampus. Theoretically, either neurons expressing the hAPP transgene or those exposed to extracellular Abeta assemblies might be specifically affected. Employing a novel, hAPP-specific rat monoclonal antibody we have recently demonstrated transgene expression by virtually all CA1 to CA3 pyramidal neurons and by scattered GABAergic interneurons throughout all hippocampal layers, but not by DG granule cells (Höfling et al., 2016). These interneurons represent a small proportion of hippocampal neurons but generate and control the rhythmic output of large populations of principal cells and modulate LTP (Chen et al., 2010; Huh et al., 2016), neurogenesis (Krezymon et al., 2013; Verdaguer et al., 2015), Abeta pathology (Ramos et al., 2006) as well as learning and memory (Perez-Cruz et al., 2011; Schmid et al., 2016). Thus, the observed early alterations in hippocampal network activity may be due to functional impairment of inhibitory GABAergic hippocampal interneurons expressing the hAPP transgene in Tg2576 mice. These GABAergic hippocampal interneurons can be subdivided based on shape, localization in defined hippocampal layers and the co-expression of specific calcium-binding proteins (CBPs) such as parvalbumin, calbindin, and calretinin as well as the peptide hormone somatostatin (Mátyás et al., 2004).

In order to identify hippocampal interneurons expressing the hAPP transgene in Tg2576 mice, double immunofluorescent labelings detecting hAPP and the CBPs and somatostatin were performed followed by quantitative stereological analyses. The data reported identify defined hippocampal populations of interneurons as cellular source for Abeta generation which may affect the neurons expressing the transgene themselves or anatomical target areas where Abeta peptides are released from these neurons.

MATERIALS AND METHODS

Animals

In order to identify GABAergic interneurons expressing the hAPP transgene we used 3-month-old female wild type ($N = 3$) and female Tg2576 mice ($N = 3$) on C57BL/6xSJL background in which transgene expression is driven by the hamster prion protein promoter (Hsiao et al., 1996). Female mice were chosen because they develop Abeta pathology earlier than males and display a higher amyloid load than males at the same age (Callahan et al., 2001) and are, therefore, used more often in experimental studies. Animals were housed at 23°C at 12 h day/12 h night cycles with food and water *ad libitum* in cages that contained red plastic houses (Tecniplast) and shredded paper flakes to allow nest building. All experimental protocols were approved by Landesdirektion Sachsen, license T28/16 and

all methods were carried out in accordance with the relevant guidelines and regulations.

Tissue Preparation

Mice were sacrificed by CO_2 inhalation and perfused transcardially with 50 ml 0.9% saline followed by perfusion with 80 ml 4% paraformaldehyde in PBS (0.1 M; pH 7.4). The brains were removed from the skull and postfixed by immersion in the same fixative overnight at 4°C. After cryoprotection in 30% sucrose in 0.1 M PBS for 3 days, coronal sections (30 μm) were cut at the level of Bregma −2.70 mm to Bregma −3.16 mm on a sliding microtome and collected in 0.1 M PBS.

Immunohistochemistry

In order to reveal the neuron type-specific labeling generated by the rat monoclonal anti-hAPP antibody 1D1 (15 μg/ml) in hippocampus of Tg2576 mice triple immunofluorescent labeling in combination with antibodies directed against the CBPs parvalbumin (rabbit anti-parvalbumin; Swant; 1:4,000), calbindin (rabbit anti-calbindin; Swant; 1:1,000), calretinin (rabbit anti-calretinin; Swant; 1:1,000) and against somatostatin (goat anti-somatostatin; Santa Cruz; 1:200) was performed. To allow normalization for total neuronal numbers a mixture of mouse anti-NeuN/anti-HuCD (1:1000 each; Invitrogen/Millipore) was added to the incubation cocktails. Brain sections were incubated with cocktails of primary antibodies overnight at 4°C. On the next day, sections were washed three times with TBS and were then incubated with cocktails of Cy3-conjugated donkey anti-rat (1:400; Dianova) and Cy2-conjugated donkey anti-rabbit or donkey anti-goat (1:400; Dianova) and Cy5-conjugated donkey anti-mouse (1:400; Dianova) for 60 min at room temperature. This procedure resulted in red labeling of hAPP-positive neurons, in green labeling of the respective interneuron types and in blue labeling of all neurons. After washing, sections were mounted onto glass slides and coverslipped.

Microscopy

Confocal laser scanning microscopy (LSM 510, Zeiss, Oberkochen, Germany) was performed to reveal co-localization of hAPP with parvalbumin, calbindin, calretinin, and somatostatin in hippocampus. For Cy2-labeled interneuron markers (green fluorescence), an argon laser with 488 nm excitation was used and emission from Cy2 was recorded at 510 nm applying a low-range band pass (505–550 nm). For Cy3-labeled hAPP (red fluorescence), a helium-neon-laser with 543 nm excitation was applied and emission from Cy3 at 570 nm was detected applying high-range band pass (560–615 nm). Photoshop CS2 (Adobe Systems, Mountain View, CA, United States) was used to process the images obtained by light and confocal laser scanning microscopy. Care was taken to keep the same brightness, sharpness, color saturation, and contrast in the various pictures.

Quantification of Neuronal Numbers

For quantification of neuronal numbers, images of immunohistochemical labelings were taken at a Keyence BZ-9000 microscope. The outline of hippocampal layers, the location of neurons inside these layers and quantitative analysis of the proportion of hAPP-immunoreactive interneuron populations were assessed by means of BZ-II Analyzer software (Keyence).

The expression of NeuN/HuCD, hAPP, parvalbumin, calbindin, calretinin, and somatostatin-positive neurons was investigated in both hippocampi of all animals. Each section was first viewed at low magnification (5×) for outlining the relevant hippocampal layers, and dissector frames were placed in a systematic consecutive fashion in the delineated regions of the sections. On average the post-processing shrinkage of the tissues resulted in a final section thickness of about 16 μm, which permitted a consistent sampling of 10 μm with the dissector and the use of guard zones of 2 μm on either sides of the section. All neurons that fell within the dissector frames were then counted at higher magnification (10×). In all sections analyzed, the total number of neurons in each hippocampal layer was set to 100%. The proportion of hAPP-immunoreactive neurons and neurons immunoreactive for interneuron markers was calculated and statistical differences were evaluated by unpaired *t* test.

RESULTS

The hAPP-specific 1D1 antibody used was shown by us to specifically detect the N-terminus of human, but not endogenous mouse APP in mouse brain sections (Höfling et al., 2016). In control experiments of the present study we included wild type mouse brain sections as negative control to validate specific hAPP transgene detection. In preceding experiments, we tested the 1D1 antibody at different concentrations on hAPP-transgenic Tg2576 and wild type mouse brain sections. With the highest 1D1 concentration not generating labeling in wild type mouse brain, we still observed the same pattern of labeling of hippocampal interneurons as reported below. The hippocampal formation can be subdivided into DG and hippocampus proper consisting of segments *cornu ammonis* (CA) 1, 2, 3, and 4. In addition, hippocampal layers with defined neuronal populations can be distinguished along these hippocampal subfields. In order to obtain highly detailed information on the specific distribution of hAPP expressing interneurons, our analyses were performed in hippocampal layers excluding pyramidal and granule cell layers. We observed hAPP expression in subsets of hippocampal interneurons ranging between 57 and 100% in hippocampal layers analyzed (**Table 1**). In contrast, endogenous mouse APP is ubiquitously expressed by virtually all neurons (Buxbaum et al., 1993; Neve et al., 1996) and critical for neuronal development and viability as well as for synapse formation and stabilization (Priller et al., 2006). Thus, endogenous mouse APP is expressed by almost all hippocampal neurons, whereas transgene expression of hAPP is limited to subsets of hippocampal neurons.

GABAergic Interneurons in Hippocampal Layers of Wild Type and Tg2576 Mice

First, we tested whether the numbers of CBP and somatostatin-expressing interneurons is similar in hippocampal layers of

3-month-old wild type and hAPP-transgenic Tg2576 mice. Since the absolute number of neurons and the neuronal number per area differ strongly along the rostro-caudal extension of the hippocampal formation, the proportion of CBP- and somatostatin-containing neurons of all neurons was calculated in brain sections at a narrow brain cutting level of bregma −2.70 to Bregma −3.16 mm by immunofluorescent co-labeling of the CBP and somatostatin with a combination of the pan-neuronal markers NeuN/HuCD (**Figure 1**). Typical examples of these labelings of wild type and Tg2576 hippocampus are displayed in **Figure 1A**. Visual examination of the staining patterns indicated a similar appearance of all CBP analyzed as well as of somatostatin, while hAPP immunoreactivity was absent in wild type brain sections. Data of the quantitative analyses of these labelings are depicted in **Figures 1B–E**.

As to the expression of the different neuropeptides we detected striking differences in the hippocampus layer-specific abundance of CBP and somatostatin-positive neurons in wild type mice. For example, approximately 25% of neurons in *stratum oriens* were *parvalbumin*-immunoreactive, whereas only 5% in *stratum radiatum*, *stratum moleculare* and the hilus of DG displayed parvalbumin immunoreactivity and *stratum lacunosum moleculare* was completely devoid of parvalbumin neurons (**Figure 1B**). *Calbindin*-expressing neurons were highly abundant in *stratum oriens* and *stratum radiatum* (30% of all neurons) and to a lesser extent in neurons of *stratum moleculare* and *stratum lacunosum moleculare* (15% of all neurons), whereas in hilus of DG only 5% of all neurons expressed this protein (**Figure 1C**). An inverse pattern in the abundance across hippocampal layers was detected for *calretinin*-containing interneurons. Here, more than 30% of all neurons in the hilus of DG and in *stratum lacunosum moleculare* were calretinin-immunoreactive, whereas only 15% of neurons in *stratum radiatum* and *stratum oriens* and less than 10% of neurons in *stratum moleculare* were calretinin-immunoreactive (**Figure 1D**). Somatostatin-containing neurons were most abundant in *stratum oriens* and hilus of DG (30% of all neurons), followed by *stratum radiatum* (10% of all neurons) and were found to be absent in DG molecular layer and in *stratum lacunosum moleculare* (**Figure 1E**).

For most labelings, there were no statistically significant differences between wild type and Tg2576 mice in the abundance of parvalbumin-, calbindin-, calretinin-, or somatostatin-positive neurons in hippocampal layers analyzed (**Figures 1B–E**). The only exceptions are a lower proportion of parvalbumin-containing neurons in *stratum oriens* (**Figure 1B**) and a higher proportion of calretinin-immunoreactive neurons in *stratum moleculare* of Tg2576 mice (**Figure 1D**). Thus, in general, the appearance and distribution of GABAergic interneurons in hippocampus of young Tg2576 mice is preserved compared to the wild type.

Human APP Transgene Expression by Hippocampal GABAergic Interneurons

The transgenic hAPP was found to be expressed by interneurons across all hippocampal layers. We, therefore, wanted to analyze the hAPP transgene expression by hippocampal GABAergic interneurons in detail. In particular, the following questions were addressed. (i) Which proportion of hAPP-expressing hippocampal interneurons is immunoreactive for parvalbumin, calbindin, calretinin, and somatostatin in defined hippocampal layers? (ii) Which proportion of parvalbumin, calbindin, calretinin, and somatostatin-positive neurons expresses hAPP?

In general, there was no GABAergic interneuron subpopulation that did not express the hAPP transgene. On the other hand, in no case all neurons of such a subpopulation expressed hAPP (**Figures 2–5**). Typical examples of parvalbumin/hAPP double labelings in *stratum oriens* are shown in **Figure 2A**. Quantitative analysis revealed that of all hAPP transgene-expressing interneurons in *stratum oriens*, 25% were *parvalbumin*-immunoreactive, whereas in *stratum radiatum* and in hilus of DG only 5% and in *stratum moleculare* only 2% of hAPP-positive neurons displayed parvalbumin immunoreactivity. *Stratum lacunosum moleculare* did not have any neurons expressing both hAPP and parvalbumin (**Figure 2B**). On the other hand, of all parvalbumin-expressing neurons, 60 to 80% expressed the hAPP transgene in hilus of DG, *stratum moleculare*, *stratum radiatum*, and *stratum oriens*, respectively (**Figure 2C**).

Double immunofluorescent labelings for calbindin and hAPP in *stratum radiatum* are shown in **Figure 3A**. The proportion of hAPP expressing neurons positive for *calbindin* differed considerably between layers and in hippocampus proper amounted to 42% in *stratum oriens*, 20% in *stratum radiatum*, and 5% in *stratum lacunosum moleculare*, respectively, and in DG to 3% in *stratum moleculare* and 2% in the hilus (**Figure 3B**). Of all calbindin-expressing neurons, 70% expressed hAPP in *stratum*

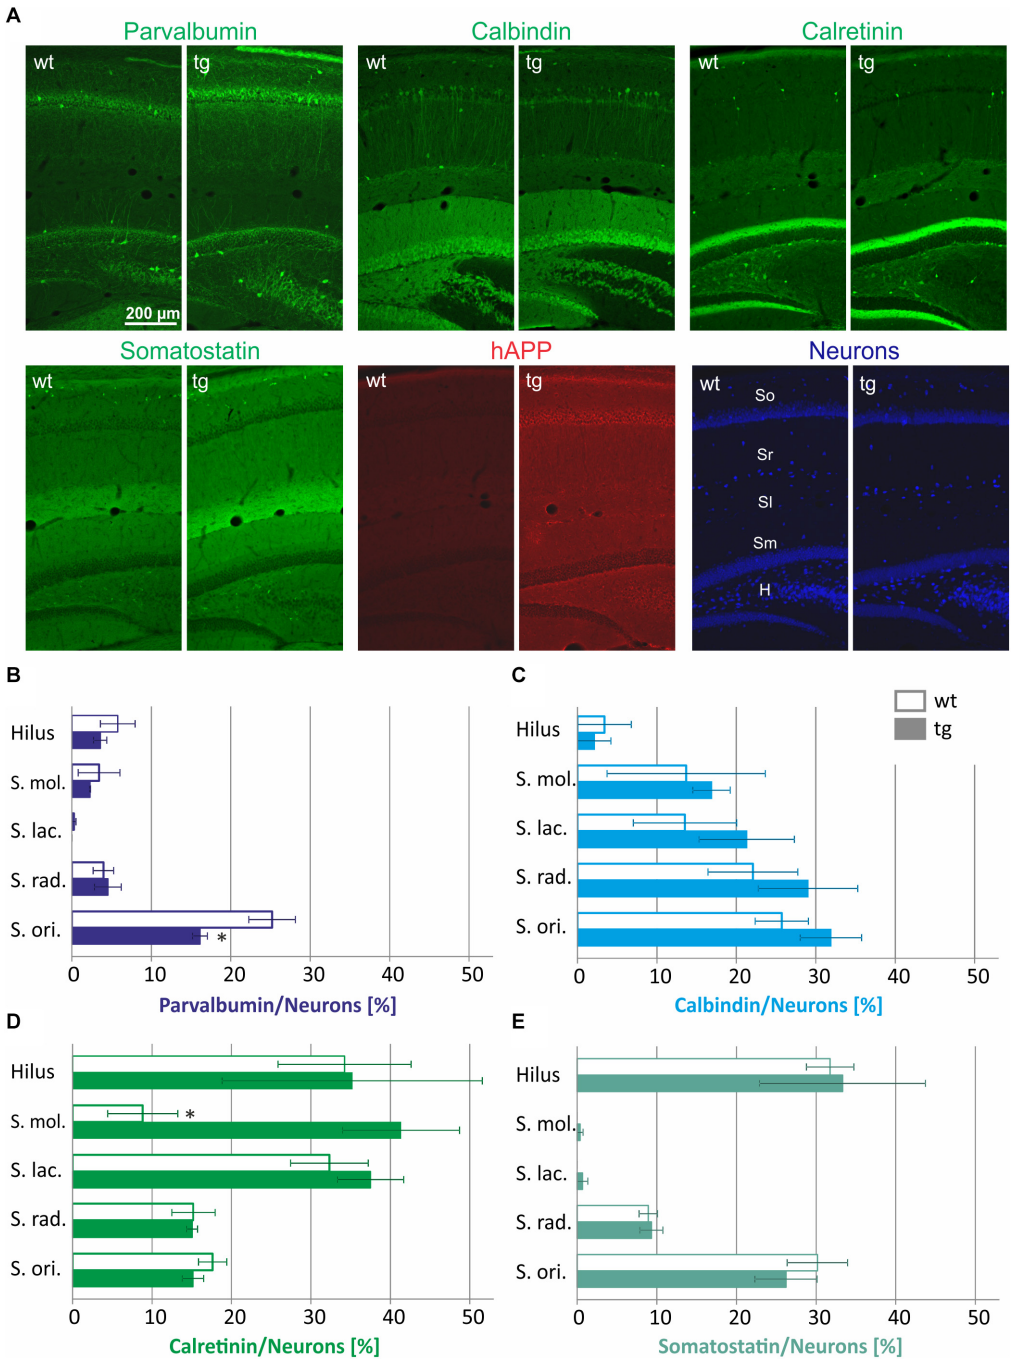

FIGURE 1 | Quantification of interneuron numbers in hippocampal layers of wild type (wt) and hAPP-transgenic Tg2576 mice (tg). In panel **(A)** typical staining patterns of parvalbumin-, calbindin-, calretinin-, somatostatin-, and hAPP-immunoreactive neurons are depicted in wt and tg mouse hippocampus. Note the similar labeling intensity in wt and tg brain sections for all antigens except hAPP. The hippocampal layers analyzed are indicated in the wt pan-neuronal labeling image (Neurons). In panels **B–E**, the proportions of parvalbumin-, calbindin-, calretinin-, and somatostatin-positive neurons in hippocampal layers of wt and tg mice are quantified. Total neuronal numbers in each layer (hilus 69.8 ± 2.8; S. mol 48.2 ± 6.7; S. lac. 68.5 ± 8.5; S. rad. 407.2 ± 49.0; S. ori. 269.5 ± 13.0) were set to 100%. Note the similar interneuron proportions in wt and tg hippocampus for most data analyzed. *significantly different from wild type ($p < 0.05$; unpaired t test).

oriens and approximately 40% in *stratum moleculare*, *stratum lacunosum moleculare*, and *stratum radiatum*, whereas less than 5% of calbindin-positive neurons in the hilus of DG expressed hAPP (**Figure 3C**).

The immunohistochemical co-localization of calretinin and hAPP in *stratum radiatum* is shown in **Figure 4A**. The highest proportion of hAPP expressing neurons that was positive for *calretinin* was detected in the hilus of DG (18%), followed

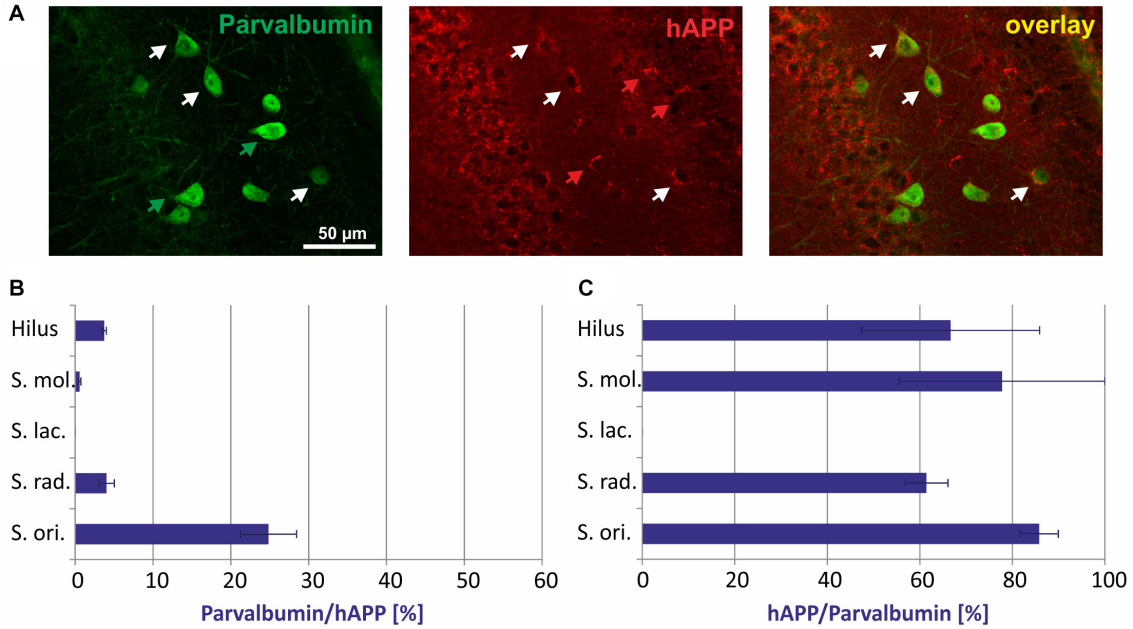

FIGURE 2 | Quantitative analyses of the co-localization between parvalbumin-immunoreactive neurons and hAPP-expressing interneurons in hippocampus of Tg2576 mice. Typical examples of double labelings in *stratum oriens* are shown in panel **(A)**. White arrows point to double-labeled neurons, green, and red arrows to neurons that are only labeled by green (parvalbumin) and red (hAPP) fluorescence, respectively. Quantitative analysis revealed that of all hAPP transgene-expressing interneurons 0% (in *stratum lacunosum moleculare*) to 25% (in *stratum oriens*) were parvalbumin-immunoreactive **(B)**. Of all parvalbumin-expressing neurons, 60 to 80% expressed the hAPP transgene in hilus of DG, *stratum moleculare*, *stratum radiatum*, and *stratum oriens* **(C)**.

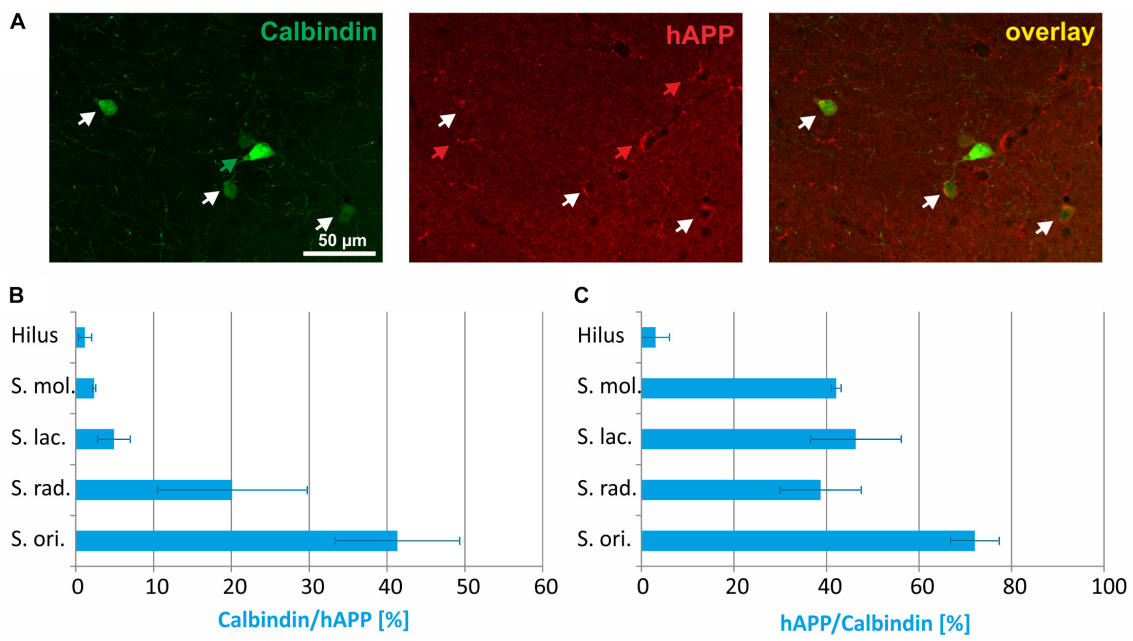

FIGURE 3 | Quantitative analyses of the co-localization between calbindin-immunoreactive neurons and hAPP-expressing interneurons in hippocampus of Tg2576 mice. Typical examples of double labelings in *stratum radiatum* are shown in panel **(A)**. White arrows point to double-labeled neurons, green, and red arrows to neurons that are only labeled by green (calbindin) and red (hAPP) fluorescence, respectively. Quantitative analysis revealed that of all hAPP transgene-expressing interneurons 2% (in DG hilus) to 42% (in *stratum oriens*) were calbindin-immunoreactive **(B)**. Of all calbindin-expressing neurons, 5 to 70% expressed the hAPP transgene **(C)**.

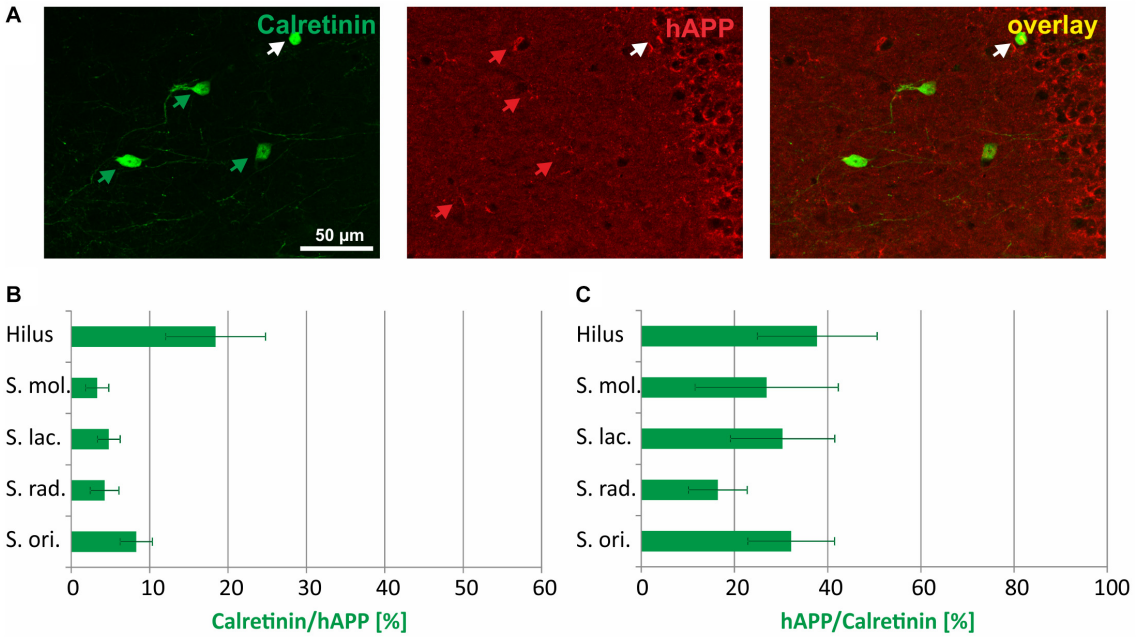

FIGURE 4 | Quantitative analyses of the co-localization between calretinin-immunoreactive neurons and hAPP-expressing interneurons in hippocampus of Tg2576 mice. Typical examples of double labelings in *stratum radiatum* are shown in panel **(A)**. White arrows point to double-labeled neurons, green, and red arrows to neurons that are only labeled by green (calretinin) and red (hAPP) fluorescence, respectively. Quantitative analysis revealed that of all hAPP transgene-expressing interneurons 4% (in *stratum moleculare*) to 18% (in DG hilus) were calretinin-immunoreactive **(B)**. Of all calretinin-expressing neurons, 18 to 38% expressed the hAPP transgene in defined hippocampal layers **(C)**.

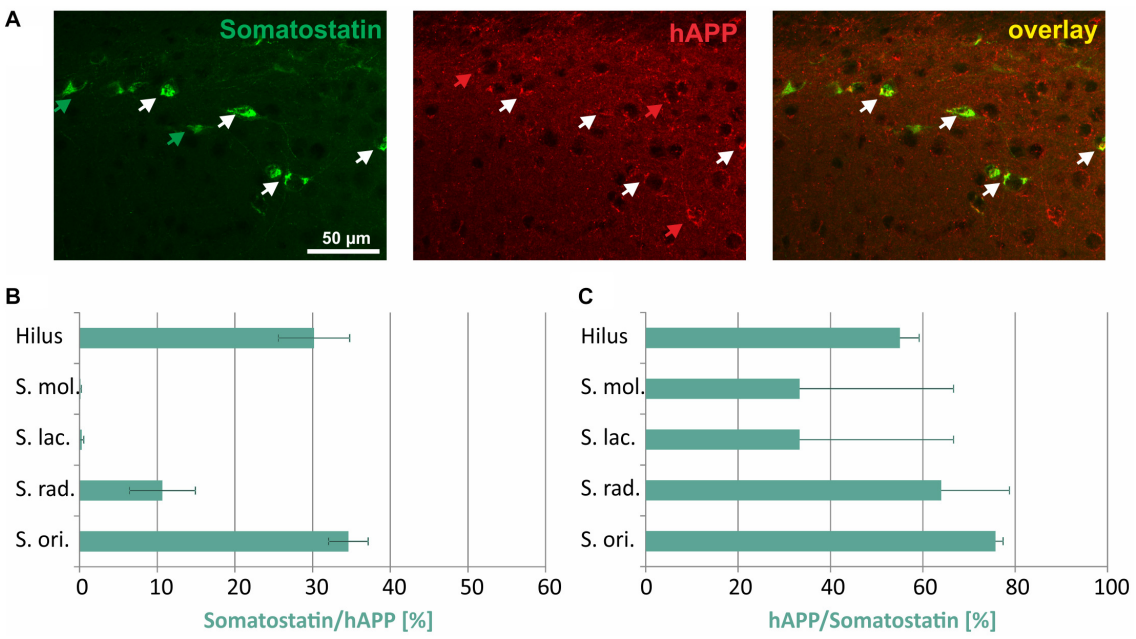

FIGURE 5 | Quantitative analyses of the co-localization between somatostatin-immunoreactive neurons and hAPP-expressing interneurons in hippocampus of Tg2576 mice. Typical examples of double labelings in *stratum oriens* are shown in panel **(A)**. White arrows point to double-labeled neurons, green, and red arrows to neurons that are only labeled by green (somatostatin) and red (hAPP) fluorescence, respectively. Quantitative analysis revealed that of all hAPP transgene-expressing interneurons 1 to 2% in *stratum moleculare* and *stratum lacunosum moleculare* to approximately 30% (in DG hilus and *stratum oriens*) were somatostatin-immunoreactive **(B)**. Of all somatostatin-expressing neurons, 30 to 76% expressed the hAPP transgene in all hippocampal layers **(C)**.

by *stratum oriens* (8%), *stratum lacunosum moleculare* (6%), *stratum radiatum* (5%), and *stratum moleculare* (4%) (**Figure 4B**). Across hippocampal layers, the proportion of calretinin-positive neurons expressing the hAPP transgene was rather homogenous, reaching 30 to 40% in hilus, and *stratum moleculare* of DG as well as *stratum lacunosum moleculare* and *stratum oriens* and 16% in *stratum radiatum* of hippocampus proper (**Figure 4C**).

In **Figure 5A**, typical examples of somatostatin/hAPP double immunofluorescent labelings in *stratum oriens* are displayed. Of all hAPP-positive neurons 30% in hilus of DG and 35% in *stratum oriens* were immunoreactive for *somatostatin*, whereas only 10% of hAPP-expressing neurons in *stratum radiatum* and 2% in *stratum moleculare* and in *stratum lacunosum moleculare* displayed somatostatin immunoreactivity (**Figure 5B**). In all hippocampal layers the proportion of somatostatin expressing neurons which was positive for the hAPP transgene was at least 25% (*stratum moleculare*, *stratum lacunosum moleculare*) and reached around 60% in hilus of DG and *stratum radiatum*, respectively, and 76% in *stratum oriens* (**Figure 5C**).

For a general overview, the proportions of hAPP-positive neurons expressing parvalbumin, calbindin, calretinin, and somatostatin across hippocampal layers are displayed in **Table 1** and the proportions of total parvalbumin-, calbindin-, calretinin-, and somatostatin-positive neurons expressing hAPP are given in **Table 2**.

When the proportion of hAPP-positive hippocampal interneurons co-expressing parvalbumin, calbindin, calretinin, and somatostatin is summed up in individual hippocampal layers, clear differences in hAPP transgene expression by these GABAergic interneurons can be established. In *stratum oriens*, the highest proportion of hAPP-expressing neurons was found to be immunoreactive for the interneuron markers tested (**Figure 6**). Among the hAPP-positive neurons in *stratum oriens*, most were immunoreactive for calbindin and somatostatin, respectively, followed by parvalbumin and calretinin (**Figure 6**). In contrast, in *stratum moleculare* and in *stratum lacunosum* moleculare less than 10% of hAPP-positive neurons expressed one of the markers investigated. Among those, most were immunoreactive for calbindin and calretinin but almost none for parvalbumin and somatostatin (**Figure 6**). In *stratum radiatum*, all four interneuron populations contributed to a total 40% of hAPP-expressing neurons, with calbindin and somatostatin-positive neurons having the biggest impact.

Thus, in defined hippocampal layers there are robust differences in CBP and somatostatin expression by hAPP-positive neurons ranging from 10% in *stratum moleculare* and *stratum lacunosum moleculare* to 100% in *stratum oriens*. Additionally, the proportion of specific GABAergic interneuron subtypes varies considerably in hippocampal layers with a large population of parvalbumin-positive hAPP neurons in *stratum oriens*, calbindin-positive hAPP neurons in *stratum oriens* and *stratum radiatum*, calretinin-positive hAPP neurons in hilus of DG and somatostatin-positive hAPP neurons in *stratum oriens* as well as in hilus of DG. It remains an open question why the promoter driving transgene expression is only active in a subset of the hippocampal interneuron populations investigated here. *Vice versa*, there is a high proportion of hAPP-positive neurons that does not express any of the interneuron markers studied; in particular in *stratum moleculare* and *stratum lacunosum moleculare*. These neurons apparently are subpopulations of hippocampal interneurons other than the ones depicted by CBP and somatostatin immunoreactivity. They might be distinguished based on different characteristics like morphology, wiring and neurochemical properties such as expression of neuropeptides, enzymes and receptors.

DISCUSSION

Many experimental studies using APP-transgenic AD animal models suffer from a lack of information on the distinct brain region and cell type-specific transgene expression patterns. These data are, however, the pre-requisite to understand pathogenic mechanisms on the subcellular, cellular, neuronal network and systemic level and to allow comparison of experimental outcome obtained from different transgenic mouse lines. Our data presented here indicate that defined interneuron populations in hippocampus expressing transgenic hAPP to different extents may selectively contribute to aspects of pathological disturbances and learning and memory deficits well before amyloid plaque pathology in Tg2576 mice. We decided to analyze young Tg2576 mice before the onset of amyloid pathology for hAPP expression because in older mice the affected neurons may have degenerated and thus escaped quantification.

Parvalbumin

In CA1 of hippocampal slices of 6- to 7-month-old Tg2576 mice LTP was found to be impaired, but restored in Tg2576 mice aged 14 to 19 months (Huh et al., 2016). The authors explained these findings with the selective loss of inhibitory

TABLE 2 | Proportions of parvalbumin-, calbindin-, calretinin-, and somatostatin-positive neurons expressing hAPP.

	Hilus	S. mol.	S. lac.	S. rad.	S. ori.
			% mean ± SEM		
hAPP/parvalbumin	66.7 ± 19.2	77.8 ± 22.2	0	61.5 ± 4.7	85.8 ± 4.1
hAPP/calbindin	3.0 ± 3.0	42.1 ± 1.1	46.3 ± 9.8	38.7 ± 8.8	72.1 ± 5.3
hAPP/calretinin	37.7 ± 12.9	26.9 ± 15.4	30.3 ± 11.2	16.4 ± 6.3	32.2 ± 9.3
hAPP/somatostatin	55.1 ± 4.2	33.3 ± 33.3	33.3 ± 33.3	64.0 ± 14.7	75.7 ± 1.6

S. mol., stratum moleculare; S. lac., stratum lacunosum moleculare; S. rad., stratum radiatum; S. ori., stratum oriens.

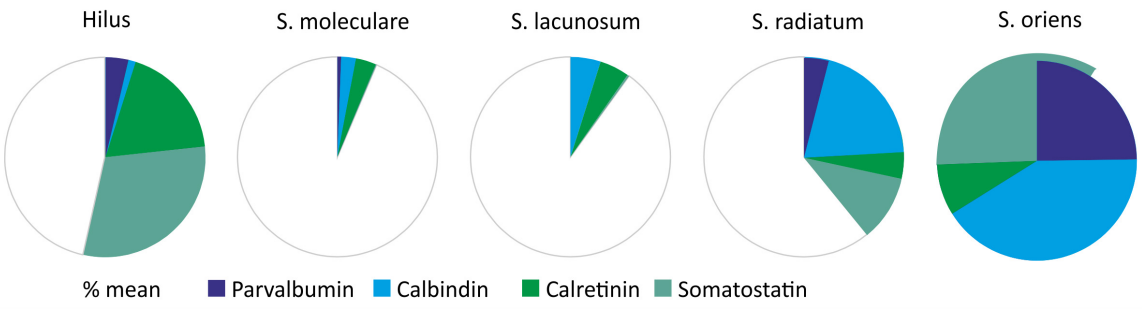

FIGURE 6 | In this Figure, the proportion of hAPP-positive hippocampal interneurons co-expressing parvalbumin, calbindin, calretinin, and somatostatin is summed up in individual hippocampal layers. In *stratum moleculare* and *stratum lacunosum moleculare* less than 10% of all hAPP-expressing neurons are immunoreactive for the four interneuron markers analyzed, whereas in *stratum radiatum* and DG hilus 40 to 50%, and in *stratum oriens* all hAPP-immunoreactive neurons are positive for these interneuron markers. Additionally, the contribution of individual interneuron types to the hAPP-expressing population varies considerably in hippocampal layers as indicated by the respective color.

parvalbumin-positive neurons in hippocampus during aging, which resulted in enhanced excitatory signaling (Huh et al., 2016). This notion is supported by findings on the critical role of parvalbumin interneurons for the down regulation of LTP at Schaffer collateral-CA1 synapses (Chen et al., 2010). Using resting-state functional MRI to assess brain functional connectivity in Tg2576 mice, network hypersynchrony was detected in hippocampus of 3- to 5-month-old Tg2576 mice but an age-dependent reduction in hippocampal functional connectivity was revealed in 8- and 18-month-old Tg2576 mice (Shah et al., 2016). Interestingly, in another hAPP-transgenic mouse model spontaneous epileptiform discharges induced by network hypersynchrony were attributed to impaired function of parvalbumin neurons (Verret et al., 2012). Our data suggest that hAPP transgene expression by parvalbumin-positive hippocampal GABAergic interneurons may contribute to the described impairments of neuronal network activity, LTP and, subsequently, hippocampus-dependent spatial learning. Moreover, Abeta deposits in old Tg2576 mice appear primarily in *strata oriens*, *lacunosum moleculare* and *moleculare* (Hartlage-Rübsamen et al., 2011), indicating a contribution of transgene expression by these neuronal populations to Abeta pathology. Similar conclusions have been drawn in a study using APP/PS1 mice, where reductions in parvalbumin, calbindin, and calretinin immunoreactivity in DG were more pronounced at Bregma levels with high Abeta plaque load than at Bregma levels with low plaque load (Popović et al., 2008).

Calbindin

The population of calbindin-immunoreactive neurons was demonstrated to be stable during aging in hippocampus of wild type mice between 3 and 18 months (Krezymon et al., 2013). In male Tg2576 mice, however, there was an age-dependent decline of calbindin immunoreactivity in the DG molecular layer resulting in significantly reduced calbindin immunoreactivity of 12- and 18-month-old Tg2576 mice compared to wild type mice. Preceding these changes in DG calbindin immunoreactivity, severe disturbances in hippocampal neurogenesis of Tg2576 mice were observed which compromised functional integration of new neurons into hippocampal circuits (Krezymon et al., 2013). Implications for a disturbed hippocampal neurogenesis were also obtained in the APPswe/PS1dE9 transgenic mouse model by reduced numbers of calretinin-positive and doublecortin-positive neurons in the subgranular zone of the DG hilus compared to wild type mice (Verdaguer et al., 2015). Moreover, in $hAPP_{FAD}$ mice, learning deficits correlated strongly with decreased levels of calbindin in the DG (Palop et al., 2003) and epigenetic suppression of hippocampal calbindin results in disturbance of spatial memory, whereas restoring calbindin expression in these mice improves performance in spatial memory (You et al., 2017).

Calretinin

In contrast to the high vulnerability of hippocampal calbindin-positive neurons in the human AD brain and its animal models, calretinin-positive fibers in proximity of Abeta plaques were shown to be less affected by dystrophic morphology than neurites containing neurofilament-triplet proteins in Tg2576 and APPswe/PS1dE9 mice and human AD affected brains (Mitew et al., 2013). However, the number of calretinin-positive interneurons is profoundly decreased in CA1 and CA2/3 hippocampal subfields of APP/PS1 mice at a very early stage of pathology, whereas hippocampal calretinin neurons belonging to the Caja-Retzius cells were not affected (Baglietto-Vargas et al., 2010). Interestingly, the early and selective calretinin cell loss preferentially occurred in parallel to the appearance of Abeta deposits in axonal terminal fields of these neurons (Baglietto-Vargas et al., 2010). Thus, the calretinin-positive population of hippocampal interneurons appears to be differentially affected by Abeta pathology.

Somatostatin

In addition to CBP-positive interneurons, a subpopulation of GABAergic hippocampal interneurons expressing the peptide hormone somatostatin has been demonstrated to be critically involved in learning and memory processes (Lovett-Barron et al., 2014), most likely by providing feedback inhibition to CA1

pyramidal neurons (Royer et al., 2012). In hippocampus of APP/PS1-transgenic mice, an early and substantial reduction of somatostatin-positive neurons, which correlated with Abeta pathology, was observed in hippocampal subfields CA1, CA2/3, and in DG (Ramos et al., 2006). The dysfunction of these neurons in APP/PS1 mice was shown to be associated with memory deficits (Schmid et al., 2016). Also in Tg2576 mice a significant reduction in the number of somatostatin-positive interneurons in *stratum oriens* of CA1 was reported and related to impairments of performance in contextual fear and spatial memory tasks (Perez-Cruz et al., 2011). Another line of evidence for the importance of somatostatin-positive hippocampal interneuron function for learning processes arises from pharmacological studies using somatostatin receptor 4 agonists (Sandoval et al., 2013). When Tg2576 mice were treated with the selective somatostatin receptor 4 agonist NNC 26-9100, learning improvements and reductions in oligomeric Abeta concentrations were observed (Sandoval et al., 2013).

Relation to AD

The presented data are relevant to the understanding of different aspects of synaptic, neuronal and network dysfunction in hippocampus of young and aged Tg2576 mice as well as systemic deficits in learning and memory and the contribution of defined hippocampal GABAergic subpopulations to these pathogenic processes. However, no direct conclusions can be drawn with regard to the involvement of these neuronal populations in AD pathogenesis because a higher, or lower, proportion of these neurons may express varying amounts of APP and produce pathogenic Abeta assemblies. Nevertheless, in the APP/PS1 model, the reduction of the number of parvalbumin expressing neurons in the CA1/2 hippocampal sublayer and of calretinin-immunoreactive neurons in DG is at the same order of magnitude as in *post mortem* hippocampal tissue from AD subjects (Takahashi et al., 2010). Reductions in the number of hippocampal parvalbumin-immunoreactive neurons in AD were already reported by Brady and Mufson (1997). They observed an up to 60% decrease in the number of parvalbumin-positive neurons in CA1/2/4 and DG, but not in CA3, subiculum, or presubiculum. They concluded, that the selective vulnerability of subsets of hippocampal parvalbumin neurons in AD may be related to differential connectivity. Accordingly, DG and CA1 parvalbumin-positive neurons connected to the cerebral cortex would be more vulnerable than neurons located in the subiculum or presubiculum, respectively, which are connectionally related to subcortical areas (Brady and Mufson, 1997). Hippocampal calbindin-immunoreactive neurons, on the other hand, were reported to be spared from neurofibrillary tangle formation and appeared to be unaffected by Abeta pathology at early stages of AD, whereas this resistance is lost at advanced disease stages (Iritani et al., 2001). Calbindin immunoreactive neurons in DG were also reported to be differentially affected in AD and other neurodegenerative disorders (Stefanits et al., 2014). The proportion of calbindin-negative DG granule neurons was found to increase with Braak stage of AD and was significantly higher than in Creutzfeldt-Jakob disease, argyrophilic grain disease, frontotemporal lobar degeneration-TDP types A and B, but not compared to frontotemporal lobar degeneration-Tau Pick's disease type (Stefanits et al., 2014). Also in entorhinal cortex, a major source of DG innervation, a differential impact of AD pathology on neurons expressing CBPs was reported (Mikkonen et al., 1999). Non-principal cells containing parvalbumin or calbindin were affected at early disease stages, whereas non-principal neurons containing calretinin were more viable, even in AD cases with severe entorhinal pathology (Mikkonen et al., 1999).

Non-neuronal hAPP Expression

In a recent study we demonstrated that hAPP expression is not neuron-specific but also detectable in subsets of resting astrocytes in neocortex and corpus callosum of Tg2576 mice before the onset of amyloid plaque formation (Heiland et al., 2019). In hippocampus, the majority of hAPP immunoreactivity arises from neurons, but there is also hAPP immunoreactivity present in glial cells of astrocytic morphology [see filmstrip links provided in Heiland et al. (2019)]. Although the proportion of astrocytic hAPP expression is low, we cannot rule out an astrocytic contribution to impairments in spatial navigation, learning, memory, hippocampal LTP formation, and neuronal network activity induced by Abeta or C-terminal APP fragments. Also in human brain, non-neuronal expression of APP mRNA has been demonstrated and related to pathology (Golde et al., 1990).

CONCLUSION

In this study, hAPP transgene expression by different populations of GABAergic interneurons in defined hippocampal layers of Tg2576 mice was investigated for the first time. Our results partly explain disturbed hippocampus-dependent processes and functions such as LTP, neuronal network activity, learning and spatial memory and neurogenesis. Thus, the detailed analysis of transgene expression patterns allows revealing pathological mechanisms and obtaining novel insights in hAPP-dependent disturbances in brain. Technical aspects of transgenic animal generation such as transgene isoform and promoter selection, the genomic integration of the transgene, co-pathologies and compensatory mechanisms result in strikingly different transgene expression patterns in different mouse lines (Höfling et al., 2016). We, therefore, strongly recommend carefully analyzing and comparing transgene expression patterns in different mouse lines used as animal models to mimic amyloid pathology of AD.

AUTHOR CONTRIBUTIONS

CH designed the study, carried out the experiments, analyzed the data, and drafted the manuscript. ES carried out the experiments and analyzed the data. P-HK and SL participated in designing the experiments and drafted the manuscript. MH-R designed the study, analyzed the data, and drafted the manuscript.

SR conceived, designed and coordinated the study and drafted the manuscript. All authors gave final approval for publication.

FUNDING

This work was supported by the German Federal Department of Education, Science and Technology, BMBF (grant #01ED1501B to SR) within the European Union Joint Program for Neurodegenerative Disease (JPND) Research, Project CrossSeeds, and by the Alzheimer Forschungsinitiative e.V. (AFI #16004) to SR as well as by the Centers of Excellence in Neurodegeneration program and the Helmholtz-Israel program to SL.

ACKNOWLEDGMENTS

We are grateful to Karen Hsiao-Ashe for providing Tg2576 mouse breeders. We acknowledge support from the German Research Foundation (DFG) and Leipzig University within the program of Open Access Publishing.

Mutations in the *PARKIN* gene cause early-onset Parkinson's disease (PD). Despite the high proportion of still missing phenotyping data in the literature devoted to early-onset PD, studies suggest that, as compared with late-onset PD, *PARKIN* patients show dystonia at onset and extremely dose-sensitive levodopa-induced dyskinesia (LID). What pathophysiological mechanisms underpin such early and atypical dyskinesia in patients with *PARKIN* mutations? Though the precise mechanisms underlying dystonia and LID are still unclear, evidence suggests that hyperkinetic disorders in PD are a behavioral expression of maladaptive functional and morphological changes at corticostriatal synapses induced by long-term dopamine (DA) depletion. However, since the dyskinesia in *PARKIN* patients can also be present at onset, other mechanisms beside the well-established DA depletion may play a role in the development of dyskinesia in these patients. Because cortical and striatal neurons express parkin protein, and parkin modulates the function of ionotropic glutamatergic receptors (iGluRs), an intriguing explanation may rest on the potential role of parkin in directly controlling the glutamatergic corticostriatal synapse transmission. We discuss the novel theory that loss of parkin function can dysregulate transmission at the corticostriatal synapses where they cause early maladaptive changes that co-occur with the changes stemming from DA loss. This hypothesis suggests an early striatal synaptopathy; it could lay the groundwork for pharmacological treatment of dyskinesias and LID in patients with *PARKIN* mutations.

INTRODUCTION

Loss of function mutations in the *PARKIN* gene cause autosomal recessive juvenile parkinsonism (ARJP) (Kitada et al., 1998). Autopsy studies have shown that neuropathological changes in patients with *PARKIN* mutations differ from those observed in idiopathic Parkinson's disease (iPD). Unlike iPD, neuronal loss is greater in the substantia nigra pars compacta (SNpc) than in the locus coeruleus in most parkin cases. Also, Lewy bodies are not detected in the majority of parkin cases, suggesting a difference in the pathogenic processes between *PARKIN*-related disease and iPD

(Schneider and Alcalay, 2017). Also, *PARKIN*-associated, early-onset PD is phenotypically distinct from iPD. Recent reviews in the clinical literature on genetic PD have pointed to the lack of a detailed description of individual phenotypic features (Kasten et al., 2017, 2018). Evidence suggests, however, that unlike late-onset PD patients, parkin patients display dystonia at early disease stages and dyskinesia at exceedingly low dosages of levodopa (Wickremaratchi et al., 2011). Early dystonia and dyskinesia are also reported in other early-onset genetic forms of PD such as *PINK1* and *DJ1* (Lohmann et al., 2009). Since *PARKIN* mutations account for about three-quarters of PD cases with an age at onset of 30 years or younger, understanding the pathophysiological mechanisms that underlie early and atypical dystonia and dyskinesia in *PARKIN* patients is a key step toward achieving a more personalized treatment for this genetic condition and toward understanding the biological basis of this phenomena in other early-onset genetic forms of PD.

Here, we review the clinical evidence for early hyperkinetic symptoms in patients with *PARKIN* mutations and the recent evidence that parkin modulates glutamatergic neurotransmission. We discuss the hypothesis that early hyperkinetic symptoms of PD patients with *PARKIN* mutation may be considered manifestations of corticostriatal synaptopathy. These features can be linked to dopamine depletion, a well-recognized mechanism in the literature, but they also may be related to a potential direct effect of parkin on the corticostriatal synapse.

CLINICAL EVIDENCE FOR DYSTONIA AND DYSKINESIA IN PARKIN PATIENTS

Since the first description of juvenile parkinsonism caused by mutations of the *PARKIN* gene in two families (Kitada et al., 1998), dystonia has been proposed as a clinical hallmark of the disease (Schrag and Schott, 2006). Recent literature reviews have reported that an overall, clinically typical form of PD with early onset, slow progression, and excellent response to levodopa treatment is frequently associated with dystonia and dyskinesia in patients with *PARKIN* mutations (Grünewald et al., 2013; Kasten et al., 2018). Usually independent of levodopa intake, dystonia is described as the presenting symptom in a large percentage of *PARKIN* patients in whom it can be present in isolation for years before the appearance of parkinsonism (Khan et al., 2003). The reported phenotypic overlap between PD patients with *PARKIN* mutation and rare forms of dystonia-parkinsonism, such as levodopa-responsive dystonia (DRD), prompts screening for *PARKIN* mutations along with *GTP cyclohydrolase* 1 and *tyrosine hydroxylase* in clinically diagnosed DRD patients (Tassin et al., 2000; Wu et al., 2005, 2008; Schneider and Bhatia, 2010; Potulska-Chromik et al., 2017). To determine whether dystonia contributes to gait abnormalities in patients with *PARKIN* mutations, a recent study used a clinical computerized video motion analysis system to evaluate lower limb dystonia severity in 15 patients. Lower limb dystonia occurred in most *PARKIN* patients who displayed a specific, abnormal gait pattern that differed from the patterns observed in healthy controls independent of the OFF/ON state (Castagna et al., 2016).

In addition to dystonia, *PARKIN* patients show dyskinesia at exceedingly low dosages of levodopa as compared with late-onset PD patients. On average, the response to low doses of levodopa is reported as being excellent and sustained. However, the likelihood of developing LID is reportedly higher than in individuals with parkinsonism resulting from other aetiologies (Brüggemann and Klein, 1993; Paviour et al., 2004) and it is inducible by very-low-dose levodopa in some cases (Khan et al., 2003). While bradykinesia responds well even to low levodopa dosages in *PARKIN* patients, the same low doses seem to exacerbate dystonia already in very early stages of the disease. Although conflicting results have also been reported (Kasten et al., 2018), the present evidence suggests that the incidence of hyperkinetic disorders at earlier disease stages is higher in *PARKIN* patients than in those with iPD.

POTENTIAL MOLECULAR MECHANISMS UNDERLYING DYSTONIA AND DYSKINESIA

The precise mechanisms underlying dystonia and LID in PD are unknown. Studies on PD animal models, mainly dopamine-depleted animals, and PD patients strongly suggest that dyskinesia results from dysfunction of glutamatergic transmission from the cortex to the striatal medium spiny neurons (MSNs) (Picconi et al., 2017). MSNs are characterized by radially projecting dendrites densely studded with spines and receiving excitatory glutamatergic inputs from the cerebral cortex which form in the order of 5000 contacts per neuron (Graveland et al., 1985; David Smith and Paul Bolam, 1990; Yelnik et al., 1991). The dendritic spines bear the asymmetrical glutamatergic synapse on the head and the symmetric dopaminergic synapses on the neck (**Figure 1A**; David Smith and Paul Bolam, 1990). This characteristic synaptic triad boosted the widely accepted theory that dopamine (DA) physiologically modulates the strength of cortical inputs to the MSNs (Gerfen and Surmeier, 2011) and that long-term DA depletion occurring over the course of idiopathic PD triggers prominent secondary changes in the corticostriatal synapses (Picconi et al., 2017). Indeed, DA depletion leads to strong sensitization of post-synaptic D1 receptors, which is critical for the development of dyskinesia (Darmopil et al., 2009), and induces a variety of molecular changes in the downstream signaling pathways, including an increase in the state of phosphorylation of the DA- and cAMP-regulated phosphoprotein of 32 KDa (DARPP-32) (Santini et al., 2007; Heumann et al., 2014; Ruiz-Dediego et al., 2015; Solís et al., 2017). DARPP-32 phosphorylation promotes a cascade of intracellular events in MSNs: activation of extracellular signal-regulated kinase 1 and 2 (ERK1 and 2) and, as a consequence, activation of the ERK and the mammalian target of rapamycin complex 1 (mTORC1) signaling pathways (Santini et al., 2012; Heumann et al., 2014).

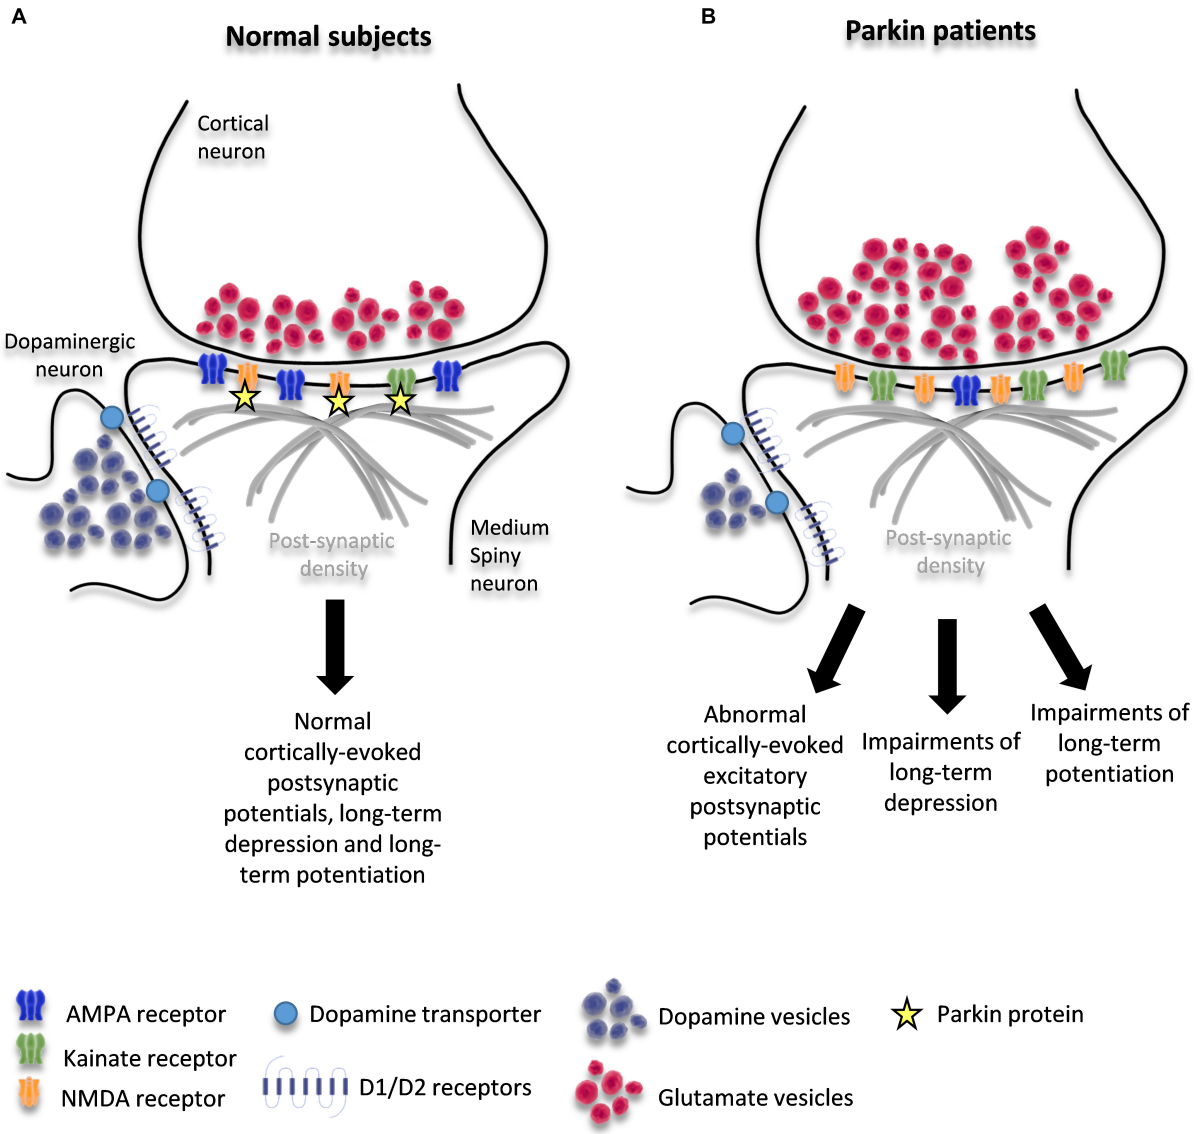

FIGURE 1 | Schematic diagram of corticostriatal synapse in healthy condition **(A)** and in patients with *PARKIN* mutations **(B)**. The figure shows the interaction of parkin with KAR and NMDAR and potential changes induced by loss of *PARKIN* function.

The molecular signatures that have recently emerged as key signals in LIDs are ERK1/2 phosphorylation (Pavón et al., 2006), abnormal activation of mitogen- and stress-activated protein kinase-1 (MSK-1), and phosphorylation of histone H3 (Santini et al., 2007; Heumann et al., 2014). The final result of this chain of events is a change in the molecular make-up of MSNs due to alterations in gene expression and protein synthesis that might account for maladaptive morphological plasticity at the corticostriatal synapse (Picconi et al., 2017). Morphological examination of MSNs in dopamine-depleted animals and in autopsy specimens from iPD patients has revealed dendrite atrophy, truncated dendrites, and decreased spine density (Stephens et al., 2005; Zaja-Milatovic et al., 2005; Suarez et al., 2016). These functional and morphological changes in the corticostriatal synapses are believed to result in dyskinesias (Picconi et al., 2017).

The question arises as to whether the same molecular mechanisms underlie the early and atypical dyskinesia displayed by *PARKIN* patients. Clinical studies with [18F] Dopa as a marker of the functional integrity of pre-synaptic dopamine nerve terminals have shown that *Parkin* mutated patients have widespread pre-synaptic dopaminergic deficits (Scherfler et al., 2004). So while the early hyperkinetic symptoms in patients with parkin mutations can be linked to DA depletion, the appearance of dyskinesia in early disease stages, before the onset of typical and cardinal signs of parkinsonism, suggests that additional mechanisms may be involved. In particular, dyskinesia-related molecular changes in patients with

PARKIN mutation may partially stem from dysfunctions of the corticostriatal synapses due to the loss of parkin function in these synapses.

THE POTENTIAL ROLE OF PARKIN AT THE CORTICOSTRIATAL SYNAPSE

In vitro studies have revealed that parkin can localize at the pre-synapse, where it associates with the cytoplasmic surface of synaptic vesicles (Kubo et al., 2001; Mouatt-Prigent et al., 2004) and binds to synaptotagmin-11, a pre-synaptic protein involved in synaptic vesicle formation, docking, and recycling (Huynh et al., 2003; Wang et al., 2018). The loss of parkin function may inhibit endocytosis and the processes of vesicle replenishment and recycling, leading to as yet undefined changes in neurotransmitter release. Interestingly, the pre-synaptic functions of parkin resemble the function of synuclein, another key protein involved in PD pathogenesis and a regulator of pre-synapse size and synaptic vesicle pool organization (Anwar et al., 2011; Vargas et al., 2017), additionally, the roles of other PD genes such as *DNAJC6*, *SYNJ1*, *SH3GL2, LRRK2*, and *VPS35* in the regulation of synaptic vesicle trafficking SVE are beginning to emerge (Nguyen et al., 2018).

In vitro studies on glutamatergic neurons showed that parkin can also localize at the post-synapse, where it directly modulates ionotropic glutamate receptor function. Parkin directly interacts with and ubiquitinates the GluK2 subunit of kainate receptor (KAR) and thus regulates its function: loss of parkin increases KAR levels in the human cortex and KAR function in glutamatergic hippocampal neurons *in vitro* (Maraschi et al., 2014). At the post-synapse, loss of parkin function probably leads to dysregulation of other neurotransmitter receptors as well: a study on brain tissues from parkin knockout mice showed up-regulation of KAR density, increased NMDA receptor density, and reduced AMPA receptor density throughout various brain regions (Cremer et al., 2015). The role of parkin in modulating AMPA receptors was further confirmed in an *in vitro* study showing that parkin-deficient hippocampal neurons exhibit significantly reduced AMPA receptor-mediated currents (Cortese et al., 2016). The suggested underlying mechanism is the decrease in the post-synaptic expression of the adaptor protein Homer1, which is necessary for coupling AMPAR endocytic zones with post-synaptic density. A more recent study evaluated the impact of four parkin point mutations on glutamatergic synaptic function in hippocampal neurons and found that these mutants alter NMDA and AMPA receptor-mediated currents and cell-surface levels and that they prevent the induction of long-term depression. The study demonstrated that parkin regulates NMDA receptor trafficking through ubiquitination of the subunit GluN1 and that the mutations impair ubiquitination activity (Zhu et al., 2018). Hence, the bulk of evidence strongly suggests that *PARKIN* mutations disturb glutamatergic synaptic transmission by directly changing NMDAR, AMPAR, and KAR receptor function. Since parkin is widely expressed in various brain regions and neuron types, including cortical neurons and MSNs, (Kitada et al., 1998; Stichel et al., 2000) it is conceivable that the loss of parkin directly induces pathological effects on these neurons and contributes to the pathophysiology of dyskinesia.

These studies on the localization of parkin and its capacity to directly regulate excitatory transmission constitute an important step toward understanding the functions of parkin at the synapses (Sassone et al., 2017). The complementary approach was to investigate the function of nigrostriatal and corticostriatal synapses in murine models knockout for *Parkin* gene. Unfortunately, studies on the nigrostriatal pathway revealed many discrepancies probably deriving from different experimental conditions and/or from *in vivo* age-dependent compensatory mechanisms. Increased spontaneous DA release from SNc DA neurons was found in *Parkin*-knockout mice aged 8 to 9 months (Goldberg et al., 2003). Decreased evoked DA release was found in 3-to-9-month-old *Parkin* knockout mice (Oyama et al., 2010). In the striatum of 22-month-old wild-type and *Parkin*-knockout mice, DA levels were reported to be indistinguishable (Perez and Palmiter, 2005). DA overflow in striatal slices from 6-to-8-week-old mice was found to be equal between wild-type and *Parkin*-knockout mice (Sanchez et al., 2014). Indeed, not all the evidence supports the idea that DA release is impaired in the nigrostriatal pathway of *Parkin*-knockout mice. Studies on corticostriatal synapses performed by intracellular recordings of MSNs revealed impairment in long-term depression and long-term potentiation in *Parkin*-knockout mice (Kitada et al., 2009). These results suggest that parkin is involved in the regulation of striatal synaptic plasticity. Unfortunately, however, *Parkin*-knockout mice do not show DA neuron loss, motor impairment, dystonic phenotype or hypersensitivity to levodopa (Perez and Palmiter, 2005). The authors suggest that this murine model may represent a tool to study the early stages of the disease (Dawson et al., 2010); nonetheless, its usefulness as a disease model is limited and complicates the interpretation of the results obtained on these mice. More promising results come from studies on dopaminergic neurons differentiated from induced human pluripotent stem cells. When glutamatergic transmission was studied in a mixed population of GABAergic, glutamatergic, and dopaminergic neurons differentiated from induced human pluripotent stem cells, *PARKIN* mutations were observed to potentiate glutamatergic transmission by modifying synaptic vesicle function at the pre-synaptic site of the corticostriatal synapse (Zhong et al., 2017). Moreover, the actions of dopamine on D1-class receptors were noted to be markedly altered in dopaminergic neurons differentiated from induced human pluripotent stem cells of PD patients with *PARKIN* mutations. In particular, as compared with control neurons, the parkin-deficient neurons had a stronger response to the activation of D1-class dopamine receptors (Zhong et al., 2017).

This raises the possibility that parkin could be involved in D1 receptor hypersensitization after dopaminergic denervation, an important mechanism underlying the dyskinesia in iPD (Heumann et al., 2014). Accordingly, a recent paper showed that parkin ubiquitinates and regulates the levels of STEP61, the striatal enriched protein tyrosine phosphatase, whereas clinically relevant parkin mutants fail to do so. Because STEP61 substrates include ERK1/2, it is conceivable that a parkin-induced

increase in STEP61 might influence D1 signaling in MSNs (Kurup et al., 2015).

Taken together, these findings suggest that parkin orchestrates a complex remodeling of corticostriatal synapses through multiple mechanisms. These mechanisms are likely to include changes due to DA depletion as well as those due to loss of parkin function at these synapses: alterations in the trafficking of glutamate vesicles at the glutamatergic pre-synapse and/or dysregulation of glutamate receptor levels on MSNs and/or dysregulation of D1-signaling. These mechanisms may be responsible for the precocious maladaptive plasticity of the corticostriatal synapses that leads to early dyskinesia (**Figure 1B**).

CONCLUSION

Since the parkin protein modulates glutamatergic receptor function and possibly glutamate release as well, it is conceivable that *PARKIN* mutation affects corticostriatal transmission, leading to early maladaptive changes in this glutamatergic synapse. This alteration could produce changes due to corticostriatal-induced depletion of DA at the synapses. What does this scenario imply for the development of specific and effective treatments? The only currently available drug for symptomatic treatment of dyskinesia is amantadine, an antiviral agent introduced in the early 1970s that also displays NMDA receptor antagonism (Hubsher et al., 2012). With a better understanding of the mechanisms by which parkin causes early dystonia and dyskinesia, researchers may be able to identify novel therapeutic targets and develop strategies that include drugs that act on the glutamatergic system. Such drugs are already under investigation for treating dyskinesias in iPD (Müller, 2017). Moreover, if our hypothesis proves true, the distinct molecular mechanisms underlying dyskinesia between *PARKIN* patients and late-onset PD patients could be relevant for devising precision medicine strategies for parkin patients. The recent discovery that LID is caused by a distinct and stable group of striatal neurons (Girasole et al., 2018) paves the way to further studies aimed at investigating the role of parkin in these neurons and at their corticostriatal synapse.

In conclusion, published data support the hypothesis of an early corticostriatal synaptopathy in parkin patients caused by parkin modulating the glutamatergic synapse. This hypothesis could provide a biological basis for studying the disease phenotype and lay the groundwork for the pharmacological treatment of PD patients with *PARKIN* mutation.

Aims: To investigate the relationship between clinical and imaging features of stroke patients with patent foramen ovale (PFO) and those with spontaneous intracranial artery dissection (SIAD).

Materials and methods: We retrospectively examined both clinical and imaging results of 40 stroke patients with PFO and 29 with SIAD. To reduce selection bias, we conducted a propensity score-matching analysis. The patients' propensity scores were estimated using a logistic regression model based on the following variables: age, sex, hypertension, diabetes mellitus, hypercholesterolemia, cigarette smoking, stroke histories, and their NIHSS scores. We compared the pattern of cerebral DWI lesions between patients with PFO and those with SIAD.

Results: After propensity score matching, 21 pairs of patients were selected. Clinical characteristics of the 2 groups were well matched. The distribution of DWI lesion patterns differed between the 2 groups. Single lesions (cortical or subcortical) were more frequently observed in the PFO group than in the SIAD group ($P = 0.026$). Multiple lesions in one vascular territory occurred more frequently in the SIAD group than in the PFO group ($P = 0.035$).

Conclusion: The present study suggests that lesion patterns observed from DWI of patients with PFO and SIAD might provide clues to the etiology of infarcts. Single lesions (cortical or subcortical) might be a typical feature of PFO associated strokes, while multiple lesions in one vascular territory might be a specific feature of SIAD associated strokes.

Keywords: patent foramen ovale, spontaneous intracranial artery dissection, ischemic stroke, embolism, DWI

INTRODUCTION

Both patent foramen ovale (PFO) and spontaneous intracranial artery dissection (SIAD) are important stroke risk factors, especially in young and middle-aged adults (1–3). About 25% of patients with ischemic stroke are cryptogenic (4), and PFO is present in ∼54% of patients with cryptogenic stroke under 54 yeas (5). PFO and SIAD might result in strokes through different mechanisms. Promptly identifying the difference in the underlying mechanisms among young and middle-aged stroke patients will facilitate selection of the best therapy for the primary disease and prevention of recurrent strokes.

A prior study has assessed brain Magnetic resonance imaging (MRI) features of stroke patients due to PFO and SIAD and found that, a single non-territorial infarct seemed to favor strokes due to PFO, whereas territorial infarcts (with or without additional smaller lesions in the same territory) were more likely to occur in patients with arterial dissection (6). However, this study did not individually compare between patients with carotid dissection, vertebral dissection, and those with PFO, respectively, though the former two types of patients had different mechanisms of stroke pathogenesis. In SIAD, spontaneous cervical artery dissection showed different clinical and imaging features from spontaneous vertebral artery dissection (7, 8). Artery-to-artery embolism and reduced blood flow due to the primary lesion are the two basic mechanisms with which spontaneous cervical artery dissection led to strokes (9, 10), whereas artery-to-artery embolism is considered to be the primary mechanism with which spontaneous vertebral artery dissection led to strokes (11, 12). Therefore, it might be more reliable to individually analyze the imaging characters of carotid dissection and vertebral dissection patients. The other thing to note is that the baseline data of some studies are not consistent with each other, which leads to systemic bias in data analysis and subsequently the findings from these studies are not trustworthy.

In the present study, we aimed to analyze the difference in imaging findings between stroke patients with PFO and those with carotid dissection or vertebral dissection through propensity analysis. Results from this study will facilitate the diagnosis of these diseases in stroke patients and initiate appropriate therapies.

MATERIALS AND METHODS

Subjects

Stroke patients with PFO and SIAD, admitted to the Department of Neurology and Neurosurgery, the First Affiliated Hospital of Wenzhou Medical University between August 2010 and June 2018, were included in the present retrospective study. This study was approved by the Human Ethics Committee of the First Affiliated Hospital of Wenzhou Medical University.

Inclusion criteria for stroke patients due to SIAD were: (1) definite angiographic findings of dissection in intracranial arteries; (2) presence of ischemic stroke lesions on Diffusion-weighted imaging (DWI); (3) according to the TOAST criteria, no definite causes had been identified apart from dissection after a standardized workup; (4) PFO was excluded by transesophageal echocardiography (TEE) and transcranial Doppler (TCD); (5) Spontaneous cervical artery dissection was diagnosed based on ≥1 of the following 3 criteria: (1) intimal flap visible on carotid ultrasound; (2) mural hematoma visible on MRI or CT; (3) a non-atherosclerotic, tapered, flame-shaped ICA-occlusion or a string-like ICA-stenosis (7). A total of 31 patients were diagnosed with SIAD, one patient was excluded due to absence of lesions on DWI, and another patient excluded due to an extracranial artery dissection. As a result, 29 patients were included in the "SIAD group."

Inclusion criteria for stroke patients with PFO were: (1) presence of ischemic stroke lesions on DWI; (2) according to the TOAST criteria, no definite causes had been identified apart from PFO after a standardized etiological workup; (3) evaluated with a standard stroke protocol including DWI sequence; (4) The presence of PFO was confirmed by transesophageal echocardiography (TEE) and the presence of right-to-left shunt was tested by transcranial Doppler (TCD) (13, 14). Forty two patients with PFO and no other definite stroke causes were chosen, but 2 were excluded due to absence of lesions on DWI, the remaining 40 patients were included in the "PFO group." A flowchart of the selection process was shown in **Figure 1**.

We reviewed age, sex, medical histories, stroke histories, physical examination, laboratory test results, and stroke severity measured by the National Institute of Health Stroke Scale (NIHSS) score. Conventional vascular risk factors were identified and listed below: hypertension, diabetes mellitus, hypercholesterolemia, cigarette smoking.

All patients underwent brain Magnetic resonance imaging, transcranial doppler, carotid and vertebral artery ultrasound, magnetic resonance angiography/computer tomography angiography or digital subtraction angiography to exclude infarction due to extracranial or intracranial atherosclerosis. Chest x-ray, electrocardiogram, transthoracic echocardiography, and transesophageal echocardiography, 24 h electrocardiogram were applied to exclude infarction due to emboli from the heart. Laboratory tests for hypercoagulation states, vasculitis, or metabolic disorders were requested at the discretion of the treating physician.

Brain MR Imaging

MRI was performed using a 3.0-T MRI unit (Signa HDx; GE Medical Systems, Milwaukee, WI). Data were obtained from the DWI sequence. DWI was performed with a repetition time of 5,000 ms, echo time of 84 ms, field of view of 24 × 24 mm, matrix number of 128 × 128, and slice thickness of 5 mm.

The following 5 lesion patterns on DWI were shown in **Figures 2–5**, using a published classification system: (1) Pattern 1: single lesions (cortical, or subcortical); (2) Pattern 2: single lesions (corticosubcortical); (3) Pattern 3: multiple lesions in one vascular territory (anterior or posterior circulation); (4) Pattern 4: multiple lesions in multiple vascular territories (same side); (5) Pattern 5:multiple lesions in multiple vascular territories (different sides) (15, 16). Multiple lesions were defined as 2 or more isolated DWI-positive lesions within the same or multiple vascular territories (9). Multiple lesions were classified into unilateral anterior circulation, posterior circulation, bilateral anterior circulations, or anterior and posterior circulations. Based on the difference in supplying

arteries, vascular territories were also divided into anterior circulation (carotid artery), posterior circulation (vertebral-basal artery), anterior and posterior circulations (carotid and vertebral-basal arteries).

Propensity Score Matching

We performed Propensity score matching (PSM) to reduce the possibility of selection bias and to adjust significant differences in baseline characteristics between the PFO and SIAD groups. The propensity score was estimated using a logistic regression model based on the following 8 variables: age, sex, hypertension, diabetes mellitus, hypercholesterolemia, cigarette smoking, stroke histories, and NIHSS scores. One-to-one pair matching was performed without replacement using a caliper of 0.20.

Statistical Analysis

Statistical analyses were performed using the statistical software package SPSS version 22.0. Continuous variables were presented as mean ± SD; categorical variables were expressed as frequencies. The statistical significance for inter-group differences was tested by the χ^2 test for categorical variables, the *t*-test for continuous variables, and the Mann–Whitney test for non-normal variables (e.g., NIHSS). The ROC curve was produced to predict the likelihood of right diagnosis of the underlying conditions based on findings from specific imaging results.

RESULTS

Demographical Information of all Patients

Clinical characteristics of the PFO and SIAD groups were shown in **Table 1**. In the SIAD group, there were 17 (59%) patients

TABLE 2 | Comparison of the radiological data of patients in the two groups.

	PFO, N, (%) ($n = 40$)	SIAD, N, (%) ($n = 29$)	*P*-Value
DWI lesion patterns[a]			
Single lesions (Corticosubcortical)	3 (8)	7 (24)	0.112
Single lesions (Cortical or subcortical)	20 (50)	6 (21)	0.013*
Multiple lesions in one vascular territory	6 (15)	12 (41)	0.014*
Multiple lesions in several vascular territories (same side)	2 (5)	2 (7)	1.000
Multiple lesions in several vascular territories (different side)	9 (23)	2 (7)	0.157
Distribution of multiple lesions [a]	17 (43)	16 (55)	
Unilateral anterior circulation	8 (20)	12 (41)	0.053
Posterior circulation	7 (18)	6 (21)	0.738
Bilateral anterior circulation	4 (10)	0	0.218
Distribution of circulation [a]			
Anterior and posterior circulations	4 (10)	2 (7)	0.985
Anterior circulation	22 (55)	15 (52)	0.788
Posterior circulation	12 (30)	12 (41)	0.327
Anterior and posterior circulations	6 (15)	2 (7)	0.299

P-values were determined with the use of Pearson χ^2-test (or Fisher's exact test where appropriate).

with vertebral artery dissection and 12 (41%) with cervical artery dissection. The mean age of patients in the PFO group (46.85 ± 14.19 years) was significantly older than that of the SIAD group (38.79 ± 9.10 years) ($p = 0.006$). The NIHSS score of the SIAD group was significantly higher than that of the PFO group ($P = 0.028$). The percentage of males was high in both groups (73 vs. 83%) and there was no significant difference between them ($P = 0.319$). No significant difference was observed in hypertension, diabetes mellitus, hypercholesterolemia, cigarette smoking, and stroke histories between the two groups.

Radiological data on DWI were presented in **Table 2**. The distribution of DWI lesion patterns differed between the 2 groups. Single lesions (cortical or subcortical, Pattern 1) was more frequent in the PFO group than in the SIAD group (50 vs. 21%; $P = 0.013$). Multiple lesions in one vascular territory (Pattern 3) were more frequently observed in the SIAD group than in the PFO group (41 vs. 15%; $P = 0.014$). Differences in the occurrence of other lesion patterns like single lesions (corticosubcortical, Pattern 2), multiple lesions in multiple vascular territories (same side and different sides, Pattern 4 and 5) did not reach statistical significance. Additionally, there was no difference in the distribution of multiple lesions between patients with PFO and those with SIAD. Six patients with PFO had both anterior and posterior circulations involved.

Propensity Score-Matched Cohort

Patients in the PFO and SIAD groups were matched 1 to 1 using PSM to minimize the effect of confounding factors. Twenty-one pairs of patients were selected and their clinical characteristics seemed to be well matched, and no significant differences were observed between the groups after PSM (**Table 3**).

TABLE 3 | Comparison of the clinical characteristics of patients in the two groups in the propensity score-matched cohort.

Patient Characteristics	PFO, N, (%) ($n = 21$)	SIAD, N, (%) ($n = 21$)	*P*-Value
Age, y, mean ± *SD*[a]	44.38 ± 16.624	37.86 ± 9.759	0.131
Male sex[b]	16 (76)	17 (81)	1.000
Vascular risk factors[b]			
Hypertension	3 (14)	2 (10)	1.000
Diabetes mellitus	1 (5)	2 (10)	1.000
Hypercholesterol	5 (24)	7 (33)	0.495
Cigarette smoking[b]	9 (43)	10 (48)	0.757
Stroke histories[b]	1 (5)	0	0.311
NIHSS score[C]	2.0 (1.0–6.0)	3 (1.0–7.5)	0.713

PFO, patent foramen ovale; SIAD, spontaneous intracranial artery dissection; NIHSS, National Institutes of Health Stroke Scale.
[a]Values expressed as mean ± standard deviation (SD).
[b]Values expressed as frequencies and percentages.
[c]Values expressed as median and interquartile range.
P-values were determined with the use of independent t-test, the Pearson χ^2-test (or Fisher's exact test where appropriate) and Mann–Whitney test.

Post-PSM comparison of radiological data were presented in **Table 4**. Single lesions (cortical or subcortical, Pattern 1) were still more frequently observed in the PFO group than in the SIAD group (57 vs. 19%; $P = 0.026$). Multiple lesions in one vascular territory were more frequently observed in the SIAD group than in the PFO group (43 vs. 10%; $P = 0.035$). Unlike the full cohort, single lesions (corticosubcortical, Pattern 2) were more frequently observed in the SIAD group than in the PFO group ($P = 0.048$). Differences in the percentage of other lesion patterns like multiple lesions in multiple vascular territories (same side and different sides) did not reach statistical significance. Distribution of multiple lesions in the PSM set did not reach significant difference. Lesions in the posterior circulation territory occurred more frequently in the SIAD group than in the PFO group (57 vs. 24%; $P = 0.028$). Five patients with PFO had both anterior and posterior circulations involved.

Receiver Operating Characteristic (ROC) Curve

ROC was produced to calculate the value of diagnosing PFO based on patterns of single cortical or subcortical infarcts. The area under ROC curve was 0.647 (**Figure 6**). Similarly, the area under ROC curve was 0.632 (**Figure 7**) for diagnosing SIAD based on the pattern of multiple infarcts in a single vascular territory.

DISCUSSION

The present study compared the imaging features between stroke patients with PFO and those with SIAD. In the full

cohort, we found that patients with PFO were older and more likely to have hypertension than patients with SIAD, while the NIHSS score was higher in stroke patients with SIAD than in those with PFO. To minimize bias due to patient selection, we conducted PSM to match patients with PFO and those with SIAD. After PSM, significant difference was not observed in their clinical characteristics but their radiological findings. Single lesions (cortical or subcortical) were more frequently observed in patients with PFO than in those with SIAD, whereas multiple lesions in one vascular territory were more frequently observed in patients with SIAD than in those with PFO. Furthermore, single lesions (corticosubcortical), and posterior circulation involvement were more frequently observed in patients with SIAD than in those with PFO after PSM.

The finding that single lesions (cortical or subcortical) were more frequently observed in the PFO group than in the SIAD group, is consistent to some extent with findings of previous reports (6, 17, 18). Bonati et al. (6) found that among cerebral infarct patients with PFO, 42% (25/60) had single cortical or subcortical infarcts in areas not fulfilling the criteria for territorial infarct, whereas only 6% (2/33) of patients with SIAD had this type of cerebral infarct. This statistical difference is consistent with our findings. In another study (17), it was found that among 25 patients with PFO, 5 (20%) had single subcortical infarct with a diameter over 15 mm, which is significantly different from what was found in the non-PFO group (0%). In the non-PFO group, 8 out of 21 patients showed subcortical infarcts, but none of them showed single subcortical infarcts larger than 15 mm. Kim et al. (18) found that among 117 patients with PFO, 40 had a single subcortical infarct (34.2%), which is significantly different from what was found in patients with atrial fibrillation (11/358, 3.1%). In that study, 46.1% of patients showed large corticosubcortical infarcts, 19% showed confluent large infarcts with additional lesions, and 16.5% showed infarcts in multiple vascular territories. This indicates

that atrial fribrillation is more likely to result in infarcts in multiple vascular territories. However, the latter two studies have different baseline information of patients, which leads to bias in their conclusions. In the present study, 50% of patients with PFO had a single cortical or subcortical infarct, which was significantly higher than that of patients with SIAD (21%). The result remained significantly different after propensity analysis (57 vs. 21%). The advantage of the present study was that propensity analysis excluded the bias caused by confounding factors and that the result was more reliable. The underlying mechanism for this finding might be that the patent foramen ovale is relatively small in diameter, and only small thrombi from the periphery can pass it and flow to the carotid or vertebral artery. Therefore, the infarcts are relatively small and often localized to one vascular territory. The other major finding in our study was that multiple lesions in one vascular territory were observed more frequently in the SIAD group than in the PFO group, which was also in line with Bonati's study which showed that territorial infarcts (with or without additional smaller lesions in the same territory) were more likely to occur in patients with arterial dissection (61%, 20/33 vs. 27%,16/60). It is likely that carotid artery dissection or vertebral artery dissection often leads to artery to artery embolism, which subsequently results in multiple infarcts in one vascular territory. A large observational study showed that there was no association between PFO and multiple acute strokes in patients with PFO and cryptogenic strokes (19). Our results are consistent with their findings in that PFO predominantly leads to single infarcts. Calculating the area under ROC curve might be a good way in predicting the likelihood of suffering from PFO or SIAD. Based on the discussion above, we could conclude that single lesions (cortical or subcortical) could be a specific feature of stroke patients with PFO, and multiple lesions in one vascular territory a specific feature of stroke patients with dissection, which could provide further support for differentiating diagnosis of the two etiologies.

After dividing patients with SIAD into carotid dissection and vertebral dissection, it was found that infarcts were more frequently observed in the posterior circulation of SIAD patients than in PFO patients, which was consistent with previously published results (20). However, patients with PFO were more likely to have both anterior and posterior circulations involved than SIAD patients with only one patient in our SIAD group having both circulations involved. The possible reason for this was that PFO tends to result in paradoxical cardioembolic strokes. Emboli from the heart might block both anterior and posterior circulations simultaneously, while emboli from artery dissection only block anterior circulations or posterior circulation, although no statistical significance was observed in our study due to the size limit. Therefore, large-size studies are needed to show whether patients with PFO have more anterior circulation or posterior circulation involved than patients with SIAD.

The present study has several limitations. Firstly, it was a single-center study and the sample size was relatively small. After PSM, the number of patients was reduced to 21 in each group. Thus, a large-scale multi-center study is essential to confirm our conclusion. Secondly, a possible bias might arise from patient selection for TEE, because TEE was an invasive procedure, some suspicious mild PFO associated stroke might be excluded. Thirdly, the cost of MRI scan is high, as a result, some small hospitals cannot perform this test for patients. Fourthly, a study published by New England Journal of Medicine showed that 30 days ambulatory ECG monitoring improves the diagnosis of atrial fibrillation (21). The present study only monitored the patients for 24 h, and the positive diagnosis of atrial fibrillation is low, which might lead to bias in our analysis.

In conclusion, single lesions (cortical or subcortical) might be a typical feature of PFO associated strokes, while multiple lesions in one vascular territory might be a specific feature of arterial dissection associated strokes.

ETHICS STATEMENT

This study was carried out in accordance with the recommendations of the Ethics Committees of the First Affiliated Hospital of Wenzhou Medical University with written informed consent from all subjects. All subjects gave written informed consent in accordance with the Declaration of Helsinki. The protocol was approved by the Ethics Committees of the First Affiliated Hospital of Wenzhou Medical University.

AUTHOR CONTRIBUTIONS

YB designed the study. YH and XZ collected the data. JZ and BS analyzed the data. YH and YC drafted the manuscript. HL analyzed the data and edited the manuscript. YB and YH approved the final version of the manuscript. All authors have read and approved the final manuscript.

Spreading depolarizations (SDs) are characterized by near-complete breakdown of the transmembrane ion gradients, neuronal oedema and activity loss (=depression). The SD extreme in ischemic tissue, termed 'terminal SD,' shows prolonged depolarization, in addition to a slow baseline variation called 'negative ultraslow potential' (NUP). The NUP is the largest bioelectrical signal ever recorded from the human brain and is thought to reflect the progressive recruitment of neurons into death in the wake of SD. However, it is unclear whether the NUP is a field potential or results from contaminating sensitivities of platinum electrodes. In contrast to Ag/AgCl-based electrodes in animals, platinum/iridium electrodes are the gold standard for intracranial direct current (DC) recordings in humans. Here, we investigated the full continuum including short-lasting SDs under normoxia, long-lasting SDs under systemic hypoxia, and terminal SD under severe global ischemia using platinum/iridium electrodes in rats to better understand their recording characteristics. Sensitivities for detecting SDs or NUPs were 100% for both electrode types. Nonetheless, the platinum/iridium-recorded NUP was 10 times smaller in rats than humans. The SD continuum was then further investigated by comparing subdural platinum/iridium and epidural titanium peg electrodes in patients. In seven patients with either aneurysmal subarachnoid hemorrhage or malignant hemispheric stroke, two epidural peg electrodes were placed 10 mm from a subdural strip. We found that 31/67 SDs (46%) on the subdural strip were also detected epidurally. SDs that had longer negative DC shifts and spread more widely across the subdural strip were more likely to be observed in epidural recordings. One patient displayed an SD-initiated NUP while undergoing brain death despite continued circulatory function. The NUP's amplitude was −150 mV subdurally and −67 mV

epidurally. This suggests that the human NUP is a bioelectrical field potential rather than an artifact of electrode sensitivity to other factors, since the dura separates the epidural from the subdural compartment and the epidural microenvironment was unlikely changed, given that ventilation, arterial pressure and peripheral oxygen saturation remained constant during the NUP. Our data provide further evidence for the clinical value of invasive electrocorticographic monitoring, highlighting important possibilities as well as limitations of less invasive recording techniques.

Keywords: cerebral ischemia, hypoxia, malignant hemispheric stroke, spreading depression, subarachnoid hemorrhage

INTRODUCTION

Spreading depolarization is the principal mechanism causing cytotoxic oedema and excitotoxicity in cerebral cortex and basal ganglia (Ochs and Van Harreveld, 1956; van Harreveld, 1959; Dreier et al., 2013, 2018a; Hinzman et al., 2015). Using ECoG, SD is observed as a large negative direct current (DC) shift (frequency band: <0.05 Hz). The SD continuum describes the spectrum from terminal SD in severely ischemic tissue to transient SDs with negative DC shifts of intermediate to short duration in tissue that is less ischemic or normal (Dreier and Reiffurth, 2015; Hartings et al., 2017b). Accordingly, SDs occur in human conditions ranging from CA, to stroke, to the harmless migraine aura (Dreier et al., 2006, 2018b; Dohmen et al., 2008; Lauritzen et al., 2011). This means that there are commonalities yet also considerable variations in SD properties along the continuum. Terminal SD, for example, is characterized by initiation of a NUP, which is similar to the negative DC shift of prolonged SD, but specifically refers to a negative potential component during progressive recruitment of neurons into cell death. The NUP has been recorded in patients dying in the wake of CA (Dreier et al., 2018b), in a patient with aSAH undergoing brain death despite continued circulatory function (Carlson et al., 2018), and in patients with ECI and DCI after aSAH (Oliveira-Ferreira et al., 2010; Dreier, 2011; Drenckhahn et al., 2012; Hartings et al., 2017c; Luckl et al., 2018).

The continuum is also manifested in the consequences of SD. In electrically active tissue, SD induces spreading depression of activity, which is measured in the AC-ECoG range (>0.5 Hz) (Dreier et al., 2017). The depression is short-lasting in normal tissue but progressively prolonged in metabolically impaired areas, such that SD can induce even persistent electrical inactivity (=isoelectricity) that develops in a spreading pattern (Oliveira-Ferreira et al., 2010). Thereafter, SDs cannot induce further spreading depression and are termed 'isoelectric SD' (Hartings et al., 2011). This state of electrical silence contrasts with 'non-spreading depression,' which is the electrical silence that develops in tissue simultaneously after the onset of severe ischemia, 1–5 min prior to terminal SD (Dreier, 2011; Dreier et al., 2018b). SD also induces tone alterations in resistance vessels, leading to either transient hyperemia (normal neurovascular response) in healthy tissue or severe hypoperfusion (inverse neurovascular response = spreading ischemia) in tissue at risk for progressive injury (Dreier et al., 1998; Shin et al., 2006). Experimentally, SI could be the sole cause of widespread cortical infarcts (Dreier et al., 2000). The continuum from SH to SI was recorded in patients with aSAH, TBI, and MHS (Dreier et al., 2009; Dreier, 2011; Woitzik et al., 2013; Hinzman et al., 2014).

Subdural recordings from platinum–iridium (Pt/Ir) electrodes have been the gold standard for intracranial monitoring of SDs in humans (Dreier et al., 2017; Eriksen et al., 2019). Despite the many translational successes achieved with these electrodes, Pt/Ir has some shortcomings as an electrode material for recording slow potentials, particularly in contrast to the Ag/AgCl-based electrodes used in animals (Masvidal-Codina et al., 2018). For instance, as a polarizable material, Pt/Ir has a capacitive nature that may result in filtering or distortion of slow potentials (Hartings et al., 2017a). Here, in an approach of reverse translation from bedside to bench (Fisher, 2013), we investigated how reliably Pt/Ir electrodes record negative DC shifts of varying duration, including the NUP, by studying the full SD continuum in rats under conditions of normoxia, hypoxia, and severe global ischemia. We then conducted a study of bench to bedside translation, based on the suggestion from animal experiments that epidural recordings are a possible semi-invasive alternative to subdural recordings (Iijima et al., 1992; Kang et al., 2013; Luckl et al., 2018). Epidural recordings are of interest as an intermediate step between invasive subdural and

non-invasive scalp EEG. Although correlates of SD were clearly identified in continuous scalp EEG recordings when performed simultaneously with subdural ECoG (Drenckhahn et al., 2012; Hartings et al., 2014), scalp EEG alone may not be sufficient to reliably diagnose SDs, particularly in patients with intact skulls (Hartings et al., 2018; Hofmeijer et al., 2018). Therefore, we investigated the performance of epidural titanium peg electrodes (Barnett et al., 1990) compared to subdural electrodes in detecting SDs in patients with either aSAH or MHS. In this series, we recorded a patient who displayed an SD-initiated NUP while undergoing brain death despite continued circulatory function, as in another case reported previously (Carlson et al., 2018). The NUP was recorded not only subdurally but also epidurally, providing further insight into the nature of this phenomenon.

MATERIALS AND METHODS

Animals

This study was carried out in accordance with the recommendations of the Landesamt für Gesundheit und Soziales Berlin (LAGeSo) (G0152/11). The protocol was approved by the LAGeSo (G0152/11). All experimental procedures were conducted in accordance with the Charité Animal Welfare Guidelines. The reporting of animal experiments complies with the ARRIVE Guidelines. Naïve, male, wild-type Wistar rats (n = 8; 250–400 g, ∼10–16 weeks old, supplied by Charles River, Germany) were anesthetized with 100 mg/kg body weight thiopental-sodium intraperitoneally (Trapanal, BYK Pharmaceuticals, Konstanz, Germany), tracheotomized, and artificially ventilated (Effenberger Rodent Respirator, Effenberger Med.-Techn. Gerätebau, Pfaffing/Attel, Germany). The left femoral artery and vein were cannulated. Body temperature was maintained at 38.0 ± 0.5°C using a heating pad. Systemic arterial pressure (Pressure Monitor BP-1, World Precision Instruments, Berlin, Germany) and expiratory pCO_2 (Heyer CO_2 Monitor EGM I, Bad Ems, Germany) were monitored. Arterial pO_2 (p_aO_2), pCO_2 (p_aCO_2) and pH were serially measured using a Compact 1 Blood Gas Analyzer (AVL Medizintechnik GmbH, Bad Homburg, Germany). Adequacy of the level of anesthesia was assessed with testing motor and blood pressure responses to tail pinch.

A parietal craniotomy was performed using a saline-cooled drill and the dura was removed. The composition of ACSF in mM was: NaCl 127.5; KCl 3.0; $CaCl_2$ 1.5; $MgSO_4$ 1.2; $NaHCO_3^-$ 24.5; glucose 3.7; urea 6.7 (Levasseur et al., 1975). The ACSF was equilibrated with a gas mixture containing 6.6% O_2, 5.9% CO_2, and 87.5% N_2. A pO_2 between 90 and 130 mmHg, a pCO_2 between 35 and 45 mmHg, and a pH between 7.35 and 7.45 were accepted as physiological. rCBF was continuously monitored using LDF (Periflux 4001, Perimed AB, Järfälla, Sweden). A double-barreled K^+-selective microelectrode was used to measure the intracortical DC/AC-ECoG and the extracellular K^+ concentration ($[K^+]_o$) in the open window (Petzold et al., 2005; Kang et al., 2013). The cortical measuring depth was 300 μm. In addition, two Pt/Ir plate electrodes (Ad-Tech Medical, Racine, WI, United States) were placed on the cortex as shown in **Figure 1A** (total diameter: 4 mm, contact surface: 2 mm, distance between electrode centers: 5 mm). An Ag/AgCl electrode was placed for a reference in the neck. Electrodes were connected to differential amplifiers (Jens Meyer, Munich, Germany). Analog-to-digital conversion was performed using a Power 1401 (Cambridge Electronic Design Limited, Cambridge, United Kingdom). Systemic arterial blood pressure as well as $[K^+]_o$, DC- and AC-ECoG, rCBF and expiratory pCO_2 were continuously recorded using a personal computer and Spike 2 software (version 6, Cambridge Electronic Design Limited).

Following surgical preparation, SDs were triggered first under normoxic conditions by applying a droplet of 2M KCl at a rostral burr hole. After cessation of SDs and recovery of baseline levels, hypoxia was then induced by gradually substituting N_2 for O_2 in the inspired air over ∼60 s. Thereafter, animals were monitored while hypoxia was maintained until animals died spontaneously. In some animals, additional SDs were provoked by KCl application during hypoxia.

Statistical Analysis in General

No prior information was available which would have enabled us to perform sample size estimations based on evidence. We thus chose a sample size of eight animals which is standard in the field. For the clinical pilot study, we had originally chosen a sample size of 20 patients, but peg electrodes were no longer available (see below). Therefore, only seven patients were included. All analyses were exploratory and are reported with the caveat that no formal power consideration was performed on them. All data in text and figures is given as median and IQR. We only used non-parametric tests because of the small sample sizes. The exact statistical tests are given in the text. $P \leq 0.05$ was accepted as significant.

Analysis of Animal Data

Animal data was prospectively collected and analyzed by comparing relative changes of rCBF and absolute changes of DC potential and $[K^+]_o$. rCBF changes were calculated in relation to baseline (=100%) using a zero level established after death. No animals were excluded from analysis. The data was analyzed in an un-blinded fashion with LabChart-8 software (ADInstruments, Bella Vista, NSW, Australia).

Patients

The study was carried out in accordance with the recommendations of the ethics committee of the Charité – Universitätsmedizin Berlin (EA4/175/17) with written informed consent from the patients or the patients' legally authorized representatives. All patients or patients' legally authorized representatives gave written informed consent in accordance with the Declaration of Helsinki. The protocol was approved by the ethics committee of the Charité – Universitätsmedizin Berlin. Results are reported in accordance with the STROBE guidelines[1]. Prospective inclusion and exclusion criteria for aSAH and MHS patients in the COSBID have been previously described (Woitzik et al., 2014; Winkler et al., 2017). Five patients with major aSAH and two patients with MHS were consecutively enrolled

FIGURE 1 | Continued
(DC/AC-ECoG) contains information on both the negative DC shift that identifies SD (Dreier, 2011) and the SD-induced depression of activity (negative is up for ECoG recordings shown in all figures). Note the differences in amplitude and shape of the DC shift between the gold standard recording technique in animals, the intracortical glass-microelectrode, and the Pt/Ir electrodes on the brain surface, gold standard in humans (cf. **Table 1**). For example, the amplitude ratio of the initial DC negativity divided by the subsequent DC positivity was significantly larger for the glass-microelectrode than for the Pt/Ir electrodes in normal tissue [Ag/AgCl: 9.1 (IQR = 8.0, 17.0); caudal Pt/Ir: 1.2 (IQR = 1.0, 1.7); rostral Pt/Ir: 1.0 (IQR = 0.7, 1.3), $P \leq 0.05$, $n = 7$, Kruskal–Wallis One-Way Analysis of Variance on Ranks with *post hoc* Dunn test]. Also note the spread of the SD in rostral (Pt/Ir-electrode 2)-caudal (Pt/Ir-electrode 1) direction. Trace 4: The hallmark of SD is the abrupt, near-complete breakdown of the transcellular ion concentration gradients. Here, the large SD-associated increase of $[K^+]_o$ is seen. Note the significant prolongation under hypoxia. Traces 5–7: The spontaneous activity is assessed in the higher frequency band between 0.5 and 45 Hz. Note that the SD under hypoxia is preceded by non-spreading depression of the spontaneous activity [blue and green asterisks in **(B,C)**]. Non-spreading depression precludes that the subsequent SD can induce spreading depression of the activity. Interestingly, the depression of activity was reversible after the SD despite continued hypoxia. Trace 8: MAP fell under hypoxia. Trace 9: SD-induced hyperemia under normoxia and hypoxia, respectively. Note the marked reactive hyperemia following the recovery from SD under hypoxia. Note also that the Pt/Ir electrodes in contrast to the glass microelectrode displayed a marked negative DC reverberation following the recovery from SD under hypoxia (red asterisks), which may hinder correct assessment of the duration of the negative DC shift of SD. The fourth SD under normoxia showed much smaller amplitude than the three previous SDs at both the Pt/Ir-electrode 2 and the Ag/AgCl-based intracortical microelectrode. Such amplitude reductions are sometimes observed in clusters of SDs and could, for example, result from a proportion of parenchymal cells that are still refractory after the previous SD.

at Campus Benjamin Franklin, Charité – Universitätsmedizin Berlin between June 2017 and January 2018 in this pilot study.

Neurosurgeons in charge recruited patients into invasive neuromonitoring when they assumed a potential benefit for the patient based on clinical presentation and preinterventional CT scan leading them to suspect an emerging serious risk of epileptic seizures or infarct progression. Patients at high risk often require ventilation and analgo-sedation. This limits neurological assessment. Therefore, diagnosis and treatment of secondary complications are often delayed. Invasive real-time neuromonitoring can help the neurointensivist to diagnose earlier and initiate treatment earlier (Dreier et al., 2017).

In patients with aSAH, a linear electrode strip (six Pt/Ir contacts spaced at 10 mm) (Wyler, Ad-Tech Medical, Racine, WI, United States) was placed on the cortical surface of the vascular territory of the aneurysm-carrying vessel following surgery to secure the aneurysm (Dreier et al., 2006, 2009). In two patients with MHS, the electrode strip was placed on perfused, non-infarcted periinfarct tissue after decompressive hemicraniectomy (Dohmen et al., 2008; Woitzik et al., 2013). In addition, two epidural titanium peg electrodes (Ad-Tech Medical) were implanted through two small burr holes separated by a distance of 10 mm from one another and at a distance of 10 mm to the subdural strip. Peg electrodes are conically shaped with a $\sim$10 mm^2 recording surface area in the epidural space. The tail of the electrodes was tunneled subcutaneously and exited 2–3 cm from the scalp incision. Technical aspects of implantation of subdural electrode strips have been described in detail elsewhere (Dreier et al., 2017).

Continuous ECoG and multimodal monitoring were performed following the COSBID recommendations while patients were in the ICU (Dreier et al., 2017). The near-DC/AC-ECoG (0.01–100 Hz) was recorded in five bipolar channels with a GT205 amplifier (ADInstruments). Data was sampled at 200 Hz and recorded and analyzed with a Powerlab 16/SP and LabChart-8 software. A subdermal Pt/Ir needle electrode on the frontal apex was used as reference. Additional monopolar, DC-coupled (0–100 Hz) recordings were performed with a BrainAmp amplifier (BrainProducts GmbH, Munich, Germany) and BrainVision Recorder software (BrainProducts GmbH). In one patient, the brain $p_{ti}O_2$ was measured using an intraparenchymal sensor (Licox CC1P1, Integra Lifesciences Corporation, Plainsboro, NJ, United States) (Dreier et al., 2009; Bosche et al., 2010; Hinzman et al., 2014; Winkler et al., 2017). ICP was monitored via ventricular drainage catheter (EVD) or ICP transducer (Codman or Camino Systems). The systemic arterial pressure was continuously recorded via radial artery catheter.

Analysis of Patient Data

No patients were excluded from analysis. The data was analyzed in an un-blinded fashion with LabChart-8 software. The first 24 h period after the initial insult was denoted as 'Day 0.' SDs were identified by the consecutive occurrence of slow potential changes ($<$0.05 Hz) of neighboring ECoG channels. The negative DC shift was measured from start to end, regardless of morphology or multi-phasic appearance. In electrically active tissue, SD typically causes spreading depression of spontaneous activity in the AC-ECoG range (0.5–45 Hz) (Dreier et al., 2006). The duration of the depression period was scored beginning at the initial decrease in the integral of power and ending at the start of the recovery phase. Depression durations were scored to measure the TDDD (Dreier et al., 2017). The peak TDDD (PTDDD) was defined as the maximal value among all recording days. SDs in electrically active tissue received the epithet 'spreading depression.' SDs measured in a zone of electrically inactive tissue were denoted with the adjective 'isoelectric.'

RESULTS

SD in Rats Under Normal Conditions

Figure 1A shows the experimental setup. During SD in normoxic rats, Pt/Ir electrodes recorded the negative DC shift of SD, albeit with early and late positivities not observed in micropipette recordings to such an extent. SD reached the rostral Pt/Ir electrode earlier than the caudal one [delay: median: 76 (IQR: 70–83) s] corresponding to a propagation velocity of 3.9 (IQR: 3.6–4.3) mm/min. SD caused a hyperemic response to 272 (IQR: 191–286) % of baseline [duration: 118 (IQR: 110–127) s]. In more detail, the recordings using the Ag/AgCl-based intracortical glass-microelectrode and the Pt/Ir electrodes are compared in **Figure 1B** and **Table 1**.

TABLE 1 | Characteristic changes along the SD continuum in rats *in vivo*.

Condition		Pre-SD DC positivity		SD DC negativity		Post-SD DC positivity		Negative DC reverberation post SD		Depression of activity	Increase of $[K^+]_o$ during SD

*Statistical comparisons were performed between SD under normoxia (control group), SD under hypoxia and the terminal SD using either Wilcoxon Signed Rank Test (two-group design) or Friedman Repeated Measures Analysis of Variance on Ranks with Dunn's post hoc test (three-group design versus control) (*P ≤ 0.05, **P ≤ 0.01). x: In recordings with microelectrodes, in contrast to Pt/Ir electrodes, the sharper negative DC shift of SD made it difficult to assess the depression periods using the integral of power. Data is given as median and IQR.*

Hypoxia-Induced SD in Rats

Partial replacement of O_2 with N_2 in the inspired air caused a decrease of arterial p_aO_2 from 102 (IQR: 95–120) to 36 (IQR: 33–39) mmHg, of hemoglobin saturation with O_2 from 98 (IQR: 97–98) to 51 (IQR: 43–52) %, of arterial pH from 7.37 (IQR: 7.36–7.39) to 6.99 (IQR: 6.88–7.22), of p_aCO_2 from 39 (IQR: 37–46) to 29 (IQR: 22–31) mmHg and of the base excess from −2.5 [IQR: (−1.4)–(−3.7)] to −23.7 [IQR: (−14.7)–(−27.3)] mM corresponding with hypoxia-induced metabolic acidosis (all $P \leq 0.05$, $n = 6$, Wilcoxon Signed Rank Tests). MAP significantly fell from 112 to 69 (IQR: 56–98) mmHg ($P = 0.016$, $n = 8$, Wilcoxon Signed Rank Test), although high doses of intravenous noradrenalin of up to 67 (IQR: 57–77) μg/kg/min were intravenously administered to maintain the systemic circulation. Although MAP decreased under hypoxia, rCBF significantly increased from 97 to 211 (IQR: 113–248) % ($P = 0.039$, $n = 8$, Wilcoxon Signed Rank Test).

Spreading depolarization developed spontaneously under hypoxia in four experiments (**Figures 1B,C**, **2A**) and was triggered by KCl application during hypoxia in the remaining ones (**Figure 3**). In all animals, initial SDs were transient with spontaneous recovery despite continued hypoxia. SDs induced spreading depression of activity under hypoxia in all animals except one in which non-spreading depression developed first (**Figure 1C**). Negative DC shifts, $[K^+]_o$ elevations, and depression periods were significantly prolonged under hypoxic compared to normoxic conditions (**Table 1**). Notably, Pt/Ir electrodes were able to record the SDs, but in contrast to Ag/AgCl microelectrodes, also displayed a negative DC reverberation in five of eight animals following the recovery from SD (**Figures 1B**, **2A** and **Table 1**). Similar to normoxia, SD occurred with a delay of 71 (IQR: 47–100) s between the two Pt/Ir electrodes. The rCBF response to SD was impaired under hypoxia and difficult to quantify due to heterogeneity. Often, no major change was seen during SD, but a delayed hyperemic response from 211 to 368 (IQR: 215–398) % followed recovery from long-lasting SDs (**Figures 1B**, **2A**). This was distinct from the hyperemia observed during SD in normoxic tissue. Thereafter, a relative oligemia to 135 (IQR: 76–182) % occurred (**Figure 2A**). The typical pattern of SI (Dreier et al., 1998; Dreier, 2011; Sugimoto et al., 2018) was not observed in any of the SDs under hypoxia that preceded the terminal one.

Terminal SD in Rats During the Dying Process

Seven animals died spontaneously from hypoxia and one from intravenous injection of an air embolus into the femoral vein. The phase transition from life to death was characterized by four events: loss of circulation, loss of respiration, loss of spontaneous brain activity and a terminal SD without repolarization. These changes occurred in all animals, but not necessarily in the same order. Four animals had CA before terminal SD and four after. Of animals dying spontaneously under hypoxia, MAP was 45 (IQR: 43–61) mmHg at the time the first of these events occurred. When CA occurred first, brain isoelectricity developed as non-spreading depression after 71 (IQR: 49–265) s, unless the tissue was already depressed, and terminal SD began 181 (IQR: 142–302) s ($n = 4$) after CA. When terminal SD occurred first, CA followed after a median delay of 878 s (range: 23–1740, $n = 4$). In all cases, the terminal SD appeared first at the rostral Pt/Ir electrode and spread either to the caudal Pt/Ir electrode with a median delay of 60 s (range: 11–195, $n = 7$) or to the glass microelectrode (delay: 12 s, $n = 1$). This is consistent with rodent imaging experiments, which showed that the persistent SD during global cerebral ischemia would usually spread from one point of origin in a rostral-caudal direction (Farkas et al., 2008, 2010; Bogdanov et al., 2016).

In four animals, isoelectricity developed in a non-spreading pattern and was followed by terminal SD. For instance, following the air embolus in one animal, MAP fell rapidly from 99 to 6 mmHg and respiratory fluctuations of expiratory pCO_2 ceased within 18 s; non-spreading depression caused isoelectricity within 26 s and terminal SD started after 98 s (**Figure 4**). In two other animals, progressive CA spontaneously developed with fluctuating drops in MAP and rCBF, and was followed by non-spreading depression and then terminal SD. In yet another case (**Figure 3**), non-spreading depression developed minutes after respiratory insufficiency and was then followed by terminal SD, which induced SI. Thereafter, CA developed.

The remaining animals showed diverse patterns in the development of isoelectric brain activity during the dying process. In one case, the terminal SD started when MAP was 44 mmHg, the respiratory rate was 71/min, and spontaneous brain activity was still present. The SD thus triggered a spreading depression that persisted through death (**Figure 2B**). 179 s after SD first appeared at the rostral Pt/Ir electrode, the LDF probe detected a marked SI with sharp drop of rCBF from 81 to 0%. Systemic CA and respiratory arrest started 23 and 42 s, respectively, after the onset of SI. In two other animals, terminal SDs started when the spontaneous activity was already depressed after previous SD-induced spreading depressions. These did not cause any obvious change in rCBF, which remained at 70 and 95%, respectively. Systemic circulatory and respiratory arrest, with simultaneous drop in rCBF, did not occur until 29 min later in one case, and 27 min in the other. The electrophysiological pattern was the same in the last animal, but terminal SD was preceded by progressive circulatory failure.

Epidural Recordings of SDs in Patients

Demographic details are given in **Table 2**. The total near-DC/AC-ECoG recording time from the cortical surface was 1117.5 h in the five patients with aSAH and 178.1 h in the two patients with MHS. Three patients had no SDs, but assessment was limited in one of these because recordings were artifact-laden. Three patients with aSAH had 98 SDs and one patient with MHS had 5 SDs. For further analysis, 808.0 h of simultaneous subdural DC/AC-ECoG and epidural DC/AC-ECoG recording time of sufficient quality was available during which 74 of the 103 SDs occurred. Ten of these occurred in patient 1, 16 in patient 4, 3 in patient 6, and 45 in patient 7. Seven of the 45 SDs in patient 7 occurred as part of the terminal cluster and are described further below.

The negative DC shift's peak-to-peak amplitude and duration of the remaining 67 SDs were 5.7 (IQR: 3.9–7.3) mV and

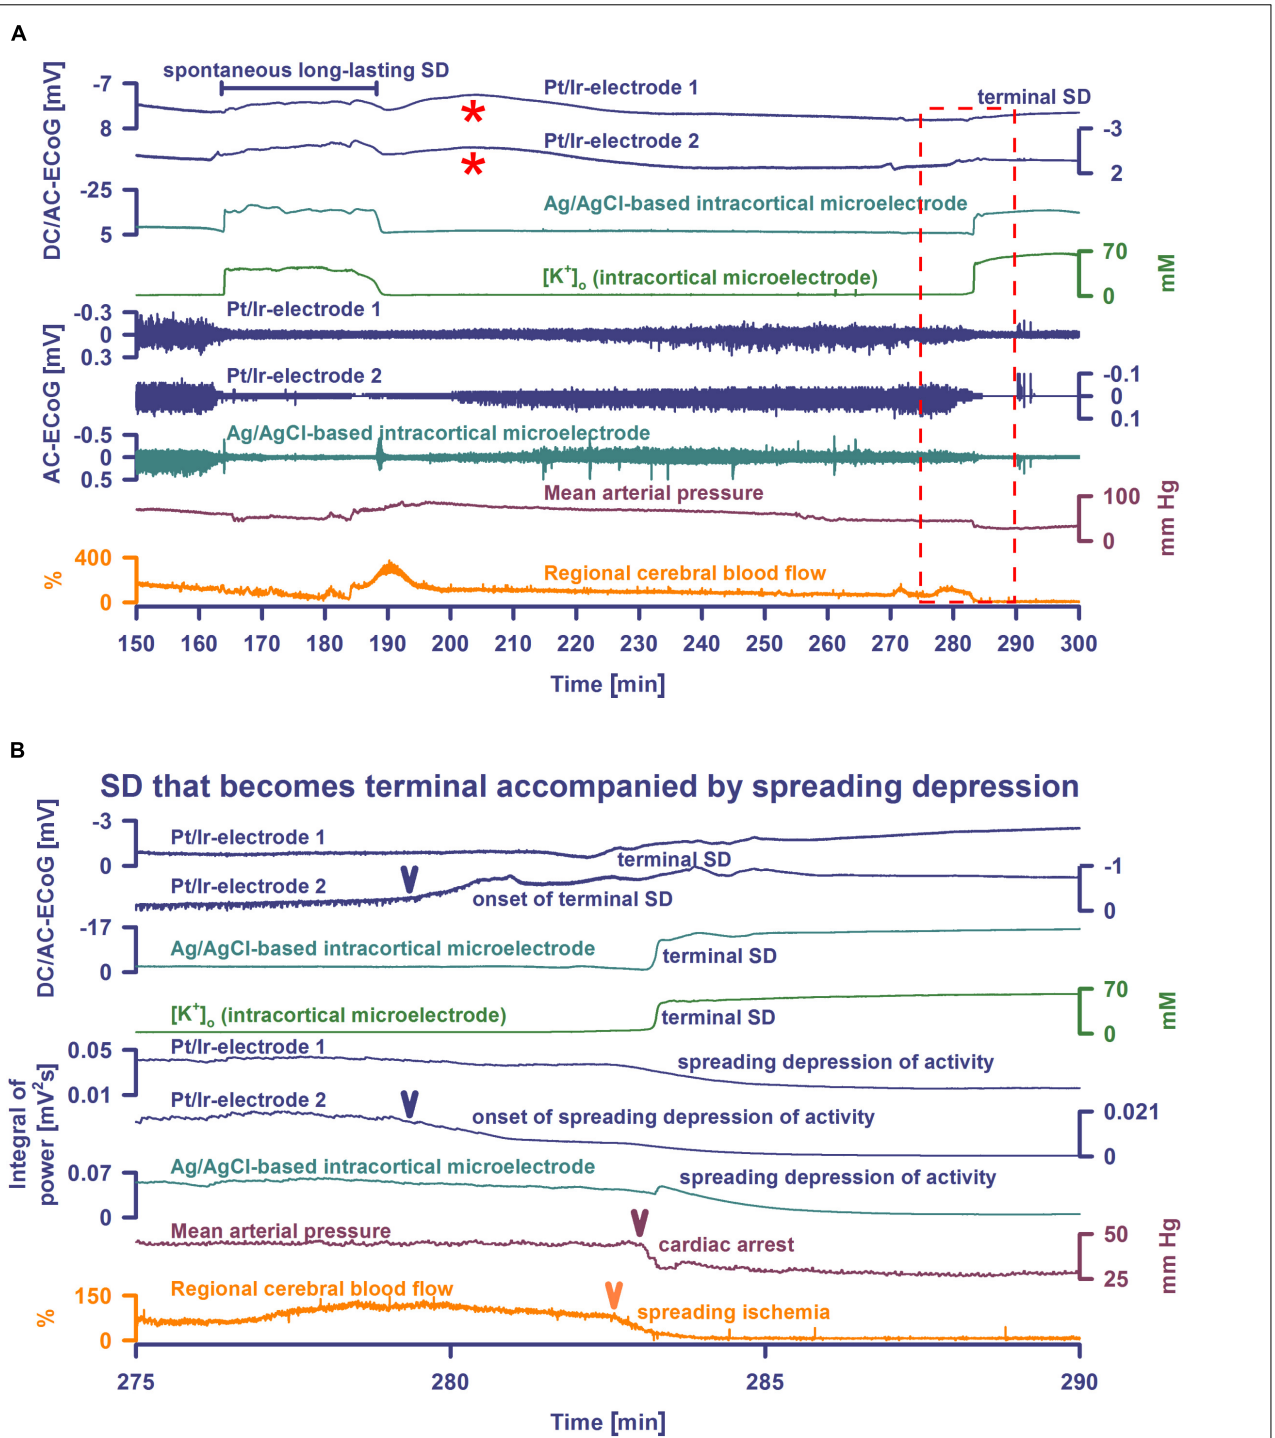

FIGURE 2 | Spontaneous SD during hypoxia compared with terminal SD in death. Traces are the same as in **Figure 1**. The Pt/Ir plate electrodes were compared with the K^+-selective glass microelectrode over the full SD continuum from SD in well-nourished tissue (0–80 min shown in **Figure 1**) to SD in hypoxic tissue to SD during global cerebral ischemia (terminal SD) (81–150 min shown in **Figure 1** and 150–300 min in **Figure 2**). Systemic hypoxia was induced by partial replacement of O_2 with N_2 in the inspired air. The negative DC shift is necessary and sufficient for identification of SD, and the duration of the negativity is a measure of the metabolic and excitotoxic burden imposed on tissue by SD (Dreier et al., 2017). Accordingly, it can be seen that both negative DC shift and increase of $[K^+]_o$ were markedly longer under hypoxia than under normoxia, and they were terminal after CA. Note that the Pt/Ir electrodes in contrast to the glass microelectrode displayed a marked negative DC reverberation following the recovery from SD under hypoxia (red asterisks), which may hinder correct assessment of the duration of the negative DC shift of SD. It is also interesting in this animal that terminal SD began spontaneously under hypoxia prior to the spontaneous CA and induced spreading depression of activity. Note the spread of the terminal SD in rostral (Pt/Ir-electrode 2)-caudal (Pt/Ir-electrode 1) direction. Panel **(B)** shows the same data from **(A)** on an expanded time scale (275–290 min). The terminal SD-induced spreading depression of the activity is shown in **(B)** using the integral of power of the spontaneous activity.

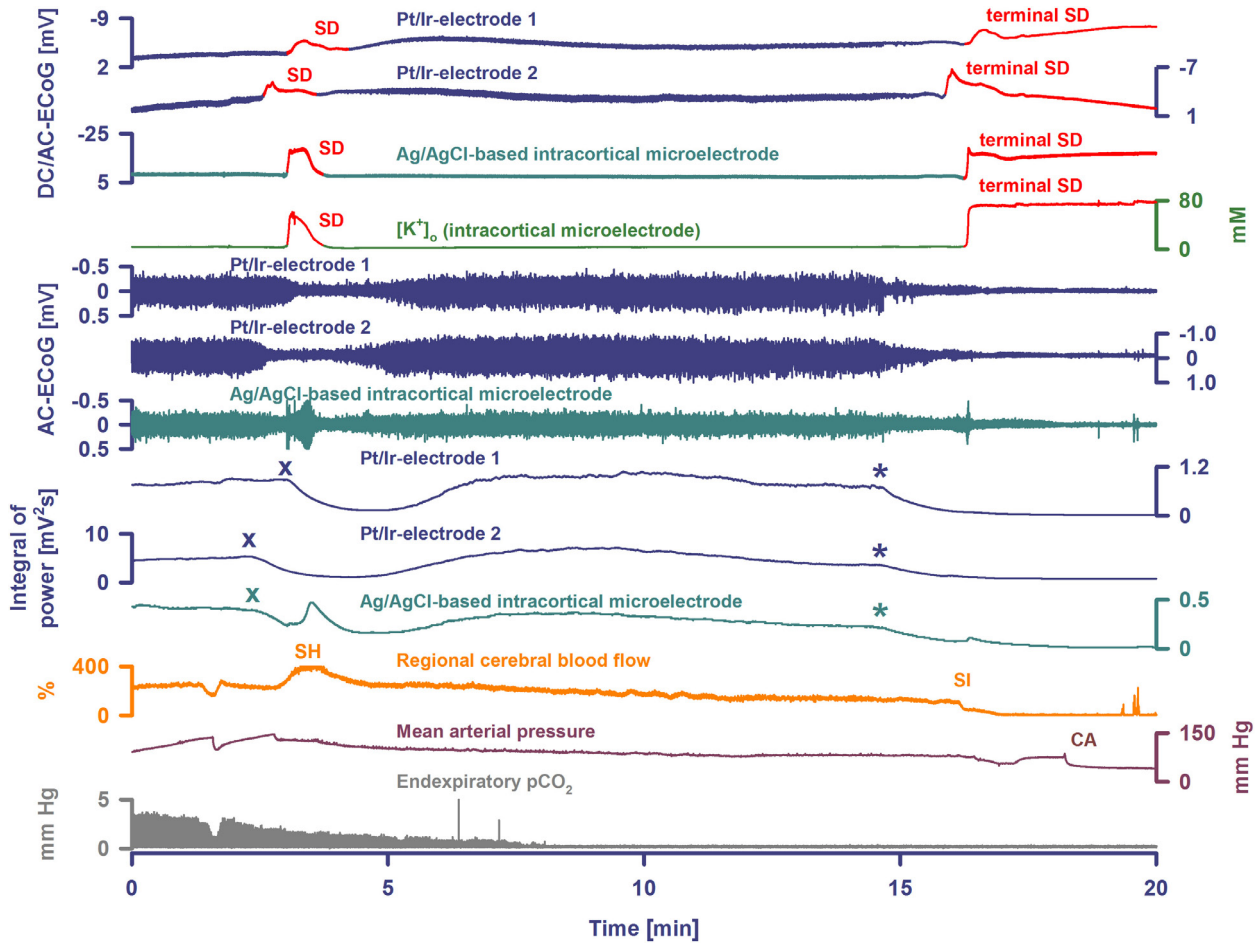

FIGURE 3 | Terminal SD during death in the rat brain. Traces are similar to **Figures 1**, **2**. A drop of KCl triggered the SD under hypoxia in this animal. Note that the hypoxic SD induced spreading depression of activity (cf. x) in contrast to the hypoxic SD in **Figure 1** which was preceded by non-spreading depression. Negative DC shift and $[K^+]_o$ were only mildly prolonged indicating that hypoxia was less severe during this experiment compared to the one displayed in **Figures 1**, **2**. Accordingly, SD induced a relatively normal spreading hyperemia (SH). Subsequently, the fraction of inspired oxygen (FiO_2) was further reduced, and a spontaneous, slowly progressive respiratory arrest (cf. end-expiratory pCO_2) eventually led to non-spreading depression of spontaneous activity (cf. asterisks). Thirty-five seconds after isoelectricity was established a spontaneous terminal SD occurred first at the rostral Pt/Ir electrode (rostral-caudal delay: 63 s) and triggered a marked spreading ischemia (SI) with rapid drop in rCBF from 112 to 1%. The SI was detected by the LDF probe 36 s after the SD had first appeared at the rostral Pt/Ir electrode. Circulatory arrest (CA) with a rapid drop in MAP occurred only 247 s after the onset of SI.

4.2 (IQR: 3.6–5.8) min. The AC-ECoG activity declined from 100 to 19 (IQR: 15–28) % during the SD-induced spreading depression. Median depression duration was 13.2 (IQR: 7.5–21.8) min. Median interval between SDs was 91 (IQR: 49–316) min.

With visual inspection of epidural DC-ECoG recordings alongside subdural recordings, negative DC shifts were identified for 31/67 (46%) SDs (**Figure 5C**). All 31 epidurally identified SDs occurred in patient 4 [14/16 SDs (88%)] and patient 7 [17/38 SDs (45%)] who had clustered SDs following COSBID's current working definition of a cluster that at least three SDs occurred within three or fewer consecutive recording hours (Dreier et al., 2017) (**Figure 6A**). When the 67 SDs were pooled, the 31 epidurally identified SDs involved significantly more subdural electrodes than the 36 SDs that could not be identified in epidural recordings (Mann–Whitney Rank Sum Test, $P \leq 0.001$, **Figures 5A,B**). Intervals between subsequent SDs were not significantly different between these two groups, but the subdural negative DC shift of epidurally identified SDs was significantly larger [5.4 (IQR: 3.9–7.8) mV versus 4.0 (IQR: 3.3–4.6) mV, Mann–Whitney Rank Sum Test, $P \leq 0.001$].

Subdural negative DC shifts were larger and shorter than epidural ones [6.1 (IQR: 5.3–7.5) versus 1.5 (IQR: 1.0–2.1) mV and 5.4 (IQR: 3.9–7.8) versus 7.2 (IQR: 4.6–13.5) min, $n = 31$, Wilcoxon Signed Rank Tests with $P \leq 0.001$]. Amplitudes and durations significantly correlated between subdural and epidural negative DC shifts (**Figure 6B**). Sometimes, a delay was noted between the onsets of the negative DC shift at the two epidural electrodes but this was difficult to quantify. SD-induced spreading depression of epidural AC-ECoG activity was only identified during 19 SDs (28%). In these, the decline in epidural AC-ECoG activity was slightly less pronounced than the subdural one [20 (IQR: 15–38) % versus 18 (IQR: 13–22) %]. Both activity

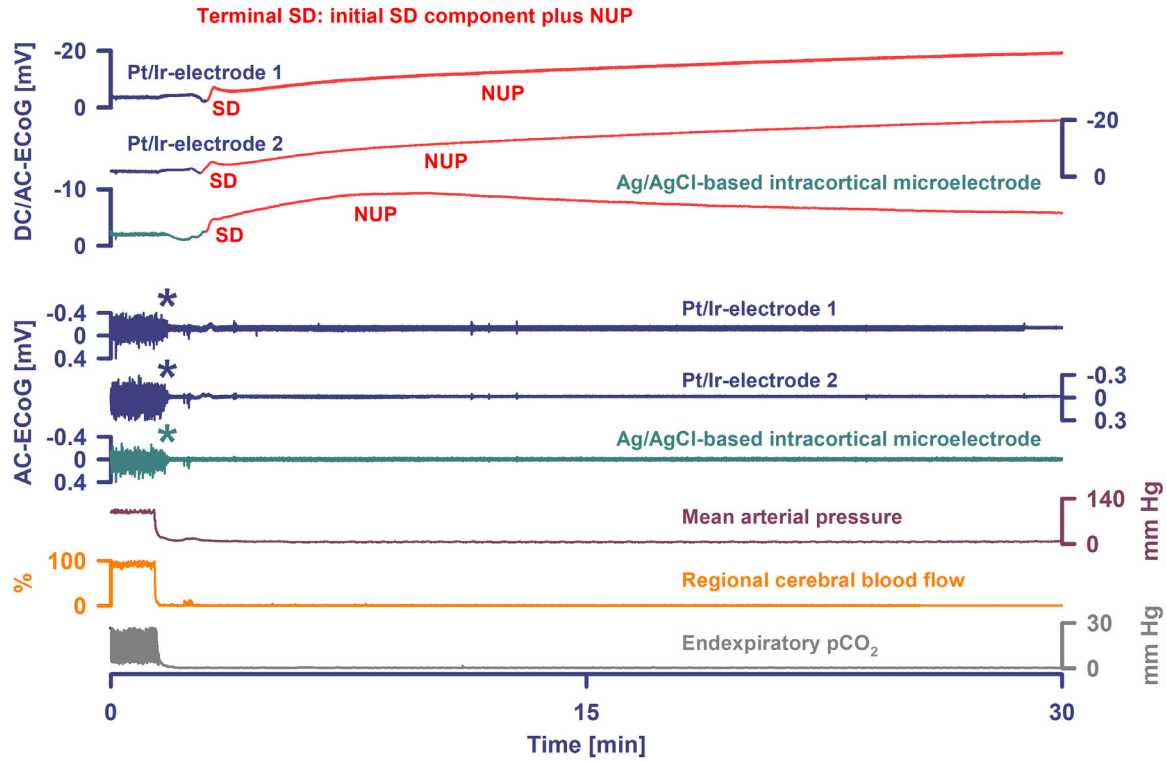

FIGURE 4 | Terminal SD in the wake of circulatory arrest. Sudden circulatory arrest was induced in this rat by injection of 10 ml of air into the heart via the femoral vein. MAP fell rapidly from 99 to 6 mmHg and respiratory fluctuations of expiratory pCO_2 ceased within 18 s; non-spreading depression caused isoelectricity within 26 s (asterisks) and terminal SD started after 98 s. Terminal SD showed an initial and a late negative DC component similar to human recordings (Dreier et al., 2018b). Whereas the initial one is the actual SD component, the late one is termed the NUP.

decline (Spearman Rank Order Correlation Coefficient: 0.599, $P = 0.00683$) and duration of spreading depression (Spearman Rank Order Correlation Coefficient: 0.898, $P = 0.0000002$) significantly correlated between epi- and subdural recordings.

A Case of Brain Death Recorded With Subdural and Epidural Electrodes

Patient 7 (cf. **Table 2**) was a 45-year-old woman with aSAH who presented with a WFNS score 4 on admission. The initial CT on Day 0 showed a grade 4 on the modified Fisher scale. CT angiography (CTA) revealed an aneurysm of the posterior communicating artery which was successfully treated with clip ligation on Day 0. After surgery, she was transferred to the ICU where prophylaxis of DCI with oral nimodipine commenced. The postoperative MRI scan on Day 1 showed widespread subarachnoid clots with oedema of the adjacent cortex. Laminar infarcts were seen at the frontal base, along the interhemispheric fissure and around a clot in the Sylvian fissure on the left side. No important parenchymal changes were noted on the CT scan on Day 3, but the CTA demonstrated signs of proximal vasospasm. Therefore, endovascular spasmolysis was performed. CT on Day 5 revealed progression of the cortical oedema. On Day 7, a wide and fixed left-sided pupil led to an emergency CT. This revealed a new infarct in the left MCA territory and a midline shift of 8 mm. Midazolam was added to the sedative regimen of propofol and sufentanil because of the increased ICP. On Day 9, another CT revealed progression of the infarct, 12 mm midline shift and beginning subfalcine herniation.

Occurrence of SDs, spreading depressions and isoelectric SDs during the clinical course are illustrated in **Figure 7B**. Clustered SDs on Day 8 after the initial hemorrhage are shown in the right panel of **Figure 6A**. Notably, when the last CT scan was performed on Day 9, the subdural electrode strip was still on viable cortex anterior to the infarct in the left MCA territory (**Figure 8**). Eleven hours thereafter, the last cluster of SDs started and led to a spreading depression with persistent loss of cortical activity through death as shown in **Figure 7A**. At all electrodes, SD then became terminal, since the negative potential shift, termed NUP, was persistent (20+ h). Additional SDs with reduced amplitude occurred superimposed on the NUP, similar to previous cases of focal or global brain death with maintained systemic circulation (Oliveira-Ferreira et al., 2010; Carlson et al., 2018; Luckl et al., 2018), but in contrast to cases when brain death followed systemic CA (Dreier et al., 2018b) (**Figure 8**). The NUP had an amplitude of −150 [IQR: (−136)–(−157)] mV at the subdural electrodes, and was also recorded at the two epidural electrodes (median amplitude: −67 mV).

At onset of the terminal cluster, MAP was at 120 mmHg, the heart rate was around 65 beats/min and the peripheral

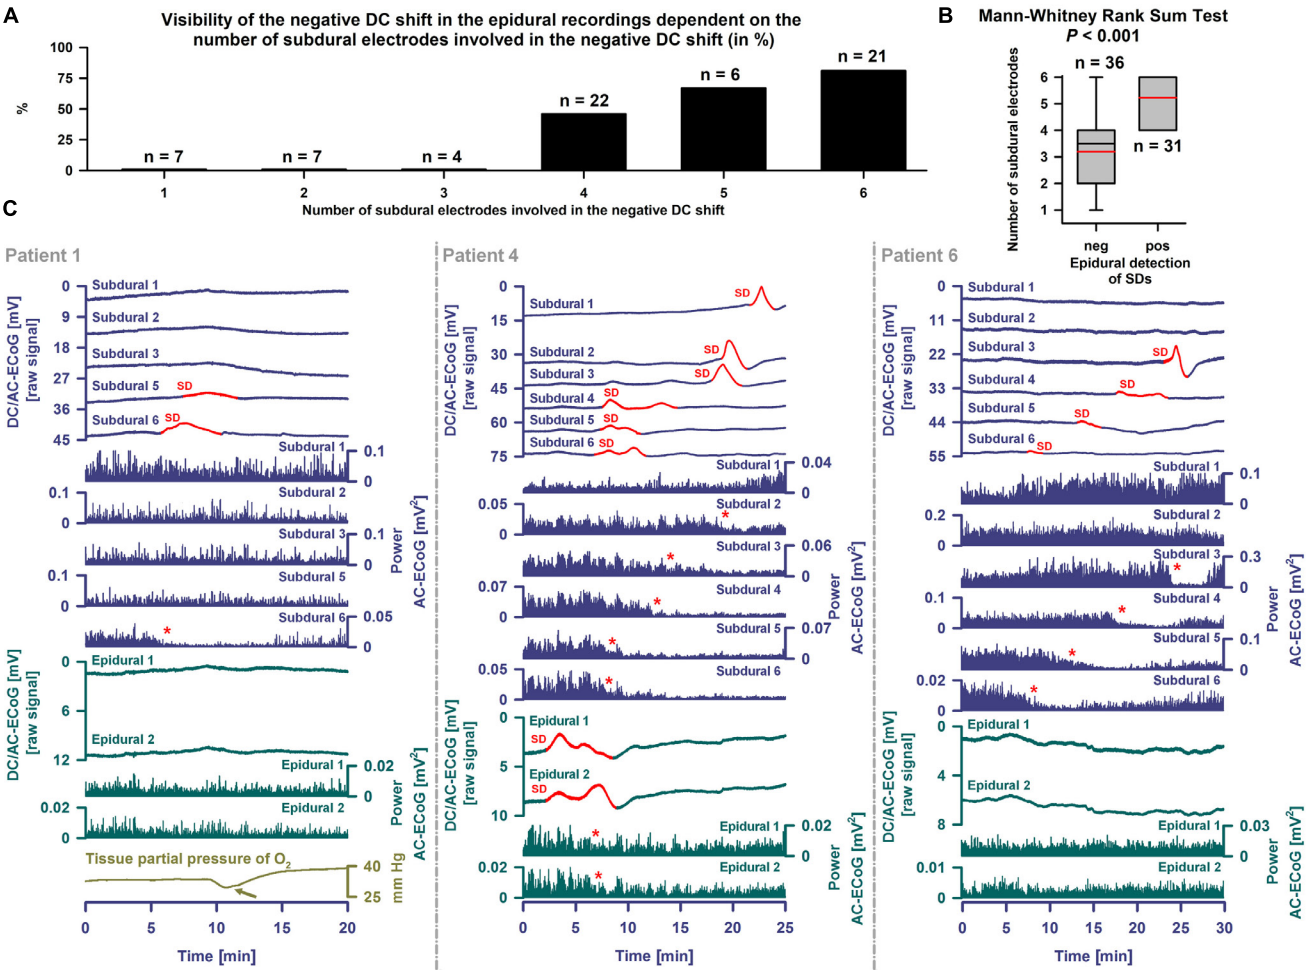

FIGURE 5 | Epidural and subdural recordings of single SDs. **(A)** The 31 epidurally identified SDs involved more subdural electrodes than the 36 SDs that could not be identified using epidural recordings. **(B)** When the SDs were pooled this was statistically significant (Mann–Whitney Rank Sum Test, $P \leq 0.001$). The whiskers (error bars) above and below the box indicate the 90th and 10th percentiles. The red reference line marks the mean. **(C)** SDs are observed as a negative DC shift propagating between neighboring electrodes (cf. top traces showing the DC/AC-ECoG (0–45 Hz) at the different electrodes, negative up). Red portions indicate potentials associated with SDs. SD-induced spreading depression is observed in the AC-ECoG recordings (0.5–45 Hz) as a rapidly developing reduction in the amplitudes of spontaneous activity that spreads together with SD between adjacent recording sites. The squared spontaneous activity is called AC-ECoG power (cf. Power AC-ECoG-traces from the different electrodes). In patient 1, 10 non-clustered SDs were recorded using subdural electrodes. Six SDs only occurred at electrode 6 and 4 also involved electrode 5. The left panel shows an example of one of these SDs. The red asterisk marks the SD-induced depression of activity at electrode 6. The light green arrow points at the SD-induced tissue hypoxia (Dreier et al., 2009; Bosche et al., 2010; Winkler et al., 2017). Different from the subdural recordings, the epidural ones did not allow clear identification of the SD, though there could be a correlate. By contrast, in patient 4 (middle panel), 14 of 16 SDs were not only seen subdurally but also epidurally. A non-clustered SD is displayed. The preceding SD occurred 12.5 h before and the subsequent one 25.1 h after this SD. Note that the SD involved all six subdural electrodes. At the epidural electrodes, not only the negative DC shift but also the SD-induced depression was visible. The red asterisks mark the SD-induced spreading depression of activity at subdural electrodes 2–5 and the two epidural electrodes. In patient 6 (right panel), the subdural DC/AC-ECoG of 3 SDs was available to the analysis. None of these showed an unambiguous correlate in the epidural DC/AC-ECoG. One of these is displayed here as an example.

O_2 saturation >98%. ICP was around 30 mmHg with a trend toward slow increase. The arterial blood gas analysis was normal, including serum lactate at 6 mg/dl, serum glucose at 155 mg/dl and normal serum electrolytes. However, shortly after onset of the terminal cluster, the patient was found to have an abrupt loss of brainstem reflexes with fixed dilated pupils. Serum lactate then increased to 12 mg/dl and serum glucose to 211 mg/dl; a sinus tachycardia up to 125/min developed. Following discussion with the family regarding the poor prognosis, the patient was terminally extubated 20 h later and expired shortly thereafter. Similar to the previous case of Carlson et al. (2018), the exact cause of death remained unclear given that there was no massive ICP increase suggestive of large stroke or oedema, and cardiac, pulmonary, and renal function were thought to be adequately supported. During CA at 20 h after brain death, a slow positive DC drift occurred which stabilized at 53 (IQR: 52–54) mV subdurally and 43 (IQR: 42–44) mV epidurally. No SDs were superimposed on this potential, consistent with the prior

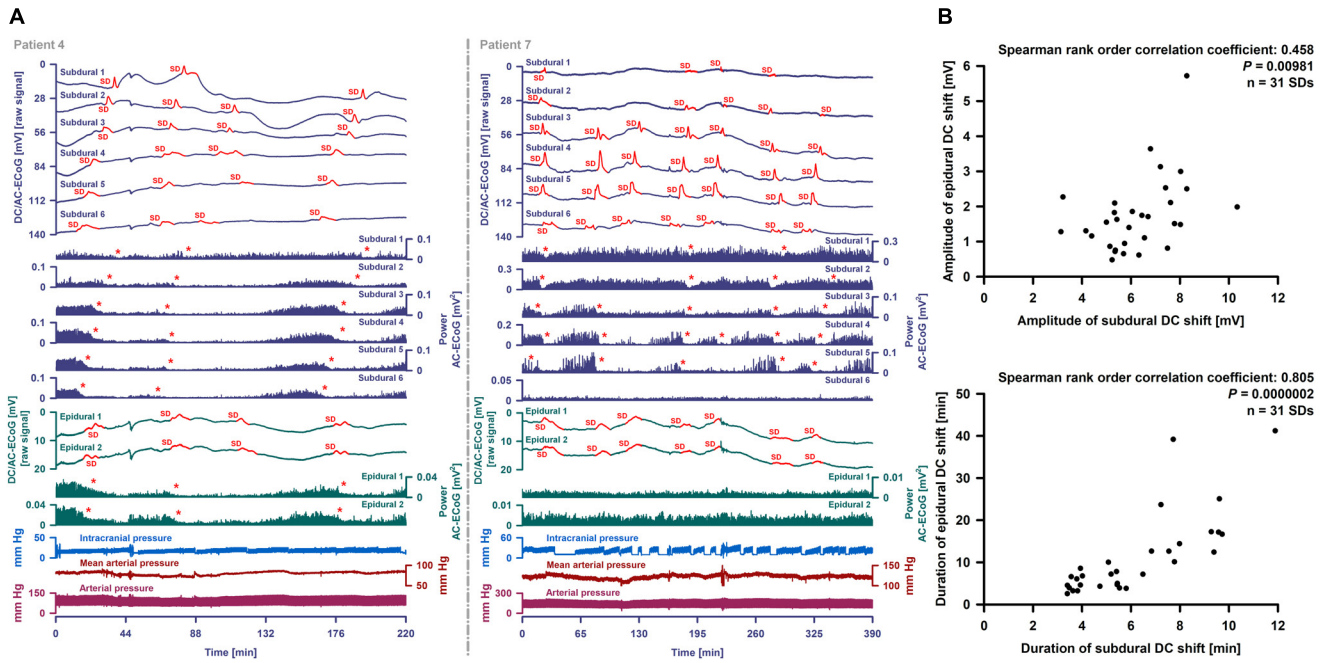

FIGURE 6 | Epidural and subdural recordings of clustered SDs. **(A)** Top six traces show the raw DC/AC-ECoG recordings from each subdural electrode (negative up). Red portions indicate potentials associated with SDs. SD-induced spreading depressions are assessed in the power of the AC-ECoG (traces 7–12). Below, the epidural recordings are shown. In the left panel, clustered SDs in patient 4 are displayed. Between an MRI on Day 2 and a CT on Day 9, the patient developed a new infarct in the vicinity of the recording strip. The SDs involved all subdural and epidural electrodes. The red asterisks mark the SD-induced spreading depressions. The third SD is an isoelectric one. In patient 7 (right panel), clustered SDs on Day 8 are shown. The electrodes were located close to a delayed cerebral infarct as shown in **Figure 8**. The SDs were observed both subdurally and epidurally in contrast to the SD-induced spreading depressions which were only seen at the subdural electrodes. **(B)** Amplitudes and durations significantly correlated between subdural and epidural negative DC shifts indicating SDs.

diagnosis of brain death and in contrast to cases where CA is the cause of subsequent brain death (Dreier et al., 2018b).

DISCUSSION

Terminal SD Under Progressive Hypoxia in Rats

The animal experiments confirmed the characteristic changes along the full SD continuum. Specifically, the duration of depolarization and near-complete breakdown of ion homeostasis, as indicated by the negative DC shift and increase of $[K^+]_o$, varied from short-lasting under normoxia to long-lasting under systemic hypoxia to persistent under severe global ischemia, since repolarization requires activation of energy-dependent membrane pumps such as Na, K-ATPases (LaManna and Rosenthal, 1975; Major et al., 2017). Short-lasting DC shifts thus indicate sufficient ATP at the recording site to fuel fast repolarization. This feature renders the negative DC shift duration a useful measure for (a) the tissue energy status and (b) the risk of injury (cytotoxic oedema and excitotoxicity) at the recording site as reviewed recently (Dreier et al., 2017; Hartings et al., 2017b).

A significant proportion of SD waves observed in patients have intermediate characteristics, as opposed to the two extremes of the SD wave in either severely ischemic or normal tissue (Dreier and Reiffurth, 2015; Dreier et al., 2017; Hartings et al., 2017b). In patients, SD waves of intermediate character might typically indicate moderate focal ischemia at the recording site. This interpretation is consistent with previous experimental observations in brain slices (Somjen, 2001) and also with the intermediate SDs recorded here in rats under systemic hypoxia. The uniformity of intermediate SDs, no matter whether they are recorded during focal ischemia or under systemic hypoxia, indicates that energy depletion is the decisive factor producing this pattern rather than, for example, diffusion of chemicals from the core of focal ischemia to the penumbra.

In contrast to the intermediate type, persistent SDs are those that are indefinitely prolonged at the recording location and will not repolarize unless oxygen and glucose availability improve. These typically occur following non-spreading depression of activity after onset of anoxia/severe ischemia, and thus historically are termed 'anoxic SD' (van Harreveld, 1946; Leão, 1947; Bures and Buresova, 1957; Marshall, 1959). However, SD can transform into intermediate and persistent types even in well-nourished tissue by the mechanism of SI, which reflects inverse neurovascular coupling (Dreier et al., 1998, 2001; Dreier, 2011; Sugimoto et al., 2018). Here, we observed SI in response to terminal SD in two out of four hypoxic animals in which the terminal SD preceded the CA. This corresponds well to previous observations under hypoxia (Sonn and Mayevsky, 2000; Sukhotinsky et al., 2008). Nonetheless, terminal SD did not cause

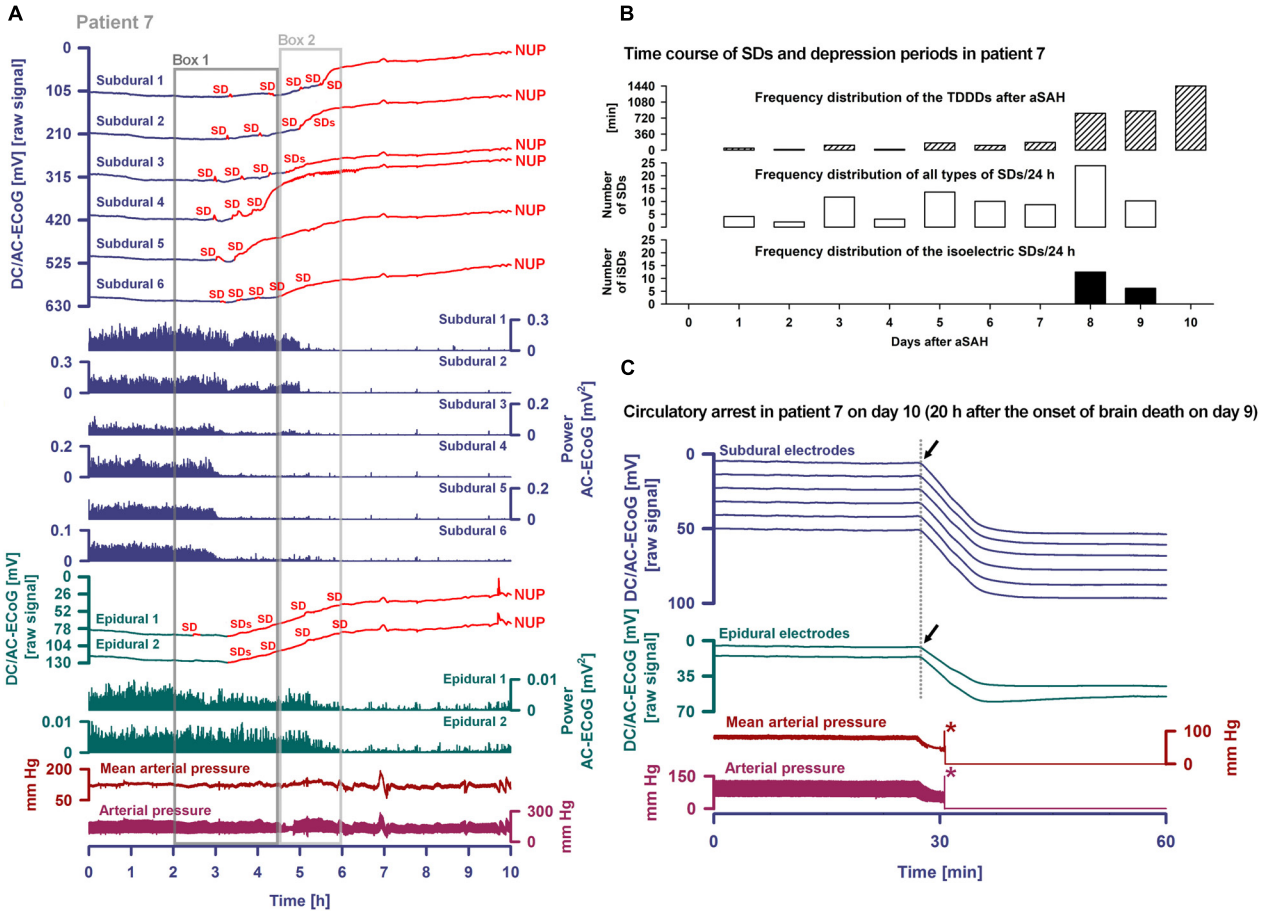

FIGURE 7 | Progress to brain death in patient 7. **(A)** The six top traces show a series of several transient SDs followed by terminal SD. The terminal SD consists of the initial SD component followed by the NUP (Dreier et al., 2018b). Traces 7–12 display the SD-induced spreading depression that persisted through death (observed as a reduction in the amplitudes of the AC-ECoG power propagating from electrode to electrode). SDs and NUP are smaller in the epidural than the subdural DC/AC-ECoG recordings. However, in particular the NUP is clearly visible also in the epidural recordings (traces 13 and 14). Also the terminal SD-induced depression of activity is seen at the epidural recordings (traces 15 and 16). Traces 17 and 18 display MAP and arterial pressure fluctuations. Regions of Box 1 outlined by the dark gray lines and of Box 2 outlined by the light gray lines are shown in detail in **Figure 8** which additionally gives the continuous ICP recordings. **(B)** The occurrence of SDs, SD-induced depression periods and isoelectric SDs in patient 7 over the whole clinical course. **(C)** When the patient underwent circulatory arrest 20 h after brain death the DC potential at all subdural and epidural electrodes showed a slow positive drift (positive down). The asterisks mark the moment when the arterial pressure monitoring was switched off.

any change in rCBF in the remaining two animals, and rCBF declined only when the systemic circulation ceased. These results evidence the continuum of hemodynamic responses to SD, which ranges from the normal hyperemic response to an increasingly inverse ischemic one (Dreier et al., 2009, 2018a).

Patterns in the development of electrocerebral silence during the dying process varied in the animals. The terminal SD could be preceded by non-spreading depression of activity, or it could trigger a spreading depression that persisted through death, or it could start when the spontaneous activity was already depressed after previous SD-induced spreading depressions. In rats, the pathophysiology of hypoxic-ischemic brain injury thus shows significant variations. In part, this may reflect whether the underlying condition is primarily hypoxic/anoxic versus abrupt circulatory collapse versus prolonged hypoperfusion. Nonetheless, the phase transition from life to death is always characterized by four events: loss of circulation, loss of respiration, loss of spontaneous brain activity and terminal SD. The latencies and even the order of the four events can vary dependent on the specific etiologies and circumstances of death.

The patterns observed in the present case and in 10 cases previously reported (Carlson et al., 2018; Dreier et al., 2018b) suggest that human death is characterized by similar variations. This is important not only for research on treatment strategies of cardiac arrest and stroke that may complement efforts to re-establish circulation, but also for the debate on organ donation after (a) either cardiocirculatory death (DCD), where death is declared between a few seconds and 10 min following the cessation of circulatory function (Boucek et al., 2008; Dhanani et al., 2012; Stiegler et al., 2012; van Veen et al., 2018), or (b) brain death.

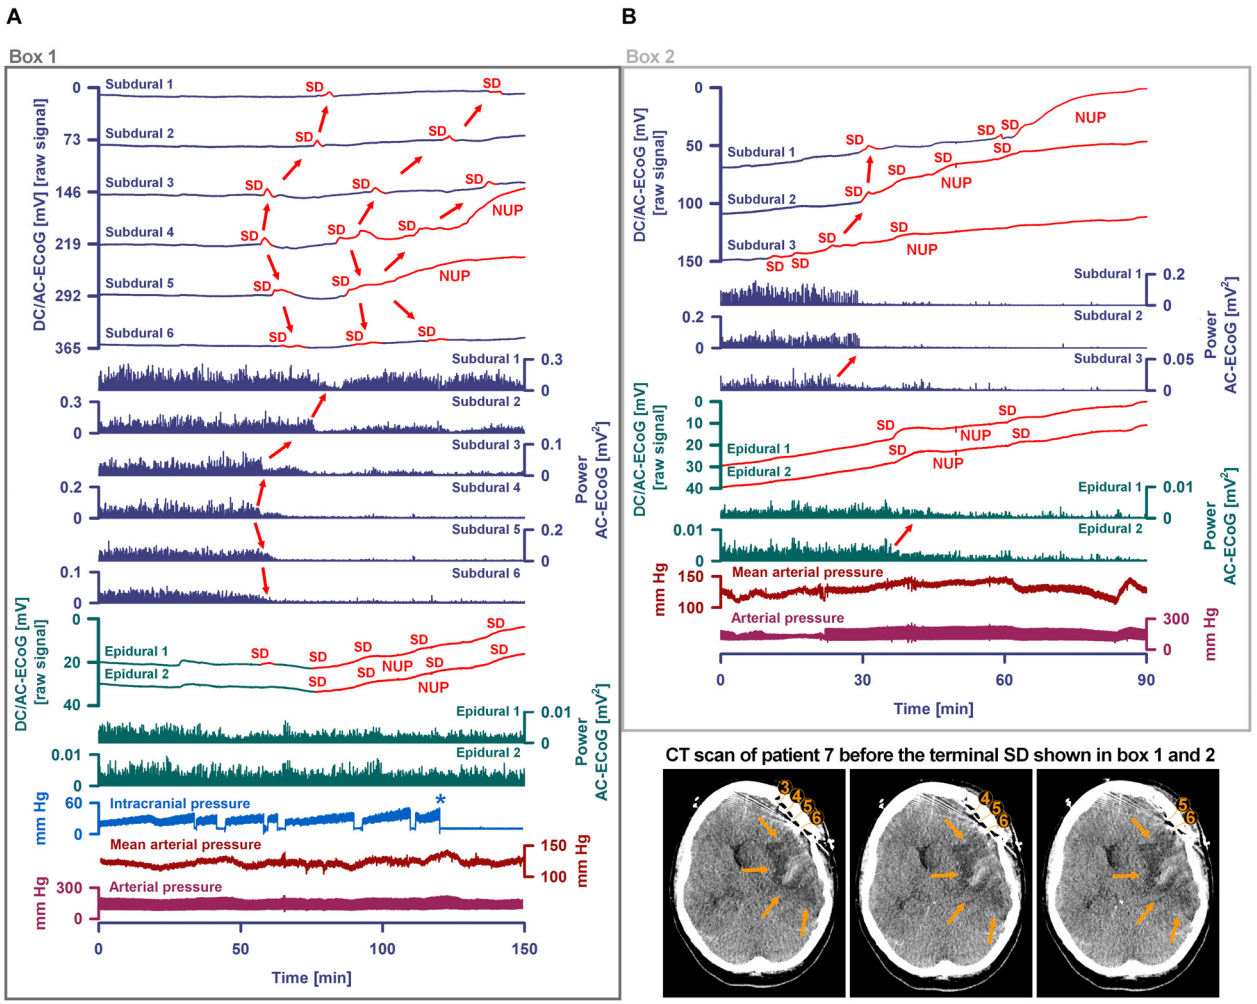

FIGURE 8 | Progress to brain death in patient 7. **(A)** A subset of the same traces in **Figure 7** is shown in greater detail. In addition, ICP is given. As outlined by Box 1 in **Figure 7**, the initial time period around the terminal SD is displayed. The SDs are marked in red. The second SD is a terminal one that starts at electrode 4 from where it spreads to electrode 5. The terminal nature of this event is indicated by the persistence of the negative DC shift. This negative potential develops further through time as a NUP, which is thought to reflect the progressive development of tissue necrosis. The red arrows mark the spreading depression of activity (middle traces). Whereas the spontaneous activity transiently recovered at subdural electrodes 1–3, the activity depression persisted through death at subdural electrodes 4–6 after the first SD. The continuous physiological variables in the bottom traces remained stable during the terminal SD. The asterisk marks the moment when the EVD was left open to counteract the ICP increase. **(B)** As outlined by Box 2 in **Figure 7**, the time period following the one in **(A)** is shown. The terminal SD spread further to subdural electrode 3 to 2 to 1. The activity depression at the subdural electrodes was eventually followed by activity depression at the epidural electrodes which persisted through death. Note that the NUP was superimposed by additional SDs of decreasing amplitude. In the right lower corner, three neighboring slices of the last CT scan are given, showing the subdural electrodes anterior to the delayed infarct in the MCA territory.

With regard to the terminal SD, it should be noted that propagation is not really the decisive property of SD and that depolarization of neurons can also take place in many other contexts. The main feature of SD is the abrupt, almost complete collapse of the small molecule gradients across cell membranes, which in the case of terminal SD is persistent and eventually leads to cell death under this condition.

Detection of SDs Using Subdural Electrodes

The animal experiments confirmed that subdural Pt/Ir electrodes reliably identify the full SD continuum. However, reliable measurement of negative DC shift durations may be complicated by multiple sensitivities of Pt/Ir electrodes, particularly in hypoxic conditions. Here, for instance we observed negative DC reverberations on Pt/Ir electrodes that were not present in Ag/AgCl electrodes. This pattern can also occur in human recordings (Drenckhahn et al., 2012). The underlying process is unclear, but may be related to the strong catalytic capacity of platinum in contrast to Ag/AgCl for many chemical reactions. To give but two examples: (a) platinum's catalytic effect on the redox reaction between hydrogen ions and molecular hydrogen renders the platinum-based hydrogen electrode method a standard among the various methods for measuring pH; (b) an additional

reaction catalyzed by platinum is the formation of water from molecular O_2 and hydrogen ions (Meunier and Popovic, 1988).

Detection of SDs Using Epidural Electrodes

A number of previous animal studies suggested that SD's negative DC shift can also be recorded using epidural electrodes (Iijima et al., 1992; Kang et al., 2013). Though subdural and intraparenchymal Pt/Ir electrodes show a good safety profile in humans (Stuart et al., 2010; Drenckhahn et al., 2016), at least theoretically, epidural electrodes pose a lower risk of bleeding and infection because they do not penetrate dura or brain (Beleza et al., 2010). However, here, only 46% of the subdurally recorded SDs could be identified using epidural electrodes. This relatively small yield may have resulted from the fact that only two epidural peg electrodes were used in each patient, in contrast to six electrodes on the subdural strip. This is supported by a previous analysis showing that a single recording location failed to detect 43% of all SDs that were identified based on consideration of a full six-electrode subdural strip (Hartings et al., 2017a). In addition, the ability to detect SDs using epidural electrodes depended on the features of a given SD. Thus, epidural electrodes were more likely to detect SDs when subdural negative DC shifts were longer and more subdural electrodes were involved in a given SD. Nonetheless, it is noteworthy that the DC shifts of SD were captured in titanium electrode recordings, since little is known about these electrodes in terms of interferences and DC recording properties. This deserves further study, not the least because titanium could also be used for intracranial recordings and is much less costly than Pt/Ir.

In a recent study, scalp EEG recordings in the rat failed to detect the negative DC shifts of SDs (Luckl et al., 2018). This supported the interpretation that DC-EEG shifts are only observable in human scalp recordings when there is an existing craniotomy (Drenckhahn et al., 2012; Hartings et al., 2014). For comparison, the median scalp DC-EEG amplitude was one twentieth of the subdural DC-ECoG amplitude (Drenckhahn et al., 2012), whereas the epidural amplitude in the present study was one quarter. The superiority of epidural peg electrodes over scalp EEG electrodes and their inferiority to subdural electrodes is congruent with findings from electrographic seizure detection (Beleza et al., 2010; Benovitski et al., 2017).

In epidural recordings, the SD-induced depression periods were even more difficult to detect than the negative DC shifts. The lower sensitivity of epidural than subdural electrodes to detect depression periods may be due to superposition of volume-conducted signals from more widespread cortical generators, due in particular to the spatial filtering of the dura. That is, epidural electrodes record from widespread sources including unaffected cortical regions that may mask and overwhelm smaller regions affected by spreading depression, making detection more difficult.

Limitations

The typical indication for the use of epidural peg electrodes in patients is the detection of epileptic foci. Unfortunately, the demand for epidural peg electrodes is low. For this reason, the manufacturer has recently discontinued their production. Therefore, we could not include more patients and the small size of the study is a limitation. However, our results provide guidance for planning future studies. For example, the next step could be to investigate whether depth electrodes placed epidurally instead of in the parenchyma are sufficient to detect SDs.

Terminal SDs Cause Electrocortical Silencing Prior to Clinical Brain Death

Similar to the previously reported case of Carlson et al. (2018), patient 7 progressed to brain death despite continued circulatory function. The neuromonitoring confirmed that (a) a series of SDs preceded the clinical signs of brain death, (b) SD-induced spreading depression initiated the final electrical silence recorded over the following 20 h, and (c) the terminal electrographic event was an SD, which initiated a NUP. The NUP is the largest bioelectrical signal ever recorded from the human brain and in the present case, similar to previous ones, had an amplitude of −150 mV (Carlson et al., 2018; Luckl et al., 2018). It is possible that the Pt/Ir-recorded NUP is not purely a biopotential, but results also in part from platinum sensitivities to diffusible chemicals. Nonetheless, the fact that the NUP was measured not only by the subdural but also the epidural electrodes affirms that the human NUP is a bioelectrical field potential. The epidural environment was likely unchanged with respect to signal-contaminating factors during the NUP, since systemic variables such as ventilation, MAP, and peripheral oxygen saturation stayed constant and the dura provides insulation from changes in the subdural compartment.

A clinical implication of this finding is that epidural electrodes may be sufficient to record the NUP. This could have relevance to patients who are at risk for secondary ischemia, but for whom placement of a subdural strip is not possible, due to lack of clinical indication for a craniotomy or a burr hole. Notably, the NUP occurs not only in brain death but also during ECI and DCI in aSAH patients (Oliveira-Ferreira et al., 2010; Dreier, 2011; Drenckhahn et al., 2012; Hartings et al., 2017c; Luckl et al., 2018). ECI and DCI predominantly affect the cerebral cortex (Birse and Tom, 1960; Stoltenburg-Didinger and Schwarz, 1987; Neil-Dwyer et al., 1994; Dreier et al., 2002; Rabinstein et al., 2005; Hartings et al., 2017c). A significant proportion of these ischemic events could thus be detectable by epidural recordings. A limitation might be that ECI- and DCI-associated NUPs are localized phenomena (Luckl et al., 2018) in contrast to the NUP during brain death (Carlson et al., 2018) or CA (Dreier et al., 2018b). Thus, recordings at multiple sites would be necessary because the exact location of future developing pathology is unknown when the neurosurgeon implants neuromonitoring devices.

When the patient underwent CA 20 h after brain death, a slow positive DC drift occurred. This was previously observed in cases of CA leading to brain death, where it occurred simultaneously with the parenchymal $p_{ti}O_2$ decline as measured by an O_2 sensor (Dreier et al., 2018b). The present findings suggest that this drift does not reflect a cerebral field potential of biological origin but

rather results from interferences, since neither brain parenchyma nor BBB should be able to generate field potentials 20 h after brain death. Consistent with this conclusion, no terminal SD was superimposed on the slow positive DC drift, in contrast to previous cases in which the brain was viable at the time of CA (Dreier et al., 2018b). The lack of terminal SD at this time, in addition to the clinical signs such as loss of brainstem reflexes and wide dilated pupils, further supports the conclusion that brain death occurred with the final cluster of SDs and associated NUP, 20 h earlier.

One remaining question is why the NUP can be at least 10 times larger in humans than in rats. The answer may relate to the different recording conditions of a closed subdural compartment in patients versus an open compartment in rats, since current leaks from the intended circuit may have occurred in the latter condition. Another possibility is that the NUP partially reflects the DC potential across the BBB and is caused by the profound interstitial and rCBF changes during the dying process. In this hypothesis, the zonal DC shift of SD, resulting from neurons and to a lesser extent from astrocytes (Makarova et al., 2008; Dreier et al., 2013), could be superimposed on a DC drift across the BBB. This hypothesis is indirectly supported by previous reports on profound differences in electrogenesis across the BBB between rats, rabbits, goats and dogs on the one hand and cats and non-human primates on the other (Tschirgi and Taylor, 1958; Held et al., 1964; Besson et al., 1970; Woody et al., 1970; Messeter and Siesjo, 1971; Kang et al., 2013). This notion may imply that future studies to uncover the generators of the NUP in humans should be performed in higher mammals rather than rodents. For example, swine share many features with humans in the pathogenesis of ischemic lesions after aSAH and would be interesting candidates for further study (Hartings et al., 2017c).

However, when considering various possible DC potential components that could contribute to the human NUP, it should not be forgotten that the NUP is experimentally defined not by simple quantifiable parameters such as its amplitude, but by three other more complex properties: (i) the beginning with SD, (ii) the fact that the ion shifts and cell oedema do not fully recover during this extremely long DC negativity, and (iii) the death of neurons (Dreier, 2011; Luckl et al., 2018). In this operational definition, however, it should be noted that the distinction of a NUP from a long-lasting SD, which has not exceeded the commitment point (Dreier and Reiffurth, 2015) and does not lead to cell damage, is currently not possible solely on the basis of electrophysiological criteria. In addition, the NUP may be experimentally of high amplitude, but may also be relatively shallow (Dreier et al., 2017). If the NUP is comparatively shallow, a cluster of SDs is typically superimposed on the NUP (Oliveira-Ferreira et al., 2010). This constellation indicates that only a fraction of the neurons in the tissue stays permanently depolarized, while the remaining fraction repolarizes after each SD. In contrast, the SD-initiated NUP in the wake of CA is typically of high amplitude and not associated with a cluster of superimposed SDs, as all neurons and astrocytes remain permanently depolarized and all cells will eventually die under this condition unless the tissue is reperfused in time.

CONCLUSION

The animal experiments indicated that Pt/Ir electrodes on the brain surface can record 100% of SDs, SD-induced spreading depressions, non-spreading depression and SD-initiated NUPs, but negative DC reverberations following the recovery from SD may complicate evaluation, especially evaluation of the NUP. To identify a very slow DC potential component as NUP, the context with other factors such as initiation by SD, possible superposition by SDs, persistent depression of neuronal activity, decrease of rCBF and $p_{ti}O_2$, occurrence of a new focal or global neurological deficit, a new ischemic lesion in sequential neuroimaging scans, or death should also be considered.

In theory, epidural electrodes are a semi-invasive alternative to subdural recordings and can be viewed as an intermediate step between invasive subdural and non-invasive scalp EEG. However, in our patients, only 46% of subdurally recorded SDs and 28% of subdurally recorded SD-induced spreading depressions were also detected epidurally. Using epidural electrodes, the NUP may be easier to detect than SDs or SD-induced spreading depressions, but measuring the initial SD component and the SD-induced persistent depression helps to distinguish the NUP from artifacts, so subdural electrodes also offer metrological advantages in the case of a NUP. Within the limits of a small study, all this indicates that the protocol investigated here with two epidural electrodes cannot replace subdural electrode strips in the clinic. The next step in the development could be to place depth electrodes with several contacts epidurally to improve the yield. In addition, such arrays could also be tested subdurally, as this could still be less invasive than the placement of a subdural electrode strip. The goal must be to find the least invasive method that still provides robust and reliable data of sufficient quality to make clinical decisions. At present, it is the subdural electrode strip that meets these criteria and whose properties need to be exceeded.

ETHICS STATEMENT

The animal study was carried out in accordance with the recommendations of the Landesamt für Arbeitsschutz, Gesundheitsschutz und technische Sicherheit Berlin (LAGetSi) (G0152/11). The protocol was approved by the Landesamt für Arbeitsschutz, Gesundheitsschutz und technische Sicherheit Berlin (LAGetSi) (G0152/11). All experimental procedures were conducted in accordance with the Charité Animal Welfare Guidelines. The reporting of animal experiments complies with the Animal Research: Reporting of *In Vivo* Experiments (ARRIVE) Guidelines. The clinical study was carried out in accordance with the recommendations of the ethics committee of the Charité – Universitätsmedizin Berlin (EA4/175/17) with written informed consent from the patients or the patients' legally authorized representatives. All patients or patients' legally authorized representatives gave written informed consent in accordance with the Declaration of Helsinki. The protocol was approved by the ethics committee of the Charité – Universitätsmedizin Berlin. Results are reported

in accordance with the STrengthening the Reporting of OBservational studies in Epidemiology (STROBE) guidelines (https://www.strobe-statement.org).

AUTHOR CONTRIBUTIONS

JD and JW contributed substantially to the conception and design of the work, and drafted and revised the manuscript for important intellectual content. SM, CL, VK, CR, KS, NH, and JH drafted corresponding sections of the manuscript. All authors have approved the final version to be published and agreed to be accountable for all aspects of the work.

FUNDING

This work was supported by grants of the Bundesministerium für Bildung und Forschung (BMBF) Center for Stroke Research Berlin 01 EO 0801 and Deutsche Forschungsgemeinschaft (DFG) DR 323/10-1 to JD, DFG DR 323/5-1 to JD and JW, DFG WO 1704/1-1 to JW, and the United States Army CDMRP PH/TBI Research Program (Contract No. W81XWH-08-2-0016) to JH.

ACKNOWLEDGMENTS

We acknowledge support from the DFG and the Open Access Publication Fund of Charité – Universitätsmedizin Berlin.

Background and Purpose: Stroke induces immediate profound alterations of the peripheral immune system rendering patients more susceptible to post-stroke infections. The precise mechanisms maintaining stroke-induced immune alterations (SIIA) remain unknown. High-Mobility-Group-Protein B1 (HMGB-1) is elevated for at least 7 days post-stroke and has been suggested to mediate SIIA. Patients with rapid clinical recovery of neurological deficits rarely develop severe infections. We therefore investigated whether rapid neurological recovery (either spontaneous or secondary to neurovascular recanalization therapy) alters the course of SIIA. National Institutes of Health Stroke Scale (NIHSS) served as surrogate marker for neurological improvement.

Methods: Fluorescence-activated cell sorting was used to define leukocyte subpopulations. C-reactive protein (CRP), procalcitonin (PCT), HMGB-1, GM-CSF; IFN-β, IFN-γ, IL-1β, IL-1RA, IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, IL-17, IL-17F, IL-18, TNF-α, MIF, IL-8, MCP-1, MCP-4, MIP-3α, MIP-3β, Eotaxin, soluble IL-6 receptor, E-selectin, and P-selectin were analyzed by ELISA or Multiplex Assays. Serum miRNA expression changes were analyzed by qPCR.

Results: Cellular parameters were similar in the improved and non-improved cohort on admission. In patients with rapid clinical recovery absolute and relative leukocyte, neutrophil, and lymphocyte numbers normalized promptly overnight. In contrast, HMGB-1 serum levels did not differ between the two groups. Nine miRNA were found to be differentially expressed between improved and non-improved patients.

Conclusions: SIIA are detectable on admission of acute stroke patients. While it was assumed that post-stroke immunosuppression is rapidly reversed with improvement this is the first data set that shows that improvement actually is associated with a rapid reversal of SIIA demonstrating that SIIA require a constant signal to persist. The observation that HMGB-1 serum concentrations were similar in improved and non-improved cohorts argues against a role for this pro-inflammatory mediator in the maintenance of SIIA. Serum miRNA observed to be regulated in stroke in other publications was counter regulated with improvement in our cohort.

INTRODUCTION

Post-stroke infections, predominantly pneumonia, are associated with increased mortality and impaired neurological outcome. In recent years, it has been clearly shown in both experimental stroke and stroke patients that these infections are closely related to stroke-induced immune alterations (SIIA) of the peripheral immune system (1, 2). SIIA develop within the first hours of ischemic stroke and persist at least for days up to weeks (3–5).

Stroke volume and stroke severity on admission as determined by NIHSS are associated with post-stroke infections (6) and patients with transitory ischemic attacks have significantly fewer infectious complications and show a milder immune response after stroke compared to patients with complete stroke (7) and it is likely that patients with initially severe ischemic stroke that improve after hyperacute treatment have a reduced risk of infections and will show milder immune alterations after stroke.

To date it is unknown how SIIA are maintained and how they are reversed. We have investigated whether SIIA are influenced by clinical improvement. We hypothesized that rapid clinical improvement is associated with a reversal of SIIA. If SIIA were self-maintained after the induction within the initial hours of stroke, the time course of cellular changes should be similar in patients with rapid neurological recovery compared to those with persistent neurological deficits. If SIIA required an ongoing signal from injured brain tissue to persist, it should be reversed rapidly in patients with neurological improvement. Therefore, we took advantage of the National Institutes of Health Stroke Scale (NIHSS) reduction from admission to day 1 as a marker for the neurological improvement. Experimental and human stroke studies delivered proof that the hypothalamic–pituitary–adrenal axis and the autonomic nervous system release catecholamines and glucocorticoids which results in stroke-induced immune suppression. These hormones and transmitters have a very short half-life and return to normal levels within 24 h after an initial increase induced by ischemic brain injury (6) while the functional deficits of the immune system persist (4).

In animal models High-Mobility-Group-Protein B1 (HMGB-1) has been suggested as an important mediator of SIIA (8, 9). Others and we have reported earlier that HMGB-1 is elevated post-stroke at least for 7 days while its decoy receptors sRAGE and esRAGE are not altered (5, 8). HMGB-1 binds DNA within the nucleus but can be passively released during brain cell death or actively secreted by immune cells as an alarmin. Post-stroke the amount of HMGB-1 correlates rather with the amount of leukocytes in the peripheral blood than with the brain lesion size (10). We quantified HMGB-1 in serum of the improved and non-improved stroke patient cohort on admission and on day 3 to determine its possible role for maintaining post-stroke immune suppression.

SIIA include quantitative and functional alterations of innate and adaptive immune cells. Granulocytes increase in number but lose their ability to fight bacterial infections through radical production and neutrophil extracellular trap release (3). Lymphocytes are lost from the peripheral blood of patients (4, 5). It is also known that IL-6 and CRP are significantly elevated in patients suffering from an ischemic stroke and that HLA-DR on monocytes is reduced (5, 11). We therefore quantified peripheral blood immune cells and a panel of cytokines, chemokines, and acute phase proteins within the serum of the improved and non-improved stroke patient cohort.

MiRNA are known to be important regulators of immune responses and several miRNA were found to be differentially expressed after stroke (12–14). We investigated fold changes of serum miRNA amounts on day 1 post-stroke between the improved and non-improved cohort.

MATERIALS

Patients and Controls

A *post hoc* analysis was performed on patients included in a prospective explorative study. This study recruited 40 ischemic stroke patients from the dedicated stroke unit of the University Medicine Greifswald from 2015 to 2016. Blood was sampled on admission within 24 h of stroke onset as well as on days 1, 2, 3, 4, 5, and 7 thereafter.

Patients aged $\geq$18 years suffering from ischemic middle cerebral artery (MCA) stroke were eligible for this study within 12 h after the onset of symptoms if their National Institutes of Health Stroke Scale (NIHSS) was $\geq$8 and if no signs of systemic infection were detected on admission (C-reactive protein (CRP) $\leq$50 mg/L and procalcitonin (PCT) $\leq$0.5 ng/mL). Patients receiving immunosuppressive drugs or diagnosed with a non-curatively treated malignoma were not recruited. Additional exclusion criteria were severe cerebral disorder in medical history (e.g., ischemic or haemorrhagic stroke, meningitis, encephalitis, severe cerebral trauma, or epilepsy), any contraindication for MRI (e.g., pace maker), clinically significant anemia (hemoglobin $<$ 3.7 mmol/l), immunosuppression and the lack of written informed consent by the patient himself or through a surrogate where appropriate (See **supplemental Table I**).

All patients received best medical care on a dedicated stroke unit according to local standards. Recanalization with recombinant tissue plasminogen activator (rtPA) and/or thrombectomy was carried out as clinically indicated. Age-matched control individuals were recruited from the ophthalmology clinics among patients scheduled to receive cataract surgery. Controls were neurologically and immunologically healthy. See the participants' characteristics in **Table 1**. The study was approved by the local ethics committee (No. BB 050/15).

METHODS

Blood Sampling

Blood was obtained immediately on admission (d0) and between 6:30 and 7:30 in the morning on days 1, 2, 3, 4, 5, and 7 in different quantities. Differential blood cell counts (XN9000, Sysmex, Norderstedt, Germany) and the values for PCT, IL-6 (Adivia Centaur XPT, Siemens Healthcare Diagnostics, Eschborn, Germany) and CRP (all measured with the Dimension Vista, Siemens Healthcare Diagnostics, Eschborn, Germany) were measured in the central laboratory facility of the University Medicine Greifswald.

**Clinical improvement was defined as a reduction of more than 25% of the NIHSS score from admission to day 1.*

Determination of Cell Subset

Fluorescence-activated cell sorting was used to measure cell counts for leukocytes, neutrophils, T cells, CD4+T cells, CD8+T cells, NK cells, and B cells (anti-CD45 FITC; anti-CD56 PE, anti-CD16 PE, anti-CD19 ECD, anti-CD3 PC5, IgG1 PC7, anti-CD4 PE, anti-CD8 PCD, anti-CD3 PC5 [Beckman Coulter]).

Determination of Inflammatory Mediators

All patients' sera were sampled on admission day (day 0), days 1, 3, and 5 and immediately frozen at −80°C for later analysis.

Biomarker determination was performed at the Multiplex Facility at University Leiden utilizing the multi-analyte profiling (xMAP) technology (Luminex, Austin, USA) for Cathepsin S, Eotaxin, E-selectin, GM-CSF; IFN-β, IFN-γ, IL-1β, IL-1RA, IL-2, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, IL-17, IL-17F, IL-18, MIF, MCP-1, MCP-4, MIP-3α, MIP-3β, P-selectin, MMP-3, soluble IL-6 receptor, TNF-α). To analyse stroke recovery effects and not inter-individual differences only those cytokines were included into the analysis where stroke patients with or without improvement had no differences on day of admission.

IL-6 was determined twice due to multiplex setup. We only show the results gained in the central laboratory facility of the University Medicine Greifswald which provide higher precision in terms of standard deviation and coefficient of variation.

HMGB-1 was determined by ELISA according to the manufacturer's instructions (IBL International, Hamburg, Germany) from serum samples gained and frozen at −80°C on admission and day 3. Haemolytic serum samples were excluded because they lead to false positive ELISA results. Some HMGB-1 levels exceeded the standard range and were set to the highest standard due to lack of sample for reanalysis.

Determination of Stroke Lesion Size

Diffusion weighted MRI images were used to calculate infarct sizes (3.0 Tesla). To analyse the location and stroke size images were analyzed using OSIRIX 5.6. To calculate the infarct size, the regions of interest were defined manually and the lesion volume was calculated semi-automatically. Initial MRI was performed between days 1 and 3; the second MRI was performed between days 5 and 7 post-stroke.

Statistical Analysis

Because this is a *post hoc* data analysis, group sizes were not calculated prior to analysis, but *post-hoc* power analysis suggests, that our group sizes are adequate to detect effect sizes from previous trials (4). All data sets were tested for adherence to the Gaussian distribution with the Kolmogorov-Smirnov test. Since some of the data failed the normality test we used non-parametric testing throughout. The Kruskal-Wallis test with Dunn's multiple comparison test as a post-test or the Mann-Whitney test were used as appropriate. For comparing dichotomous data fisher's exact test was used. Correlations were determined by Spearman analysis. GraphPad-PRISM 5.0 (GraphPad Software Inc., San Diego, CA, USA) was used for all analyses. A $p < 0.05$ was regarded as significant.

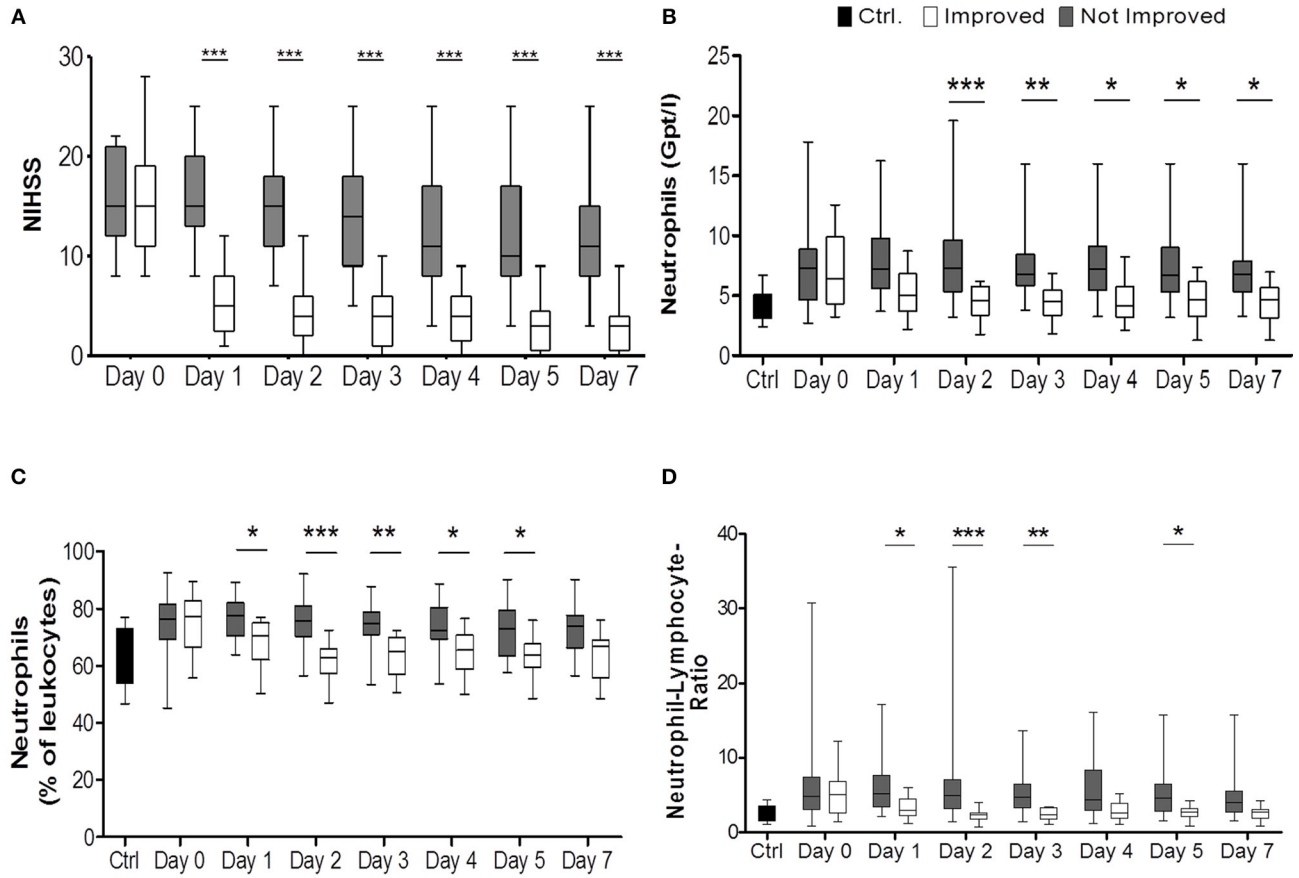

FIGURE 1 | Comparison of improved patients (white bars) vs. non-improved patients (gray bars) on the day of stroke unit admission (day 0), days 1, 2, 3, 4, 5, 7. National Institutes of Health Stroke Scale (NIHSS) served as surrogate marker for neurological improvement **(A)** ($n_{imp} = 13$, $n_{non-imp} = 27$). Healthy control patients are given in black bars. **(B)** illustrates the absolute numbers of neutrophils (Gpt/l) ($n_{imp} = 12$, $n_{non-imp} = 25$) while **(C)** shows relative numbers (%) ($n_{imp} = 12$, $n_{non-imp} = 25$). In **(D)** the lymphocyte-neutrophil ratio is shown ($n_{imp} = 12$, $n_{non-imp} = 25$). $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$; Box and whiskers (Min–Max) are given.

MiRNA Groups were tested for differential expression by applying a *t*-test. None of the 9 herein found regulated miRNA passed a Benjamini-Hochberg correction to avoid false positive results at a significance level of 0.05. The results of the *t*-test reported in this manuscript are therefore explorative.

Definition of Clinical Improvement

To study the effect of rapid clinical improvement on SIIA we took advantage of the NIHSS score and defined a reduction of more than 25% from admission to day 1 as marker of rapid clinical improvement after stroke. Thirteen patients did profoundly improve by this definition while 27 patients did not (see **Table 1**; **Figure 1A**).

miRNA

We investigated fold changes of serum miRNA amounts on day 1 post-stroke between the improved and non-improved cohort. Serum miRNA was isolated from all patient samples and then analyzed by SYBR Green based miRCURY LNA PCR Human Panel I assay by Qiagen. The assay included 372 different miRNA. Samples were analyzed individually. Quality controls included melting curve analysis, calculation of amplification efficiency and comparison of Cq values to background level in the negative control sample. Spike-ins served as RNA isolation and cDNA synthesis control. To avoid data variation Quiagen controlled for hemolysis by the ratio between red blood cell miR-451 and miR-23a that is relatively stable in serum and plasma and not affected by hemolysis. Normalization was performed based on the average of the assays detected in all samples as this was shown to be the best normalization for qPCR studies involving numerous assays (15). For the present study, this included 43 assays.

RESULTS

Notably, all patients who improved rapidly after stroke according to our definition received some form of treatment, either mechanical thrombectomy or systemic thrombolysis with rtPA or both, while in the groups without rapid improvement only 63% of patients received some form of treatment. This difference was statistically significant ($p = 0.0164$). While both groups had nearly identical median NIHSS scores on admission

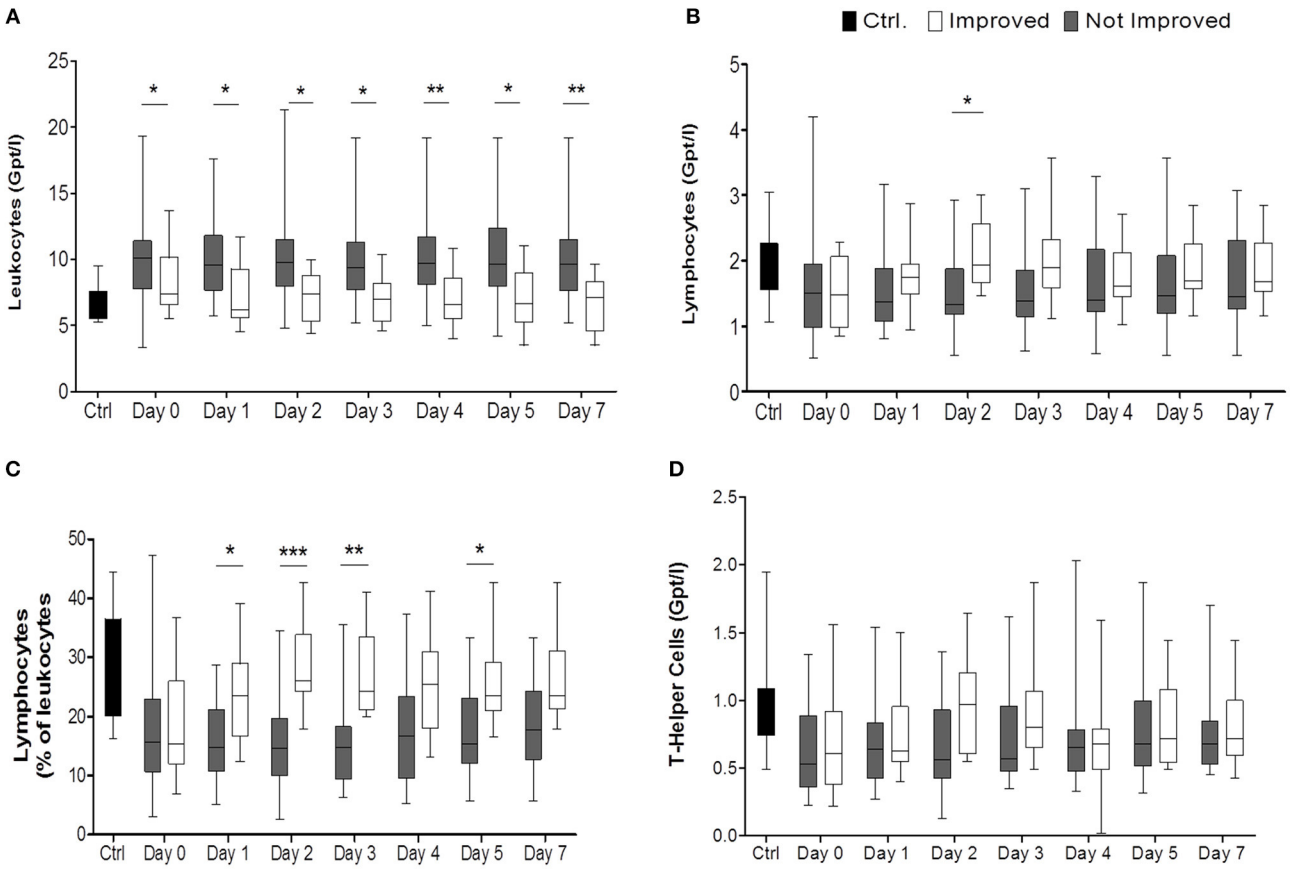

FIGURE 2 | Comparison of improved patients (white bars) vs. non-improved patients (gray bars) on the day of stroke unit admission (day 0), days 1, 2, 3, 4, 5, 7, while healthy control patients are given in black bars. In **(A)** the absolute numbers of leukocytes (Gpt/l) ($n_{imp} = 13$, $n_{non-imp} = 26$), in **(B)** absolute numbers of lymphocytes (Gpt/l) and in **(C)** relative numbers of lymphocytes (%) are shown. Absolute T helper cells (Gpt/l) are given in **(D)**. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$; Box and whiskers (Min–Max) are given ($n_{imp} = 12$, $n_{non-imp} = 25$).

[$NIHSS_{improved}$: 15 (IQR 11–19), $NIHSS_{non-improved}$: 15 (IQR 12-21)], median NIHSS scores were significantly different on all other days ($p < 0.0001$; **Figure 1A**). Stroke volumes measured by MRI after treatment and early improvement were markedly smaller for patients with clinical improvement compared to patients without clinical improvement (**Table 1**) between days 1 and 3 ($p = 0.001$) and days 5 and 7 ($p = 0.012$).

Cellular Parameters

Comparison of the total stroke cohort with controls revealed changes in agreement with previous reports: Total leukocyte numbers increased significantly on all days compared to controls (**Supplemental Figure IC**), and absolute and relative neutrophilia ($p_{absolute} = 0.0041$, **Figure 1C**; $p_{relative} = 0.0025$, **Supplemental Figures IA,B**) was observed. Also, the absolute number of CD4+ T cells was significantly reduced on admission and on day 1 ($p = 0.0345$, **Supplemental Figure IIA**). CD8+ T cells, NK cells, and B cells weren't altered in absolute numbers or percentage of parent leukocytes (**Supplemental Figures IIB–D**).

On admission, the immune alterations observed in patients with subsequent improvement and without improvement were remarkably similar, no significant differences were observed for the cell populations investigated.

Improved patients had lower neutrophil counts and frequency than non-improved patients from days 1 or 2 until day 7 after stroke ($p_{absolute} < 0.0001$; $p_{relative} < 0.0001$; *post-hoc*: days 1, 2, 3, 4, 5) (**Figures 1B,C**, **Supplemental Figures IIIB, IVA**). The lymphocyte-neutrophil ratio was significantly increased in patients without improvement on days 1, 2, 3, and 5 (**Figure 1D**, **Supplemental Figure IIID**).

From days 1 to 7 absolute leukocyte counts were significantly elevated in the non-improved group compared to the improved one ($p < 0.001$) (**Figure 2A**, **Supplemental Figure IIIA**). Non-improved patients had more pronounced absolute and relative lymphocytopenia during the observation period than patients with neurological improvement (for absolute numbers: $p < 0.0306$, *post-hoc*: day 2; for relative numbers: <0.0001, *post-hoc*: days 1, 2, 3, 5) (**Figures 2B,C**, **Supplemental Figures IIIC, IVB**). The absolute CD4+ T lymphocyte count tended to be higher in improved patients than in not improved patients especially on day 2 (**Figure 2D**). CD8+ T cells, NK cells, and B cell subpopulations did not differ between the two groups (data not shown).

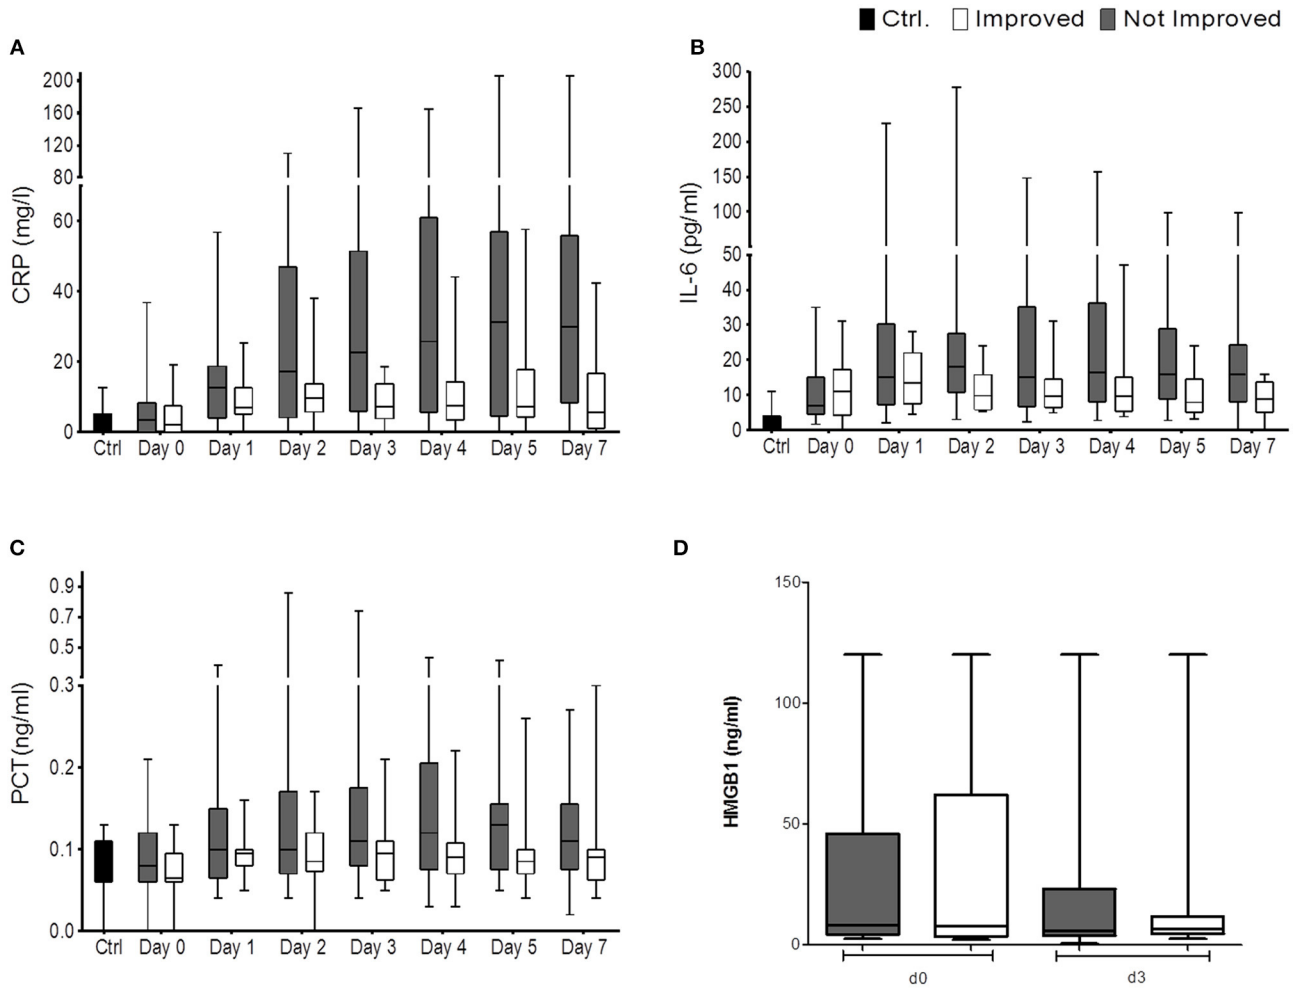

FIGURE 3 | CRP (mg/L) **(A)**, IL6 (pg/ml) **(B)**, PCT (ng/ml) **(C)**, and HMGB-1 **(D)** are shown for the comparison of improved patients (white bars) vs. non-improved patients (gray bars) on the day of stroke unit admission (day 0), days 1, 2, 3, 4, 5, 7 ($n_{imp} = 13$, $n_{non-imp} = 27$). HMGB-1 (in ng/ml) is shown for improved patients (white bars) and non-improved patients (gray bars) on the day of stroke unit admission (day 0) and day 3. Box and whiskers (Min–Max) are given ($n_{imp} = 11$, $n_{non-imp} = 16$).

Acute Phase Proteins

Despite an apparent trend toward higher CRP, PCT, and IL-6 in the non-improved cohort, statistical significance was not reached throughout the observation period (**Figures 3A–C**).

We found serum concentrations of HMGB-1 similar to our last study (5, 10). While the investigated immune alterations post-stroke had promptly reversed in the improved cohort, HMGB-1 concentrations were not differentially regulated between the improved and non-improved cohort at the investigated time points (**Figure 3D**).

Serum Pro- and Anti-inflammatory Cytokines, Chemokines, and Biomarkers

To analyse the effect of clinical improvement on soluble immune markers we measured cytokines (GM-CSF; IFN-β, IFN-γ, IL-1β, IL-1RA, IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, IL-17, IL-17F, IL-18, TNF-α, MIF), chemokines (IL-8, MCP-1, MCP-4, MIP-3α, MIP-3β, Eotaxin), and biomarkers (Cathepsin S, MMP-3, soluble IL-6 receptor, E-selectin, P-selectin).

Cathepsin S was significantly elevated in the improved cohort on day 3 ($p = 0.0006$) (**Figure 4A**). MIP-3a and MMP-3 were significantly reduced from days 1 to 5 in the improved cohort and also displayed the same trend on admission (MIP-3a $p = 0.0001$; MMP-3 $p = 0.0003$) (**Figures 4B,C**). Other cytokines, chemokines, and biomarkers were not regulated or showed inter-individual differences on admission (data not shown).

Post-stroke Infections

We used a previously established definition of infections (4) to categorize patients. To fulfill these criteria patients had to show clinical signs of infection and have a serum CRP above 50 mg/L and PCT above 0.5 ng/mL. Only one patient in the non-improved cohort fulfilled all three criteria, suffering from pneumonia. Considering also patients fulfilling 1 or 2 criteria only (defined

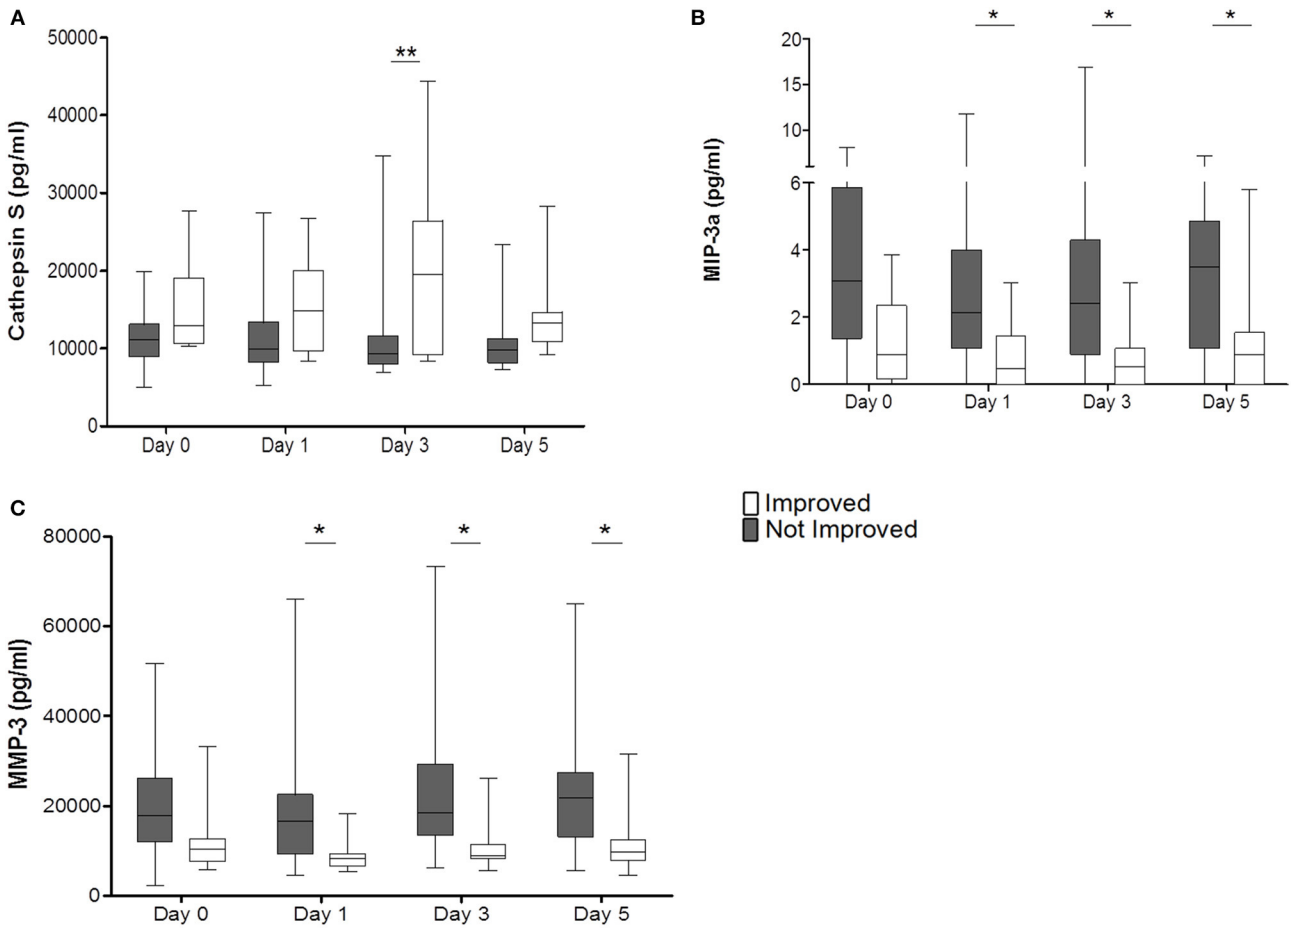

FIGURE 4 | Improved patients (white bars) and non-improved patients (gray bars) are given for Cathepsin S (pg/ml) **(A)**, MIP-3a (pg/ml) **(B)**, and MMP-3 (pg/ml) **(C)**. $^{*}p < 0.05$; $^{**}p < 0.01$; Box and whiskers (Min–Max) are given ($n_{imp} = 13$, $n_{non-imp} = 27$).

unclear infection status according to our criteria) 56% of the non-improved cohort had signs of infections, compared to 23% of the improved cohort.

miRNA

Forty three of the Three hundred and seventy two analyzed miRNA were detectable in all samples investigates. The average number of miRNA detected per sample was 112. Nine miRNA were differentially expressed between the improved and non-improved patient group (cut-off $p < 0.05$) (**Table 2**).

DISCUSSION

Post-stroke immune alterations are a well-described phenomenon. Its functional characteristics have been investigated in different immune cell populations and its clinical relevance is revealed by the fact that in human and experimental studies the extent of SIIA correlates with post-stroke infection (4, 7, 16, 17). While stroke severity and the extent of SIIA correlate (10), the relationship of early neurological recovery and SIIA has not been investigated. Here, we describe the novel observation that early clinical improvement is associated with a rapid reversal of SIIA in stroke patients within 24 h. At admission, patients with and without improvement had identical stroke severity, as measured with the NIHSS score [15 (IQR 11–19) vs. 15 (12–21)]. As a rough estimate the NIHSS on admission can be considered a surrogate marker for the tissue at risk. Therefore, the neurological improvement can be considered to correlate with rescued penumbra. While the MRI imaging would allow for a better assessment of tissue at risk and the volume of brain tissue rescued due to recanalization therapy this MRI data on admission were not available for this study. Although we only measured stroke lesion size between days 1 and 3 (MRI 1) and days 5 and 7 (MRI 2) after stroke the observation that the MRI lesions of patients with an improvement are markedly smaller than in patients without improvement supports the use of these surrogate markers. Among patients with rapid improvement, the treatment protected viable brain parenchyma in the penumbra and thereby not only reduced the neurological deficit (NIHSS) but also reverted parts of the SIIA.

While the initiation of SIIA has been in the focus of many studies, data on the mechanisms that maintain or reverse SIIA remain scarce. HMGB-1 has been suggested to play a

role in SIIA or influence the outcome of tested patients and animals in at least 6 studies (8–10, 18–20). With a given sample size that allows to detect large effect sizes only, we observed no difference in the regulation of HMGB-1 serum levels in patients with and without rapid clinical improvement. While our data do not support the hypothesis that HMGB-1 is involved in maintaining immunosuppression, additional studies are required to further define the role of HMGB-1 in stroke induced immunosuppression.

In our explorative analysis of miRNA expression we detected 9 miRNAs which were differentially regulated between improved and non-improved stroke patients. Five of these had been described as regulated in ischemic stroke compared to healthy controls. In agreement with our hypothesis, the miRNAs in the cohort of improved stroke patients appear to be regulated toward healthy controls. Of interest, miR99a which is enhanced in our improved cohort has been suggested to exert neuroprotective effects through inhibition of pro-caspase-3 and caspase-3 expression following cerebral ischemic stroke (21). Let-7e and miR-145 were reported to be upregulated by Sepramaniam et al. in acute stroke while miR-505 and miR-30c were reported to be downregulated (14). These miRNA were regulated in the opposite direction in our improved cohort accordingly.

MiRNA data regarding stroke are controversial discussed due to different methods, tissues, in man and animal studies (12–14, 21). Due to our small sample size our results are limited but proof the value of further investigations. Since miRNA seem to be differentially regulated between the improved and non-improved cohort they might emerge as possible targets for therapy to improve outcome especially in patients with an unsuccessful acute therapy.

Some limitations apply to our *post hoc* study. Due to the design of the original study the sample size is limited to 40 patients and no preceding sample size calculation was performed. As a consequence, resulting subgroups are small, limiting our power to the detection of large effects. Due to the exploratory nature of the study no adjustment for multiple testing was performed. Nevertheless, our findings are robust across the parameters investigated.

CONCLUSION

While the course of stroke induced immunosuppression and the gradual recovery of immune function after the first week from stroke onset is well-described the change of the patients' immune status in dependence on successful acute recovery due to recanalization strategies had not been investigated. Here we report the novel finding that successful recanalization therapies by rtPA and thrombectomy not only improve neurological function but also reverse SIIA promptly. The rapid recovery observed in the improved cohort therefore strongly supports the requirement of continuous signals to maintain stroke induced immune alterations as early as day 1 post-stroke to maintain SIIA. Future studies should therefore focus on brain injury-induced signal cascades to fight the detrimental effects of SIIA in severe ischemic stroke.

ETHICS STATEMENT

The study protocol was approved by the ethics committee of the Medical Faculty, University of Greifswald (No. BB 050/15). Controls gave direct informed and written consent to participate. Patients gave informed and written consent directly or through a surrogate.

AUTHOR CONTRIBUTIONS

AV, AD, and JR designed the study. CW, CH, and BvS recruited patients and controls. CW and CH evaluated the FACS and cytokine data. JG measured HMGB-1 and evaluated the data. SL evaluated stroke lesion size. JS, AV, AD, JR, and CW are responsible for data interpretation. AV, CW, JR, and AD wrote the manuscript.

FUNDING

AV received funding from the University of Greifswald—Käthe-Kluth-Research-Group. JR was funded by the Gerhard-Domagk-Program of the University Medicine

Greifswald. The funders had no role in the study design, data collection and analysis, decision to publish or preparation of the article.

ACKNOWLEDGMENTS

We thank the patients and their next of kin for participating in this study and stroke physicians for their support in the recruitment of patients. We thank Dr. Sabine Ameling for assistance in analyzing miRNA data. We thank Sonya Ceesay for supporting the study through control recruitment, blood sampling and data handling.

Stem cell therapy has emerged as a new promising therapeutic strategy for intracerebral hemorrhage (ICH). However, the efficiency of stem cell therapy is partially limited by low retention and engraftment of the delivered cells. Therefore, it's necessary to improve the migration ability of stem cells to the injured area in order to save the costs and duration of cell preparation. This study aimed to investigate whether overexpression of CX3CR1, the specific receptor of chemokine fractalkine (FKN), in adipose-derived stem cells (ADSCs) can stimulate the cell migration to the injured area in the brain, improve functional recovery and protect against cell death following experimental ICH. ADSCs were isolated from subcutaneous adipose tissues of rats. ICH was induced by means of an injection of collagenase type VII. ELISA showed that the expression levels of fractalkine/FKN were increased at early time points, with a peak at day 3 after ICH. And it was found that different passages of ADSCs could express the chemokine receptor CX3CR1. Besides, the chemotactic movements of ADSCs toward fractalkine have been verified by transwell migration assay. ADSCs overexpressing CX3CR1 were established through lentivirus transfection. We found that after overexpression of CX3CR1 receptor, the migration ability of ADSCs was increased both *in vitro* and *in vivo*. In addition, reduced cell death and improved sensory and motor functions were seen in the mice ICH model. Thus, ADSCs overexpression CX3CR1 might be taken as a promising therapeutic strategy for the treatment of ICH.

Keywords: intracerebral hemorrhage, adipose-derived stem cells, migration, fractalkine, FKN, CX3CR1

INTRODUCTION

Intracerebral hemorrhage (ICH) is a severe neurological disease with high morbidity and mortality (Balami and Buchan, 2012; Rabinstein, 2017). Current treatment options for ICH mainly include surgical evacuation of hematoma, reduction of intracranial pressure, prevention of cerebral edema, and general supportive measures (Mayer and Rincon, 2005; Rabinstein, 2017). In recent years,

stem cell therapy has emerged as a new promising therapeutic strategy for ICH (Sun et al., 2015; Hu et al., 2016; Bedini et al., 2018). It is reported that stem cells can promote functional recovery through the mechanisms of directly transdifferentiation, paracrine effects, and immune regulation (Bronckaers et al., 2014; Liu et al., 2014; Wei et al., 2017). Based on the results of these animal studies, clinical trials of stem cells for recent ICH and cerebral hemorrhage sequela are ongoing now (NCT03371329; NCT02283879). Adipose tissue is one of the most abundant and easily accessible sources for mesenchymal stem cell (MSCs), with the advantages of high yield, low immunogenicity and avoidance of ethical issues (Schäffler and Büchler, 2007; Forcales, 2015; Gutiérrez-Fernández et al., 2015). A large number of preclinical studies and several clinical trials have shown that adipose-derived stem cells (ADSCs) transplantation could reduce neuronal apoptosis, promote regeneration of neurons and vessels and improve functional recovery after brain injury (Gimble et al., 2012; Neirinckx et al., 2013; Gutiérrez-Fernández et al., 2015; Konala et al., 2016). It has been found in some studies that ADSCs can improve ICH-induced neurological deficits (Chen et al., 2012; Yang et al., 2012; Kuramoto et al., 2019).

It is generally believed that the efficiency of stem cell therapy to attenuate inflammation, or injuries after ischemia depends on the number of MSCs migrating and homing to the target tissues (Chavakis et al., 2008; Karp and Leng, 2009). Despite the tendency of MSCs migrating to the lesion site, however, only a small percentage of the infused MSCs reach the target tissue, due to the effects of entrapment in peripheral filter organs and the existence of blood-brain barrier (BBB) (Detante et al., 2009; Arbab et al., 2012; Liu et al., 2013; Tang et al., 2015). Furthermore, the exact mechanisms underlying the migration and homing of MSCs are not fully understood. It is proposed that like leukocyte homing, recruitment and incorporation of MSCs into injured tissues may also involve circulation, capture rolling, adhesion, crawling, transendothelial migration and interstitial migration (Chavakis et al., 2008; Emmanouil Chavakis, 2011; Nitzsche et al., 2017). Therefore, it is of great importance to enhance the migration ability of MSCs in order to improve cell engraftment and transplant efficiency. Up to now, studies about the migration and homing of exogenous MSCs for ICH treatment have been extremely rare.

Recently, it has been reported that the chemokines play pivotal roles in MSCs homing process, and MSCs exhibit chemotactic movement toward different chemokines (Stamatovic et al., 2003; Zhu et al., 2009; Guo et al., 2013; Li et al., 2015; Zhang et al., 2015; De Becker and Riet, 2016; Xiao et al., 2016; Xu et al., 2016). Fractalkine, or FKN for short, also known as CX3CL1, is one of the most abundant chemokines constitutively expressed on both neurons and astrocytes in the central nervous system (CNS) (Re and Przedborski, 2006; Miller et al., 2008). The specific receptor of Fractalkine /FKN, CX3CR1, is primarily expressed on microglial cells (Harrison et al., 1998). Meanwhile, an increased expression of fractalkine has been associated with development of ischemic stroke, brain and spinal cord injury and epilepsy (Xu et al., 2012; Poniatowski et al., 2017; Chen et al., 2018). Notably, elevated fractalkine levels at the lesion site can attract cells expressing CX3CR1, resulting in cell migration. Therefore, this study aimed to investigate whether overexpression of CX3CR1 in ADSCs can stimulate the cell migration to the injured brain, protect against neuronal apoptosis and improve functional recovery following experimental ICH.

MATERIALS AND METHODS

Animals

Adult male C57BL/6 mice (8–10 weeks, 20–25 g, n = 95) and female Sprague-Dawley rats (5 weeks, 100–120 g, n = 75) were obtained from the Animal Center of Tongji Hospital of Tongji Medical College of Huazhong University of Science and Technology (Wuhan, China). The experimental procedures were approved by the Experimental Animal Ethics Committee of Huazhong University of Science and Technology.

ICH Induction

Intracerebral hemorrhage was induced by a stereotactic intrastriatal injection of collagenase type VII (Sigma) as previously described (Pan et al., 2018). In brief, C57BL/6 male mice, 8–10 weeks old and weighing 20–25 g, were used in the experiments. Once anesthetized, the animals were fixed in a prone position in a stereotaxic frame, and a burr hole was drilled into the skull. Then, 0.1 U collagenase dissolved in 1 μl saline was stereotactically injected into the right basal ganglia (coordinates 0.2 mm anterior, 2.0 mm lateral, and 3.5 mm ventral to the bregma) at a rate of 0.2 μL/min. After injection, the syringe was left in place for 7 min and the needle was then withdrawn at a rate of 1 mm/min. After the suturing of wounds, all animals were monitored with free access to food and water.

Assessment of ICH Model

After 8 h of modeling, the neurologic function was evaluated with Zea Longa's five-grade scale (Longa et al., 1989). The five-point scoring criteria are as follows: a score of 0 indicated no neurologic deficit, a score of 1 (failure to extend left forepaw fully) indicated a mild focal neurologic deficit, a score of 2 (circling to the left) indicated a moderate focal neurologic deficit, and scores of 3 (falling to the left) and 4 (no spontaneous walk or a depressed level of consciousness) indicated severe focal deficits.

Isolation and Characterization of ADSCs

Adipose-derived stem cells were isolated from the subcutaneous inguinal adipose tissues of female Sprague-Dawley rats (weighing 100–120 g) as previously described (Zhang et al., 2014). Briefly, fatty plaques were cut into pieces (1 mm^3) and then digested with 0.1% collagenase Type I (Invitrogen) for 60 min at 37°C with gentle agitation. After centrifugation, the cell pellet was resuspended in the basal growth medium consisting of Dulbecco's modified Eagle medium/Ham's F12 (DMEM/F12; Hyclone) supplemented with 1% penicillin/streptomycin (Gibco), 1% L-glutamine (Gibco), and 10% fetal bovine serum (FBS; Sera Pro). Later, the suspension solution was filtered through a 40 μm cell strainer (BD Falcon) to remove debris. The remaining cells were seeded onto a 25 cm^2

tissue culture bottle (Eppendorf) and incubated at 37°C in a humidified atmosphere of 5% CO_2. After 1 h incubation, non-adherent cells were collected and transferred into a new culture bottle, in order to eliminate any impurities. The culture medium was changed in the following day and every 2–3 days thereafter. When reaching 80–90% confluency, the cells were detached by using a trypsin-EDTA solution (0.25% trypsin, 0.02% EDTA; Gibco) and were then passaged at a split ratio of 1:2. ADSCs between passages 2 and 5 were used for subsequent experiments.

Adipose-derived stem cells were analyzed for surface marker expression by flow cytometry. The isolated cells were incubated with fluorescein isothiocyanate (FITC)-conjugated antibodies against CD29, CD45 (eBioscience), phycoerythrin (PE)-conjugated antibodies against CD90, CD31 (BD Biosciences) and PBS (negative control) in a dark chamber at 4°C for 45 min. For each sample, at least 5×10^5 cells were acquired for detection and analysis.

Cell Transfection

The lentivirus for overexpressing CX3CR1 (LV-CX3CR1) and controls (Ubi-MCS-3FLAG-CBh-gcGFP-IRES-puromycin) were obtained commercially from GeneChem Corporation (Shanghai, China). When the ADSCs reached 30% confluency, lentiviral vectors were transferred to ADSC monolayer and incubated for 8 h [Multiplicity of Infection (MOI) = 40]. After lentivirus infection and transduction of ADSCs, CX3CR1-overexpressing cells (CX3CR1-GFP-ADSCs) and control cells (Ctr-GFP-ADSCs) were selected with 4 μg/ml puromycin. The effects of gene interference on CX3CR1 expression were verified using quantitative reverse transcription-polymerase chain reaction (qRT-PCR) and immunocytochemistry.

Enzyme-Linked Immune Sorbent Assay (ELISA)

Animals were terminally anesthetized at indicated time points after collagenase-induced ICH. The ipsilateral perihematomal brain tissues (bregma: −2 to 2 mm) were then removed and homogenized in PBS with protease inhibitors (900 μl of PBS were added to each 100 mg brain tissues). Quantitative analysis of mouse fractalkine/FKN was performed using a double-antibody sandwich ELISA Array Kit (Elabscience, China) according to manufacturer's instructions. In brief, tissue homogenates or standards were added to micro ELISA plate wells pre-coated with mouse fractalkine antibodies. Then, a biotinylated detection antibody specific for mouse fractalkine and avidin-horseradish peroxidase (HRP) conjugate was added into each micro plate well and incubated to wash away the free components. Afterward, the substrate solution was added into each well to yield a blue color, as a result of enzyme-substrate reaction. Immediately, sulfuric acid solution was added to terminate the reaction, which changed the color to yellow. The optical density (OD) was measured spectrophotometrically at a wavelength of 450 nm ± 2 nm. All determinations were performed in triple for each sample. Standard curve was generated to calculate the concentrations of fractalkine/FKN.

Transwell Migration Assay

The migration assay was performed by using transwell plates with pore size of 8 μm (Corning Costar). The upper chambers were loaded with $2.3 \sim 4 \times 10^4$ ADSCs in 200 μl of DMEM/F12, while the lower chambers were loaded with 600 μl of DMEM/F12 (negative control), DMEM/F12 containing 10% FBS (positive control), and different concentrations of recombined fractalkine/FKN dissolved in DMEM/F12 (Sigma). These chambers were incubated at 37°C with 5% CO_2. After 24 h of incubation, non-migrated cells on the upper surface of the filter were removed by gentle scraping and washed with PBS. Next, the adherent cells were fixed in 4% paraformaldehyde (PFA) for 20 min and then stained with 1% crystal violet for 30 min. The average number of migrated cells was determined by examining five random fields per well. All experiments were performed in triplicate for each group.

Cell Transplantation

Approximately $2 \sim 4 \times 10^5$ ADSCs in 2 μl PBS were transplanted into the right cerebral cortex (coordinates 0.1 mm posterior, 3.0 mm lateral, and 2.0 mm ventral to the bregma) of mice on the 3rd day after ICH. Mice were randomized allocated into three experimental groups: (1) PBS treatment; (2) Ctr-GFP-ADSC transplantation; and (3) CX3CR1-GFP-ADSC transplantation ($n = 7$ mice per group).

Adhesive Removal Test

The adhesive removal test is a sensitive method that assesses sensorimotor deficits in mice (Bouët et al., 2007). This test was carried out blind at days 1, 3, 7, 14, and 21 after cell transplantation. The mice were trained for 5 consecutive days before surgery, to obtain an optimal level of performance and to reduce the inter-individual variations. Before the experiment, each mouse was placed into a transparent perspex box (15 cm × 25 cm) for a habituation period of 60 s. Thereafter, two small pieces of adhesive surgical tape of equal size (0.3 cm × 0.4 cm) were placed with an equal pressure on each forepaw, covering their hairless parts (i.e., the three pads, thenar, and hypothenar). The order of placement (right or left) was alternated between each animal and session. The mice then transferred back to the perspex box, and the time for sensing and removing each adhesive tape were recorded with a maximum of 180 s.

Cylinder Test

The cylinder test was used to assess forelimb preference and asymmetry in each mouse on days 1, 3, 7, 14, and 21 after cell transplantation (Vahid-Ansari et al., 2016). Mice were placed in a transparent cylinder (diameter: 10 cm, height: 16.5 cm) for 10 min and the number of forepaw contacts to the cylinder wall was counted. The final score was calculated as: (Right forelimb movement – Left forelimb movement)/(Right forelimb movement + Left forelimb movement + both movement). The behavioral tests were performed by the two co-authors blind to the group of mice.

TTC Staining

Animals were sacrificed 3 days following transplantation of ADSCs. Hematoma volume was quantified using TTC staining method. Mice were perfused with normal saline solution, and then the brains were dissected and sectioned into 2 mm coronal sections from the frontal pole. The slices were incubated in a 2% solution of TTC at 37°C for 30 min. The sections were subsequently fixed with 4% paraformaldehyde solution. The volume of hematoma was calculated by summing the relative areas of hematoma from the individual sections and multiplying them by the distance between the sections.

Immunocytochemistry and Immunofluorescence Staining

Mice were transcardially perfused with saline and 4% PFA. The brains were dissected out and post-fixed in 4% PFA for 24 h, followed by dehydration with 25 and 30% sucrose. The brain tissues were cut into 30 μm thick sections (Leica CM1950, Germany) and picked up on a glass slide for staining. The tissue sections or adherent cells were then fixed in 4% PFA, washed three times with PBS, and incubated in 0.5% Triton X-100 for 30 min. After blocking with 5% Bovine Serum Albumin (BSA) for 1 h at room temperature, slices or cells were incubated with primary antibodies rabbit anti-CX3CL1 (1:500, Abcam, Cambridge), mouse anti-NeuN (1:500, Abcam, Cambridge), mouse anti-GFAP (1:500, Santa Cruz, CA, United States), rabbit anti-CX3CR1 (1:100, Abcam, Cambridge), goat anti-Iba-1 (1:100, Abcam, Cambridge), or chicken anti-GFP (1:1000, Abcam, Cambridge) at 4°C overnight. Secondary antibodies of FITC conjugated goat anti rabbit IgG (1:100, Boster Biological Technology Co., Ltd., United States), Cy3 conjugated goat anti mouse IgG (1:100, Boster Biological Technology Co., Ltd., United States), Cy3 conjugated donkey anti mouse IgG (1:200, Servicebio, China), Alexa Fluor® 594 donkey anti-goat IgG (1:400, life technologies, the United States) or Alexa Fluor® 488 conjugated Goat anti-chicken IgG (1:500, Abcam, Cambridge) were subsequently incubated for 1 h at 37°C. Counterstaining was performed with 4′,6-diamidino-2-phenylindole (DAPI; Beyotime, China).

Terminal Deoxynucleotidyltransferase-Mediated dUTP End Labeling (TUNEL) Staining

The paraffin-embedded tissue sections were prepared for TUNEL staining with the *in situ* Cell Death Detection Kit, POD (Roche, Switzerland). The numbers of TUNEL-positive cells were quantified with the use of Image-Pro Plus software. To determine the frequencies of apoptotic cells, five microscopic fields were examined for each sample. The apoptotic index was defined as the average proportion of TUNEL-positive cells in each area.

Western Blot

The total protein concentration in cells and tissues was determined using bicinchoninic acid assay (BCA) (Beyotime, China) according to manufacturer's instructions. After sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), the detected proteins were transferred onto nitrocellulose filter (NC) membranes. Subsequently, the membranes were blocked in 5% skim milk for 1 h at room temperature with gentle shaking. After that, the membranes were incubated with primary antibodies of rabbit anti-CX3CR1 (1:500, Abcam, Cambridge), mouse anti-bcl-2 (1:500, Santa Cruz, CA, United States), mouse anti-caspase-3 (1:500, Santa Cruz, CA, United States), and/or mouse anti-β-actin antibody (1:1000, Proteintech, China) at 4°C overnight, followed by 1 h incubation with anti-rabbit IgG (H+L) (DyLight 800 Conjugate; Cell Signaling Technology, United States) or anti-mouse IgG (H+L) (DyLight 800 Conjugate; Cell Signaling Technology, United States) secondary antibody at room temperature. The protein bands were visualized with Odyssey Infrared Imaging System (LI-COR Biosciences, Lincoln, NE, United States), and the intensity of each band was analyzed using Image J (National Institutes of Health, United States).

Statistical Analysis

All experimental data from three independent experiments were analyzed using SPSS software (version 20.0 for Windows, SPSS Inc., United States) and the results were expressed as mean ± standard deviation (SD). One-way analysis of variance (ANOVA) followed by Tukey's *post hoc* test was used for parametric data and multiple comparisons between groups. In **Figure 5D**, two-way ANOVA was used to assess the main effect of each independent variable and the latent interaction between them. *P*-values of less than 0.05 were considered statistically significant.

RESULTS

Increased Expression of Fractalkine/FKN After ICH

After the establishment of ICH model, the mice exhibited weakness of left limbs, uncoordinated movement and spontaneous rotation (**Figure 1A**). A proper size of hematoma could be induced with 0.1 U collagenase (**Figure 1B**). Mice scoring grades 1–3 of Zea Longa's scale were selected for further experiments. ELISA method was used to detect the dynamic changes of fractalkine in the brain tissue homogenates at 6 h, 12 h, and days 1, 2, 3, 5, and 7 after ICH. The results indicated that the expression levels of fractalkine were significantly increased at early time points, with a peak at day 3 after ICH (**Figure 1C**). Therefore, we transplanted ADSCs on the 3rd day after ICH in the following *in vivo* experiments. The immunofluorescence staining revealed that fractalkine was constitutively expressed in normal brain tissues by neurons and astrocytes, distributed mainly in the cortex, basal ganglia and other regions (**Figures 1D,E**).

Characterization of ADSCs

Primary ADSCs exhibited short bar shapes during the early stages, and maintained a spindle-shaped morphology thereafter

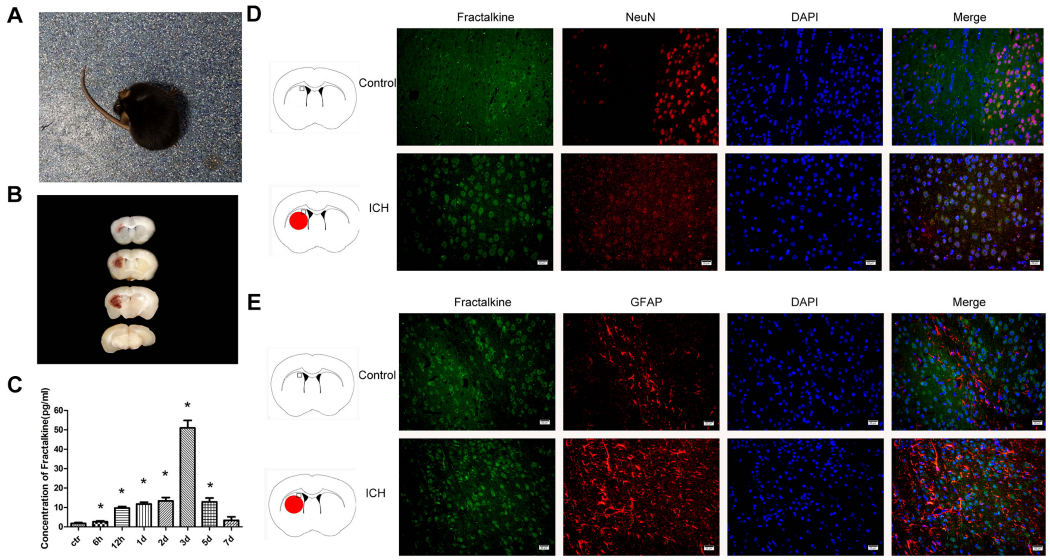

FIGURE 1 | Mice began to turn around spontaneously 8 h after ICH **(A)**, and hematoma was seen in the right basal ganglia at day 3 **(B)**. ELISA showed that the expression level of fractalkine could be increased at early time points, with a peak at day 3 after ICH **(C)** (n = 3 each group, $^*P < 0.001$, as compared to normal control group). Fractalkine, mainly produced by neurons and astrocytes, was constitutely expressed in basal ganglion of the brain tissue (**D,E**, scale bar = 20 μm; the square in the schema diagram showed the area where from the pictures were taken).

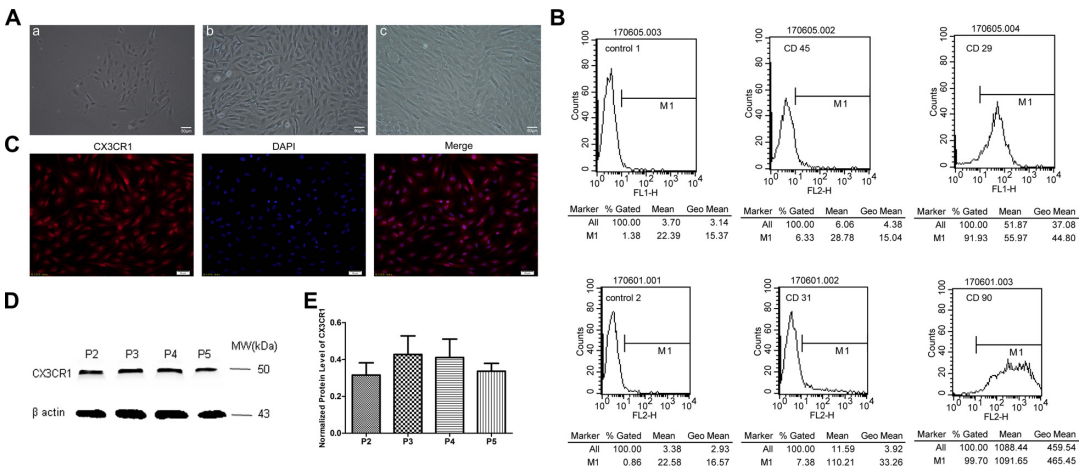

FIGURE 2 | Cellular morphology of ADSCs **(A)**. The primary ADSCs displayed short bar shapes initially (**a**, the 3rd day of cell culture), and maintained spindle-shaped morphology thereafter (**b**, the 7th day of cell culture) and could stable proliferate (**c**, passage 3 ADSCs) (scale bar = 50 μm). P2 ADSCs were positive for CD29 (91.93%) and CD90 (99.70%), and the expression level of CD45 (6.33%) and CD31 (7.38%) were very low **(B)**. P2-P5 ADSCs could stably expressed CX3CR1 in both membrane and cytoplasm detected by immunocytochemistry (**C**, scale bar = 50 μm) and western blot **(D,E)**.

(**Figure 2A**). Flow cytometry analysis showed that these cells were positive for MSC markers CD29 (91.93%) and CD90 (99.70%), while the expression of hematopoietic cell markers CD45 (6.33%) and CD31 (7.38%) were relatively low (**Figure 2B**).

CX3CR1 Protein Expression in ADSCs

The results of immunocytochemical staining revealed that ADSCs were found to express CX3CR1, which distributed mainly in the cell membrane and cytoplasm (**Figure 2C**). Western blot results demonstrated that the stable expression of CX3CR1 could be detected in ADSCs at passage 2–5 (**Figures 2D,E**).

Establishment of Stable CX3CR1 Overexpressing ADSCs

Following lentivirus transfection and puromycin screening, the transfection rate of ADSCs could remain up to 80–90% until day 11 of transfection (**Figure 3A**). The mRNA and protein expression levels of CX3CR1 were significantly higher ($P < 0.05$) in CX3CR1-GFP-ADSCs than normal ADSCs (**Figures 3B–D**).

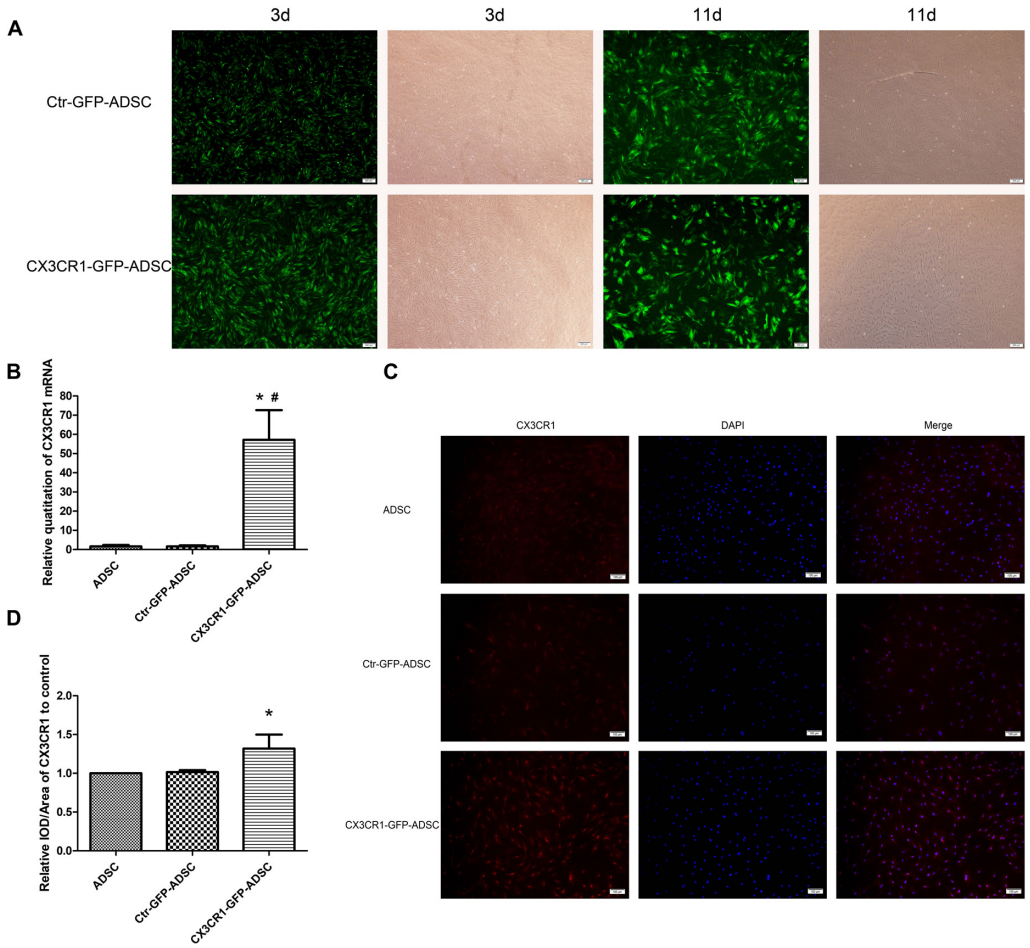

FIGURE 3 | After transfection with lentivirus and screen with puromycin, most ADSCs expressed the tag protein of GFP on the 3rd day, and the transfection rate could still remain at 80–90% till the 11th day (**A**, scale bar = 200 μm). qRT-PCR showed that mRNA expression levels of CX3CR1 in CX3CR1-GFP-ADSCs were significantly higher than the other two groups (**B**, $^{*}P < 0.01$, as compared with ADSC group; $^{\#}P < 0.01$, as compared with Ctr-GFP-ADSC group). IOD analysis of immunocytochemical images showed a higher CX3CR1 protein expression level in CX3CR1-GFP-ADSCs (**C,D**, scale bar = 100 μm; $^{*}P < 0.05$, as compared with ADSC group, IOD, integrated optical density).

Overexpression of CX3CR1 Augments ADSC Migration *in vitro*

Transwell migration assay was used to detect the chemotactic movements of ADSCs toward fractalkine/FKN. The results showed that the number of ADSCs migrated to the bottom of chamber was significantly increased with the elevated concentrations of fractalkine/FKN (**Figures 4A,B**). So FKN with the concentration of 200 ng/ml was loaded in the lower chamber in the following transwell migration assays to detect the migration ability of CX3CR1-GFP-ADSCs. The upper chamber was filled with (1) untransfected ADSCs, (2) Ctr-GFP-ADSCs, and (3) Ctr-GFP-ADSCs, and then the number of migrated cells toward FKN was compared. Finally, the augmented *in vitro* migration ability of CX3CR1-GFP-ADSCs was confirmed, as it migrated more efficiently toward FKN compared to untransfected ADSCs ($P < 0.05$). However, there were no statistically significant differences in the migration rate between Ctr-GFP-ADSCs and untransfected ADSCs (**Figures 4C,D**).

Overexpression of CX3CR1 Augments ADSCs Homing to the Hemorrhagic Brain

Most of the transplanted cells were distributed throughout the transplant area and survived on the 3rd day after transplantation (**Figure 5A**). Few ADSCs migrated to the lesion site over comparatively short distances. In contrast, more cells were seen to migrate to the target site in the CX3CR1-GFP-ADSC group as compared to the Ctr-GFP-ADSC group, and the distance of migration was comparatively longer (**Figures 5B,C**). We also detected the immunological response after transplantation. It was found that there was no obvious microglial activation against rat-derived ADSCs (**Supplementary Figure S1**).

ADSCs Overexpressing CX3CR1 Promote Functional Recovery After ICH

At day 21 after cell transplantation, the mice in both Ctr-GFP-ADSC and CX3CR1-GFP-ADSC groups had a tendency to sense

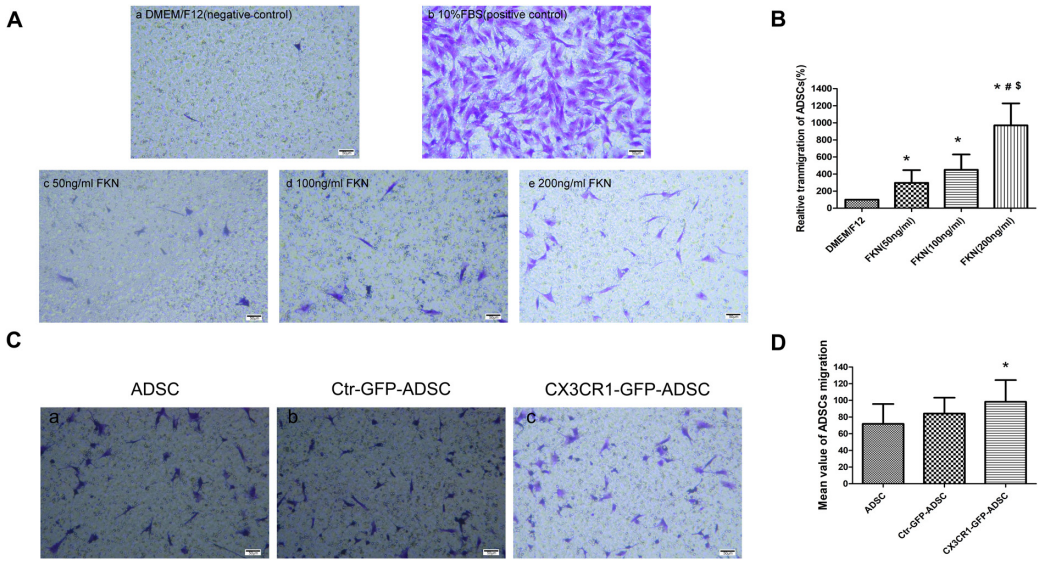

FIGURE 4 | *In vitro* transwell migration assay. Chemotactic movements of ADSCs toward fractalkine/FKN *in vitro* **(A)**. The lower compartment was filled with 600 μl DMEM/F12 (negative control) **(a)**, 10% FBS (positive control) **(b)**, 50 ng/ml FKN **(c)**, 100 ng/ml FKN **(d)**, and 200 ng/ml FKN **(e)** in DMEM/F12. The upper chamber were cell suspensions of ADSCs (2.3–2.4 × 10^4 cells/200 μl). It was found that the number of ADSCs directed migration to the bottom of chamber increased significantly with the increase of the concentration of fractalkine/FKN (**B**, relative transmigration of ADSCs = migration number of experimental group/migration number of negative control group,$^*P < 0.01$, as compared with DMEM/F12 group; $^{\#}P < 0.05$ as compared with FKN (50 ng/ml) group; $^{\$}P < 0.01$, as compared with FKN (100 ng/ml) group. *In vitro* migration ability of ADSCs after overexpressing CX3CR1 **(C)**. There were totally three groups: Ctr-GFP-ADSCs, CX3CR1-GFP-ADSCs, and untransfected ADSCs. The corresponding ADSCs (4 × 10^4 cells/200 μl) were placed in the upper chamber, and the lower chamber was loaded with 200 ng/ml FKN in the DMEM/F12 solution. The results showed that compared with untransfected ADSCs, CX3CR1 – GFP – ADSCs migrated more toward FKN (**D**, $^*P < 0.01$, as compared with ADSC group).

and remove stickers earlier and faster than those in the PBS group, as indicated by adhesive removal test (**Figures 5Da,b** and **Table 1**, $0.05 < P < 0.1$). In the cylinder test, scores were lower in CX3CR1-GFP-ADSC group than PBS group on days 7 post-transplantation, but no difference was observed between the Ctr-GFP-ADSC and PBS group (**Figure 5Dc** and **Table 1**, $P < 0.05$).

ADSCs Overexpressing CX3CR1 Reduce ICH-Induced Cell Death

The results of Western blot analysis revealed that anti-apoptotic protein bcl-2 expression level was significantly higher ($P < 0.05$) in the cell transplantation group (i.e., Ctr-GFP-ADSC and CX3CR1-GFP-ADSC groups) than that in the PBS group. However, no significant difference was observed between the two cell transplantation groups (**Figures 6A,B**). Meanwhile, the expression level of pro-apoptotic protein caspase-3 was significantly decreased ($P < 0.05$) in the CX3CR1-GFP-ADSC group compared to Ctr-GFP-ADSC and PBS groups (**Figures 6A,B**). TUNEL assay showed significantly reduced number of apoptotic cells in the cell transplantation groups compared to the PBS group ($P < 0.01$). Similarly, a significant difference ($P < 0.05$) was observed between Ctr-GFP-ADSC group and CX3CR1-GFP-ADSC group with respect to the apoptosis rate (**Figures 6C,D**). In addition, we also detected the hematoma volume in different groups. TTC staining showed that reduced volumes of hematoma were seen in both cell transplantation groups, but no difference was observed between the Ctr-GFP-ADSC and CX3CR1-GFP-ADSC group (**Supplementary Figure S2**).

DISCUSSION

Fractalkine/FKN, or CX3CL1, is the only member of CX3C subfamily of chemokines with two isoforms (Poniatowski et al., 2017). The membrane-bounded form of fractalkine is related to the adhesive effects, while the soluble form enhances the recruitment and activation of inflammatory cells (Réaux-Le Goazigo et al., 2013). Unlike most chemokine peptides, fractalkine can be expressed in non-hematopoietic tissues, including brain, kidney, lung, and heart. In particular, fractalkine is constitutively expressed in the CNS at relatively high levels, which produced mainly by neurons and astrocytes (Harrison et al., 1998; Re and Przedborski, 2006; Sciumè et al., 2010; Réaux-Le Goazigo et al., 2013). Meanwhile, its unique receptor CX3CR1, is primarily expressed on microglia (Donohue et al., 2012; Réaux-Le Goazigo et al., 2013). Previous studies reported that cerebrospinal fluid levels of soluble fractalkine are elevated in patients with traumatic brain injury and inflammatory brain diseases (Kastenbauer et al., 2003; Rancan et al., 2004). Similarly, increased serum levels of fractalkine have been reported in multiple sclerosis and systemic lupus erythematosus with neuropsychiatric involvement (Kastenbauer et al., 2003; Yajima et al., 2005). Here, we firstly detect the dynamic

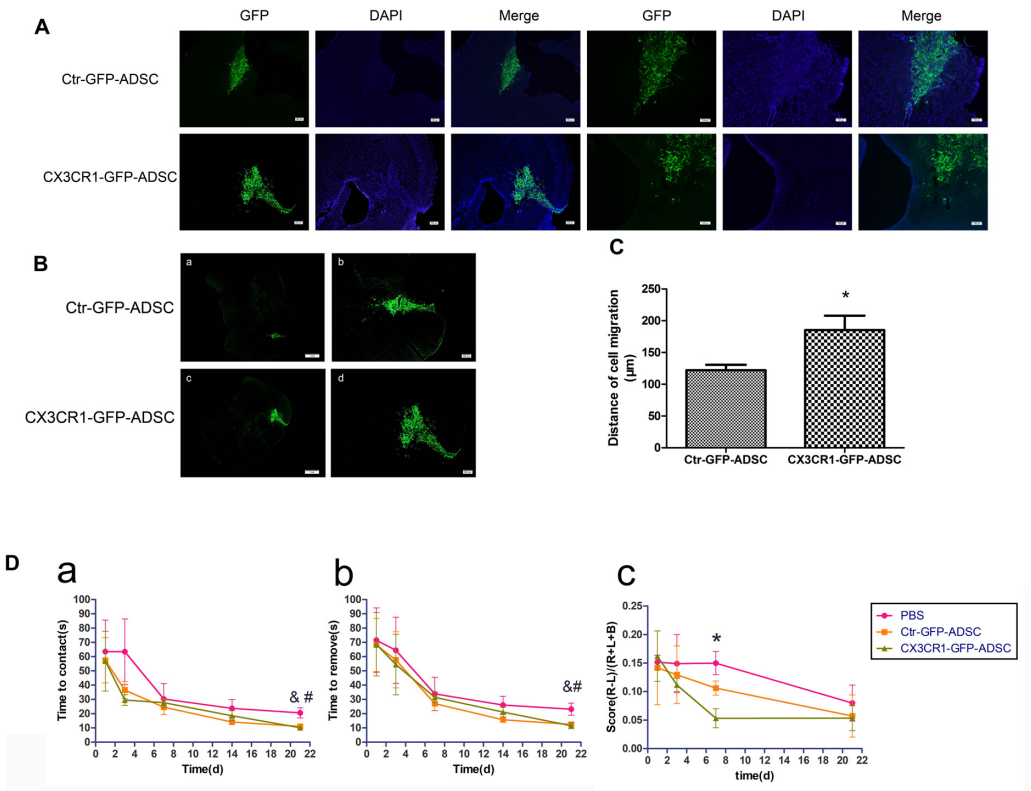

FIGURE 5 | Three days after transplantation, most of cells were distributed near the transplantation site (**A**, scale bar = 200 μm, 100 μm). Compared with Ctr-GFP-ADSC group, more CX3CR1 – GFP – ADSCs migrated toward the lesion loci (**B**, scale bar = 1 mm, 200 μm), and the distance of migration was comparatively longer (**C**, $^{*}P < 0.05$, as compared with Ctr-GFP-ADSC group). Adhesive removal test and cylinder test was use to assess functional recovery after cell transplantation in ICH **(D)**. Mice in both cell transplantation groups had a tendency to sense and remove stickers faster in the affected extremity on the 21st day after transplantation (**a**, time to contact the stickers in the left forepaw; **b**, time to remove the stickers in the left forepaw, $n = 7$ each group, $^{\&}P < 0.1$, Ctr-GFP-ADSC group vs. PBS group; $^{\#}P < 0.1$, CX3CR1-GFP-ADSC group vs. PBS group). In the cylinder test, scores were lower in CX3CR1-GFP-ADSC group than PBS group on days 7 post-transplantation, but no difference was observed between the Ctr-GFP-ADSC and PBS group (**c**, the final scores to assess forelimb preference and asymmetry, $n = 7$ each group, $^{*}P < 0.05$, CX3CR1-GFP-ADSC group vs. PBS group).

changes of fractalkine in brain tissue homogenates after ICH. We found that the levels of fractalkine can be increased at early time points, with a peak on the 3rd day after ICH. Despite controversies over the neuroprotective and neurotoxic roles of fractalkine (Donohue et al., 2012; Réaux-Le Goazigo et al., 2013), it is of great significance to study the dynamic changes of fractalkine expression after CNS diseases or injury. It's known that elevated fractalkine can attract endogenous or exogenous CX3CR1-expressing cells to migrate toward lesion loci. Consequently, studying the dynamic change of fractalkine can help to decide the time point of cell transplantation so that the grafting efficiency of stem cell therapy might be further improved through modifying infused cells or internal microenvironment. In addition, fractalkine expression has been considered as an essential biomarker in predicting the severity and prognosis of diseases (Kim et al., 2008; Donohue et al., 2012; Grosse et al., 2014).

Stem cell therapy is a promising therapeutic strategy for neurological diseases. It is generally believed that an adequate number of stem cells homing and migrating toward lesion site is important for efficient cell transplantation (Chavakis et al., 2008; Karp and Leng, 2009). Although infused cells tend to migrate to the lesion site, the decreased rate of cell homing, retention and survival can be the major limitations (Karp and Leng, 2009; Emmanouil Chavakis, 2011; Tang et al., 2015). MSC homing has been first defined by Karp and Leng (2009), as the arrest of MSCs within the vasculature of a tissue followed by transmigration across the endothelium. Recently, Nitzsche et al. (2017) expanded the definition of MSC homing to non-systemic and systemic homing according to MSC administration routes. However, the exact mechanisms underlying the homing and migration of MSCs are not fully understood. It is proposed that systemic homing require a coordinated multistep process involving ingress to the circulation, extravasation at the lesion vicinity, and interstitial migration toward the target site. For non-systemic homing, locally infused MSCs directly possess interstitial migration following activation and polarization (Chavakis et al., 2008; Emmanouil Chavakis, 2011; Nitzsche et al., 2017). Chemokines play an important role during the process of cell migration. In this study, we found that the expression level of fractalkine increased after ICH, and different passages of ADSCs express its receptor CX3CR1. Besides, the

*$P < 0.1$ compared to PBS group; #$P < 0.05$ compared to PBS group.

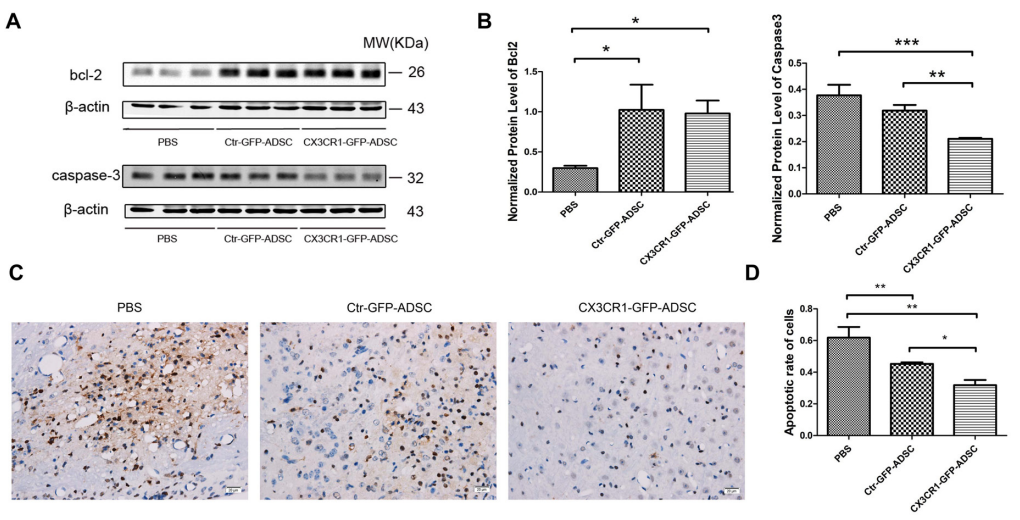

FIGURE 6 | Western blot showed that both cell transplantation group could reduce the expression of bcl-2, while the CX3CR1-GFP-ADSC group could more significantly lower the expression of caspase-3 compared to Ctr-GFP-ADSC and PBS group (**A,B**, *$P < 0.05$; **$P < 0.01$; ***$P < 0.001$). TUNEL staining showed that both cell transplantation groups could reduce the apoptosis rate of the foci (**C**, scale bar = 20 μm), and a lower apoptosis rate was found in the CX3CR1-GFP-ADSC group (**D**, *$P < 0.05$; **$P < 0.01$).

chemotactic movements of ADSCs toward fractalkine have been confirmed *in vitro*. So, we want to detect whether ADSCs overexpressing CX3CR1 could migrate more to the hemorrhagic site to achieve a higher therapeutic efficiency with the same former transplantation dosage.

Stem cell transplantation involves various delivery routes. Local infusion can be used to inject MSCs directly into the tissues of interest, but this strategy may not be clinically feasible due to its high invasiveness and diffusion limitations of nutrients and oxygen (Karp and Leng, 2009). Intravenous delivery has the

advantages of being more convenient, less invasive and much safer process than intrathecal or intracerebral administration (Lanza et al., 2009), but the MSCs homing is limited. It's reported that a high engraftment rate might be achieved by intra-arterial delivery, through the bypassing of filtration organs (Walczak et al., 2008). It still seems unclear whether systemically infused MSCs can actively migrate across BBB. MSCs were found to transmigrate across the brain microvascular endothelial cells monolayers *in vitro* through the transient intercellular gaps between them, but the endothelial cell monolayers do not fully recapitulate the *in vivo* BBB properties (Matsushita et al., 2011). In this study, we applied intracortical transplantation method to preliminarily investigate the short-term distribution and migration ability of CX3CR1 overexpressing ADSCs. Since the site of transplantation is relatively superficial, it is conducive to oxygen and nutrition diffusion. In addition, the short distance from the injection site to the injury center is favorable for observing the migration of cells.

The stable overexpression of CX3CR1 ADSCs (CX3CR1-GFP-ADSCs) were established with lentivirus transfection. Our findings demonstrated that the *in vitro* migration ability of ADSCs was increased after overexpressing CX3CR1. Additionally, the infused cells could survive until day 3 after transplantation, and a small part of ADSCs could migrate to the hemorrhagic brain site. In this study, CX3CR1-GFP-ADSC group showed better efficiency as compared to Ctr-GFP-ADSC group, with respect to the number of cells migrate toward the target region and their migration distances. There are various strategies to improve the migration ability of stem cells up to now (Li et al., 2017). And genetic manipulation remains one of the stable and efficient methods to improve their migration and mobility. However, the risk of malignant transformation and time-consuming should be noticed during the process (Liu et al., 2014). The ultimate aim of this study is to achieve increased homing and engraftment of MSCs by using lower or the same dosage of transplanted cells, in order to decrease the costs and duration of cell preparation (Maijenburg et al., 2012; Li et al., 2017). Interestingly, we observed the positive effects of ADSCs overexpressing CX3CR1 in reducing neuronal apoptosis and improving functional recovery after ICH. A tendency of improved sensory and motor functions and reduced expression of caspase-3 and increased expression of bcl-2 in CX3CR1-GFP-ADSC transplantation group were found in our research. Furthermore, a lower apoptosis rate around the foci was observed in CX3CR1-GFP-ADSC group as compared to Ctr-GFP-ADSC group. However, there are some limitations for our study. We transplanted rat ADSCs to the mice in this experiment, and human ADSCs will be used in our later studies, which is closer to the actual clinical situation. In addition, we should observe for a longer time to determine whether the transplanted ADSCs have teratogenic effects.

CONCLUSION

In summary, ADSCs overexpressing CX3CR1 demonstrated an increased migration ability both *in vitro* and *in vivo*, and may improve therapeutic efficiency in the ICH model.

ETHICS STATEMENT

The study was carried out in accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The protocol was approved by competent ethics committees at Huazhong University of Science and Technology.

AUTHOR CONTRIBUTIONS

GL and HY were responsible for the cellular and animal experiments. GL performed the ELISA, immunohistochemical staining, qRT-PCR, and cell transplantation experiments. HY was responsible for the animal model and preparation of frozen sections of brain tissues. GL and HD performed the Western blot experiments. GL and JW performed the behavioral tests. NL, PZ, YT, YH, YZ, CP, QL, and ZT were responsible for the conception or design of the work. QL and ZT drafted the work or revisited it critically. All authors approved the final version of the manuscript.

Cerebral stroke is a leading cause of death and persistent disability of elderly in the world. Although stroke prevention by targeting several risk factors such as diabetes and hypertension has decreased the stroke incidence, the total number of strokes is increasing due to the population aging and new preventive therapies are needed. Moreover, post-stroke acute pharmacological strategies aimed to reduce stroke-induced brain injury have failed in clinical trials despite being effective in animal models. Finally, approximately 30% of surviving stroke patients do not recover from stroke and remain permanently dependent on supportive care in activities of daily living. Therefore, strategies to improve stroke recovery in the post-acute phase are highly needed. Linagliptin is a dipeptidyl peptidase-4 inhibitor which is clinically approved to reduce hyperglycemia in type 2 diabetes. The regulation of glycemia by dipeptidyl peptidase-4 inhibition is mainly achieved by preventing endogenous glucagon-like peptide-1 (GLP-1) degradation. Interestingly, linagliptin has also shown glycaemia-independent beneficial effects in animal models of stroke, Parkinson's disease and Alzheimer's disease. In some case the preclinical data have been supported with some clinical data. Although potentially very interesting for the development of new strategies against stroke and neurodegenerative disorders, the mode of action of linagliptin in the brain is still largely unknown and seems to occur in a GLP-1R-independent manner. The purpose of this mini-review is to summarize and discuss the recent experimental and clinical work regarding the effects of linagliptin in the central nervous system, with special emphasis on acute neuroprotection, stroke prevention and post-stroke recovery. We also highlight the main questions in this research field that need to be addressed in clinical perspective.

Keywords: dipeptidyl peptidase-4 inhibitors, linagliptin, stroke, stroke recovery, neuroprotection

INTRODUCTION

Stroke is a highly prevalent condition and a major cause of death and disabilities (1–5). Globally, 15 million people suffer a stroke every year with up to a 40% death rate (6). Of the surviving patients, up to 30% remain permanently disabled and require assistance in activities of daily living (5). In recent years, the incidence and mortality rates of stroke have significantly declined in high-income

countries (4, 7). The decrease in stroke incidence is probably due to targeted intervention programs against major stroke risk factors such as type 2 diabetes (T2D), obesity, smoking, sedentary lifestyle, hypertension, and alcohol abuse (8), while the decrease in mortality rate and disability could be attributed to faster intervention by thrombolytics and/or clot removal surgery resulting in blood flow restoration which minimize stroke damage (9). However, there is a significant geographic variations of stroke burden (10), and the total number of strokes and associated disability burden have substantially increased due to the increase of global population and life expectancy (4, 7). For instance, in Europe the number of elderly is projected to increase by 35% by 2050 (11). Thus, the total number of stroke cases is unlikely to decrease, unless more advanced preventive and/or curative strategies will be developed.

Potential future approaches to reduce acute stroke damage that have been investigated over the last decades are therapeutic hypothermia and pharmacological neuroprotection (12, 13). However, neither of these strategies have seen successful translation into clinical practice. The major obstacle for this type of strategies is the rapid tissue death in ischemic core and the limited effective intervention time-window in the ischemic *penumbra* (14–16).

Pharmacological interventions of stroke aimed toward recovery to combat chronic post-stroke disabilities is also promising based on animal studies, although full translation from bench-to-bed remains to be achieved (17–20).

Recent research suggests that stroke therapeutics could be developed from diabetes research. In fact, several studies have shown that anti-diabetic drugs targeting the glucagon-like protein 1 receptor [(GLP-1-receptor agonists and dipeptidyl peptidase-4 inhibitors (DPP-4i)] can mediate anti-stroke efficacy in animal models, and has been suggested to decrease the incidence of stroke in some clinical studies [reviewed in (21, 22)]. These drugs are in clinical use for T2D and their robust safety profile suggest high potential for the possible repositioning into stroke therapies.

The aim of this review was to summarize the recent experimental and clinical data regarding the effects of DPP-4i (also named gliptins) in the central nervous system, with special emphasis on linagliptin and stroke. Specifically, we focused our discussion about the effects of DPP-4i in relation to stroke prevention, acute neuroprotection, and post-stroke recovery. We also highlighted the main gaps of knowledge that will need to be addressed in clinical perspective.

METHODS

This review is based on a literature search in Pubmed, or at the scientific conference websites of major international cardiology (e.g., ESC, ESC HF, ACC, or AHA) or diabetes (i.e., EASD or ADA) societies until Jan 31st 2019. Pubmed was searched using free-text terms and medical subject heading. A uniform search strategy was applied to Pubmed to identify the reported studies. The primary MeSH terms and keywords used were as follows: dipeptidyl peptidase 4 inhibitor, DPP IV, gliptins, linagliptin, stroke, ischemia, neuroprotection, Parkinson's, Alzheimer's, dementia, neurogenesis, and neuroplasticity. Studies were screened by title, abstract and full text.

LINAGLIPTIN'S PHARMACOLOGY

Linagliptin is a once daily oral DPP-4i launched in 2011 for the treatment of T2D. The IC_{50} of linagliptin on its primary target, DPP-4, is 1 nM, which makes it one of the most potent inhibitors within the class (23). The other DPP-4 inhibitors possess lower potency in the range of IC_{50} 7–95 nM. Linagliptin shows high selectivity for DPP-4, over other dipeptidyl peptidases and related proteases (such as DPP-8 and 9) Chemically the drug is based on an optimized and unique xanthine scaffold (See **Figure 1**) possessing very slow dissociation from the human DPP-4 enzyme ($k_{off} < 0.00002\ s^{-1}$). This extremely slow off-rate is the main factor for the high affinity (K_D =6.6 pM) and results in a prolonged drug-target residence time over several hours (24).

Following absorption, linagliptin is distributed into tissues with high DPP-4 expression, e.g., the kidney and liver. At low concentrations (< 1 nM), 99% of linagliptin is bound to soluble and circulating DPP-4 and elimination is low. In higher concentrations (>100 nM) plasma DPP-4 is saturated and protein binding decreases to 70–80%. That is one of the reasons why in contrast to other DPP-4 inhibitors with linear pharmacokinetics, linagliptin is unique in having non-linear pharmacokinetics in the therapeutic dose (5 mg, human dose) range. The linagliptin's binding characteristics were shown to be absent in DPP-4 deficient animals (25). Moreover, renal excretion of linagliptin at its therapeutic dose is <7%, which is unique in the DPP-4 inhibitor class, that are primarily eliminated via the kidney (26). Linagliptin further shows low interaction with Cytochrom P450 and high stability in human cytosolic

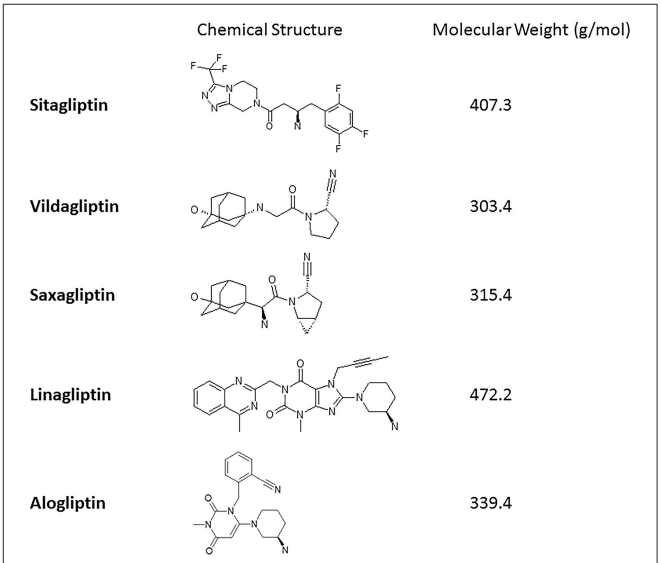

FIGURE 1 | The molecular structure and weight of selected DPP-4i.

and microsomal compartment, however linagliptin is a P-gp (P-glycoprotein) substrate (27) limiting penetration across the blood brain barrier (bbb) under normal conditions (28).

LINAGLIPTIN AND THE TREATMENT OF T2D

The concept behind DPP-4i for therapeutic use in T2D is based on the prolongation of the half-life of the incretins GLP-1 and glucose-dependent insulinotropic polypeptide (GIP), both secreted via specific endocrine gut cells following meal digestion. Incretins cause subsequently glucose-dependent insulin secretion for mainly postprandial glucose regulation. Further, DPP-4 inhibition suppresses glucagon secretion from α-cells. Numerous other substrates for DPP-4 have been described (29) such as SDF1α, GLP-2, NPY, substance P, which are activated or deactivated by the DPP-4 protease and play additional roles in inflammation, food intake, pain and vascular regulation, however less contribute to glucose control. Most clinically used DPP-4 inhibitors, like linagliptin, are once daily drugs because they show >80% inhibition of DPP-4 activity over 24 h. This is associated with the high increase of plasma GLP-1 and consistent reductions in elevated plasma glucose and HbA1c in various patient populations and across various background therapies (30). The recently completed cardiovascular outcome trial CARMELINA (CArdiovascular and Renal Microvascular outcomE study with LINAgliptin) confirmed the tolerability of linagliptin, and its cardiovascular (CV) safety, without any signal of heart failure (31). Due to an excretion primarily via the bile, linagliptin does not need dose adjustment, including in patients with T2D and impaired kidney function. CARMELINA proved safety in these renally impaired patients, and additionally showed a significant reduction in risk for progression albuminuria (32), which has not been assessed in a similar robust manner with the other members of the class of DPP-4 inhibitors.

LINAGLIPTIN MEDIATES BENEFICIAL EFFECTS IN EXPERIMENTAL MODELS OF BRAIN DISORDERS

Beside their glycemic properties, it has been recently reported that DPP-4 inhibitors can also affect the brain. For instance, studies have shown that DPP-4i exert neuroprotective actions in animal models of Parkinson's disease (PD) (33–35) and ongoing studies investigating the safety of intranasal delivery of the DPP-4i omarigliptin for the treatment of PD are ongoing (36). Moreover, D'Amico et al. (37) have shown that sitagliptin delayed AD-like pathology in a mouse model, and several studies confirmed these findings by using different DPP-4i inhibitors, including linagliptin [(38–41) and reviewed in (42)]. Other effects improving cognitive function, neuroplasticity and neurogenesis have been recently reported by employing vildagliptin (43), sitagliptin (44–48), and linagliptin (49). Furthermore, Hasegawa et al. (50) showed that linagliptin decreased hippocampal neuronal cell death and improved cognitive function in a model of aging. However, one study has also shown negative effects of sitagliptin in the brain, i.e., increased tau phosphorylation and insulin resistance (51). Finally, a recent study showed neuroprotection by sitagliptin in a model of brain trauma (52). In summary, although the passage of DPP-4i through the bbb in the damaged brain is undetermined and the mechanisms are unknown, the evidence of favorable effects of DPP-4i on brain complications is substantial.

LINAGLIPTIN PROVIDES ACUTE NEUROPROTECTION AFTER STROKE IN EXPERIMENTAL MODELS

It is difficult to study the potential efficacy of candidate drugs to reduce stroke risk using animal models. However, to determine the efficacy for acute neuroprotection, several animal models exist. A few studies have tested the potential efficacy of DPP-4i for acute neuroprotection and/or recovery after stroke. Moreover, acute ischemic stroke severity has been recently associated to changes in DPP-4 activity (53), suggesting that the regulation of this enzyme might have a therapeutic value.

Rohnert et al. (54) first showed that DPP-4 inhibition is neuroprotective in stroke via intracerebral administration of sitagliptin in the rat. We recently showed that 4 weeks per-oral pretreatment followed by 3 weeks post-stroke treatment with linagliptin reduced brain damage after stroke, in both normal and T2D/obese mice (55). Similar effects in non-diabetic rats were recently shown by Yang et al. (56) using alogliptin and by El-Sahar et al. (57) using vildagliptin. In the Yang et al. study, neuroprotection correlated to increased levels of brain BDNF. Moreover, DPP-4 inhibition by genistein resulted in similar findings (58). By using an experimental design consisting of chronic administration of linagliptin before and after stroke, Darsalia et al. (59) also showed that linagliptin-mediated neuroprotection against stroke occurred in correlation with increased neural stem cells proliferation (60) and, importantly, was not mediated by the GLP-1R.

A recent work by Ma et al. (61) has shown that the linagliptin treatment starting after stroke can decrease the stroke-induced brain damage in a rat model of transient cerebral ischemia induced by bilateral common carotid artery occlusion. Similar data using transient middle cerebral occlusion were reported by Chiazza et al. (62) who also showed that linagliptin improved functional recovery 3 days after stroke through the activation of the SDF-1α/CXCR4 pathway. Although one cannot rule out that the results of these two studies are due to the presence of linagliptin close to stroke time (suggesting acute neuroprotective effects), the data also suggest a pharmacological effect that goes beyond acute neuroprotection because the study design allowed extending the observation period from days to weeks after experimental stroke, thus evaluating the effects of linagliptin treatment in the post-stroke recovery phase. The likelihood of positive effects during the post-stroke recovery phase is also supported by the work of Darsalia et al. (59) showing that a single, acute *bolus* administration of linagliptin at stroke time was ineffective in reducing the brain damage. Furthermore, the potential role of DPP-4 inhibition in endogenous brain tissue

remodeling and repair processes after stroke has been recently suggested by Wesley et al. (63).

Whether DPP-4i leads to neuroprotection and promotes recovery after stroke by directly acting on neurons remains to be determined, although a recent *in vitro* study suggested direct neuroprotection in neural cells (64). However, additional cellular mechanisms may be involved. Indeed, Mi et al. (65) showed that linagliptin increases the *in vitro* proliferation of rat brain microvascular endothelial cells via the SIRT1/HIF-1α/VEGF pathway. Furthermore, recent works have shown that linagliptin improves cerebrovascular dysfunction and remodeling in a rat model of T2D, independent of glycemic control (66, 67).

Admission hyperglycemia is *per se* a negative prognostic marker for patients suffering acute ischemic stroke. Interestingly, hyperglycemia in patients without previously known diabetes is associated with a greater risk for poor outcome compared to patients with identified diabetes prior the stroke (68–70). Remarkably most of the effects reviewed here occurred independently from the regulation of glycemia in both normal and diabetic models, suggesting that the potential efficacy of DPP-4i to increase acute neuroprotection and/or recovery may be clinically relevant not only for the diabetic population under a DPP-4i-mediated therapy.

DPP-4 INHIBITORS AND STROKE PREVENTION WITH A FOCUS ON CARMELINA, A CARDIORENAL OUTCOME TRIAL WITH LINAGLIPTIN

The incidence of CV complications in T2D, including stroke, has declined substantially but it is still high (71). An increasing CV risk factor control attainment has probably contributed to this, and recently, it was demonstrated that maintaining control of glycated hemoglobin level, low-density lipoprotein cholesterol level, albuminuria, and blood pressure, as well as abstaining from smoking, was associated with no excess risk of CV death or stroke in T2D as compared to the general population (72). Interestingly, glycated hemoglobin was the strongest risk factor for stroke in this registry analysis.

Because, historically, there have been CV safety concerns regarding anti-diabetic drugs in the treatment of T2D, regulators in US and Europe focus specifically on this issue [(73) and http://www.ema.europa.eu/docs/en_GB/document_library/Scientific_guideline/2012/06/WC500129256.pdf], and as a response, fifteen CV outcome trials assessing 3 novel classes of antihyperglycemic therapies (i.e., DPP-4 inhibitors, GLP-1 receptor agonists, and SGLT-2 inhibitors) had been completed by end of 2018, of which none reported an increase in risk for major adverse CV events (MACE), whereas 6 agents have demonstrated CV benefits (74). Within the class of DPP-4i, four large CV outcome trials have been published till date for saxagliptin (75), sitagliptin (76), alogliptin (77), and linagliptin (32).

These trials have used the composite Major Adverse CV events (MACE); i.e., CV death, non-fatal myocardial infarction and stroke, with or without hospitalized unstable angina, as primary outcome. All trials have demonstrated CV safety, without incremental benefit for MACE, including no statistical significant difference in risk for non-fatal stroke. In the saxagliptin trial there was however a significantly higher numbers of patients hospitalized for heart failure (75), a signal also reported in the alogliptin trial (77). Due to this, the class has received a heart failure warning by the US Food and Drug Administration, especially if used in patients with high CV risk underlying heart and kidney disease (73). The linagliptin trial (CARMELINA®) (32) was designed to evaluate the CV safety and kidney outcomes of linagliptin in patients with T2D at high CV risk (75% of patients had prevalent kidney disease). Despite a frailer population, in comparison with the other DPP4i trials, linagliptin resulted in a non-inferior risk of MACE [compared to placebo added to standard care; hazard ratio 1.02 (95% CI: 0.89, 1.17)], including across a number of subgroups such as by sex and age, and did not affect the risk of heart failure [hazard ratio 0.90 (95% CI: 0.74, 1.08)] (31). Furthermore, the progression of albuminuria occurred less frequently in the linagliptin group [hazard ratio 0.86 (95% CI: 0.78, 0.95)] (32), but despite MACE safety, no significant protection for stroke [fatal/non-fatal stroke hazard ratio 0.91 (95% CI: 0.67, 1.23)] was observed. Nonetheless, their broad tolerability and the safety profile are today well-documented and a good choice for the pharmacology treatment of T2D. Importantly, it remains to be determined if these class of drugs can improve stroke outcome in the recovery phase (78) as it has been shown in several experimental studies. Interestingly, outcome trials with linagliptin (32, 79) will be exploring this question by determining the post-stroke functional outcome in a subgroup of patients hospitalized with stroke with T2D by using the modified rankin scale 3–6 months after stroke.

LINAGLIPTIN AND CLINICAL EFFECTS ON COGNITIVE OUTCOMES

Cognitive impairment, including mild cognitive impairment (MCI) and dementia, is increasingly recognized as an important T2D complication (80). High HbA1C concentration and glucose variability are negatively associated with subtle cognitive changes but the association is weak and more randomized controlled trials are needed (81). The underlying processes of cognitive dysfunction in T2D are largely unknown and till date, no pharmacological intervention has proven efficacious (82). Given that incretin therapies have emerged as a potential therapeutic lead for vascular brain injury, studying effects of these on cognitive outcomes are of interest. This is further supported by findings, in an observational study in elderly patients with T2D, that increased plasma DPP-4 activity is associated with elevated risk of MCI (83) and some small, and hypothesis generating, and underpowered, clinical observational studies, reporting some benefits of DPP-4i on clinical cognitive outcomes (84–86).

Both in CARMELINA, and in CAROLINA (a recently completed head-to-head study of linagliptin vs. the sulfonylurea glimepiride) cognitive studies with linagliptin have been completed, but none yet published. The CARMELINA-cognition and the CAROLINA-cognition sub-studies were integral parts of CARMELINA (32) and CAROLINA trials (87), respectively. Both cognition sub-studies aimed to test whether linagliptin prevents accelerated cognitive decline by applying the mini-mental state

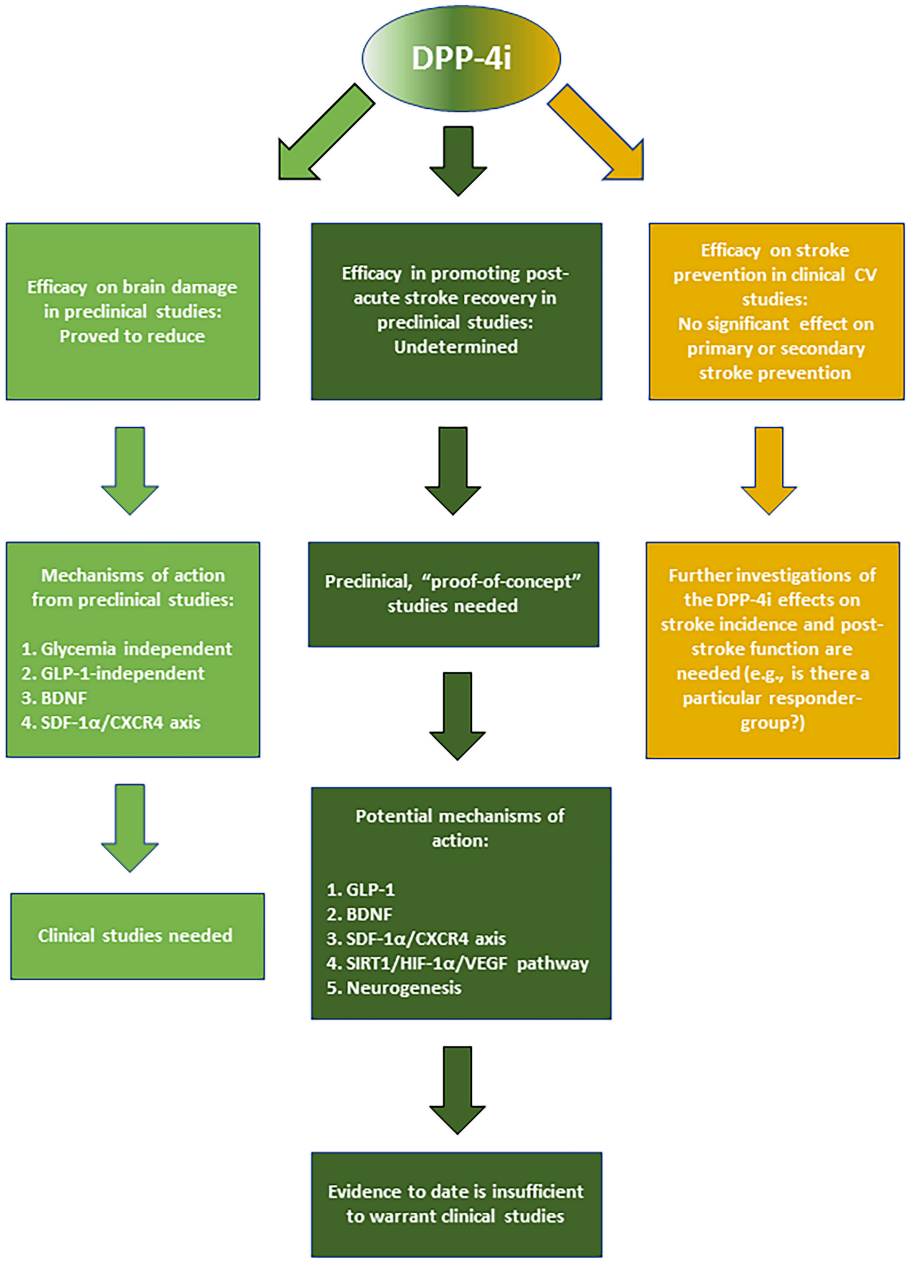

FIGURE 2 | Summary of the reported effects and mechanisms mediated by DPP-4i in stroke prevention, acute neuroprotection, and post-stroke recovery.

examination, as a measure of global cognitive function. In addition, more domain-sensitive composite measure of attention & executive functioning, using two additional tests: the Trail Making Test and the verbal fluency test, have been applied. The results of these sub-studies will be informative for refining the research area within this emerging and highly developing field.

FUTURE DIRECTIONS

Preclinical studies showing favorable effects of DPP-4i in several CNS disorders and stroke, encourage further research aiming to clinically reposition these diabetic drugs as active CNS-centric drugs. Clinical studies mainly investigating the safety of DPP4i have shown that these drugs are safe albeit no effect to decrease stroke incidence has been shown.

The clinical efficacy of acute neuroprotection after stroke is largely dependent on timely intervention within a very short therapeutic window (few hours from stroke onset), which is difficult to achieve. However, if the neuroprotective substance is systemically present at stroke time, the chances of minimizing stroke-induced tissue loss are significantly greater. The success of this strategy could be achieved in T2D patients (at high stroke

risk) who routinely take DPP-4i for the daily management of T2D. These patients could benefit from this treatment when suffering from stroke.

Another potential strategy to exploit the advantages of a DPP4i-based stroke therapy could be the promotion of stroke recovery and rehabilitation in the post-acute/chronic phase that could be theoretically applicable to all stroke patients. However, the potential of this approach has not yet been thoroughly investigated in animal studies and research in this field is highly needed, also in the clinical setting (78), including exploring whether there are differences in effects according to patient-characteristics; a field of emerging importance in the personalized medicine area. Indeed recent animal studies have shown pro-neurogenic (46), anti-inflammatory (54) and neuroplasticity (49) effects mediated by DPP-4i that could result beneficial in the post-stroke recovery phase and long-term clinical outcome.

Finally, studies are needed to understand the molecular mechanisms of DPP-4i in the brain, since the passage of DPP-4i through the bbb seems not to occur under normal conditions and after stroke is undetermined. Therefore, to study the mechanism of action of DPP4i in the brain substances with bbb permeability need to be synthesized in the future. Moreover, the systemic peripheral doses of GIP and GLP-1 after DPP-4i administration are low in comparison to GLP-1 agonists, e.g., in the pg range, and neuroprotection by linagliptin treatment has been shown to occur independently from GLP-1R (59). This suggest that alternative mechanisms are likely involved. Since the DPP-4 is an enzyme with over 40 known, biologically active substrates, many of which with proven CNS effects, the deeper understanding of how exactly DPP-4i regulate these substrates could lead to the identifications of new therapeutic targets in the CNS.

CONCLUSIONS

The demonstrated beneficial CNS effects in preclinical studies and the proven clinical safety of DPP-4i make them good candidates for their potential repositioning against stroke. While the data so far suggest that DPP-4i cannot reduce stroke risk, studies are needed to determine if T2D people who use them for daily T2D management could gain advantages in terms of reduced brain damage in the event of stroke. Both T2D and non-diabetic stroke patients could also benefit from the use of DPP-4i as post-stroke curative agents promoting recovery and rehabilitation in post-acute phase. However, more pre-clinical and clinical research is highly needed in this research field (See **Figure 2** for the summary of DPP-4i-mediated effects in stroke and potential mechanisms of action).

AUTHOR CONTRIBUTIONS

VD conceived and wrote the review. OJ wrote the Linagliptin and Clinical Effects on Cognitive Outcomes section and edited the manuscript. GL wrote the Introduction section. TN wrote and reviewed the DPP-4 Inhibitors and Stroke Prevention With a Focus on CARMELINA, a Cardiorenal Outcome Trial With Linagliptin section. TK conceived the review and wrote The Pharmacology of Linagliptin and Linagliptin and the Treatment of T2D sections. CP conceived, wrote, and coordinated the review.

FUNDING

Financial support in our laboratory is provided by the European Foundation for the Study of Diabetes (EFSD), the Swedish Research Council (2018-02483), the Swedish Heart-Lung Foundation (20160511), the Novo Nordisk foundation (NNF17OC0026924), Karolinska Institutet (Foundation for Geriatric Diseases), KI Stiftelser och Fonder, Stohnes Stiftelse, O. E. och Edla Johanssons Stiftelse, STROKE Riksförbundet, Gamla Tjänarinnor Stiftelse, and by the regional agreement on medical training and clinical research (ALF) between Stockholm County Council and the Karolinska Institutet. All foundations have provided funding that may also include publication costs.

Cross-Reactivity as a Mechanism Linking Infections to Stroke

Guglielmo Lucchese[1,2]*, *Agnes Flöel*[1] and *Benjamin Stahl*[1,3,4,5]

[1] Department of Neurology, University of Greifswald, Greifswald, Germany, [2] Department of Computing, Goldsmiths, University of London, London, United Kingdom, [3] Department of Neurology, Charité Universitätsmedizin Berlin, Berlin, Germany, [4] Department of Neurophysics, Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany, [5] Psychologische Hochschule Berlin, Berlin, Germany

The relevance of infections as risk factor for cerebrovascular disease is being increasingly recognized. Nonetheless, the pathogenic link between the two entities remains poorly understood. Consistent with recent advances in medicine, the present work addresses the hypothesis that infection-induced immune responses may affect human proteins associated with stroke. Applying established procedures in bioinformatics, the pathogen antigens and the human proteins were searched for common sequences using pentapeptides as probes. The resulting data demonstrate massive peptide sharing between infectious pathogens—such as *Chlamydia pneumoniae*, *Streptococcus pneumoniae*, *Tannerella forsythia, Haemophilus influenzae*, Influenza A virus, and Cytomegalovirus—and human proteins related to risk of ischemic and hemorrhagic stroke. Moreover, the shared peptides are also evident in a number of epitopes experimentally proven immunopositive in the human host. The present findings suggest cross-reactivity as a potential mechanistic link between infections and stroke.

Keywords: stroke, infections, cross-reactivity, peptides, inflammation

INTRODUCTION

When considered separately from other cardiovascular diseases, stroke ranks fifth among all causes of death (1) and, critically, its incidence is on the rise (2).

The etiology of stroke is multifactorial with various environmental and genetic risk factors. Hypertension, diabetes and insulin resistance, smoking, dyslipidemia, obesity, heavy alcohol consumption, atrial fibrillation, and carotid stenosis are all established and well-investigated modifiable risk factors of stroke (3–5).

Additionally, there is evidence that environmental factors may also increase risk of stroke, including viral and bacterial infections, such as periodontitis (6) and respiratory infections (7), and infection with *Chlamydia pneumoniae* (8) or Cytomegalovirus (9). However, relatively little is known so far about the role of different pathogens as well as the molecular basis and the mechanisms that potentially link infections to stroke.

Here we set out to investigate whether or not infections can induce immune responses capable of cross-reacting with human proteins that, when altered, have been associated with stroke. Our hypothesis was that immune responses induced by infectious agents might cross-react with crucial stroke-related proteins, thus contributing to the multifactorial pathogenesis of cerebrovascular disease.

To address this hypothesis, we analyzed pathogens, as well as proteins that are known to be associated with increased risk of ischemic and hemorrhagic stroke by searching for common peptides that might underlie cross-reactions.

Specifically, we analyzed antigens from the following pathogens that have been reported to have a possible influence on stroke: the periodontal bacterium *Tannerella forsythia* (10), *Haemophilus influenza* (11), *Streptococcus pneumoniae* (7), *Chlamydia pneumoniae* (8), Influenza A viruses (12, 13), and Human Cytomegalovirus (9).

METHODS

We analyzed the amino acid (aa) primary sequence of pathogen antigens (with short name and UniProt ID in parentheses):

- Surface antigen repeat/outer membrane protein (OMP; UniProtKB: A0A0F7WYE8_CHLPN) from *Chlamydia pneumoniae*;
- Pneumococcal vaccine antigen A (PVAA;UniProtKB: PVAA_STRR6) from *Streptococcus pneumoniae*;
- Surface antigen BspA (BspA; UniProtKB: O68831_TANFO) from *Tannerella forsythia*;
- Outer membrane antigenic lipoprotein B (LPPB; UniProtKB: LPPB_HAEIN) from *Haemophilus influenzae* (strain ATCC 51907);
- Hemagglutinin (HA H1N1; UniProtKB: HEMA_I34A1) from Influenza A virus (strain A/Puerto Rico/8/1934 H1N1);
- Hemagglutinin (HA H5N1; UniProtKB: HEMA_I96A0) from Influenza A virus (strain A/Goose/Guangdong/1/1996 H5N1);
- Hemagglutinin (HA H3N2; UniProtKB: HEMA_I68A6) from Influenza A virus (strain A/Northern Territory/60/1968 H3N2); and
- 65 kDa phosphoprotein (pp65; UniProtKB: PP65_HCMVM) from Human Cytomegalovirus (HCMV; strain Merlin).

The primary sequence of pathogen antigens was dissected into partially overlapping pentapeptides with a one-residue-offset: i.e., MFKRI, FKRIR, KRIRR, and so on. Then, each pentapeptide was analyzed for occurrences within a library consisting of primary sequences of human proteins involved in stroke. The human protein library was *a priori* chosen from the UniProtKB Database (https://www.uniprot.org) (14) using the keyword "stroke." We obtained an unbiased list of 74 human proteins (in)directly associated with stroke (**Table S1**). Stroke-related proteins are indicated as UniProtKB entry names throughout the present article, except when discussed in detail. The pathogen antigens and the human proteins were searched for common sequences using the pentapeptide as a probe unit because a pentapeptide is an immunobiological determinant sufficient for epitope-paratope interaction and for inducing specific immune responses (15–18).

The immunologic potential of the shared peptides was analyzed using the Immune Epitope Database (IEDB; www.iedb.org) (19). All evaluations were based only on epitopic sequences that had been experimentally validated as immunopositive in the human host.

This linear peptide similarity analysis procedure has been used and described before (20, 21).

RESULTS

In a detailed overview, **Table 1** shows that 49 out of the 74 human stroke-related proteins share peptide sequences with antigens from pathogens that proved to be (in)directly involved in stroke (6–10). It can be seen that

- The pathogen vs. human peptide overlap is unexpectedly high when considering that the probability for two proteins to share a pentapeptide is 1 out of 20^{-5}, that is, 0.0000003125 or close to zero.
- The peptide overlap varies widely, with *T. forsythia* BspA and Influenza A HA H3N2 being the pathogen more and less involved in the peptide sharing, respectively.
- The high number of stroke-related proteins involved in the viral peptide overlap precludes a detailed protein-by-protein analysis. However, an example worth noting is the human ATP-binding cassette sub-family C member nine (ABCC9 or SUR2) that shares peptide sequences with all of the pathogen antigens analyzed, with the exception of the Influenza A HA H3N2 virus. ABCC9 is a subunit of ATP-sensitive potassium channels (K_{ATP}) that can form cardiac and smooth muscle-type KATP channels with KCNJ11 and mediates neuroprotection (22).

In summary, **Table 1** describes a peptide platform that connects the infectious agents under analysis human proteins related to stroke.

Subsequently, in order to define the immunologic potential of the shared peptides, we conducted analyses throughout the peptide immunome cataloged in the Immune Epitope Database (IEDB; www.iedb.org) (19). The search was finalized to identify epitopic sequences corresponding to (or containing) the peptide sequences shared between stroke-related infectious agents and stroke-related human proteins. It was found that a great number of the shared peptides listed in **Table 1** are also distributed through hundreds of epitopic sequences with an immunological potential. A list of such epitopic sequences is reported in **Table 2.**

CONCLUSION

Stroke risk appears to be the result of a complex combination of multiple genetic non-modifiable and environmental modifiable factors that can be further classified as either "traditional" or new, "emerging" ones (23). As highlighted by Grau et al. (24, 25), the occurrence of stroke is only partially explained by traditional modifiable cardiovascular

AYLAG	PDE3A. cGMP-inhibited 3′,5′-cyclic phosphodiesterase A
LLPLS;**AYLAG**; **VTSSV**; QEVKA	RN213. E3 ubiquitin-protein ligase RNF213
GPIKS	SCN5A. Sodium channel protein type 5 subunit alpha
KKSFL	SYLM. Probable leucine–tRNA ligase, mitochondrial
Influenza A HA H1N1:	
DGVKL	ADA2. Adenosine deaminase 2
LLVSL	ATP6. ATP synthase subunit a
ENAYV	**ABCC9**. ATP-binding cassette sub-family C member 9
ASSLV	PDE3A. cGMP-inhibited 3′,5′-cyclic phosphodiesterase A
AELLV; **ELLVL**; LLVLL; LVLLV	**DAPK1**. Death-associated protein kinase 1
TVLEK; YVSVV; QTPLG; FLDIW	**RN213**. E3 ubiquitin-protein ligase RNF213
TSNAS	NMDE2. Glutamate receptor ionotropic, NMDA 2B
CALAA	GAS6. Growth arrest-specific protein 6
LLVLL;YAADQ; KVDGV	KLOT. Klotho
EELRE	LMNA. Prelamin-A/C
YSEES	**ZFHX3**. Zinc finger homeobox protein 3
Influenza A HA H5N1:	
LLAIV	AL5AP. Arachidonate 5-lipoxygenase-activating protein
LLLAI	**ABCC9**. ATP-binding cassette sub-family C member 9
AQDIL; ISGVK	PDE4D. cAMP-specific 3′,5′-cyclic phosphodiesterase 4D
LLLAI	CYTC. Cystatin-C
QRLVP; **AELLV**; **ELLVL**	**DAPK1**. Death-associated protein kinase 1
ILEKT; LKHLL; **VSSAC**	**RN213**. E3 ubiquitin-protein ligase RNF213
EGGWQ	KLOT. Klotho
SLALA	NU5M. NADH-ubiquinone oxidoreductase chain 5
KIVLL; LVLAT	**NU155**. Nuclear pore complex protein Nup155
ARLNR; SIYST	KCNQ1. Potassium voltage-gated channel subfamily KQT member 1
VSSAC	SCN1B. Sodium channel subunit beta-1
VPEWS	TBX5. T-box transcription factor TBX5
SVAGW	S19A2. Thiamine transporter 1
SLALA	GATA5. Transcription factor GATA-5
Influenza A HA H3N2:	
GGSNA; **AELLV**	**DAPK1**. Death-associated protein kinase 1
INSNG	SAMH1. Deoxynucleoside triphosphate triphosphohydrolase SAMHD1
KITYG	MYL4. Myosin light chain 4
LLGDP	KCNA5. Potassium voltage-gated channel subfamily A member 5
ISFAI	HTRA1. Serine protease HTRA1
VLNVT	SCN3B. Sodium channel subunit beta-3

risk factors, such as increasing blood pressure, cigarette smoking, and diabetes mellitus. Most importantly, infectious diseases appear to play a key role in contributing to the risk of stroke and are to be counted among "emerging" modifiable risk factors that receive increasing scientific interest (6–10, 23, 26, 27).

Searching for possible immunopathogenic links between infection and risk of stroke, the present study aimed to analyze

TABLE 2 | Epitopes immunopositive in the human host and containing peptide sequences common to antigens from stroke-related pathogens and human proteins associated with stroke.

Column 1: Epitopes listed according to the IEDB-ID number. Epitope details and references at www.immuneepitope.org (19). Column 2: Sequences common to pathogen antigens and human proteins related to stroke are indicated in capital letters.

the potential immunologic relationship between pathogens and human proteins that, when altered, have been associated with risk of stroke. In line with our hypothesis, we found that immune cross-reactions between infectious pathogens and human stroke-related proteins might occur, thus increasing the risk of stroke (see **Tables 1**, **2**).

The immunologically relevant peptide sharing reported in the present study depicts a complex scenario. Some potential molecular targets of cross-reactions are proteins belonging to the cardiovascular system, thus possibly directly accounting for cerebrovascular damage. Other possible targets are proteins of the immune system, thus suggesting mechanisms resulting in immune dysregulation which could lead to cerebrovascular damage.

An example of the first type of potential targets are ion-channels, particularly potassium (K^+) and sodium (Na^+) channels (ABCC9, KCNE2, KCNA5, KCNQ1, SCN4B, SCN5A, SCN1B, SCN3B, see **Table 1**). Accordingly, a growing body of evidence points to the involvement of cardiac K^+ and Na^+ channel dysfunction (cardiac channelopathies as a result of genetic mutations and/or inflammatory mechanisms) in the pathogenesis of atrial fibrillation (AF), an established risk factor for stroke (28, 29). Moreover, autoantibodies targeting ion-channels may be involved in cardiac arrhythmias (30). In light of the potential cross-reactivity suggested by the observed peptide sharing, AF and subsequent stroke could result from antibodies primarily targeting epitopes of infective agents but also cross-reacting with cardiac ion channels. For instance, activating antibodies could lead to a gain-of-function of K^+-channels and inhibiting antibodies to a loss-of-function of of Na^+-channels. This could promote re-entry or increase susceptibility to early and/or delayed afterdepolarizations, two mechanisms that can generate AF (31, 32).

The second class of potential targets includes proteins that actively modulate the inflammatory response, such as cytokines and colony-stimulating factor receptors (IL-4, macrophage colony-stimulating factor 1 receptor, see **Table 1**) (33, 34). IL-4, for example, is a well-investigated tolerogenic cytokine that is able to suppress inflammatory responses and organ-specific autoimmunity in both animal models and humans (35, 36). It is then conceivable that autoantibodies downregulating the function of these proteins can promote inflammatory responses, thus increasing the risk of cerebrovascular damage and stroke. Indeed, inflammatory responses appear to be crucial in the pathogenesis of stroke by inducing atherosclerosis progression, pro-thrombotic activation, and AF—among other mechanisms (37). Inflammation can therefore be considered as one key factor underpinning the relationship between classical stroke risk factors and comorbidities. It appears that not just single infections, but overall infectious burden from multiple agents predicts stroke incidence. Moreover, poor outcome may be proportional to systemic inflammatory burden both in patients and experimental models. For instance, Influenza and Streptococcus infection seem to contribute to stroke incidence and outcome, and evidence from experimental models indicate that blocking inflammatory processes might be an effective prevention strategy (38, 39).

The increasingly recognized relevance of inflammation in stroke is consistent with a possible role of peptide sharing-based cross-reactivity as contributing factors to cerebrovascular damage. In fact, the past two decades of immunologic research have radically changed the way we think of inflammation and innate immunity. It is now known that innate immune responses can "specifically" drive the following adaptive responses through recognition of pathogen-associated molecular patterns (PAMPs) (40, 41). That is to say that peptide epitopes, cell-wall components, and other PAMPs activate immune cells already from the very first stages of immune reactions and drive inflammation. Indeed, there are examples of cross-reactivity between host and pathogen-associated molecular patterns: identical inflammasomes and toll-like receptors (TLRs) recognizing molecular fingerprints of both pathogens (the PAMPs) and injured host cells (so-called danger-associated molecular patterns; DAMPs). For instance, both bacteria LPS and HMGB1 from injured host cells activate TLR4, with consequent inflammation in various tissues including the brain (41, 42). TLR- and inflammasome-dependent pathways seem to be important drivers of inflammation, vascular disease, and reportedly contribute to stroke outcome (43, 44).

Our preliminary results underline the importance of further experimental efforts to define the molecular basis through which microbial infections might contribute to an increased risk of stroke (45–50). Future studies should evaluate immunoreactivity against the peptides shared by infectious pathogens and human stroke-related proteins in sera from stroke patients. Possibly, such serological analyses could also help identify specific markers predicting a higher risk of stroke and might therefore be useful to design preventive strategies following an infection. The ultimate translational relevance of our finding lies in the possibility of adopting effective individualized primary and secondary preventive strategies in patients at risk for stroke after infections. Generic hygienic measure, as well as antibiotic prophylaxis and vaccination campaigns have already been proposed and tested with contrasting results (37). Identifying and stratifying patients according to individual biomarker profiles would allow to personalize treatment for each patient, thus possibly increasing overall efficacy.

Until now, stroke is a leading cause of preventable death and adult disability (1–5, 47–52), but preventive strategies mostly concentrate on traditional cardiovascular risk factors (53–56). Moreover, "cryptogenic" stroke (i.e., ischemic stroke with no obvious cause) poses a challenge in terms of primary and secondary prevention (57, 58).

Given the burden of cerebrovascular disease, and the potential to identify immunological markers that may then serve as prognostic indicators of risk of cerebrovascular damage after an infection, our results justify further intensive research on the cross-reactive link between infections and risk of stroke.

AUTHOR CONTRIBUTIONS

GL formulated the hypothesis, analyzed the data and wrote the manuscript. GL, AF, and BS interpreted the data, revised and finalized the manuscript.

Endothelial progenitor cells (EPCs) are multipotential stem cells considered to have immense clinical value for revascularization. However, the clinical application of EPCs has been hampered by their clinical potency in ischemic anoxic environments. This study aimed to explore the effect of microRNA-210 (miR-210) on EPCs under oxygen-glucose deprivation (OGD) conditions. We generated a model of EPCs cultured under OGD conditions to simulate ischemia and explore the expression of miR-210 *in vitro*. With longer exposure to hypoxia, we found that miR-210-3p expression was highly upregulated in OGD groups compared to that in controls from 4 to 24 h, but not miR-210-5p. We then transfected a miR-210-3p mimic and inhibitor into EPCs, and after 24 h, we exposed them to OGD conditions for 4 h to simulate ischemia. We detected miR-210 by real-time polymerase chain reaction (RT-PCR) and tested the proliferation, migration, and tube formation of normal EPCs and OGD-treated EPCs by CCK-8, transwell chamber, and Matrigel assays, respectively. The direct targets of miR-210-3p were predicted using miRWalk. Compared to that in normal EPCs, higher miR-210-3p expression was found in OGD-treated EPCs ($p < 0.05$). Moreover, upregulation of miR-210-3p was found to promote proliferation, migration, and tube formation in EPCs under normal and OGD conditions ($p < 0.05$), whereas down-regulation inhibited these abilities in OGD-treated EPCs ($p < 0.05$). Repulsive guidance molecule A (RGMA), a negative regulator of angiogenesis, was predicted to be a target of miR-210-3p. Accordingly, upregulation of miR-210-3p was found to inhibit its expression at the protein level in OGD-treated EPCs, whereas downregulation of miR-210-3p inhibited its expression ($p < 0.05$). A dual-luciferase reporter system confirmed that RGMA is a direct target of miR-210-3p. MicroRNA-210-3p overexpression enhances the angiogenic properties of OGD-treated EPCs by inhibiting RGMA.

INTRODUCTION

Characterized by high mortality, morbidity, and disability, ischemic stroke causes immense health and economic burdens to families and society (Benjamin et al., 2017). However, the pathogenesis of stroke remains unclear and there are currently no effective treatments.

Endothelial progenitor cells (EPCs) are multipotential stem cells considered to have immense clinical value for revascularization. Previous research has demonstrated that EPCs can differentiate into mature endothelial cells (ECs) to take part in angiogenesis and vasculogenesis after cerebral ischemic injury (Chong et al., 2016). They have also been shown to participate in the repair of dysfunctional endothelia and to suppress endothelial injury through their direct incorporation into newly forming vessels or the secretion of pro-angiogenic growth factors or cytokines (Asahara et al., 2011). However, the clinical application of EPCs has been hampered by the limited numbers of surviving cells and their clinical potency in ischemic anoxic environments, in addition to the controversies surrounding their identities and functions (Zhao et al., 2013). Our study began with the key point of improving the ability of EPCs to resist hypoxia and ischemia.

As a class of conserved, single-stranded, endogenous, non-coding RNA, microRNAs (miRNAs) exert physiological effects mainly by negatively regulating gene expression at the post-transcriptional level. Further, they have been widely researched in both experimental and clinical settings. Usually, one miRNA can target more than one mRNA and one mRNA is targeted by more than one miRNA (Lim et al., 2005). This phenomenon results in the formation of an intricate regulatory network that plays important roles in biological processes such as cell proliferation, differentiation, apoptosis, early development, immunity, hematopoiesis and longevity, and angiogenesis, among others (Xu et al., 2003; Calin et al., 2004; Chen, 2004; Wang et al., 2009; de Rie et al., 2017). MicroRNA-210 (miR-210), the key hypoxia-related miRNA, was found to be upregulated in many different types of cells under hypoxic conditions. Studies revealed that this miRNA is involved in angiogenesis, regulating the cell cycle, differentiation, deoxyribonucleic acid repair, and apoptosis by targeting Ephrin-A3, E2F3, NPTX1, RAD52, ACVR1B, MNT, and CASP8AP2, among others (Chan and Loscalzo, 2010). Moreover, miR-210 improves cardiac function in a murine model of myocardial infarction by inhibiting apoptosis and enhancing angiogenesis (Hu et al., 2010). We have previously performed the peripheral blood miRNAs expression profiling in patients with acute cerebral ischemia (Zeng et al., 2016), and miR-210 is one of 10 significant differentially expressed miRNAs. Our previous studies also demonstrated that it is upregulated during the acute stage following cerebral ischemia in transient middle cerebral occlusion (tMCAO) mice (Zeng et al., 2016). Further, its overexpression was found to promote angiogenesis and neurogenesis and improve the prognosis of mice with cerebral ischemia by upregulating vascular endothelial growth factor (VEGF) and brain-derived neurotrophic factor (BDNF) levels (Zeng et al., 2014). MiR-210 has robust anti-hypoxia ability (Chan and Loscalzo, 2010), and it has been reported that miR-210 could enhance the hypoxia tolerance of bone marrow mesenchymal stem cells (MSCs) (Chang et al., 2013). Recent research has shown loading miR-210 in EPCs derived exosomes could boost the beneficial effects on hypoxia/reoxygenation injured human ECs (Ma et al., 2018). However, the function of miR-210 on EPCs was not previously known. Therefore, we hypothesized that the function of EPCs under ischemic conditions might be improved by miR-210 overexpression. We considered that the combination of miR-210 and EPCs could be a more effective therapy for treating stroke.

In this study, we used an *in vitro* cell model with oxygen-glucose deprivation (OGD) injury to simulate an ischemic environment. We investigated the possible functions of miR-210 in EPC under the hypoxic condition and further explored the potential underlying molecular mechanism in controlling cellular behavior.

MATERIALS AND METHODS

Cell Culture and OGD Treatment

Endothelial progenitor cells were extracted from the umbilical cord blood of the healthy parturient women. Umbilical cord blood was provided by the International Peace Maternity and Child Health Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China. And all participants were informed about the study protocol and given written informed consent according to the Declaration of Helsinki principles. The study protocol was approved by the Ethics Committee of Ruijin Hospital, Shanghai Jiao Tong University School of Medicine. Cells were cultured in Endothelial Growth Medium-2 (EGM-2) (Lonza, United States) at 37 ± 1°C with 5% CO_2, 90 ± 2% humidity in 10-cm^2 culture dishes. To mimic ischemia conditions *in vitro*, the culture medium was replaced and washed with phosphate buffered saline (PBS) (HyClone, United States), and cells were placed in an airtight experimental hypoxia chamber containing a gas mixture comprising 95% N_2 and 5% CO_2 for 4, 12, or 24 h. EPCs cultured with normal oxygen levels served as controls. All cells were collected for total RNA extraction using TRIzol (Invitrogen, United States). EPCs used in all experiments were fourth to the sixth generation.

Immunocytochemistry

Endothelial progenitor cells were washed with PBS (HyClone, United States), and then fixed in 4% paraformaldehyde (PFA) for 10 min. EPCs were then washed with PBS three times after PFA was discarded. Cells were permeabilized with 0.3% Triton-100 (Sigma-Aldrich, United States) for 10 min and blocked with 10% bovine serum albumin (BSA) (Sigma-Aldrich, United States) for 1 h. EPCs were incubated for 20 h at 4°C with primary antibodies in PBS as follows: polyclonal sheep anti-CD31 (1:200; R&D, United States), polyclonal sheep anti-CD34 (1:200; R&D, United States), polyclonal rabbit anti-Von Willebrand Factor (vWF) (1:200; Abcam, United Kingdom), polyclonal goat anti-KDR (1:200; R&D, United States), polyclonal rabbit anti- repulsive guidance molecule A (RGMA) (1:300; Abcam, United Kingdom). The

secondary antibodies were Alexa 488/594-conjugated donkey anti-sheep/rabbit/goat (1:1000; Invitrogen, United States) and the nuclei were stained by adding DAPI (1:1000; Invitrogen, United States). All samples were observed with a confocal laser scanning microscope (Leica, Germany).

Flow Cytometry

Endothelial progenitor cells were digested and centrifugalized when the cell density was 80–90%. Cells were then resuspended in PBS at a concentration of 1×10^7/ml. We used 1×10^6 cells in a 100-μl sample (test). EPCs were incubated with fluorescent antibodies including CD34-PE (1:5; BD Biosciences, United States), CD31-PE (1:5; BD Biosciences, United States), KDR-APC (1:5; BD Biosciences, United States), CD105-APC (1:20; BD Biosciences, United States), and CD133-PE (1:10; Miltenyi Biotec, Germany) in the dark for 30 min on the ice. Without washing, samples were analyzed by flow cytometry.

Cell Transfection

For miR-210-3p overexpression and suppression, a miR-210-3p mimic (5′-CUGUGCGUGUGACAGCGGCUGA-3′), miR-210-3p inhibitor (5′-UCAGCCGCUGUCACACGCACAG-3′), mimic control (5′-GCGCUCGUGGAGUGCGUGUCAA-3′) and inhibitor control (5′-GCCAGAGCCUGACCGCUACCUA-3′) were purchased from TuoRan (Shanghai, China). According to the manufacturer's protocol, we transfected mimic or mimic control at a concentration of 50 nM and inhibitor or inhibitor control at a concentration of 200 nM using Lipofectamine 2000 (Invitrogen, United States) in accordance with the manufacturer's instructions. All related experiments were performed within 24 h after transfection.

RNA Extraction, Reverse Transcription, and Real-Time PCR

Using the protocol for TRIzol (Invitrogen, United States), RNA extraction was performed. RNA concentration and purity were detected using the NanoDrop1000 spectrophotometer (Thermo Fisher Scientific, United States). Samples with an absorbance ratio at 260–280 nm between 1.8 and 2.0 were adopted. The Starter Kit (EXIQON, Denmark) was used for reverse transcription and real-time quantitative polymerase chain reaction (qPCR) according to the manufacturer's protocol in the measurement of miR-210. A fast real-time PCR system (7900 HT, ABI) was used for this amplification. The relative expression of miR-210 was normalized to the expression of the internal reference U6 and calculated by the $2^{-\Delta\Delta Ct}$ relative quantification method. As for RGMA (forward primer 5′-TCACCGACCGCTTCCAGACC-3′; reverse primers 3′-CTCCTTCACCAGTTACGACACCTC-5′), the PrimeScript^{TM} RT reagent Kit (Takara, Japan) was used for reverse transcription and real-time qPCR according to the manufacturer's protocol in the measurement of RGMA. The relative expression of RGMA was normalized to the expression of the internal reference GAPDH (forward primer 5′-GATGGTGAAGGTCGGTGTGA-3′; reverse primers 3′-TGAACTTGCCGTGGGTAGAG-5′) and calculated by the $2^{-\Delta\Delta Ct}$ relative quantification method.

Proliferation Assay

We used the cell counting kit-8 (CCK-8) (Dojindo, Japan) to examine EPC proliferation. For this, 1×10^4 cells with 100 μl of EGM-2 were inoculated into each well of a 96-well plate and incubated for 24 h. Then, a new medium containing CCK-8 reagent (10:1 v/v) was added to each well. Cells were further incubated at 37°C for 2 h. The absorption at 450 nm was examined using a microplate reader.

Migration Assay

As a classical *in vitro* model of angiogenesis, migration was assessed in 24-well plates with 8.0-mm pore polycarbonate membranes inserted (Corning, United States). In brief, we added 800 μl of EGM-2 into each well of the 24-well plate, which was followed by inserting chambers with polycarbonate membranes. Then, 2×10^4 cells with 200 μl of EBM-2 were added into each chamber in triplicate. After further incubation for 20 h, cells were fixed with PFA and stained with crystal violet for 10 min. The images of cells that migrated across the membrane were captured using a microscope (Leica, Germany). The tinctorial cells under the membranes were then counted and analyzed.

Tube Formation Assay

As another classical *in vitro* model of angiogenesis, tube formation assays were carried out in 96-well plates. Approximately 40 μl of Matrigel (BD, United States) was added into each well of a 96-well plate and incubated at 37°C for 30 min for solidification. Then, 1.5×10^4 cells were inoculated into the coated plate in triplicate. After culturing for 8 h at 37°C. After having obtained a series of three-dimensional focal stack images of the microvascular structure via a bright field microscope, we imported the stack images into Intensify3D to enhance and optimize the cell signal (Yayon et al., 2018). Then we used the AngioTool to calculate the tube length as previously reported (Zudaire et al., 2011).

Western Blotting

Endothelial progenitor cells were lysed and proteins were extracted separately from cells with radioimmunoprecipitation assay buffer (10 mM Tris/HCl, pH 8.0, 150 mM NaCl, 1 mM EDTA, 1% sodium deoxycholate, 1% Triton X-100, 0.1% SDS, and protease inhibitor cocktails) at 4°C and centrifuged at 12000 × *g* for 25 min to remove cell debris. The supernatant was transferred to a new tube and mixed with 5× loading buffer. For the detection of RGMA, samples were electrophoresed with a 10% polyacrylamide gel, and the proteins were electrophoretically transferred to polyvinylidene difluoride membranes. The membranes were blocked with Block Ace (Sangon, China) and incubated with a polyclonal rabbit anti-RGMA antibody (1:1000; Abcam, United Kingdom) and a monoclonal mouse anti-GAPDH antibody (1:1000; Invitrogen, United States) in TBST for 16 h at 4 °C. Antibodies were detected by incubating the samples with an HRP-conjugated secondary antibody (1:5000; Invitrogen, United States) for 1 h at room temperature. The blots were detected using Super Signal West Femto Substrate (Thermo Fisher Scientific, United States) and a

LAS-4000 imaging system. For densitometric quantification, the band density of RGMA relative to that of β-actin was quantified by NIH ImageJ software.

Luciferase Reporter Assays

In this study, the full length of the 3′UTR sequence was cloned (base from 1636 to 3227) to construct the luciferase reporter vectors. The full 3′UTR fragments from *RGMA* containing the predicted miR-210-3p-binding sites were amplified by PCR and subcloned downstream of the luciferase gene in the luciferase vector. The 3′UTR of *RGMA* with or without the mutant sequence was then amplified. For luciferase assays, EPCs were cultured in 24-well plates and co-transfected with 200 ng of firefly luciferase constructs, 4 ng of *Renilla* luciferase plasmid, and 50 nmol/L miR-210-3p mimic using Lipofectamine 2000. *Renilla* luciferase activity was measured using a dual-luciferase reporter assay 48 h after transfection. The results were expressed as relative luciferase activity (firefly luciferase/*Renilla* luciferase).

Data Analysis and Statistics

All statistical tests were performed using GraphPad Prism7. Data are presented as the mean ± SEM. Three or more replicates were always performed for each experiment in all assays. Statistical analyses were performed by one-way ANOVA followed by Student-Newman-Keuls tests. A probability value of $p < 0.05$ was considered statistically significant.

RESULTS

Culture and Identification of EPCs

We extracted mononuclear cells from the umbilical cord blood of healthy parturient women using lymphocyte separation liquid. The medium was changed twice per week until primary EPCs were passaged. Primary EPCs grew out at approximately the third week. We could see small, cobblestone-shaped cell clusters and growth and proliferation were highly apparent (**Figure 1A**). We subjected the fourth generation of EPCs to direct staining (**Figure 1B**) and under the microscope, we could see that nearly half of EPCs were stained for CD34 (green) and CD31 (green), whereas most of the EPCs were stained for KDR (red) and vWF (red). Flow cytometric analysis (**Figure 1C**) was used to identify the proportion of EPCs that were stained with endothelial surface antigens (CD105, 88.5%; CD31, 94.8%; KDR, 45.78∼63.85%) and stem cell surface markers (CD34, 59.54%; CD133, 2.12%). Our results thus showed that cultured cells derived from human cord blood were EPCs.

Upregulation of MiR-210-3p in EPCs Under OGD Conditions

We next generated a model of EPCs cultured under OGD conditions to simulate ischemia and explore the expression of miR-210 *in vitro*. Although the majority of EPCs survived when deprived of oxygen and glucose for 4 h, cell debris could still be observed under the microscope. With longer exposure to hypoxia, EPCs became deformed and disaggregated and died progressively from 4 to 24 h (**Figure 2A**). Correspondingly, miR-210-3p expression was highly upregulated in OGD groups compared to that in controls, whereas miR-210-5p expression was upregulated in OGD groups compared to expression in controls but did not rise markedly; in addition, there were no differences in expression among groups subjected to OGD for 4, 12, and 24 h (**Figure 2B**).

Upregulated MiR-210-3p Enhances the Angiogenic Ability of EPCs Under Normal Oxygen Conditions

To elucidate the involvement of miR-210-3p in the functional behaviors of EPCs, we transfected a miR-210-3p mimic, mimic control, miR-210-3p inhibitor, and inhibitor control into EPCs and subjected them to normal oxygen conditions. MiR-210-3p was upregulated in the mimic group but was not downregulated by the inhibitor (**Figure 3A**). We chose CCK-8, transwell, and Matrigel assays to test the proliferation (**Figure 3B**), migration (**Figure 3C**), and tube formation (**Figure 3D**) abilities, respectively, of these cells. Results showed that the EPC-miR-210-3p mimic group exhibited enhanced proliferative and migration abilities compared to EPCs alone. A similar outcome was observed for tube formation assays. Further, the EPC-miR-210-3p mimic group displayed the best tube formation ability among all groups. Other experimental conditions had no effect on EPCs. These data suggested that upregulated miR-210-3p expression enhances the angiogenic ability of EPCs under normal oxygen conditions.

Upregulated MiR-210-3p Enhances the Angiogenic Ability of EPCs Under OGD Conditions

To further elucidate the involvement of miR-210-3p in the functional behaviors of EPCs, we transfected a miR-210-3p mimic, mimic control, miR-210-3p inhibitor, and inhibitor control into EPCs under OGD conditions and performed the same experiments. MiR-210-3p was upregulated in the mimic group and downregulated in the inhibitor group (**Figure 4A**). We found that the EPC-miR-210-3p mimic group still exhibited enhanced proliferation, migration, and tube formation compared to those in EPCs alone under OGD conditions. However, the EPC-miR-210-3p inhibitor group showed the opposite result. Specifically, miR-210-3p inhibitor treatment resulted in reduced proliferation, subdued migration, and diminished tube formation (**Figures 4B–D**). These data suggested that upregulated miR-210-3p enhances the angiogenic ability of EPCs under OGD conditions, and in contrast, that downregulation of miR-210-3p inhibits these processes.

MiR-210-3p Targets RGMA

We next investigated the involvement of upregulated miR-210-3p, induced by OGD, in regulating RGMA expression in EPCs. First, the nucleotide coding region of *RGMA* mRNA was analyzed. A screen utilizing the online miRWalk software revealed putative binding between miR-210-3p and the *RGMA* 3′UTR. Further, *RGMA* mRNA expression was increased in EPCs

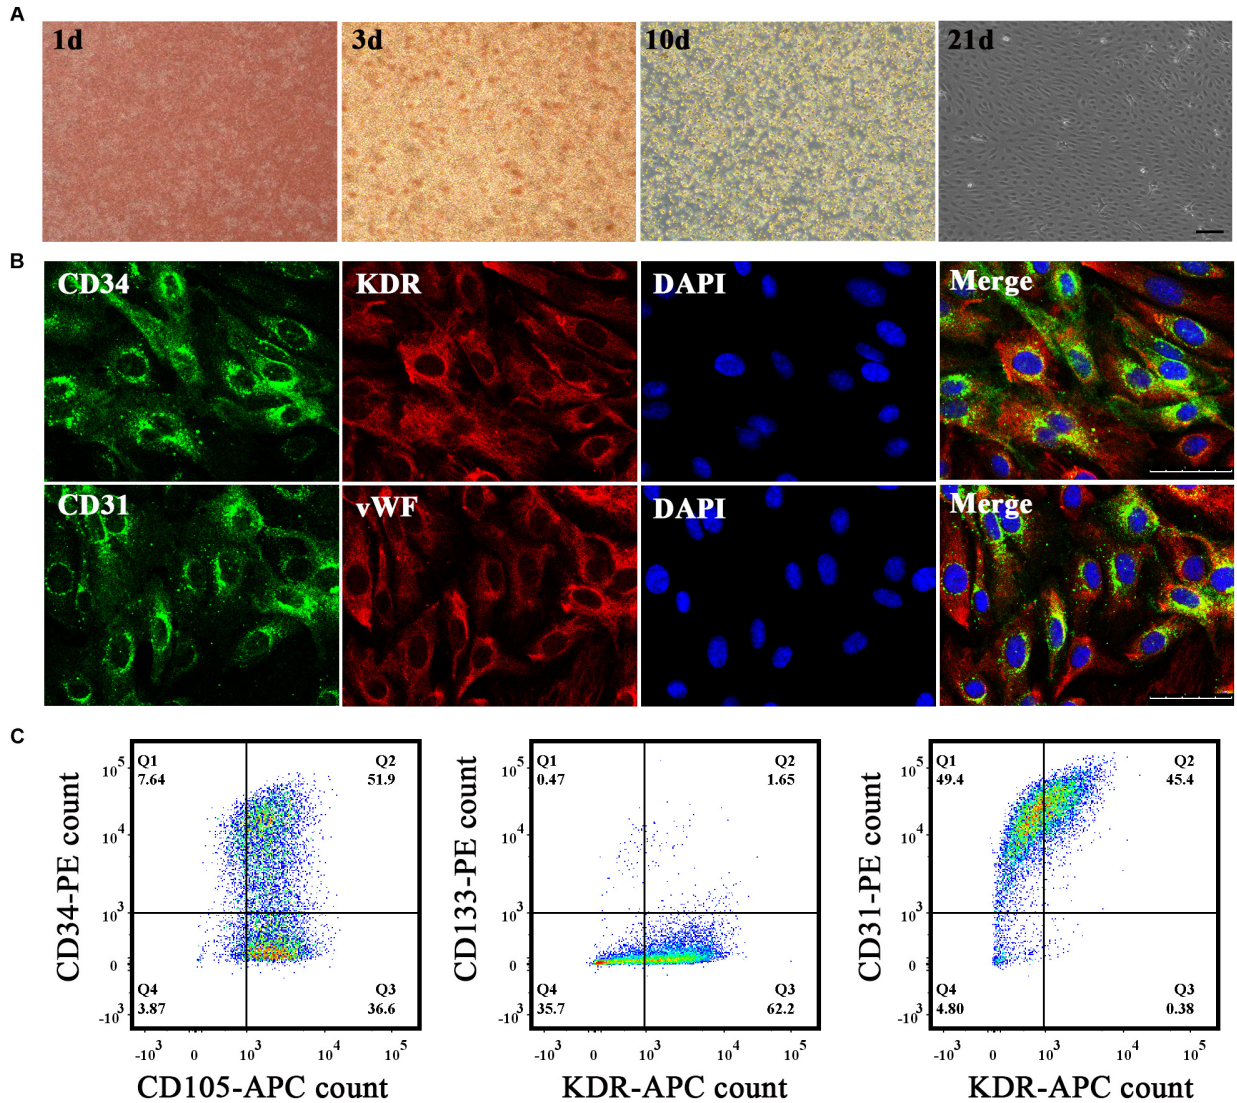

FIGURE 1 | Cultivation and identification of endothelial progenitor cells (EPCs). **(A)** EPCs were extracted from umbilical cord blood and morphological changes in primary EPCs were observed *in vitro* on the first, third, tenth, and twenty-first days successively under a microscope. Bar = 100 μm. **(B)** Immunohistochemistry staining results to identify EPCs. Biomarkers adopted were CD34, CD31, KDR, and vWF. Bar = 50 μm. **(C)** Flow cytometry results to identify EPCs. Biomarkers adopted were CD34, CD105, CD133, KDR, and CD31.

alone under OGD conditions (**Figure 5A**) but there was no difference among groups after mimic or inhibitor of miR-210-3p was transfected into EPCs under OGD conditions (**Figure 5B**). Subsequent experiments showed that the protein expression of RGMA was significantly suppressed in the miR-210-3p mimic group of EPCs but increased in the miR-210-3p inhibitor group (**Figures 5C,D** and **Supplementary Figure S1**). In addition, when performing reported assays, co-transfection of RGMA-WT and the miR-210-3p mimic resulted in the significant downregulation of luciferase activity compared to that with transfection of RGMA-WT alone or with co-transfection of RGMA-MT and the miR-210-3p mimic. In addition, upon comparing RGMA-WT alone and RGMA-MT and miR-210-3p mimic co-transfection groups, no significant difference was noted, supporting the contention that the miR-210 mimic can directly bind the *RGMA* 3′UTR (**Figure 5E**). Hence, *RGMA* is a target of miR-210-3p.

DISCUSSION

The results presented in our study are the first to reveal that miR-210-3p is overexpressed in OGD-treated EPCs. Further, miR-210-3p overexpression might enhance the angiogenic ability of EPCs under hypoxia conditions via the suppression of RGMA expression at the protein level. This study could provide a theoretical basis to uncover the molecular mechanisms underlying recovery after stroke and suggest a new treatment approach for this event.

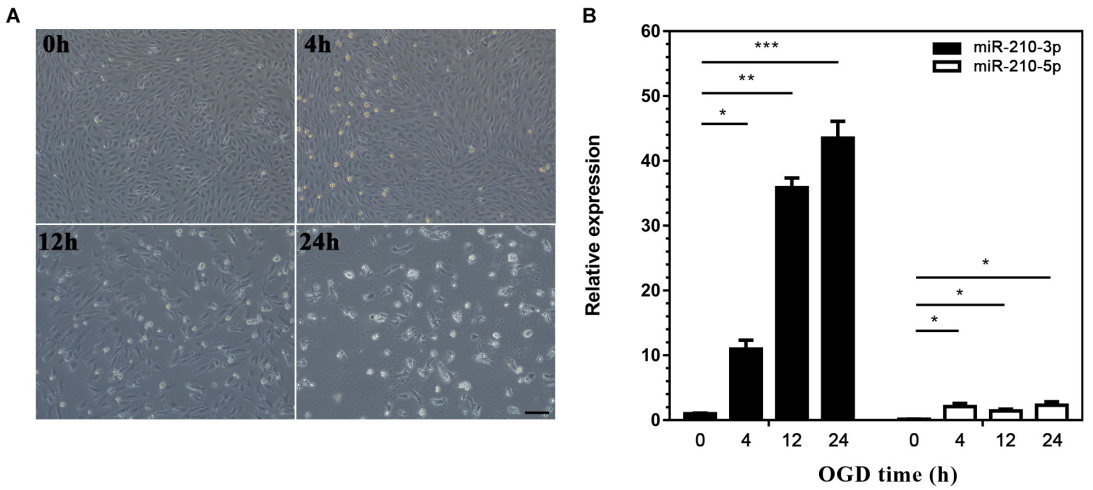

FIGURE 2 | Construction of oxygen and glucose deprivation (OGD) model and expression of microRNA (miR)-210. **(A)** Endothelial progenitor cells (EPCs) were exposed to OGD conditions for 0, 4, 12, and 24 h to simulate ischemia. Bar = 100 μm. **(B)** Real-time PCR was used to detected miR-210 expression in OGD-treated EPCs; $n = 3$ per group. Data are presented as the mean ± SEM, $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

Previously, only the 3-arm of precursor microRNA (designated as the guide strand) was thought to mature and become functional, whereas the complementary 5′-arm (referred to as microRNA* or the passenger strand) was considered destined for degradation. However, research results in recent years have discovered that both arms of the pre-microRNA might be expressed differently and modulate various aspects of biological processes (Essandoh et al., 2016). To avoid confusion, miRNA/miRNA* nomenclature is now replaced by miRNA-3p and miRNA-5p, respectively. To this end, we explored the expression of both arms of miR-210, namely miR-210-3p and miR210-5p, in OGD-treated EPCs. MiR-210-3p is the guide-strand that integrates into the RNA-induced silencing complex, whereas miR-210-5p is the passenger-strand that is inactivated through degradation (Bartel, 2004). In this study, we examined the expression of miR-210-3p and miR-210-5p on EPC cells after OGD in the meantime. The results showed that the expression of miR-210-3p was significantly increased after hypoxia, which was several tens of times higher than the baseline level. And the expression of miR-210-3p was positively correlated with OGD time. However, Although 5p increased after ischemia, the expression of miR-210-5p was very low, only 3–5 times higher than baseline, and there was no noticeable correlation with time increase. Based on the above facts, we speculate that during the formation process of mature miRNAs (miR-210-3p and -5p) from precursor miR-210, miR-210-3p plays the major biological function. So for subsequent experiments on EPC function under hypoxic conditions, we focused on miR-210-3p to explore the underlying molecular mechanism.

With a functional hypoxia-responsive element in its promoter region (Huang et al., 2009), miR-210 has been found to be expressed at high levels in many cell types such as cardiomyocytes (Martinez et al., 2017), adipose-derived stem cells (Kim et al., 2013), and tumor cells (Ying et al., 2011; McCormick et al., 2013) upon exposure to hypoxia. Moreover, miR-210 has been shown to be related to the development of different diseases including immunological diseases (Wang et al., 2014), cancers (Ying et al., 2011; McCormick et al., 2013), and cardiovascular and cerebrovascular diseases (Zeng et al., 2016; Martinez et al., 2017). Accumulating evidence has shown the diverse functions of miR-210 in multiple critical biological processes concerned with hypoxia such as cell cycle, proliferation, angiogenesis, apoptosis, DNA damage repair, mitochondrial metabolism, differentiation, and tumor growth. Hypoxia decreases cell viability, migration and invasion while increasing apoptosis. Previous studies demonstrated that miR-210 is upregulated in the serum of patients with acute cerebral infarction and that it might be involved in the pathogenesis of this disease by regulating the proliferation and apoptosis of endothelial cells (Wang et al., 2018). Similar to these results, our study demonstrated that the overexpression of miR-210, and specifically miR-210-3p, is precise and protects EPCs against OGD injury, in addition to enhancing angiogenesis in OGD-treated EPCs. We also showed that a miR-210-3p mimic could ameliorate hypoxia-induced injury in EPCs, whereas a miR-210-3p inhibitor had the opposite effects. In addition, among all data, statistics showed that the expression of miR-210-3p could not be suppressed under normal oxygen conditions to affect cell function. We suggested that this might due to its low original expression such that the inhibitors could not function efficiently. However, inhibitors worked well and restrained the angiogenic ability of EPCs under OGD conditions, which confirmed our hypothesis. Based on these data, miR-210-3p might have a possible proangiogenic effect on EPCs.

Research indicates that EPCs can contribute to the growth of new blood vessels, potentially restoring the health of ischemic tissue (Tongers et al., 2010; Fadini et al., 2012). Upon searching ClinicalTrials.gov, many trials involving EPCs for the treatment of ischemia have used systemic infusion directly as the delivery method. However, most results showed poor efficacy due to high cell death and a lack of control with respect to cell targeting.

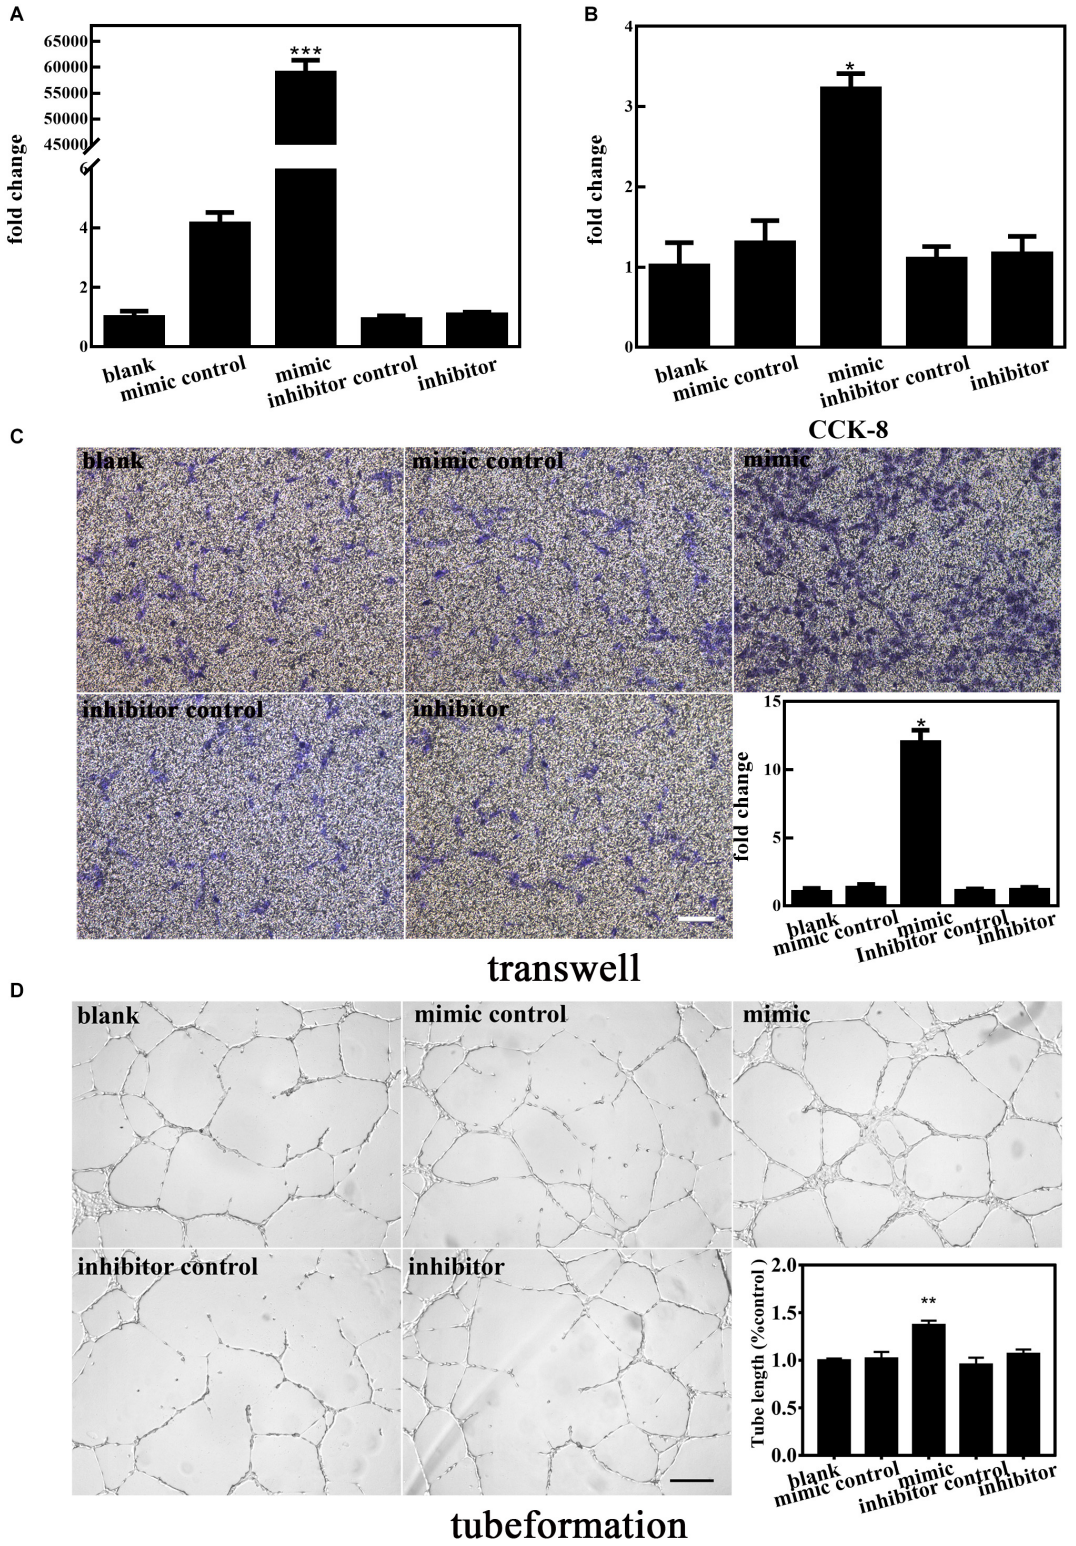

FIGURE 3 | Effect of altered miR-210-3p expression on normal endothelial progenitor cell (EPC) angiogenesis. **(A)** Expression of miR-210-3p increased obviously in the mimic group. **(B)** Graph of CCK-8 results showed that the proliferation rate in the mimic group was improved compared to that in the other four groups. **(C)** Representative images showing EPC migration. Bar graph indicates that overexpression of miR-210-3p in EPCs resulted in enhanced migration ability. Bar = 100 μm. **(D)** Representative images showing EPC tube formation ability. Bar graph indicates that overexpression of miR-210-3p in EPCs resulted in larger tube length. Bar = 250 μm; $n = 3$ per group. Data are presented as the mean ± SEM, $^{*}p < 0.05$, $^{**}p < 0.01$, and $^{***}p < 0.001$.

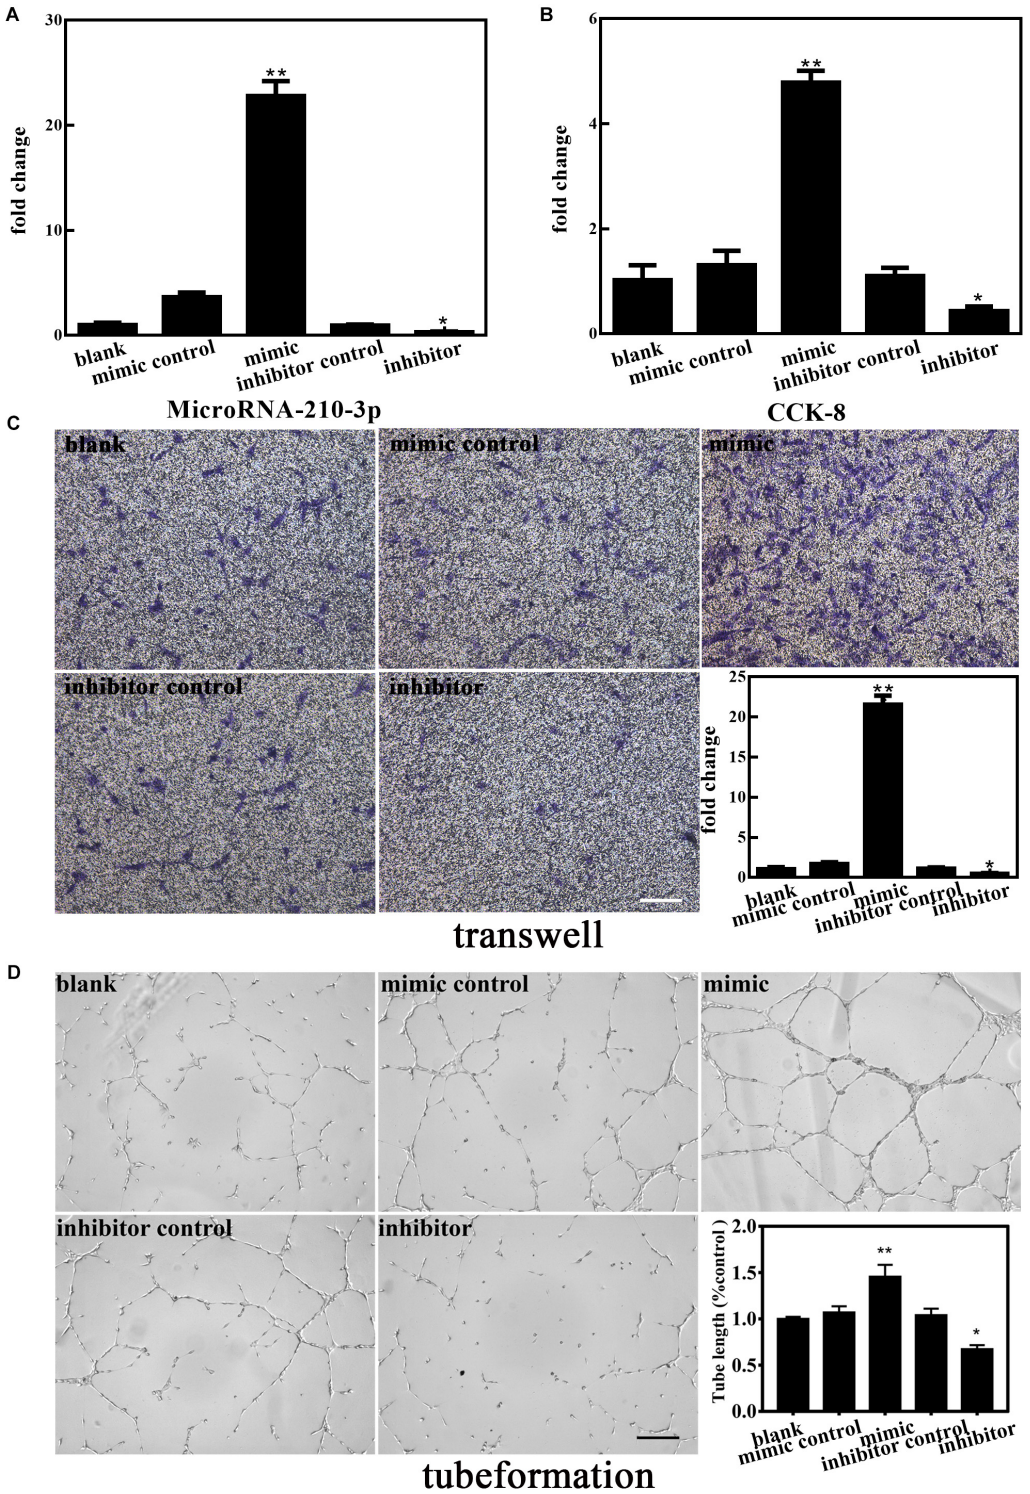

FIGURE 4 | Effect of altered miR-210-3p expression on angiogenesis of endothelial progenitor cells (EPCs) under oxygen and glucose deprivation (OGD). **(A)** The expression of miR-210-3p increased in the mimic group but the opposite results were observed in the inhibitor group. **(B)** Graph of CCK-8 results showing that the proliferation rate in the mimic group was improved compared to that in the blank group, with opposite results in the inhibitor group. **(C)** Representative images showing the effects of 4 h of OGD on EPC migration. Bar graph indicating that the overexpression of miR-210-3p under OGD conditions for 4 h resulted in higher migration ability, with opposite results observed in the inhibitor group. Bar = 100 μm. **(D)** Representative images showing tube formation under the condition of OGD for 4 h in EPCs. Bar graph indicating that the overexpression of miR-210-3p resulted in EPCs resulted in larger tube length under the OGD condition, with opposite results observed in the inhibitor group. Bar = 100 μm; $n = 3$ per group. Data are presented as the mean ± SEM, $^{*}p < 0.05$ and $^{**}p < 0.01$.

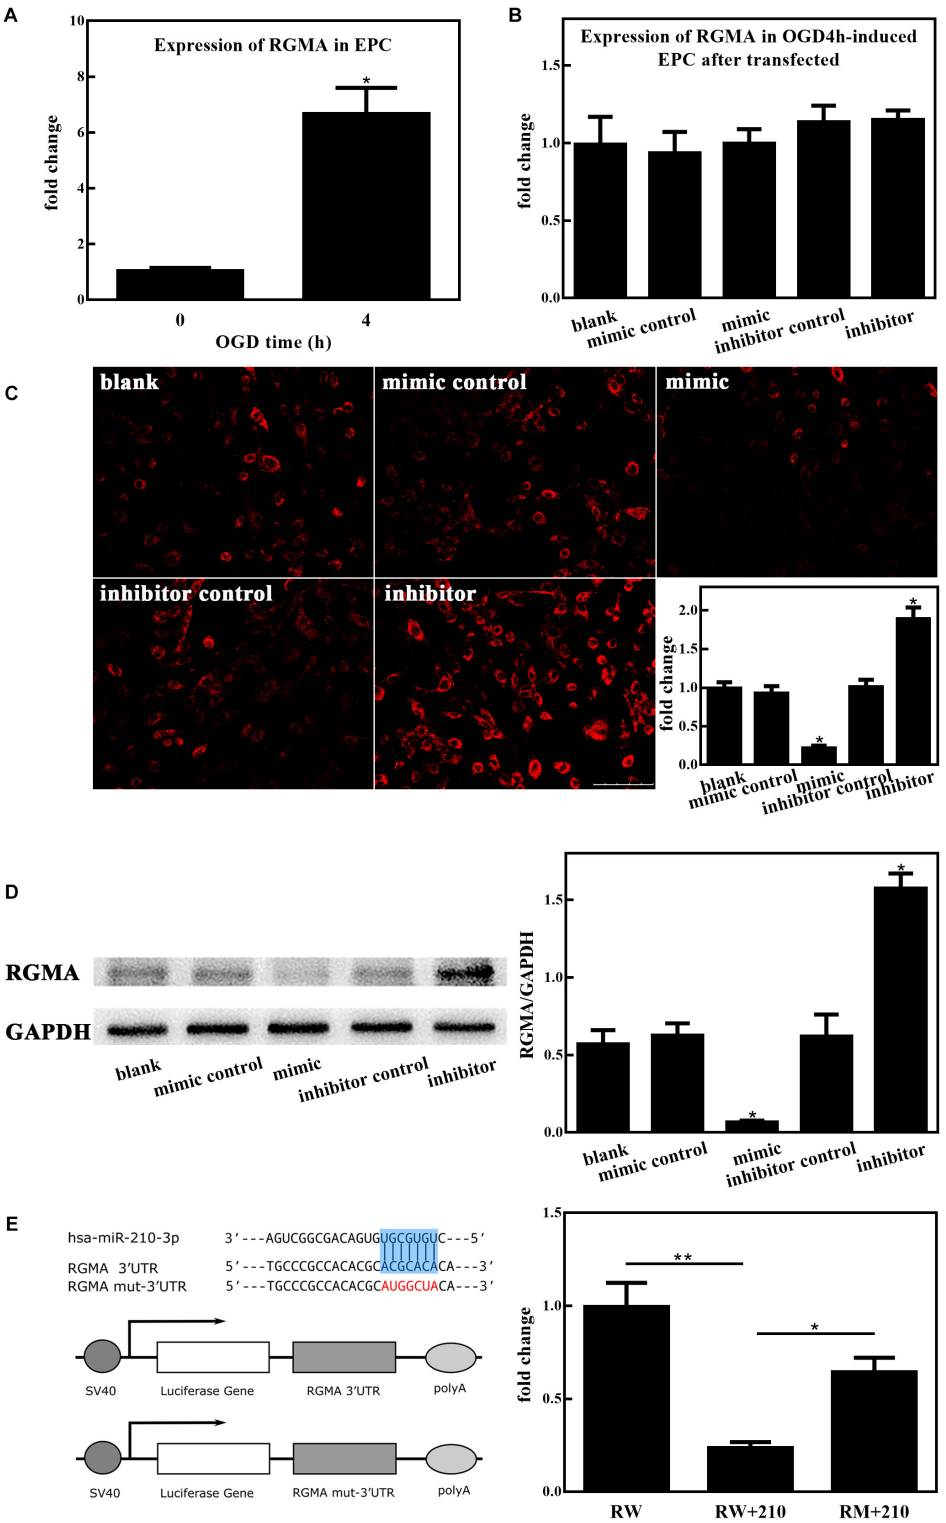

FIGURE 5 | MiR-210-3p overexpression enhances angiogenesis by inhibiting RGMA. **(A)** Bar graph indicating that the expression of *RGMA* mRNA increased in endothelial progenitor cells (EPCs) upon culture under oxygen and glucose deprivation (OGD) conditions for 4 h. **(B)** There were no statistically significant differences among groups in terms of the expression of *RGMA* mRNA. **(C,D)** Immunohistochemistry staining and western blot results of EPCs cultured under conditions of OGD for 4 h after transfection; the expression of RGMA protein were reduced in the mimic group, and opposite results were observed in the inhibitor group. Bar = 100 μm. **(E)** Luciferase reporter assay showing that miR-210-3p can directly bind *RGMA*; $n = 3$ per group. Data are presented as the mean ± SEM, $^{*}p < 0.05$ and $^{**}p < 0.01$.

EPCs are thus limited in their applications. One strategy to improve therapeutic outcomes is to combine such approaches with molecular therapy, thereby improving the survival rates and increasing the probability that cells will contribute to new blood vessel growth. We suggest that miR-210-3p overexpression could help to solve the existing problems and contribute to the application of EPCs to clinical treatment.

To shed light on the molecular mechanisms underlying the miR-210-3p-mediated control of cellular behavior, we used a bioinformatics method to virtually screen possible targets of miR-210-3p. Based on this, we focused on the interaction between miR-210-3p and *RGMA*, as results indicated that RGMA could be negatively regulated by miR-210-3p. Additional luciferase reporter assays further established that the *RGMA* 3′UTR was recognized by miR-210-3p. In previous studies, RGMA was shown to limit axonal regeneration after CNS injury (Hata et al., 2006) and to modulate T cell responses involved in autoimmune encephalomyelitis (Muramatsu et al., 2011). In summary, early research on RGMA was mainly focused on inflammation and autoimmune diseases. Recently, studies on the correlation between RGMA and ischemic disease have increased gradually. Zhang et al. found that RGMA suppresses the proliferation, tube formation, and migration of ECs by downregulating VEGF and p-FAK (Tyr397) via neogenin and Unc5b *in vitro* (Zhang et al., 2017). Wang et al. reported that RGMA might suppress angiogenesis via VEGF, Ang2, Ang1, and BDNF after cerebral ischemia/reperfusion injury through neogenin, thereby inhibiting neovascularization (Wang et al., 2018). Results of our study found that miR-210-3p overexpression has positive effects on cell proliferation, tube formation, and migration, suggesting that miR-210-3p might function through the negative regulation of RGMA. In addition, there was no difference in *RGMA* mRNA expression among groups, whereas the protein expression was significantly suppressed by a miR-210-3p mimic, suggesting that this miRNA primarily acts on gene translation and post-translational modification instead of transcription. Our study is the first to report that RGMA is a target of miR-210-3p in EPCs under hypoxia, and is consistent with previous reports (Wang et al., 2018) on the function of RGMA in ECs.

CONCLUSION

In conclusion, we report that miR-210-3p protects EPCs against OGD injury and enhances angiogenesis in OGD-treated EPCs. The suppression of RGMA, directly regulated by miR-210-3p overexpression, might partially contribute to the protection against hypoxic injury in EPCs and enhanced angiogenesis. Considering the potential application of these results, there are still many unknowns that require further exploration. For example, it will be more stringent to perform an unbiased screen by mass proteomics to identify the preferred targets of this miR. Secondly, downstream signaling pathways, in addition to the interaction between miR-210-3p and RGMA, in OGD-treated EPCs need to be studied. Moreover, we also need to further design related experiments *in vivo* to investigate Whether miR-210-3p overexpression could enhance the angiogenic function of EPCs on an MCAO mice model and the post-stroke long-term functional recovery.

AUTHOR CONTRIBUTIONS

L-LZ involved in all aspects of the study, supervised the tissue assay analysis, and participated in the study design, data analysis, and revision of the manuscript. X-YX participated in the revision of the manuscript and data analysis. W-JL drafted the enclosed manuscript and collected the human donor cells. H-BL performed the data analysis. Y-FL, X-QT, and K-QD revised the manuscript. J-RH and G-YY participated in the design of the present study and revision of the manuscript.

Dysfunction of 67-kDa Laminin Receptor Disrupts BBB Integrity via Impaired Dystrophin/AQP4 Complex and p38 MAPK/VEGF Activation Following Status Epilepticus

*Hana Park[1,2], Seo-Hyeon Choi[1,2], Min-Jeong Kong[1,2] and Tae-Cheon Kang[1,2]**

Status epilepticus (SE, a prolonged seizure activity) impairs brain-blood barrier (BBB) integrity, which results in secondary complications following SE. The non-integrin 67-kDa laminin receptor (67-kDa LR) plays a role in cell adherence to laminin (a major glycoprotein component in basement membrane), and participates laminin-mediated signaling pathways including p38 mitogen-activated protein kinase (p38 MAPK). Thus, we investigated the role of 67-kDa LR in SE-induced vasogenic edema formation in the rat piriform cortex (PC). SE diminished 67-kDa LR expression, but increased laminin expression, in endothelial cells accompanied by the reduced SMI-71 (a rat BBB barrier marker) expression. Astroglial 67-kDa LR expression was also reduced in the PC due to massive astroglial loss. 67-kDa LR neutralization led to serum extravasation in the PC concomitant with the reduced SMI-71 expression. 67-kDa LR neutralization also decreased expressions of dystrophin and aquaporin-4 (AQP4). In addition, it increased p38 MAPK phosphorylation and expressions of vascular endothelial growth factor (VEGF), laminin and endothelial nitric oxide synthase (eNOS), which were abrogated by SB202190, a p38 MAPK inhibitor. Therefore, our findings indicate that 67-kDa LR dysfunction may disrupt dystrophin-AQP4 complex, which would evoke vasogenic edema formation and subsequent laminin over-expression via activating p38 MAPK/VEGF axis.

INTRODUCTION

Vasogenic edema is the most common type of brain edema and a result from increased capillary permeability due to breakdown in intact brain-blood barrier (BBB) that is important for the maintenance of brain homeostasis. Vasogenic edema results in an abrupt increase in intracranial pressure and abnormal blood-brain transports of serum-derived molecules, which affect neuronal excitability, properties of regenerating (recovering) vessels, white matter injury and reactive gliosis in brain tumor, exposure of insecticides, traumatic brain injury (TBI), ischemia and brain inflammation (Papadopoulos et al., 2004; Song et al., 2004; Bloch et al., 2005; Kim et al., 2010b;

Li and Ehrich, 2013; Kim Y.J. et al., 2015; Ko and Kang, 2015; Bennett et al., 2016; Zhao et al., 2018; Sun et al., 2019). Therefore, the prevention or attenuation of vasogenic edema formation is one of the major therapeutic strategies, which help to alleviate undesirable secondary complications in various neurological diseases.

Status epilepticus (SE) is a medical emergency condition with significant mortality showing continuous seizure activity. SE is considered as one of the precipitating factors for temporal lobe epilepsy (TLE) that is observed in one-third of all cases of epilepsy. Human TLE patients present neuronal loss and reactive astrogliosis in various brain regions including the hippocampus, which are influenced by SE (Fountain, 2000; Koh et al., 2005; Téllez-Zenteno and Hernández-Ronquillo, 2012; Sørensen and Kokaia, 2013). Similar to human patients, SE-induced epilepsy animal models show massive neuronal loss and astroglial dysfunctions in the various brain regions. Furthermore, vasogenic edema is one of the early post-SE events in the hippocampus and extrahippocampal limbic systems including the piriform cortex (PC). Since serum extravasation during vasogenic edema formation leads to spreading depolarizations and epileptiform discharges due to neuronal hyperexcitability, dysfunction of astrocytes and potassium buffering (Sisodiya et al., 2002; Löscher and Potschka, 2005; Kim Y.J. et al., 2015; Lippmann et al., 2017), it is likely that vasogenic edema may be one of the risk factors inducing pharmacoresistant epilepsy and life-threatening complications following SE.

The BBB consists of endothelial cells, astroglial endfeet, pericytes and basement membrane (BM; Banerjee and Bhat, 2007). The BM is vital for endothelial cell adhesion, migration and stabilization under physiological conditions. The BM is a structural and specialized complex of extracellular matrix protein including laminin, fibronectin, vitronectin, collagen, and heparin sulfate proteoglycans (Tilling et al., 2002; Yurchenco and Patton, 2009). Among them, laminin is a major glycoprotein component of BMs in vessels, and is involved in cellular adhesion and migratory processes (Miner, 2008). Thus, laminin is essential for vascular development, vessel dilation and physical integrity (Thyboll et al., 2002). Interestingly, laminin expression is remarkably upregulated in the BM of vessels following SE (Biagini et al., 2008; Gualtieri et al., 2012). Indeed, we have reported that laminin over-expression is closely relevant to the repair of BBB disruption accompanied by the reconstruction of endothelial barrier following SE (Kim et al., 2014). However, the underlying mechanism of up-regulation of laminin expression in vasogenic edema formation has not been fully elucidated.

The laminin functions are mediated by cell-surface receptors of two main classes: the integrins and the non-integrin 67-kDa laminin receptor (67-kDa LR; Lesot et al., 1983; Malinoff and Wicha, 1983; Rao et al., 1983). 67-kDa LR is composed of a 32 ∼ 33 kDa precursor (approximately 37 kDa in sodium dodecyl sulfate polyacrylamide gel electrophoresis). 67-kDa LR plays a role in cell adherence to laminin and stabilizes or modulates the binding of laminin to other receptors (Pellegrini et al., 1994; Ardini et al., 1998). In addition, 67-kDa LR is involved in laminin-mediated extracellular signal-regulated kinase 1/2 (ERK1/2), c-Jun N-terminal kinase (JNK) and p38 mitogen-activated protein kinase (p38 MAPK) signaling pathways (Givant-Horwitz et al., 2004). It also binds to several exogenous agents (including prion proteins, viruses and bacteria) and regulates cellular migration, viability and cytoskeleton reorganization (Wewer et al., 1986; Rao et al., 1989; Huang and Jong, 2009; Vana et al., 2009; Kielian et al., 2010). Furthermore, 67-kDa LR is expressed in the adult rat brain (Baloui et al., 2004). With respect to these profiles of 67-kDa LR, elucidating the correlation between 67-kDa LR expression and vasogenic edema formation may be noteworthy to understand the mechanisms of BBB disruption and laminin over-expression in response to SE. Therefore, during the course of this study, we investigated the alteration in 67-kDa LR expression induced by SE, and the effect of blockade of 67-kDa LR by neutralization on laminin expression or BBB integrity in efforts to understand the role of vascular dysfunction in epileptogenic insult.

MATERIALS AND METHODS

Experimental Animals and Chemicals

Male Sprague-Dawley (SD) rats (7 weeks old) were used in the present study. Animals were housed in a controlled temperature (22 ± 2°C), humidity (55 ± 5%) and a light-dark cycle (12:12). Food and tap water were provided *ad libitum* throughout the experiments. All experimental protocols described below were approved by the Institutional Animal Care and Use Committee of Hallym University (Chuncheon, South Korea). Every effort was made to reduce the number of animals employed and to minimize animal's discomfort. All reagents were obtained from Sigma-Aldrich (St. Louis, MO, United States), except as noted.

SE Induction

Rats were pretreated with an intraperitoneal injection of LiCl (127 mg/kg i.p) 24 h before the pilocarpine (PILO) treatment. Animals were intraperitoneally (i.p) treated with PILO (30 mg/kg) 20 min after atropine methylbromide (5 mg/kg i.p.). PILO injection resulted in stereotypical behavioral responses, which included the following: akinesia, staring, salivation, facial automatisms, slight tremors and head bobbing. These behavior responses built up progressively into motor limbic seizures that recurred repeatedly and rapidly developed into SE characterized by forelimb clonus and tonic-clonic seizures with loss of righting reflexes. SE was defined by continuous or intermittent seizures without full recovery between seizures. Control animals received an equal volume of normal saline instead of PILO after the pretreatment with atropine methylbromide. Diazepam (Valium; Hoffman la Roche; 10 mg/kg, i.p.) was administered 2 h after onset of SE and repeated, as needed. Three days after SE, animals were used for Western blot and immunohistochemistry.

Surgery

Under Isoflurane anesthesia (3% induction, 1.5–2% for surgery and 1.5% maintenance in a 65:35 mixture of N_2O:O_2), animals were infused each chemical into the right lateral ventricle (1 mm posterior; 1.5 mm lateral; −3.5 mm depth to the bregma) with a brain infusion kit 1 and an Alzet 1003D osmotic pump (Alzet,

United States) for 3 days. Osmotic pump contained (1) control IgG (Abcam, #ab37425, United Kingdom, 50 ug/ml) + vehicle, (2) control IgG + SB202190 (a p38 MAPK inhibitor, 0.3 mg/ml), (3) anti-67-kDa LR IgG (Abcam, #133645, United Kingdom, 50 ug/ml) + vehicle and (4) anti-67-kDa LR IgG (Abcam, #133645, United Kingdom, 50 ug/ml) + SB202190 (0.3 mg/ml). In pilot study and our previous studies (Kim et al., 2016; Ko and Kang, 2017), each compound treatment did not show behavioral and neurological defects and could not change the seizure susceptibility and seizure severity in response to PILO in normal animals. Three days after surgery (infusion), animals were used for Western blot and immunohistochemistry.

Western Blot

After animals were sacrificed via decapitation, the PC was obtained. The PC tissues were homogenized, and determined protein concentration using a Micro BCA Protein Assay Kit (Pierce Chemical, United States). Western blot was performed by the standard protocol. Membranes were incubated with primary antibody against 67-kDa LR (Abcam, #133645, United Kingdom, diluted 1:1,000), aquaporin-4 (AQP4, Alomone labs, #AQP-004, Israel, 1:5,000), dystrophin (Abcam, #ab15277, United Kingdom, diluted 1:5,000), endothelial nitric oxide synthase (eNOS, Abcam, #ab66127, United Kingdom, diluted 1:1,000), laminin (Abcam, #ab11575, United Kingdom, diluted 1:1,000), p38 MAPK (Cell signaling, #9212, United States, diluted 1:1000) or p-p38 MAPK (Abbiotec, #251246, United States, diluted 1:200), rat IgG (Vector, #PI9400, United States, diluted 1:200) or VEGF (Abcam, #ab46154, United Kingdom, diluted 1:1000) and visualized by an ECL Kit (Amersham, United States). The bands were detected and quantified on ImageQuant LAS4000 system (GE Healthcare, United States). As an internal reference, rabbit anti-β-actin primary antibody (#A5316, 1:5000) was used. The values of each sample were normalized with the corresponding amount of β-actin. The ratio of phosphoprotein to total protein was described as phosphorylation ratio.

Immunohistochemistry

Rats were anesthetized with urethane anesthesia (1.5 g/kg, i.p.) and intracardially perfused with 4% paraformaldehyde in 0.1 M phosphate buffer (PB, pH 7.4). Subsequently, brains were post-fixed in the same fixative overnight, followed by cryoprotection with 30% sucrose/0.1 M PBS, and sectioned at 30 μm with a cryo-microtome. Standard procedures for immunohistochemistry were used to detect vasogenic edema formation. Briefly, free-floating sections were washed three times in PBS (0.1 M, pH 7.3). Next, to inactivate the endogenous peroxidase, slides were incubated in 3% H_2O_2 and 10% methanol in PBS (0.1 M) for 20 min at room temperature. Later, sections were incubated in biotinylated rat IgG (Vector, #BA9400, United States, diluted 1:200) and ABC complex (Vector, #PK-6100, United States, diluted 1:200). Tissue sections were developed in 3,3′-diaminobenzidine in 0.1 M Tris buffer and mounted on gelatin-coated slides. The volume of vasogenic edema lesion in the PC was measured by AxioVision Rel. 4.8 software and estimated by the modified Cavalieri method: $V = \Sigma area \times$ section thickness (30 μm) $\times$ 1/the fraction of the sections (1/6). The volumes are reported in mm^3 (Kim et al., 2016).

Some sections were incubated with a cocktail solution containing the primary antibodies against 67-kDa LR (Abcam, #ab133775, United Kingdom, diluted 1:500), AQP4 (Alomone labs, #AQP-004, Israel, diluted 1:500), dystrophin (Abcam, #ab15277, United Kingdom, diluted 1:500), eNOS (Abcam, #ab66127, United Kingdom, diluted 1:500), glial fibrillary acidic protein (GFAP, Millipore, #MAB3402, United States, diluted 1:5,000), laminin (Abcam, #ab11575, United Kingdom, diluted 1:200) and SMI-71 (Covance, #SMI-71R, United States, diluted 1:1000) in PBS containing 0.3% Triton X-100 overnight at room temperature. Thereafter, sections were visualized with appropriate Cy2- and Cy3-conjugated secondary antibodies. Immunoreaction was observed using an Axio Scope microscope (Carl Zeiss Inc., Germany). To establish the specificity of the immunostaining, a negative control test was carried out with preimmune serum instead of the primary antibody. No immunoreactivity was observed for the negative control in any structures (data not shown). All experimental procedures in this study were performed under the same conditions and in parallel. To quantify relative fluorescence intensity, sections (10 sections per each animal) were captured using an AxioImage M2 microscope. A 300-μm^2 box was then randomly placed within the region of interest. Thereafter, mean fluorescence intensity of each section was measured by using AxioVision Rel. 4.8 software. Fluorescence intensity measurements were represented as the number of a 256 gray scale. Fluorescence intensity values were corrected by subtracting the average values of background noise (mean background intensity) obtained from five image inputs. Fluorescent intensity of each section was standardized by setting the threshold level (mean background intensity obtained from five image inputs). Manipulation of the images was restricted to threshold and brightness adjustments to the whole image (Kim et al., 2013, 2014; Kim and Kang, 2017).

Statistical Analysis

Quantitative data are expressed as mean ± standard error of the mean. Data are analyzed by Student *t*-test or one-way ANOVA followed by Newman–Keuls *post hoc* test. A $p < 0.05$ is considered to be statistically different.

RESULTS

SE-Induced Reduction in 67-kDa LR Expression in Vasogenic Edema Lesion

Consistent with our previous studies (Sheen et al., 2011; Kim et al., 2012, 2013, 2014), **Figure 1** shows that SE led to serum extravasation in the PC ($p < 0.05$ vs. control animals, Student *t*-test, $n = 7$, respectively). In addition, SE increased laminin expression to 3.2-fold of control level in the PC ($p < 0.05$ vs. control animals, Student *t*-test, $n = 7$, respectively; **Figures 1A,B** and **Supplementary Figure S1**). However, 67-kDa LR expression level was diminished to ∼ 0.68-fold of control level in this region ($p < 0.05$ vs. control animals, Student

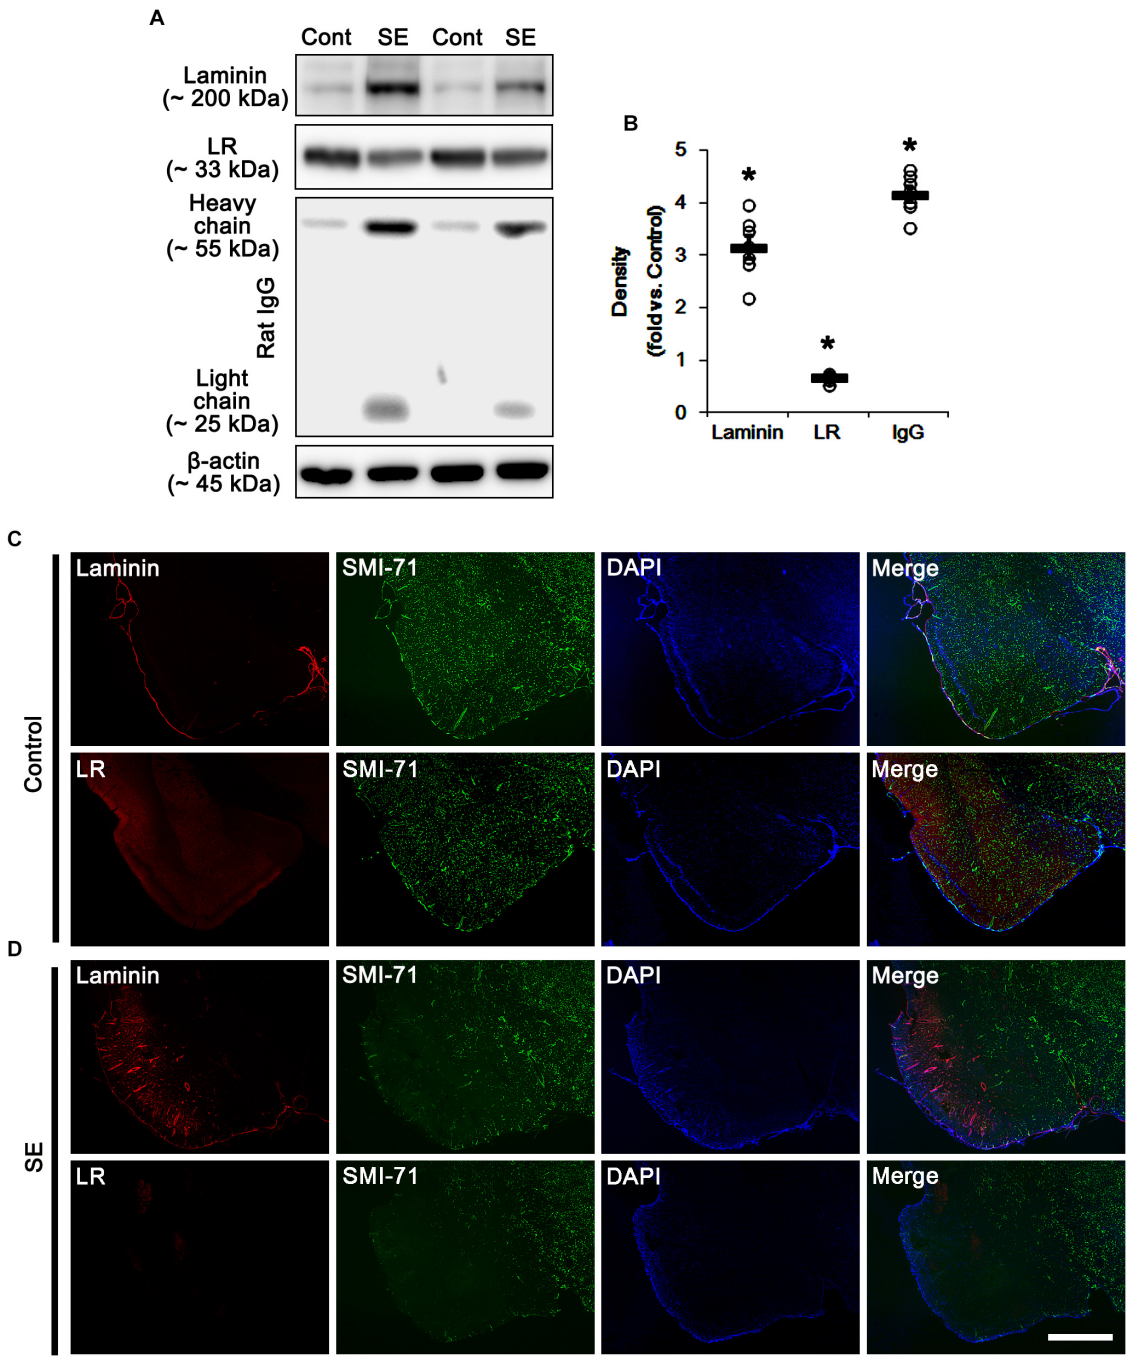

FIGURE 1 | Alterations in laminin and 67-kDa LR (LR) expression in the PC following SE. **(A)** Western blot image for expression levels of laminin and 67-kDa LR, and serum extravasation following SE. SE increases laminin expression and serum extravasation, but reduces 67-kDa LR expression. **(B)** Quantitative values (mean ± S.E.M) of the Western blot data concerning expression levels of laminin and 67-kDa LR, serum extravasation induced by SE (n = 7, respectively). Open circles indicate each individual value. Horizontal bars indicate mean value. Significant differences are $^*p < 0.05$ vs. control animals (Student t-test). **(C,D)** Representative photographs of expression levels of laminin and 67-kDa LR in vasogenic edema (SMI-71-deleted) lesion in the PC in control **(C)**- and post-SE condition **(D)**. In SMI-71-deleted area, laminin expression is enhanced, while 67-kDa LR expression is decreased. Bar = 400 μm.

t-test, n = 7, respectively; **Figures 1A,B** and **Supplementary Figure S1**). Furthermore, SE reduced SMI-71 (a rat BBB barrier antibody) expression in the PC (**Figures 1C,D**), which is an indicative of vasogenic edema formation (Sheen et al., 2011; Kim et al., 2012, 2013, 2014). However, laminin expression was increased in SMI-71-deleted areas in the PC (**Figures 1C,D**). Although laminin over-expression would predict astroglial loss following SE (Gualtieri et al., 2012; Willis et al., 2013), our

previous study has revealed that laminin over-expression is not relevant to astroglial death induced by SE. This is because laminin expression is unaltered in the frontoparietal cortex where vasogenic edema is not detected following SE. Furthermore, laminin over-expression is ameliorated by inhibition of vasogenic edema formation and during recovery of vasogenic edema (Kim et al., 2014). Thus, the present data revel that SE-induced BBB disruption may be a cause of laminin over-expression, and that the subsequent laminin over-expression may be one of compensatory responses for recovery of BBB integrity. In contrast to laminin expression, 67-kDa LR expression was decreased in SMI-71-deleted areas in the PC (**Figures 1C,D**), indicating 67-kDa LR expression may be relevant to BBB integrity.

Decreased 67-kDa LR Expression in Astrocytes Following SE

Next, we investigated the cellular localizations of laminin and 67-kDa LR in the PC. In control animals, laminin expression was detected in endothelial cells, and 67-kDa LR expression was weakly observed in endothelial cells and astrocytes within the PC (**Figure 2A**). Following SE, laminin expression was increased in vasogenic edema lesion within the PC where astroglial loss was observed ($p < 0.05$ vs. control animals, Student *t*-test, $n = 7$, respectively; **Figures 2B,C**). In contrast to laminin, 67-kDa LR expression was diminished in endothelial cells accompanied by loss of SMI-71 expression. Astroglial 67-kDa LR expression was also reduced in the PC due to massive astroglial loss. In addition, the remaining astrocytes in this region showed the decrease in 67-kDa LR expression ($p < 0.05$ vs. control animals, Student *t*-test, $n = 7$, respectively; **Figures 2B,C**). These findings indicate that SE-induced down-regulation of 67-kDa LR expression may be relevant to vasogenic edema formation.

Laminin Over-Expression and BBB Disruption Induced by 67-kDa LR Neutralization

In our previous study, we have reported that control IgG and interleukin-18 antibody infusions differently affects SE-induced vasogenic formation in the PC (Jung et al., 2012). To directly confirm the role of 67-kDa LR in vasogenic edema formation, thus, we applied 67-kDa LR antibody infusion (neutralization) to control animals and explored its effect on BBB integrity. As compared to control IgG, 67-kDa LR neutralization led to serum extravasation in the PC without changing 67-kDa LR expression level ($p < 0.05$ vs. control IgG, Student *t*-test, $n = 7$, respectively; **Figures 3A,B** and **Supplementary Figure S1**). 67-kDa LR antiserum increased laminin expression to 2.26-fold of control IgG level in the PC ($p < 0.05$ vs. control IgG, Student *t*-test, $n = 7$, respectively; **Figures 3A,B** and **Supplementary Figure S1**). It also up-regulated laminin and eNOS expressions in endothelial cells, accompanied by the reduced SMI-71 expression in this region ($p < 0.05$ vs. control IgG, Student *t*-test, $n = 7$, respectively; **Figures 3A–F**). Together with the data obtained from SE induction, our findings indicate that the blockade of 67-kDa LR functionality may lead to vasogenic edema formation by BBB breakdowns, and that 67-kDa LR may negatively regulate laminin expression in BM of brain capillary.

67-kDa LR Neutralization-Induced Reductions in Dystrophin and AQP4 Expression in Astrocytes and Endothelial Cells

In the present study, we found that SE and 67-kDa LR neutralization induced laminin over-expression, which is closely relevant to the repair of BBB disruption accompanied by the reconstruction of endothelial barrier (Kim et al., 2014). Interestingly, laminin interacts with dystrophin-glycoprotein complex that maintains the anchoring astroglial endfeet to BM, the polarized expression of AQP4 water channel and the BBB integrity (Neely et al., 2001; Nico et al., 2003; Wolburg et al., 2009), which are down-regulated by SE (Kim et al., 2010b; Sheen et al., 2011). With respect to these previous reports, it is likely that 67-kDa LR-mediated regulation of dystrophin expression would maintain AQP4 expression and BBB integrity under physiological condition. Consistent with our previous studies (Kim et al., 2010b; Sheen et al., 2011), the expression of dystrophin and AQP4 were observed in astrocytes and brain capillaries in control IgG-infused animals. 67-kDa LR neutralization decreased dystrophin and AQP4 expressions without astroglial loss in the PC ($p < 0.05$ vs. control IgG, Student *t*-test, $n = 7$, respectively; **Figures 4A–E** and **Supplementary Figure S2**). Therefore, our findings indicate that 67-kDa LR may play a role in maintenance of dystrophin-AQP4 complex in astrocytes and brain capillaries.

Elevated p38 MAPK Phosphorylation Induced by 67-kDa LR Neutralization

The remaining question is what underlying signaling pathway is involved in vasogenic edema formation induced by 67-kDa LR neutralization. Recently, we have reported that p38 MAPK-mediated VEGF over-expression leads to BBB breakdown following SE (Kim et al., 2016; Kim and Kang, 2017). Interestingly, reduced 67-kDa LR expression increased p38 MAPK phosphorylation (activation), regardless of the exposure to exogenous laminin (Givant-Horwitz et al., 2004). Furthermore, mice lacking dystrophin show but a high endogenous p38 MAPK phosphorylation, as compared to wild-type animals (Smythe and Forwood, 2012; Wissing et al., 2014). Therefore, it is likely that 67-kDa LR-mediated regulation of dystrophin expression may be one of the up-stream signals to regulate BBB integrity via p38 MAPK/VEGF axis.

In the present study, 67-kDa LR neutralization led to up-regulation of p38 MAPK phosphorylation and VEGF expression in the PC, as compared to control IgG ($p < 0.05$ vs. control IgG, one-way ANOVA, $n = 7$, respectively; **Figures 5A,B,E** and **Supplementary Figure S2**). SB202190 (a p38 MAPK inhibitor) co-treatment did not affect 67-kDa LR expression levels in both control IgG- and 67-kDa LR IgG-infused animals (**Figures 5A,C** and **Supplementary Figure S2**). However,

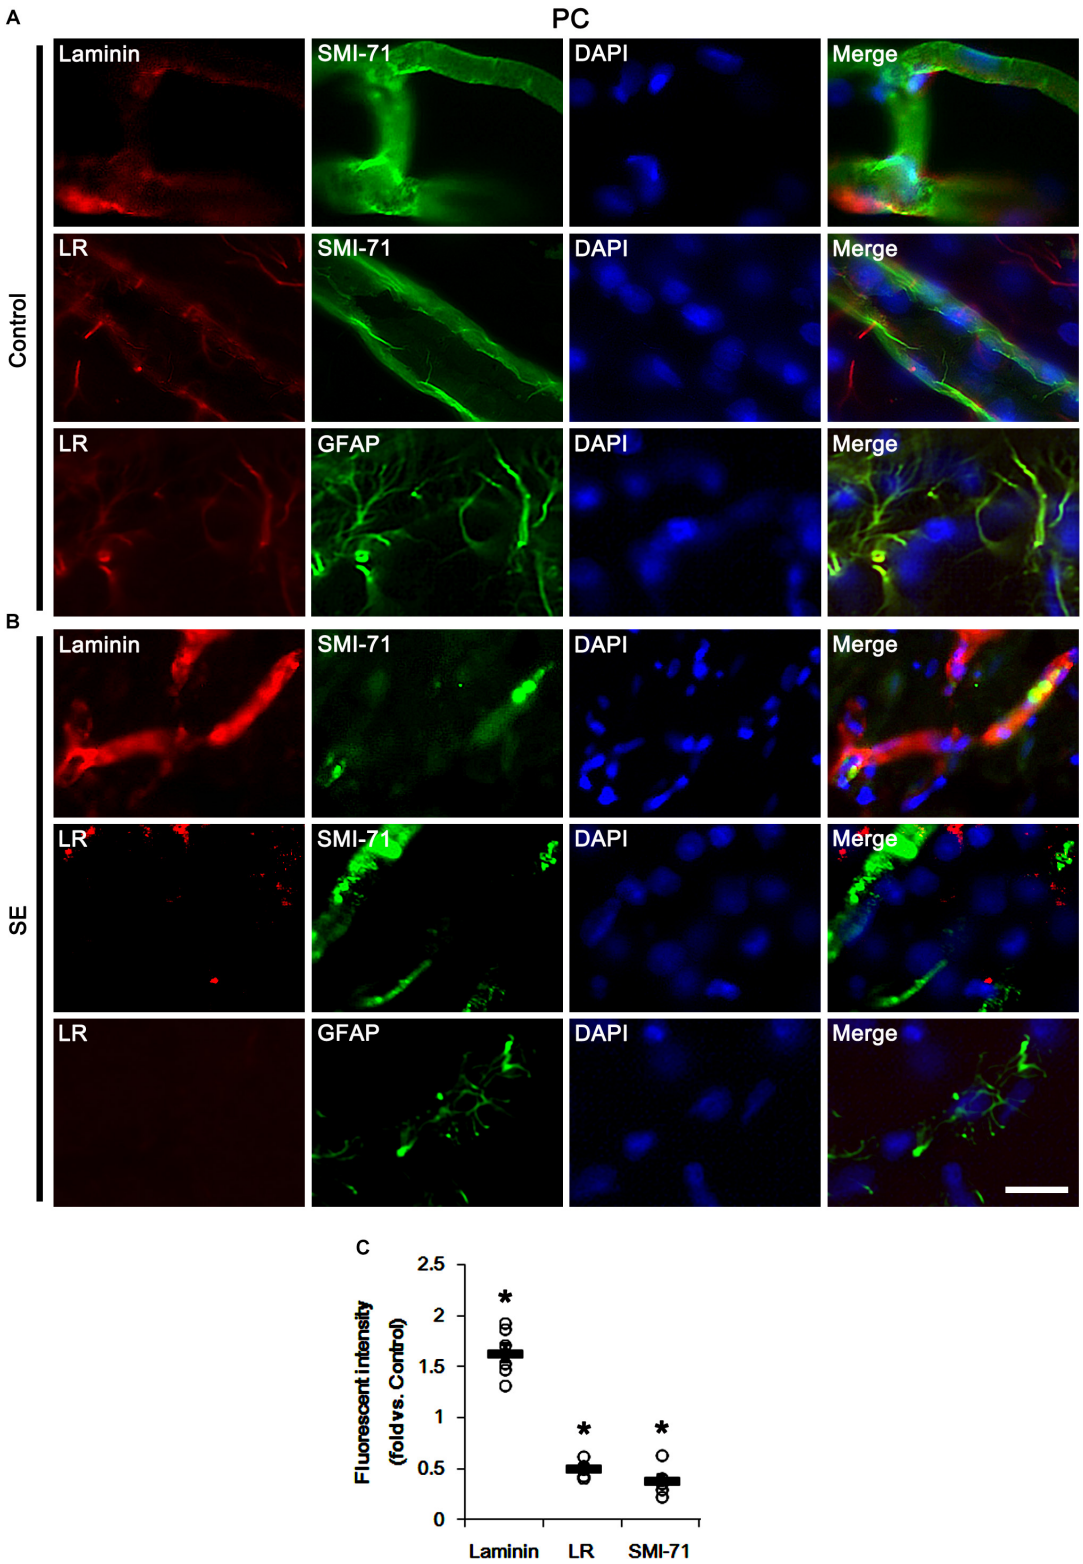

FIGURE 2 | Alterations in laminin and 67-kDa LR (LR) expression in capillaries and astrocytes within the PC following SE. **(A,B)** Representative photographs of SMI-71, laminin and 67-kDa LR expression in control **(A)**- and post-SE animals **(B)**. SE increases laminin expression, but reduces 67-kDa LR expression, accompanied by BBB disruptions (SMI-71 degradation) in capillaries. SE also diminished astroglial 67-kDa LR expression. Bar = 12.5 μm. **(C)** Quantitative values (mean ± S.E.M) of the fluorescent intensities of laminin, 67-kDa LR and SMI-71 (n = 7, respectively). Open circles indicate each individual value. Horizontal bars indicate mean value. Significant differences are *$p < 0.05$ vs. control animals (Student t-test).

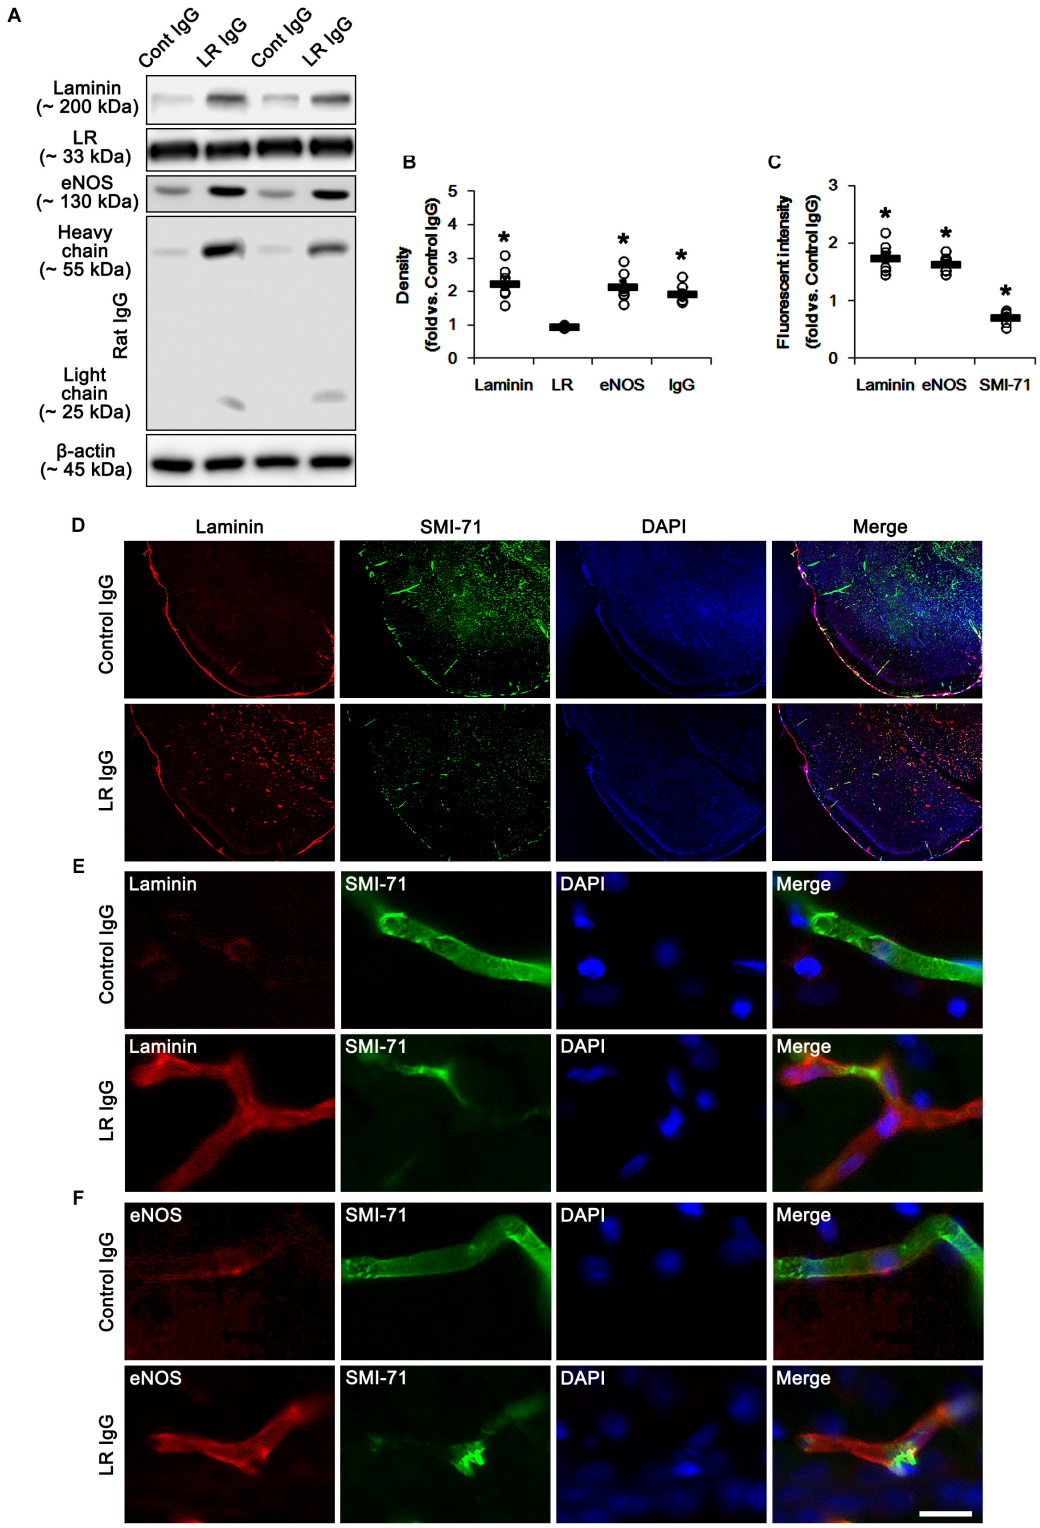

FIGURE 3 | 67-kDa LR (LR) neutralization-induced serum extravasation in normal animals. **(A)** Western blot image for expression levels of laminin, 67-kDa LR and eNOS, and serum extravasation induced by 67-kDa LR neutralization. 67-kDa LR IgG infusion increases expression levels of laminin and eNOS and serum extravasation, without changing 67-kDa LR expression. **(B)** Quantitative values (mean ± S.E.M) of the Western blot data concerning expression levels of laminin, 67-kDa LR and eNOS, and serum extravasation induced by 67-kDa LR neutralization ($n = 7$, respectively). Open circles indicate each individual value. Horizontal bars indicate mean value. Significant differences are $^*p < 0.05$ vs. control IgG (Student t-test). **(C)** Quantitative values (mean ± S.E.M) of the fluorescent intensities of SMI-71, eNOS and laminin ($n = 7$, respectively). Significant differences are $^*p < 0.05$ vs. control IgG (Student t-test). **(D–F)** Representative photographs of expression levels of laminin, eNOS, and SMI-71 in the PC. Bar = 400 μm **(D)** and 12.5 μm **(E,F)**.

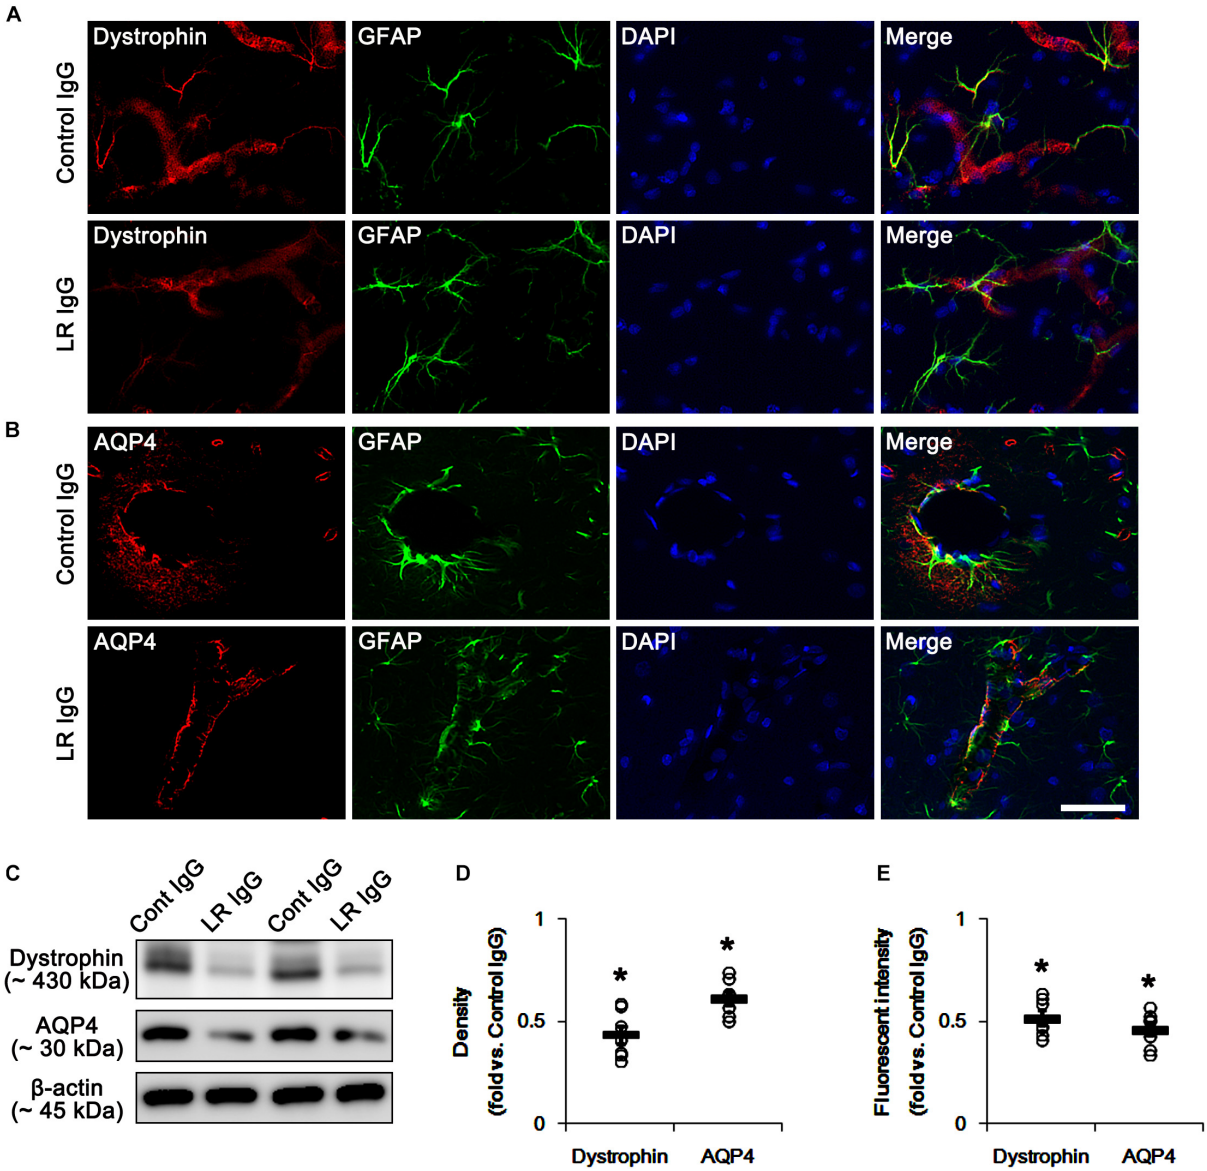

FIGURE 4 | Effect of 67-kDa LR (LR) neutralization on dystrophin and AQP4 expression in the PC of normal animals. **(A,B)** Representative photographs of dystrophin **(A)** and AQP4 **(B)** expressions in the PC. As compare to vehicle, 67-kDa LR neutralization leads to the reduction in dystrophin and AQP4 expressions in the PC. Bar = 12.5 μm. **(C)** Western blot image for expression levels of dystrophin and AQP4. **(D,E)** Quantitative values (mean ± S.E.M) of the Western blot data **(D)** and the fluorescent intensities concerning expression levels of dystrophin and AQP4 induced by 67-kDa LR neutralization (n = 7, respectively). Open circles indicate each individual value. Horizontal bars indicate mean value. Significant differences are *$p < 0.05$ vs. control IgG (Student t-test).

SB202190 co-treatment abrogated p38 MAPK activation, eNOS induction, VEGF induction and laminin over-expression induced by 67-kDa LR neutralization, although it could not abolish reductions in dystrophin and AQP4 expressions ($p < 0.05$ vs. vehicle, one-way ANOVA, $n = 7$, respectively; **Figures 5A–H** and **Supplementary Figure S2**). Furthermore, SB202190 inhibited serum extravasation in the PC induced by 67-kDa LR IgG ($p < 0.05$ vs. vehicle, one-way ANOVA, $n = 7$, respectively; **Figures 5I,J**). Thus, our findings indicate that the disruption of dystrophin-AQP4 complex by 67-kDa LR dysfunctions may trigger vasogenic edema formation and laminin over-expression by activating p38 MAPK-mediated VEGF expression.

DISCUSSION

Recently, we have reported that p38 MAPK-mediated VEGF over-expression leads to phosphatidylinositol-3-kinase (PI3K)/AKT-mediated eNOS activation during SE-induced vasogenic edema formation, which is also regulated by tumor necrosis factor-α (TNF-α)/nuclear factor-κB (NF-κB)/endothelin

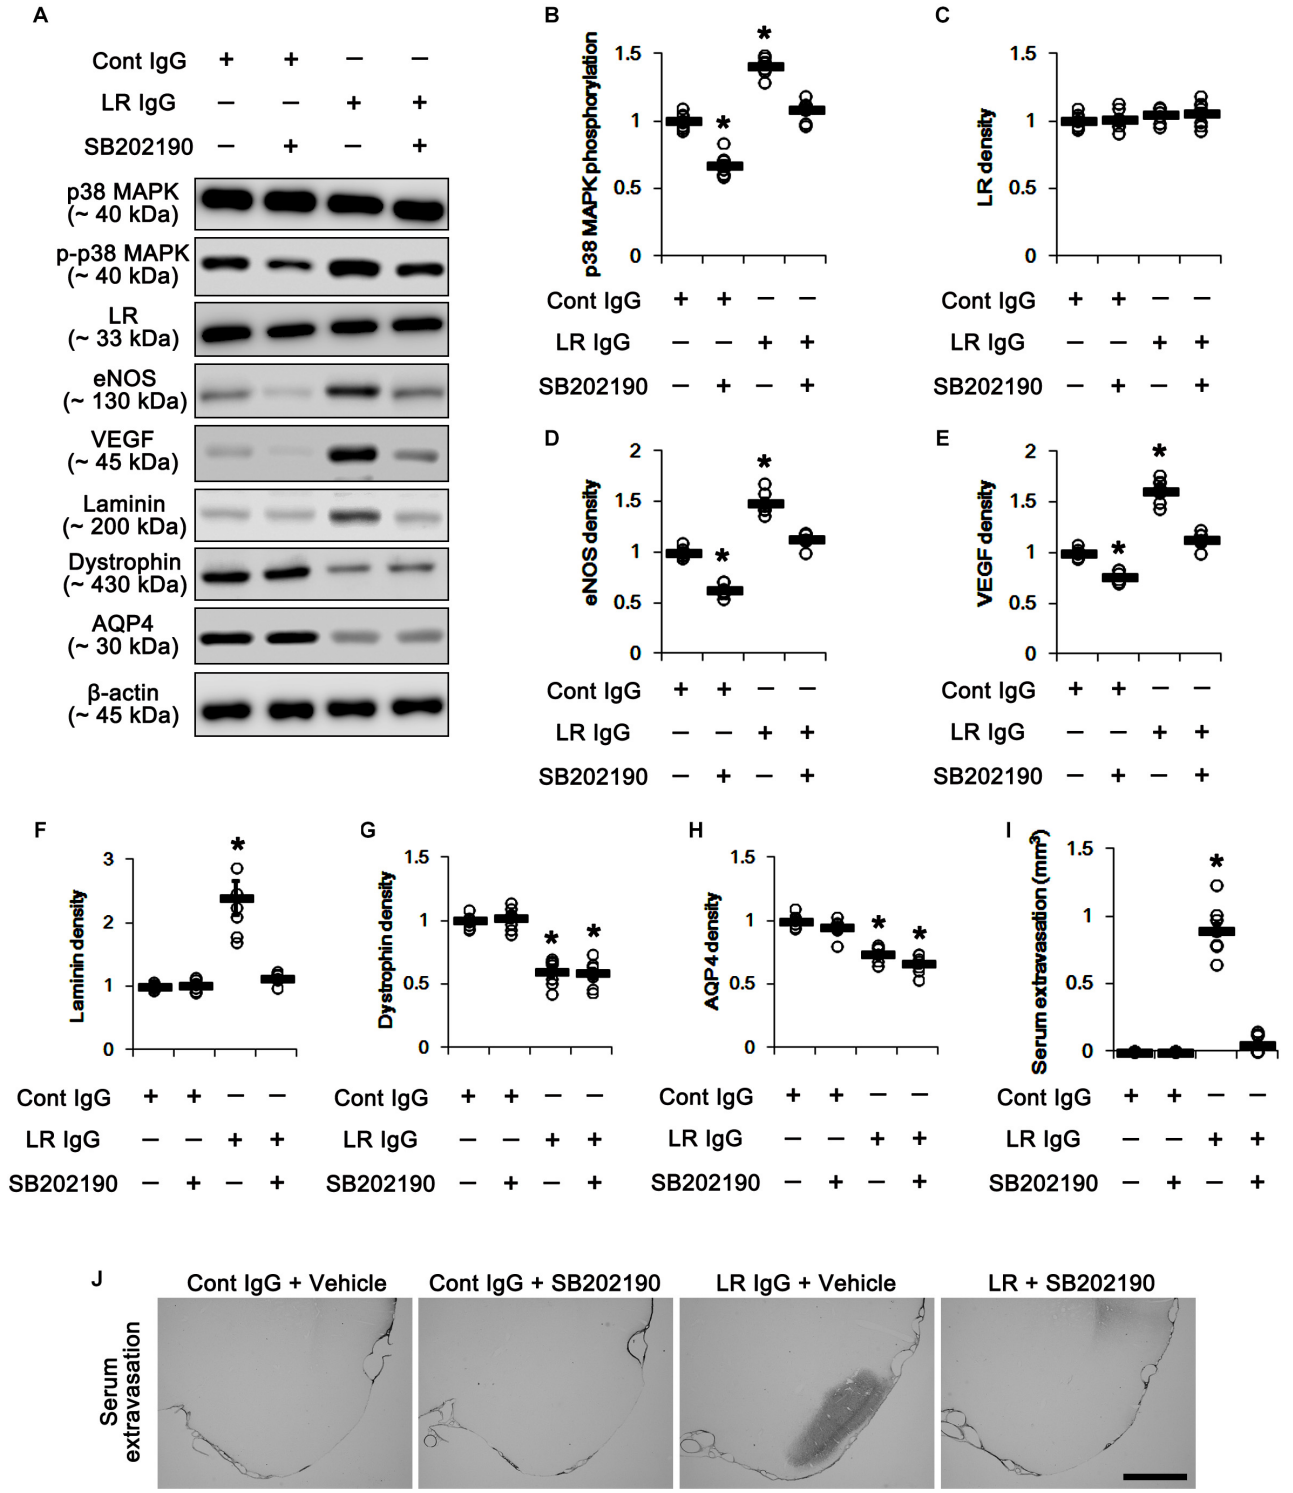

FIGURE 5 | Effect of 67-kDa LR (LR) neutralization and SB202190 co-treatment on serum extravasation in the PC of normal animals. **(A)** Western blot image for expression levels of p38 MAPK, phospho (p)-p38 MAPK, 67-kDa LR, eNOS, VEGF, laminin, dystrophin, and AQP4. **(B–H)** Quantitative values (mean ± S.E.M) of the Western blot data concerning expression levels of phospho (p)-p38 MAPK, 67-kDa LR, eNOS, VEGF, laminin, dystrophin, and AQP4 (n = 7, respectively). B (ET_B) receptor-mediated signaling pathway (Kim et al., 2016; Min and Kang, 2016; Kim and Kang, 2017). However, we could not elucidate the up-stream effectors/signaling pathways concerning p38 MAPK/VEGF-mediated vasogenic edema formation. In the present study, we found that 67-kDa LR might inhibit this signaling pathway by maintaining the integrity of dystrophin-AQP4 complex (**Figure 6**).

Consistent with previous studies (Castronovo et al., 1991; Guo et al., 1992), the present study shows that 67-kDa LR is identified in astrocytes and vascular endothelial cells. Furthermore, SE diminished its expression level in the PC. The present data also reveal that 67-kDa LR neutralization evoked the up-regulations of p38 MAPK phosphorylation, VEGF induction and eNOS expression in the normal animals, accompanied by serum extravasation and the reduced dystrophin expression, which were abrogated by SB202190. VEGF is a chemokine inducing impairment of BBB integrity, which potentially causes vasogenic edema (Pavlicek et al., 2000; Walter et al., 2001; Argaw et al., 2009; Bates, 2010; Kim et al., 2016; Kim and Kang, 2017). Aforementioned, 67-kDa LR and dystrophin expression levels regulate p38 MAPK activity (Givant-Horwitz et al., 2004; Smythe and Forwood, 2012; Wissing et al., 2014), and activation of p38 MAPK-VEGF axis participates in SE-induced vasogenic edema via the increased PI3K/AKT-mediated eNOS expression (Kim et al., 2016; Kim and Kang, 2017). Thus, our findings indicate that the reduced 67-kDa LR expression may be one of the up-stream molecules to regulate this signaling pathway during vasogenic edema formation. On the other hand, it is plausible that 67-kDa LR neutralization-induced up-regulations of p38 MAPK phosphorylation, VEGF induction, laminin and eNOS expression would be an adaptive reaction to rescue the BBB breakdown rather than a part of further detrimental mechanisms. If this hypothesis were true, the blockade of p38 MAPK signaling pathway would deteriorate vasogenic edema formation induced by 67-kDa LR neutralization. However, the present study reveals that SB202190 co-treatment mitigated serum extravasation induced by 67-kDa LR IgG infusion. Therefore, our findings suggest that 67-kDa LR may negatively regulate p38 MAPK/VEGF axis, which evokes BBB disruption.

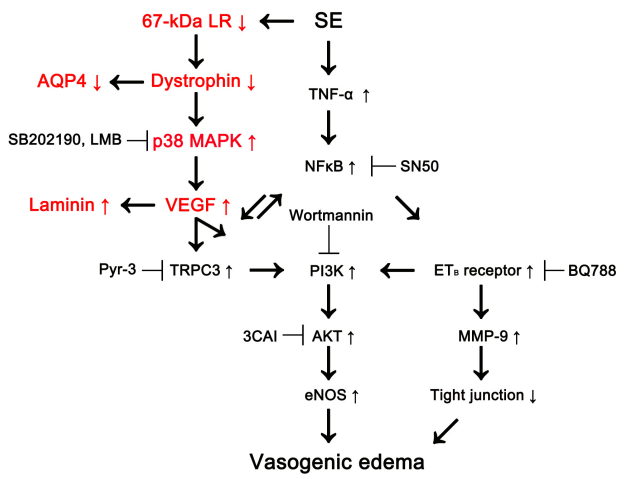

FIGURE 6 | Scheme of role of 67-kDa LR in vasogenic edema formation induced by SE based on the present data and previous reports (Kim et al., 2013, 2016; Kim J.Y. et al., 2015; Min and Kang, 2016). SE reduces 67-kDa LR and dystrophin expressions in astrocytes and endothelial cells, which activates p38 MAPK/VEGF axis. Subsequently, VEGF increases eNOS activity via transient receptor potential canonical channel-3 (TRPC3)/PI3K/AKT signaling pathway, which evokes vasogenic edema formation, along with ET_B receptor activation. Down-regulation of dystrophin also decreases AQP4 expression leading to exacerbation of vasogenic edema. In addition, VEGF induces laminin over-expression for recovery of damaged brain capillaries.

In addition to VEGF, p38 MAPK activates cytosolic phospholipase A2 (cPLA2) that mediates arachidonic acid metabolism causing BBB dysfunction and edema. Indeed, p38 MAPK/cPLA2 pathway promotes BBB disruption with secondary vasogenic edema after ischemia-reperfusion injury (Nito et al., 2008). Furthermore, p38 MAPK activates Src family kinase regulates BBB permeability in response to VEGF. p38MAPK/VEGF/Src kinase pathway is also involved in BBB disruption and vasogenic edema formation via inflammation-associated BBB dysfunction in subarchnoid hemorrhage (Han et al., 2018), ischemic stroke (Liang et al., 2009) and cold-induced brain injury, but not experimental pneumococcal meningitis (Paul et al., 2007). Therefore, it is not excluded the possibilities that p38 MAPK-VEGF axis would lead to SE-induced vasogenic edema formation activating the cPLA2 and Src pathways.

Brain-blood barrier breakdown induces the leakage of albumin from blood into brain tissue. Albumin activates microglia and affects its cytokine releases and synthesis of inducible nitric oxide synthase (iNOS) via p38 MAPK pathway (Ralay Ranaivo and Wainwright, 2010; Yang et al., 2016). In addition, albumin results in the productions of inflammatory mediators, matrix metalloproteinase-9 (MMP-9) and myosin light chain kinase (MLCK) in astrocytes through p38 MAPK activation, which lead to disruption of vascular barrier integrity by the reorganization of the cytoskeleton and the dissociation of laminin as well as tight junctions (Rossi et al., 2011; Ralay Ranaivo et al., 2012; Kim Y.J. et al., 2015; Amtul et al., 2018). With respect to these previous reports, it is likely that extravasation of albumin may also reinforce p38 MAPK/VEGF signal pathway, accompanied by down-regulation of 67-kDa LR expression, following vasogenic edema formation.

The interaction between laminin and dystrophin plays an important role in the BBB integrity and AQP4 polarization in brain capillaries and astrocytes (Neely et al., 2001; Nico et al., 2003; Wolburg et al., 2009; Kim et al., 2010b; Sheen et al., 2011). Absence of dystrophin or deletion of base pairs in the dystrophin gene is a cause of Duchenne and Becker muscular dystrophy, which are allelic X-linked disorders with a progressive muscle weakness, a static cognitive impairment, autism and problems of behavior and attention (Young et al., 2008; de Brouwer et al., 2014). In mice models, deletion of dystrophin increases blood-retinal barrier (BRB) permeability by VEGF over-expression, and AQP4 delocalization/down-regulation (El Mathari et al., 2015; Vacca et al., 2016). In the brain, dystrophin deletion also reduces AQP4 expression over perivascular astroglial endfoot membranes (Enger et al., 2012). However, the regulatory signaling pathways for AQP4

expression have been still controversial. For example, p38 MAPK and JNK inhibitors decrease AQP4 protein levels in cultured human primary cortical astrocytes (Salman et al., 2017). In contrast, temozolomide (an effective drug for malignant glioma) decreases AQP4 expression level with increasing p38 MAPK phosphorylation, which is blocked by p38 MAPK inhibitor (Chen et al., 2017). Similarly, ERK1/2 pathway down-regulates AQP4 expression in scratch-injured astrocytes (Shi et al., 2015), while ERK1/2 activation up-regulates AQP4 expression in oxygen-glucose deprivation-recovery-induced injury (Qi et al., 2011). In the present study, 67-kDa LR neutralization diminished expression levels of dystrophin and AQP4 in the PC. These findings indicate that 67-kDa LR-mediated regulation of dystrophin expression may maintain AQP4 expression and BBB integrity under physiological condition. The present study also demonstrates that SB201290 did not affect expression levels of dystrophin and AQP4 in control IgG-infused animals. Furthermore, SB202190 co-treatment could not affect decreases in dystrophin and AQP4 expressions, although it abolished serum extravasation induced by 67-kDa LR neutralization. These findings indicate that impairment of dystrophin-AQP4 complex without activation of p38 MAPK/VEGF signaling pathway may not trigger BBB disruption in the PC, and that p38 MAPK activity may not influence expressions of dystrophin and AQP4. Indeed, AQP4 deletion does not affect the brain morphology and baseline intracranial pressure under physiological condition, while it worsens vasogenic edema in a freeze-injury model and a brain tumor edema model (Papadopoulos et al., 2004). Furthermore, acetazolamide (an AQP4 inhibitor) exacerbates vasogenic edema and astroglial loss in the PC following SE, although it did not induce vasogenic edema under physiological conditions (Kim et al., 2010b). Therefore, our findings suggest that the disruption of dystrophin may trigger BBB breakdown by activating p38 MAPK-mediated VEGF expression, and subsequently may aggravate vasogenic edema due to diminishing AQP4−dependent vasogenic water elimination.

Laminin is a key component of vascular BMs and contributes to vascular permeability by generating the physical barrier of the gliovascular BM and BBB maturation (Menezes et al., 2014). Laminin is also involved in the communication among the cellular components forming the gliovascular units via the integrins and non-integrin receptors (Lesot et al., 1983; Malinoff and Wicha, 1983; Rao et al., 1983; Menezes et al., 2014). In the present study, SE resulted in the down-regulated 67-kDa LR expression accompanied by laminin over-expression. Furthermore, 67-kDa LR neutralization evoked the similar effects in normal animals. Considering the essential roles of laminin in brain vascular development and vessel integrity (Thyboll et al., 2002) and its proteolytic cleavage by 67-kDa LR (Ardini et al., 2002), it is likely that the SE-induced reduction in 67-kDa LR expression and 67-kDa LR neutralization may up-regulate laminin expression to inhibit or recover vasogenic edema formation. Furthermore, SB202190 co-treatment abrogated laminin expression and serum extravasation induced by 67-kDa LR neutralization. Therefore, our findings indicate that 67-kDa LR dysfunction may up-regulate laminin expression via p38 MAPK/VEGF signaling pathway, and that laminin over-expression may be a secondary adaptive response to serum extravasation.

Similar to 67-kDa LR neutralization, recombinant tissue plasminogen activator (r-tPA) induces BBB disruption, and subsequently results in vasogenic edema (Copin et al., 2011), which is mitigated by p38 MAPK inhibitor (Garraud et al., 2016). Rosuvastatin (a lipid-lowering agent) also ameliorates r-tPA-induced BBB damage by reducing the activities of JNK and p38 MAPK (Lu et al., 2018). Indeed, tPA activates ERK1/2, JNK, AKT and p38 MAPK signaling pathways (Pineda et al., 2012). Thus, it is plausible that 67-kDa LR neutralization may lead to vasogenic edema through tPA activation and various signaling pathways as well as p38 MAPK. Further studies are needed to validate the relationship between 67-kDa LR and tPA and the related signaling pathways.

Pilocarpine is a cholinergic agent, which activates muscarinic M1 receptors (Hamilton et al., 1997; Kim and Kang, 2011). Acetylcholine induces vasodilation by eNOS activation (Gericke et al., 2013) and cholinesterase inhibitors such as chlorpyrifos and paraoxon (organophosphorus insecticides) evoke vasogenic edema (Song et al., 2004; Li and Ehrich, 2013). Thus, it is presumable that the direct PILO-mediated eNOS activation would affect seizure activity and vasogenic edema formation, although we blocked its peripheral cholinergic effects by atropine methylbromide in the present study. Recently, our laboratory reveals that *N*-nitro-L-arginine methyl ester (L-NAME, a non-selective NOS inhibitor) abrogates NO synthesis without altering seizure activity in response to PILO by the real-time simultaneous monitoring of NO and EEG. Thus, we have speculated that NO synthesis may be a consequent response to seizure activity, and that NO itself may not be directly involved in ictogenesis (Lee and Kim, 2018; Jeon and Kim, 2018). Furthermore, ET_B receptor antagonist attenuated vasogenic edema formation via reducing eNOS expression without altering PILO-induced seizure activity (Kim J.Y. et al., 2015). Therefore, it is unlikely that the direct cholinergic effect of PILO on eNOS activity may not influence seizure activity and vasogenic edema formation, at least in our model.

Various brain insults induce an osmotic potential across central necrotic tissue, inflammatory reaction, tight junction degradation and protein extravasation, which are regulated by inflammatory cytokines, MMP, VEGF and leukocyte/neutrophil infiltration (for review; Jha et al., 2019). Similar to other disease models, SE-induced vasogenic edema formation is relevant to neuroinflammation, MMP-9 activation and neutrophil infiltration (Kim et al., 2010a, 2012; Jung et al., 2012; Kim J.Y. et al., 2015). Thus, it is likely that the fundamental mechanisms of vasogenic edema formation induced by SE may be similar to those under various pathophysiological conditions. However, there are many underlying factors including age, sex and genetics to contribute vasogenic edema formation in animal model and human patients. For example, the major population of patients of posterior reversible encephalopathy syndrome (PRES), which is a neurotoxic encephalopathic state showing seizures and SE with white matter vasogenic edema in occipital and parietal lobes, is woman (Kamiya-Matsuoka and Tummala, 2017). Therefore, it seems that vasogenic edema would show

gender-dependent characteristics. Indeed, sex steroids influences vascular reactivity in the brain via various signaling molecules including eNOS (Krause et al., 2006; Parikh et al., 2017). However, AQP4 expression is down-regulated in glioma patients without gender−dependent difference in AQP4 expression, although sex hormones such as estrogen, progesterone and testosterone modulate AQP4 expression in astrocytes (Warth et al., 2007). Ischemic stroke also shows the relative protection from brain injury in the female as compared with male, which is conferred by endogenous sex steroids. However, AQP4 is not involved in gender-specific differences in stroke volume and finally, the perivascular pool of AQP4 does not alter after ischemic stroke (Liu et al., 2008). Furthermore, age and genetic polymorphisms (e.g., cytokines, apolipoprotien E, Tau, and mitochondrial genes) affect BBB integrity (Song et al., 2004; Bennett et al., 2016). Therefore, studies concerning gender-, age-, and genetic-based difference in vasogenic edema formation in animal models and human patients are needed to elucidate the underlying mechanisms, the prediction of outcome and clinical management in various neurological diseases relevant to vasogenic edema.

CONCLUSION

In conclusion, to the best of our knowledge, the present data show novel evidence that 67-kDa LR may be one of the up-stream regulators of dystrophin/p38 MAPK/VEGF/eNOS axis, which plays an important role in the maintenance of BBB integrity (**Figure 6**). Thus, our findings suggest that 67-kDa LR-mediated astroglio-vascular interface may be a therapeutic target for treatment of vasogenic edema.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

ETHICS STATEMENT

All experimental protocols described below were approved by the Institutional Animal Care and Use Committee of Hallym University (Chuncheon, South Korea). Every effort was made to reduce the number of animals employed and to minimize animal's discomfort.

AUTHOR CONTRIBUTIONS

T-CK designed and supervised the project, analyzed the data, and wrote the manuscript. All authors performed the experiments described in the manuscript.

FUNDING

This work was supported by Hallym University (HRF-201903-011).

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fncel.2019.00236/full#supplementary-material

The Inflammatory Response After Ischemic Stroke: Targeting β_2 and β_1 Integrins

Danielle N. Edwards[1,2] *and Gregory J. Bix*[3,4]*

[1] Sanders–Brown Center on Aging, University of Kentucky, Lexington, KY, United States, [2] Department of Neuroscience, University of Kentucky, Lexington, KY, United States, [3] Department of Neurology, University of Kentucky, Lexington, KY, United States, [4] Department of Neurosurgery, University of Kentucky, Lexington, KY, United States

Ischemic stroke is a leading cause of death and disability with limited therapeutic options. Resulting inflammatory mechanisms after reperfusion (removal of the thrombus) result in cytokine activation, calcium influx, and leukocytic infiltration to the area of ischemia. In particular, leukocytes migrate toward areas of inflammation by use of integrins, particularly integrins β_1 and β_2. Integrins have been shown to be necessary for leukocyte adhesion and migration, and thus are of immediate interest in many inflammatory diseases, including ischemic stroke. In this review, we identify the main integrins involved in leukocytic migration following stroke ($\alpha_L\beta_2$, $\alpha_D\beta_2$, $\alpha_4\beta_1$, and $\alpha_5\beta_1$) and targeted clinical therapeutic interventions.

INTRODUCTION

Ischemic stroke is a leading cause of death and disability in the United States with limited therapeutic interventions available, including tissue plasminogen activator (t-PA) and endovascular mechanical thrombectomy (Rao et al., 2014; Benjamin et al., 2017; Rai et al., 2017). These interventions are focused on the removal of the thrombus, restoring blood flow, oxygen and glucose to hypoperfused areas, but are unable to affect the inflammatory, necrotic, and blood-brain barrier (BBB) mechanism that follow. In particular, the initial inflammatory cascade is initiated by the decrease in ATP production, release of cytokines, influx of intracellular calcium, reactive oxygen species, etc., that develops during occlusion and continues for days afterward (Sandoval and Witt, 2008). Using shear forces from cerebral blood flow, marrow-derived leukocytes (including polymorphonuclear leukocytes (PMNs), neutrophils, lymphocytes and monocytes) are recruited to the site of injury (Dereski et al., 1993; del Zoppo, 1994; Stefanidakis and Koivunen, 2006).

For the purpose of this review, we will focus on the recruitment and rolling of leukocytes under the direction of integrins, as well as some of their ligands following reperfusion after ischemic stroke. We will then introduce recent β_2 and β_1 integrin-specific stroke clinical trials, and, finally, discuss potential future directions for the field.

LEUKOCYTIC INFILTRATION FOLLOWING ISCHEMIC STROKE

Leukocyte Recruitment

The initial endothelial response upregulates endothelial selectins, particularly P-selectin and E-selectin, translocating them from an intracellular, inactive state, to the available extracellular matrix for leukocytic binding, while the upregulation of L-selectin on the leukocyte is essential for recruitment to the site of injury (Bargatze et al., 1994). Both are acutely regulated, P-selectin at

15 min and E-selectin at 2 h post ischemia. These extracellularly located selectins then facilitate the recruitment and activation of leukocytes to the area of ischemia (Zhang et al., 1998). Leukocytes then undergo a conformational change, facilitating polarization and the development of certain cellular characteristics: a leading edge, main body, and rear-uropod protrusion. The uropod, or posterior protrusion, in fast moving leukocytes promotes mobility, while the leading protrusions (lamellipodia and filopodia, small leg-like projections) are less likely to be used due to the rate limiting interaction with actin filaments (Ridley et al., 2003) (summarized in **Figure 1**). Though this mechanism is less obvious in the highly mobile leukocytes. Once leukocytes are bound to selectins, additional binding to integrins and adhesion molecules (intracellular adhesion molecule (ICAMs and vascular adhesion molecule-1 (VCAM) occurs, permitting leukocytic rolling (del Pozo et al., 1995; Lorant et al., 1995; Kindzelskii et al., 1996; Becker, 2002). Additional damage can occur once at the site of ischemia, as infiltration into the brain parenchyma across the BBB destroys surrounding vasculature (Clark et al., 1993; Chou et al., 2004), and leukocytes continually release additional factors (reactive oxygen species, cytokines, and proteases) that enhance leukocytic recruitment (Wang et al., 2008).

Leukocyte Infiltration

At the site of injury, leukocytes continue to increase binding on cerebrovasculature up to 48 h following ischemic stroke, and use transendothelial migration as a method for infiltration from the cerebrovasculature into the surrounding brain parenchyma. Early adhesion, prior to 24 h following reperfusion, is attributed to neutrophils. Within 30 min to a few hours following reperfusion, neutrophils arrive at the site of injury, peaking at maximum expression around 1–3 days, though expression can still be detected 7–15 days later in preclinical stroke models (Weston et al., 2007). This upregulation is also seen in ischemic stroke patients, where neutrophils have been detected beginning at 6 h, with radiolabeled imaging, and continue to be detected up to 72 h (Aspey et al., 1989). The early recruitment and infiltration of neutrophils across the BBB appears to be highly significant in stroke, as high neutrophilic infiltration is associated with damaged cerebrovasculature (Enzmann et al., 2013), while depletion reduces infarct volume and dysfunction in stroke models (Chou et al., 2004).

As reperfusion injury continues, the circulating leukocytes switch from neutrophils to mononucleuar leukocytes (monocytes/lymphocytes) which dominate the adherent culture from 24 h to 7 days post reperfusion (Schroeter et al., 1994; Stevens et al., 2002; Ishikawa et al., 2005). Of the two types of lymphocytes, B- and T-, T cells have emerged as the dominant, damage-inducing lymphocyte in ischemic stroke (Brait et al., 2011). Preclinical studies have shown that the inhibition of all lymphocytes results in smaller infarct and improved neurological outcomes, but only the reintroduction of T-lymphocytes to mice reversed any benefits (Yilmaz et al., 2006; Kleinschnitz et al., 2010). Activated T-lymphocytes, not B-, have been detected in patients up to 60 days post-stroke, and are correlated with an increased risk of stroke reoccurrence and death (Tarkowski et al., 1995; Nadareishvili et al., 2004).

Clinical Importance of Leukocytes

Multiple studies have established the importance of leukocytic adherence and infiltration into the brain parenchyma following ischemic stroke, but targeting the leukocytes has a high degree of risk. This is evident as inhibition of leukocytic cells increase the occurrence of bacterial infection and mortality as evident by Leukocytic Adhesion Deficiency (LAD-1) (Stefanidakis and Koivunen, 2006). Because these cells are necessary for bacterial resistance, systemic inhibition following ischemic stroke is exceptionally risky. However, studies in stroke patients show a strong correlation between increased levels of peripheral leukocytes and neutrophils, and increased infarct volume (Price et al., 2004; Buck et al., 2008). Thus, some current therapeutic strategies have focused on the inflammatory cascade have focused on blocking the adhesion and infiltration of cells at the site of injury, primarily endothelial expressed ICAMs and VCAM. This method has shown success in preclinical studies, but has failed to translate to the clinic. Thus, the focus has switched to directly targeting the integrins, a primary mediator of leukocyte adhesion, rather than their ligands, as discussed above. This review is focused on integrins β_2 and β_1 that have shown promise in therapeutically targeting the ischemic stroke inflammatory cascade.

ROLE OF INTEGRINS POST-STROKE: AN OVERVIEW

Integrins are a diverse group of heterodimers composed of 18 different α and β subunits, creating 24 unique combinations. Integrins exist on every cell type, while exhibiting a high diversity of ligands and grouped into four different receptor groups: RGD (Arg-Gly-Asp), laminin receptors, collagen receptors, and leukocyte-specific receptors. Within these groups, integrins can have a variety of ligands and roles following ischemic stroke (reviewed in Edwards and Bix, 2019). Under normal cerebrovascular conditions, integrins are in a highly inactive state, typically in a bent conformation (Takagi et al., 2002; Nishida et al., 2006). Following ischemic stroke, activation signals are sent. Chemokines are translocated to the lumen, on the apical side of endothelial cells, to induce "inside-out" signaling (Chavakis, 2012). Integrins then undergo a conformational change to increase integrin affinity for potential ligands while enhancing detection by localizing to the leading or rear-facing edge of the leukocyte's cell wall for ligand detection (Ridley et al., 2003; Hyun et al., 2009). Activated integrins then bind to available ligands, permitting leukocytic rolling and intracellular signaling. This is termed "outside-in" signaling (Hato et al., 1998; Tominaga et al., 1998; Ley et al., 2007). Leukocytes continue movement to the site of injury, looking for areas to cross the endothelial cell barrier, and eventually coming to a halt. Aggregation/clustering of integrins increases binding avidity (strength of binding), preventing flow conditions from detaching leukocytes from the endothelial cells (Ley et al., 2007). Using transmigration, leukocytes will infiltrate into the cerebral parenchyma using these integrin-ligand connections.

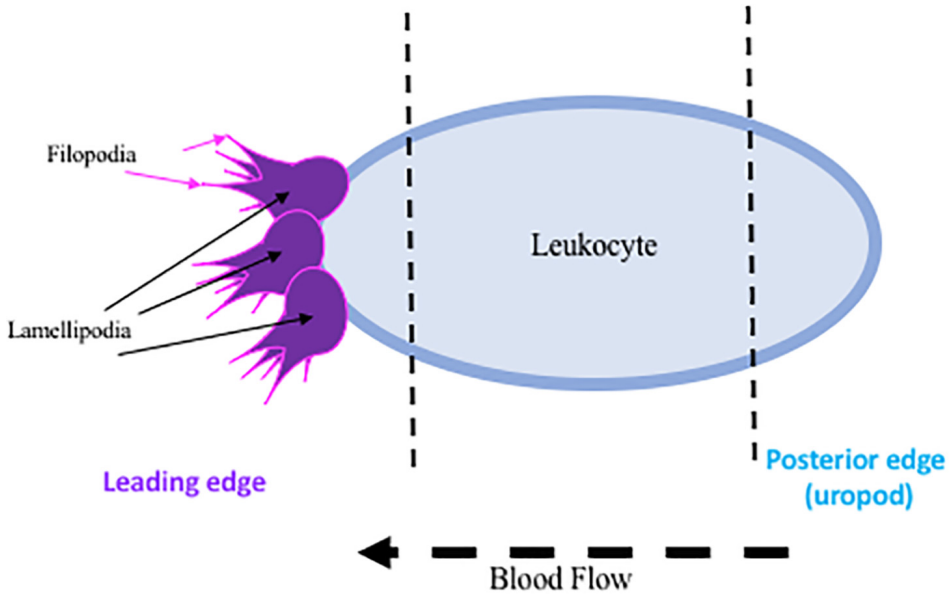

FIGURE 1 | Representative diagram of regions of interest on activated leukocytes.

β_2 Integrins

β_2 integrins are the only group of integrins exclusively expressed on leukocytes (derived from hematopoietic cells) (Schenkel et al., 2004), and like most integrins, are highly conserved across species (Schittenhelm et al., 2017). They are also the most highly expressed integrin on circulating blood leukocytes, tending to cluster at the retraction area of the cell (the rear), in both an active and inactive state, compared to other β_1, β_4, β_3, and β_7 integrins found on circulating leukocytes (Pierini et al., 2000; Lindbom and Werr, 2002). Genetic leukocyte adhesion changes (LAD-1, as discussed above) has been attributed to mutations in the β_2 subunit, reducing β_2 expression. Thus, leukocytic movement is reduced on the cell surface with less movement toward the site of inflammation (Arnaout, 1990; Scharffetter-Kochanek et al., 1998). Importantly, in β_2 inhibited mice, there is not total arrest of leukocytic recruitment or infiltration (Pierini et al., 2000), suggesting that other factors likely play a role. There are 4 identified heterodimers of β_2 integrins, and of these, the most highly studied are $\alpha_L\beta_2$ and $\alpha_M\beta_2$ in ischemic stroke, and will be reviewed in more detail below. The other β_2 integrins, $\alpha_X\beta_2$ and $\alpha_D\beta_2$, have not been individually studied in the context of stroke as have $\alpha_L\beta_2$ and $\alpha_M\beta_2$ integrins, though CD18 (β_2) inhibition in addition to t-PA has been shown to increase the time window of t-PA administration without an increase in hemorrhagic transformation in a rat embolic stroke model (Zhang et al., 1999). Furthermore, **Figure 2** summarizes the results in this section.

$\alpha_L\beta_2$ Integrin

Integrin $\alpha_L\beta_2$ is also referred to as CD11a/CD18 and LFA-1 (lymphocyte functional-associating antigen-1). $\alpha_L\beta2$ integrin acutely increases in ischemic stroke patients, with detectable amounts through 72 h associated around the area of ischemia (Gerhard et al., 2000; Zhao et al., 2002). This suggests a correlation between $\alpha_L\beta_2$ integrin expression and inflammatory damage following ischemia. $\alpha_L\beta_2$ is expressed on all leukocytes (Soriano et al., 1999), though at particularly high levels on T-lymphocytes (Hammond et al., 2014; Walling and Kim, 2018). In healthy individuals, extracted blood analysis revealed that $\alpha_L\beta_2$ activation requires leukocytic rolling on P- or E-selectins, inducing an active conformational change (Kuwano et al., 2010), but it is the binding of chemokines g-protein coupled receptors (GPCR) and Rap-1 activation that induces the high-affinity conformational state of $\alpha_L\beta_2$ (Steffen et al., 1994; Greenwood et al., 1995; Ghandour et al., 2007). In this state, $\alpha_L\beta_2$ has many possible ligands, ICAM-1, ICAM-2, ICAM-3, ICAM-4, ICAM-5, and junctional adhesion molecule-1 (JAM-1) (Marlin and Springer, 1987; de Fougerolles et al., 1991, 1994; Tian et al., 2000), though ICAM-1 is preferentially bound (Walling and Kim, 2018). The high avidity $\alpha_L\beta_2$-ICAM-1 complex, once formed, allows t-lymphocytes to move against circulatory flow and the shear forces, resulting in the high-speed movement of leukocytes (Katakai et al., 2013; Dominguez et al., 2015).

In an intraluminal model of experimental ischemic stroke, $\alpha_L\beta_2$ inhibition with the use of transgenic mice results in reduced infarct volume, edema volume and mortality. However, this phenomenon is evident in transient, but not permanent middle cerebral artery occlusion (Arumugam et al., 2004). This may be due to the previously mentioned high avidity of $\alpha_L\beta_2$-ICAM-1 bonds, and is evident in an *in vitro* study using $\alpha_L\beta_2$ (LFA-1) knock-in mice that experience high avidity through binding of lymphocytes mediated through ICAM-1 binding, but are unable to continue movement due to a non-polarized uropod (Park et al., 2010). An explanation for this phenomenon may be that the recycling process within the leukocyte is overwhelmed (Shaw et al., 2004). By enhancing $\alpha_L\beta_2$ expression, recycling may not be able to allow for dislocation of $\alpha_L\beta_2$-ICAM-1

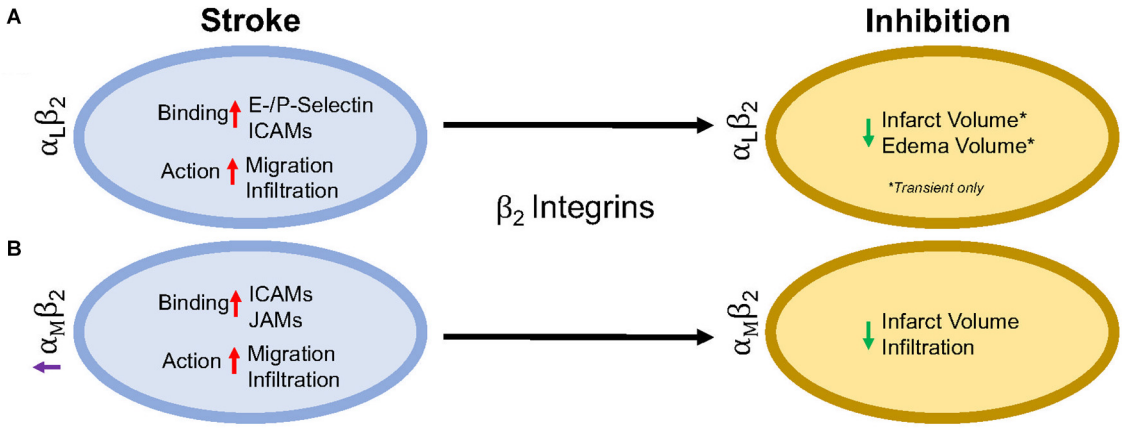

FIGURE 2 | Representative image of the β_2 integrin response following experimental stroke and inhibitory antibody treatment in preclinical trials. Inhibition of **(A)** $\alpha_L\beta_2$ and **(B)** $\alpha_M\beta_2$ integrins post-stroke responses and effects.

complexes, preventing movement from the loss of high adhesion bonds. Enhanced $\alpha_L\beta_2$ expression could be a potential new avenue for therapy, especially if no enhanced mortality, infection, etc., are observed.

Independently, ICAMs play a significant role in inflammation following ischemic stroke. ICAM-1, in particular, is acutely increased in both cultured human endothelial cells undergoing hypoxia and following intraluminal suture middle cerebral artery occlusion, while expression remains sustained for up to a week post-injury (Hess et al., 1994a,b; Zhang et al., 1995). ICAM-2, another possible ligand, does not change in expression following cytokine stimulation (de Fougerolles et al., 1991; Nortamo et al., 1991a,b). Furthermore, serum of ischemic stroke patients contains soluble ICAM-1, but not ICAM-2 in addition to being a risk factor (Kaplanski et al., 1994; Shyu et al., 1997). Antibodies targeting ICAM-1 in rodents and humans have shown contradictory results. An intraluminal suture middle cerebral artery occlusion model in mice and rats showed a decrease in leukocyte infiltration and infarct volume (Connolly et al., 1996; Kitagawa et al., 1998; Vemuganti et al., 2004), while one study reported opposing effects (Furuya et al., 2001). ICAM-1 inhibition was translated to the clinic through testing of the murine ICAM-1 antibody, Enlimomab in ischemic stroke. Unfortunately, the study was halted early due to increased rate of infection, infarct volumes, neurological scores and mortality for patients (Furuya et al., 2001).

$\alpha_M\beta_2$ Integrin

Integrin $\alpha_M\beta_2$, also known as CD11b/CD18 and Mac-1 (macrophage-1 antigen), exhibits many similarities to $\alpha_L\beta_2$ through its expression on all leukocytes (Springer et al., 1979), and common ligand binding partners such as the family of ICAMs and JAMs (von Andrian et al., 1991). Additional ligands are fibrinogen, heparin (von Andrian et al., 1991), elastase (Cai and Wright, 1996), complement C3 fragment (C3bi) (Micklem and Sim, 1985), kinogen components, and urokinase and its receptor (Chavakis et al., 1999). Just as $\alpha_L\beta_2$, hypoxia induced factors (cytokines, chemokines, etc.) induce conformational change of $\alpha_M\beta_2$ to a high affinity ligand-binding state (Stanimirovic et al., 1997). Binding assays with ICAM-1 as a ligand and both $\alpha_L\beta_2$ and $\alpha_M\beta_2$ as receptors show $\alpha_L\beta_2$ integrin is preferably bound (Lub et al., 1996). This suggests that the binding sites on both $\alpha_L\beta_2$ and $\alpha_M\beta_2$ compete for ICAM-1 binding.

Following experimental ischemic stroke in rats, integrin $\alpha_M\beta_2$ is upregulated (Campanella et al., 2002), and has shown benefit when inhibited. Antibodies against both CD11b/CD18 reduce infarct volume and reestablish cerebral blood flow as a result of decreased neutrophil infiltration following intraluminal stroke surgery (Chen et al., 1994; Bowes et al., 1995; Zhang et al., 1995). In a different approach, the addition of recombinant neutrophil inhibitory factor (rNIF) inhibits a binding domain on Mac-1 and yields similar results in the same intraluminal occlusion model (Jiang et al., 1998). Furthermore, and similarly to $\alpha_L\beta_2$ integrin inhibition, inhibition of $\alpha_M\beta_2$ is also effective in transient, but not permanent experimental ischemic stroke in an embolic occlusion model (Zhang et al., 2003).

β_1 Integrins

β_1 integrins are a diverse set of integrins, with laminin-binding, collagen-binding, RGD-binding and leukocyte heterodimers. β_1 integrins are not as highly expressed on leukocytes as β_2 integrins, but they do play a major role in leukocyte adhesion and migration following ischemic stroke. The activity of β_1 integrins is similar to β_2 integrins. They undergo a conformational change to induce "inside-out" and "outside-in" cellular signaling (Campanero et al., 1994). As the cells migrate, the β_1 integrins are most commonly clustered around the uropod, but will be located in any area of the leukocyte that is in contact with the endothelial cell or extracellular matrix (Campanero et al., 1994; Caimi et al., 2001). Inhibition of the β_1 integrin, just as with β_2 integrin inhibition, does not fully stop leukocyte rolling. However, when both β_1 and β_2 integrins are inhibited, complete leukocyte arrest occurs (Lobb and Hemler, 1994; Pierini et al., 2000). This suggests that both β_1 and β_2 integrins are necessary for leukocyte migration, regardless of expression load. Of all the β_1 integrins, both $\alpha_4\beta_1$ and $\alpha_5\beta_1$

appear to be the most highly expressed and the most studied in post-stroke inflammation. The other β_1 integrin expressed on leukocytes, $\alpha_9\beta_1$, has not been studied in the context of stroke as its expression and role has not yet been fully elucidated in the brain. **Figure 3** summarizes the results discussed in this section.

$\alpha_4\beta_1$ Integrin

$\alpha_4\beta_1$, also known as CD49d/CD29 VLA-4 (very late antigen-4), is localized primarily to leukocytes (neutrophils, monocytes, lymphocytes, macrophages, etc.) and microglia as a leukocyte-specific receptor. Additionally, α_4 will also dimerize with β_4, which is found in gut endothelium (Hammond et al., 2014). Activation of $\alpha_4\beta_1$ integrin results from the binding of upregulated chemokines to GPCRs in the same manner as $\alpha_L\beta_2$ as discussed above (Vajkoczy et al., 2001). This stimulates binding to $\alpha_4\beta_1$'s preferred ligand, VCAM-1, but experiments have shown some preference for paxillin ICAM-1 (Steffen et al., 1994; Ghandour et al., 2007), and fibronectin (Hart and Greaves, 2010) as well. Interestingly, instead of using the β_1 submit of the heterodimer for binding, integrin $\alpha_4\beta_1$ uses its α subunit of $\alpha_4\beta_1$ to mediate binding to VCAM-1 (Luo et al., 2007).

Preclinical ischemic stroke studies targeting $\alpha_4\beta_1$ have shown increasingly varied results. Most researchers reported a decrease in VCAM-1 expression, cytokine production, and infiltrating leukocytes (Liesz et al., 2011; Langhauser et al., 2014; Llovera et al., 2015), but this reduction in inflammation did not result in reduced infarct volumes or functional deficit following analysis of a randomized preclinical trial involving six different centers (Llovera et al., 2015). Langhauser et al went one step further and found that no treatment paradigm (prophylactic or therapeutic) and no model (transient or permanent) showed efficacy (Langhauser et al., 2014). On the other hand, both Becker, 2002 and Relton et al., 2000 found that inhibition of α_4 improved both infarct volumes and functional deficits. When a preclinical randomized control trial was implemented at multiple centers, researchers found efficacy only in patients with small infarct volumes (Llovera et al., 2015). Collectively, these contradictory results may be caused by a couple of scenarios, 1) the varying expression of integrin $\alpha_4\beta_1$ expression following ischemic stroke resulting in continued leukocyte infiltration, or 2) integrin $\alpha_4\beta_1$ is not a primary driver of post-stroke pathophysiology, but other factors, including other integrins, promote leukocyte migration (Hammond et al., 2014).

$\alpha_5\beta_1$ Integrin

$\alpha_5\beta_1$, also known as CD49e/CD29 and VLA-5, plays an as yet largely undetermined role in inflammation, with studies primarily limited to cell culture. What is known is that leukocytes express different β_1 integrins with $\alpha_5\beta_1$ composing around 50% of all β_1 –integrins expressed on neutrophils (Pierini et al., 2000) and monocytes (Pacifici et al., 1994). Additionally, $\alpha_5\beta_1$ is necessary for leukocyte adhesion. Only inhibition of both $\alpha_5\beta_1$ and β_2 integrins completely blocks adhesion *in vitro* (Pierini et al., 2000), while inhibition of $\alpha_5\beta_1$ alone prevents transmigration across the BBB (Labus et al., 2018) *in vitro*. As an RGD receptor, fibronectin has been shown to be the primary and preferred [over other potential ligands such as fibrinogen (Suehiro et al., 1997)] ligand for $\alpha_5\beta_1$ on endothelial cells and leukocytes (Schaffner et al., 2013; Bharadwaj et al., 2017). Importantly, in the presence of activated $\alpha_L\beta_2$, leukocyte $\alpha_5\beta_1$ binding to fibronectin is enhanced (Bohnsack, 1992; Loike et al., 1999; Gronholm et al., 2016). $\alpha_5\beta_1$ integrin expression is induced by cytokines, particularly TNFα (Li et al., 2011) toward the leading edge of the cell in contrast with other integrins at the uropod (Pierini et al., 2000). Furthermore, $\alpha_5\beta_1$ integrin appears to be highly sensitive to calcium (Pierini et al., 2000), an ion that is increased rapidly following reperfusion (Sandoval and Witt, 2008). Upon calcium buffering, $\alpha_5\beta_1$ expression moves from the front of the cell to the uropod and the leukocyte becomes elongated. The change in expression localization and morphology is attributed to non-movement as the leukocyte cannot detach $\alpha_5\beta_1$ from the vascular wall (Pierini et al., 2000). Recently, Edwards et al. (2019) found that inhibition of $\alpha_5\beta_1$ integrin by the small peptide ATN-161 prevented CD45+ leukocytes from infiltrating the brain

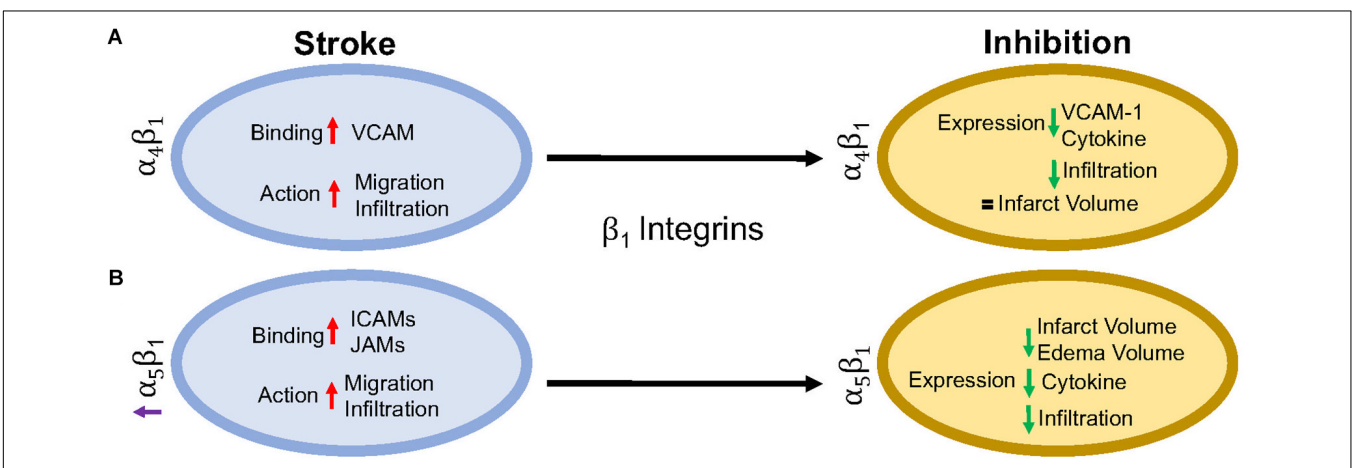

FIGURE 3 | Representative image of the β_1 integrin response following experimental stroke and inhibitory antibody treatment in preclinical trials. Inhibition of **(A)** $\alpha_4\beta_1$ and **(B)** $\alpha_5\beta_1$ integrins post-stroke responses and effects.

parenchyma following the tandem/transient common carotid artery/middle cerebral artery occlusion model. Additionally, mice were observed to have reduced BBB permeability, functional deficits, edema, and infarct volume following middle cerebral artery occlusion (Roberts et al., 2015; Edwards et al., 2019). Thus, targeting $\alpha_5\beta_1$ after ischemic stroke could be a new avenue for reduction of inflammation following ischemic stroke.

CLINICAL IMPLICATIONS

The preclinical studies discussed here point towards the potential of targeting β_2 and β_1 integrins in the treatment of post-stroke inflammation. Though their potential has not fully been elucidated, many clinical trials, not just limited to stroke, have been approved in the last 10 years targeting these integrins.

The most common target for post-stroke inflammation are the β_2 integrins. Though some efficacy has been reported, no clinical stroke trials to date have targeted the α_L subunit in stroke patients. However, one clinical trial with the monoclonal antibody, Efalizumab, has shown promise in decreasing T-lymphocyte rolling in patients with moderate-severe plaque psoriasis (Lebwhohl et al., 2003).

In preclinical studies targeting $\alpha_M\beta_2$, a hookworm isolated recombinant glycoprotein targeting rNIF (UK279276) (Zhang et al., 2003) and humanized Hu23F2G (Leukarrest) (Yenari et al., 1998), were both shown to decrease infarct volume and increase functional recovery following reperfusion. Both therapies had negligible side effects in Phase 1 studies and thus were continued to a Phase II study, respectively, before the trials were halted due to no observed efficacy (Becker, 2002; Krams et al., 2003). The failure to target $\alpha_M\beta_2$ integrin may be due to the observation that human ischemic stroke patients do not experience the increase in $\alpha_M\beta_2$ expression as seen in rodent stroke models (Caimi et al., 2001). Interestingly, when given in conjunction with United Kingdom279276, patients experienced a slight improvement (Krams et al., 2003), but no follow-up has been conducted. This interesting effect may be worth additional investigation in future clinical trials.

Clinical inhibition of β_1 integrins, on the other hand, is small and varied. Of the current clinical trials, one trial has emerged targeting $\alpha_4\beta_1$ in the context of ischemic stroke. The monoclonal antibody targeting the α_4 subunit (Natalizumab) has been successful in protecting patients from relapses in multiple sclerosis (Polman et al., 2006) and Crohn's disease (Sandborn et al., 2015). However, in a Phase II ischemic stroke study, patients receiving Natalizumab showed no improvement in infarct growth or neurological scores over 30 days. Furthermore, two patients (out of 79) died from serious infections attributed to Natalizumab treatment (Elkins et al., 2017). At this time, there are no further clinical trials planned.

FUTURE CONSIDERATIONS

As discussed in this review, targeting leukocytic integrins has had limited to no efficacy in clinical trials. Importantly, these studies have collectively employed only three different therapeutics and two targets; there are still significant areas that can be investigated. Though not discussed here, most preclinical investigations have focused on the ligands themselves rather than the integrin as the therapeutic target, highlighting the continued importance of integrins in stroke.

It is also important to note that preclinical studies carried out in rodents inadequately model the post-stroke pathophysiology that patients experience. Preclinical stroke research is also typically limited, focusing on one species, sex, and age that do not necessarily match the demographic of stroke patients (see Kahle and Bix, 2012 for a review of this topic). Furthermore, as the changes following stroke and/or reperfusion are inadequately understood, identifying appropriate therapeutic targets that translate from the lab to clinical trials, has been particularly challenging.

However, this does not suggest abandoning therapeutic trials for ischemic stroke. As mentioned above, stroke is a leading cause of death and disability, separate from cardiovascular disease. This will not improve without intervention with our aging and obese population. Fortunately, with the advent of stroke mortality-altering therapies, i.e., t-PA and endovascular mechanical thrombectomy, our financial burden has shifted to aftercare. When we review the amount of trials performed for thrombolytic agents (Multicentre Acute Stroke Trial–Italy (MAST-I) Group, 1995; National Institute of Neurological Disorders and Stroke rt-Pa Stroke Study Group, 1995; The Multicenter Acute Stroke Trial–Europe Study Group, 1996) and endovascular thrombectomy [MR CLEAN (Berkhemer et al., 2015), ESCAPE (Goyal et al., 2015), EXTEND IA (Campbell et al., 2015), SWIFT PRIME (Saver et al., 2015), and REVASCAT (Jovin et al., 2015)] as potential treatments of ischemic stroke, it is obvious that the complexities of stroke affect the outcome of the clinical trial. This includes, but is not limited to, the time a patient takes to arrive at an ER, time to treatment, location of the stroke, amount of surrounding collaterals, current medications and co-morbidities (diabetes, cancer, etc.), and if the patient has experienced multiple strokes.

Based on current advances, as well as previous failures, a focus on integrins as a therapeutic target for stroke is emerging. A significant reason for this focus may be the complex, multi-dimensional role that integrins appear to play in brain pathophysiology. Integrins are diverse, existing on all cell types with varying roles depending upon expression and activation. This complexity can represent a significant challenge to integrin-targeted therapies inasmuch as such therapies could have diverse, even unintended off-target effects. However, we believe that this can be overcome by a better understanding of how integrin function and expression is altered after stroke, with the potential to exploit stroke-dependent integrin changes to therapeutic effect. For example, identifying a specific integrin to be upregulated in select cells in the post-stroke brain or brain-targeting cells, but not in other organs, could render it a viable therapeutic target. This emphasizes the need and importance of preclinical stroke research to discover and unravel the complexities of integrin biology. We are confident that such studies will result in viable new stroke therapies.

CONCLUSION

In this review, we have implicated integrins as an area of research for limiting inflammation following ischemic stroke. To date, therapeutic inhibition of $\alpha_L\beta_2$, $\alpha_M\beta_2$, and $\alpha_4\beta_1$ has shown promising results in preclinical studies, but translation to the clinic has been disappointing. Going forward, more targeted antibodies to all reactive β_1 and β_2 integrins after ischemic stroke may prove more beneficial, but more research needs to be done to completely understand the human inflammatory response and how that relates to changes in preclinical models.

We observed fine fibrin deposition along the paravascular spaces in naive animals, which increased dramatically following subarachnoid hemorrhage (SAH). Following SAH, fibrin deposits in the areas remote from the hemorrhage. Traditionally it is thought that fibrinogen enters subarachnoid space through damaged blood brain barrier. However, deposition of fibrin remotely from hemorrhage suggests that fibrinogen chains Aα, Bβ, and γ can originate in the brain. Here we demonstrate *in vivo* and *in vitro* that astroglia and neurons are capable of expression of fibrinogen chains. SAH in mice was induced by the filament perforation of the circle of Willis. Four days after SAH animals were anesthetized, transcardially perfused and fixed. Whole brain was processed for immunofluorescent (IF) analysis of fibrin deposition on the brain surface or in brains slices processed for fibrinogen chains Aα, Bβ, γ immunohistochemical detection. Normal human astrocytes were grown media to confluency and stimulated with NOC-18 (100 μM), TNF-α (100 nM), ATP-γ-S (100 μM) for 24 h. Culture was fixed and washed/permeabilized with 0.1% Triton and processed for IF. Four days following SAH fibrinogen chains Aα IF associated with glia limitans and superficial brain layers increased 3.2 and 2.5 times ($p < 0.05$ and $p < 0.01$) on the ventral and dorsal brain surfaces respectively; fibrinogen chains Bβ increased by 3 times ($p < 0.01$) on the dorsal surface and fibrinogen chain γ increased by 3 times ($p < 0.01$) on the ventral surface compared to sham animals. Human cultured astrocytes and neurons constitutively expressed all three fibrinogen chains. Their expression changed differentially when exposed for 24 h to biologically significant stimuli: TNFα, NO or ATP. Western blot and RT-qPCR confirmed presence of the products of the appropriate molecular weight and respective mRNA. We demonstrate for the first time that mouse and human astrocytes and neurons express fibrinogen chains suggesting potential presence of endogenous to the brain fibrinogen chains differentially changing to biologically significant stimuli. SAH is followed by increased expression of fibrinogen chains associated with glia limitans remote from the hemorrhage. We conclude that brain astrocytes and neurons are capable of production of fibrinogen chains, which may be involved in various normal and pathological processes.

INTRODUCTION

Arrest of cerebrospinal fluid (CSF) flow can be triggered by subarachnoid hemorrhage (SAH). Following SAH, fibrin is deposited in the paravascular space hindering CSF flow (Gaberel et al., 2014; Siler et al., 2014; Golanov et al., 2017). The blockage of CSF flow can be partially reversed by rt-PA or anti-tissue factor (TF, FIII) antibodies, suggesting that fibrin deposition in subarachnoid space (SS) may play an important role in CSF arrest (Gaberel et al., 2014; Siler et al., 2014; Golanov et al., 2017).

Astrocyte endfeet form the glia limitans on the brain surface placing astrocytes, a primary source of TF in the brain (Eddleston et al., 1993), in direct contact with blood following SAH. Activation of factor VII to factor VIIa in the blood and its interaction with TF (to form the TF: VIIa complex), initiate the extrinsic pathway of coagulation that ultimately convert prothrormbin to thrombin and hence promote fibrin formation.

Fibrinogen is not considered to be present in the brain, unless there is breach of the cerebral vasculature blood-brain or permeability barrier (BBB) and leakage of plasma/blood into the neuropil or fluid spaces (Akassoglou and Strickland, 2002; Adams et al., 2004; Petersen et al., 2018). Levels of fibrinogen in the CSF are very low, ∼0.65 μg/ml (Thompson, 2005), especially compared to the blood levels of fibrinogen (2–3 mg/ml) (Redman and Xia, 2001; Colman and Budzynski, 2011).

Blood coagulation is considered to participate in certain intravascular immunity responses targeted toward immobilization of the foreign agent (Doolittle, 2011, 2016; Gaertner and Massberg, 2016), and thus is a part of acute phase response (Gruys et al., 2005; Cray et al., 2009). Fibrinogen and prothrombin are necessary components of both intrinsic and extrinsic coagulation pathways. Fibrinogen is a 340 kDa glycoprotein consisting of three dimers. Each dimer is formed by identical polypeptides formed by fibrinogen chains Aα, Bβ, and γ, respectively. Fibrinogen is assembled in the endoplasmic reticulum of hepatocytes with the help of chaperon proteins, contains 29 disulfide bonds, and after glycosylation is released into the circulation (Redman and Xia, 2001; Mosesson, 2005; Weisel, 2005). Each of the three polypeptide chains forming fibrinogen is encoded by the respective genes, FGA, FGB, and FGG. It is thought that these genes are paralogs and are common for extant vertebrates (Doolittle et al., 1997). Thrombin, serine protease, which is present in brain (Deschepper et al., 1991; Dihanich et al., 1991) cleaves fibrinogen releasing fibrinopeptide A and B and initiating of fibrin polymerization and fibrin gel formation (Weisel, 2005).

Earlier observations and our recent experiments (Golanov et al., 2017) suggest that fibrin in the subarachnoid/paravascular space present in naïve animals and is being deposited in the areas remote from the hemorrhage following the SAH (Suzuki et al., 1977). Fibrin(ogen) was observed intracellularly (Marik et al., 2007; Yates et al., 2017) under pathological conditions such as multiple sclerosis. It is generally accepted that BBB insufficiency leads to blood-born fibrinogen penetration into the brain and consequent formation of fibrin depositions accompanying neurological disorders (Petersen et al., 2018).

The majority of circulating fibrinogen is being synthesis in liver (Tennent et al., 2007). However, fibrinogen can also be synthesized in extrahepatic sites such as bone marrow, lungs, intestine epithelial cells (see Weisel, 2005). We hypothesize that non-vascular brain cells, including astroglia and, probably, neurons, are capable of expressing fibrinogen chains Aα, Bβ, and γ, which, in turn, may exert multiple effects in the brain in normal and pathological conditions. Here we provide *in vivo* and *in vitro* data that support this hypothesis.

MATERIALS AND METHODS

All animal procedures were conducted in accord with the U.S. National Institutes of Health "Guide for the care and use of laboratory animals" and approved by the Institutional Animal Care and Use Committee of Houston Methodist Research Institute, Houston, TX, United States. Animals were housed in the institutional animal facilities on 12 h day/night cycle with *ad libitum* access to food and water. Studies were performed in sixteen 10–14 weeks old male C56BL/6J mice (Jackson Labs).

General Procedures

Anesthesia was induced by placing animals in a closed chamber flushed with 3% isoflurane in air; after reaching sufficient depth of anesthesia the animals were maintained at depth by 1.5–1.75% isoflurane in 80%/20% N2/O2 mixture delivered by facemask. Core body temperature was maintained at 37°C using a thermoblanket with the feedback from the rectal probe.

SAH in Mice

Subarachnoid hemorrhage was triggered by monofilament perforation of the Circle of Willis as previously described (Bederson et al., 1995; Parra et al., 2002; Feiler et al., 2010). Briefly, animals were anesthetized and placed in the supine position. The left common, external and internal carotid arteries were exposed through the midline incision. All three arteries were mobilized using silk sutures (7-0). The stump was formed from the external carotid artery by cutting it between two ligatures. A proline monofilament (6-0) was advanced into the internal carotid artery the stump until slight resistance was felt. The filament was advanced further forward for ∼1 mm and withdrawn. The stump was ligated, the wound was closed, and the animal was allowed to recover. In the sham group, the filament was advanced to the resistance point and withdrawn without perforation. After surgery, the animals were allowed to recovery and then returned to the home cage.

Immunohistochemistry

Four days after SAH (or sham operation) the mice were deeply anesthetized and sacrificed by transcardiac perfusion with saline followed by 4% paraformaldehyde in PBS. Brains were removed, post-fixed for 24 h, and cryoprotected in 30% sucrose in PBS until complete submersion. The brains were quick frozen on dry ice, embedded in mounting media (NEG50, Richard-Allan Scientific, Thermo Scientific), and stored at −80°C until further processed. Ten micrometer thick coronal sections were prepared using a

cryotome (Microm HM550, Thermo Scientific) and collected on glass slides. The glass slides with samples were washed in PBS-0.3% Triton X-100 for 30 min at room temperature, rinsed in distilled water, and air dried. A paraffin pen was used to contour the brain slices on the glass slides (ImmEdge Pen, Vector Laboratories). After the slides were rinsed in PBS to re-wet tissue, the sections were blocked with 2% normal donkey serum (Jackson ImmunoResearch) in PBS-0.3% Triton X-100 for 2 h. After blocking, the slides were incubated overnight (12–14 h) with the primary specific antibodies against fibrinogen-α, -β and -γ chains (1:200; rabbit polyclonal; Proteintech). The slides were washed three times for 15 min in PBS-0.3% Triton X-100, and then incubated with secondary antibodies for 3 h (donkey anti-rabbit-Alexa Fluor® 488 and Alexa Fluor® 594; 1:1000; Life Technologies, Thermo Fisher Scientific). The slides were rinsed in PBS and distilled water, covered with protective Fluorescent Mounting Medium with DAPI (GBI Labs), glass covered, and sealed with nail polish. In control slides, primary antibodies were omitted.

Cell Cultures

Normal human astrocytes (NHA) were obtained from Lonza (Walkersville, MD, United States) and human cortical neurons (HCN) from the American Type Culture Collection (ATCC, Manassas, VA, United States) and grown subject to vendor recommendations. NHA were grown in Astrocyte Basal Medium supplemented with 3% FBS, glutamine, insulin, fhEGF, GA-1000, and ascorbic acid. HCN were prepared using ATCC-formulated Dulbecco's modified Eagle's medium (cat# 30-2002) and supplemented with 10% FBS. HCN and NHA were grown to confluence in the appropriate media on Costar 96-well growth plates (Corning, NYC, NY, United States), and were grown for 24 h in the presence/absence of all effectors, in a total volume of 250 μL. The cells were fixed in ice-cold 4% PFA, were washed/permeabilized with 0.1% Triton X-100 in PBS, and then treated with Dako protein blocking solution. The cells were then incubated in 0.1% avidin (Sigma) for 30 min, washed and then incubated 10 μM biotin for 15 min, and washed in PBS.

The following primary antibodies were used: rabbit polyclonal fibrinogen chain Aα antibody ([H-300] (Santa Cruz Biotechnology, Santa Cruz, CA, United States), fibrinogen chain Bβ antibody ([H-270] Santa Cruz), fibrinogen chain γ antibody ([H-194] Santa Cruz) and mouse monoclonal antibodies to GFAP ([2A5] Santa Cruz). The following secondary antibodies were used: Donkey Anti-Mouse IgG H&L (Alexa Fluor® 488) (ab150105) and (Alexa Fluor® 594) (ab150108), Donkey Anti-Rabbit IgG H&L (Alexa Fluor® 488) (ab150073) and (Alexa Fluor® 594) (ab150076), all from Abcam (Abcam, Cambridge, MA, United States). All antibodies were diluted using Dako antibody diluent (S3022) at 1:100 for the primary antibodies and 1:250 for the secondary antibodies. Cell nuclei were labeled using DAPI.

Culture Stimulation

Normal human astrocytes and neurons grown to confluence were stimulated with the nitric oxide donor, NOC-18 (100 μM; Santa Cruz, CA, United States), tumor necrosis factor alpha, TNF-α (100 nM; Life Technologies, Carlsbad, CA, United States), or the stable ATP analog, ATP-γ-S (100 μM, Sigma, MS) for 24 h. The cultures were fixed and washed/permeabilized with 0.1% Triton and processed for quantitative immunofluorescence.

Fluorescent Imaging

Fluorescent images were captured using a Nikon Eclipse TE2000-E at 4×, 20×, or 30× magnification using a CoolSnap ES digital camera system (Roper Scientific) containing a CCD-1300-Y/HS 1392-1040 imaging array that is cooled by Peltier. Images were recorded and analyzed using Nikon NIS-Elements software (Elements 3.22.11). All images were saved as JPEG2000 files using Nikon NIS-Elements. In culture, cell numbers in the field of view in one well were counted manually, using DAPI nuclei fluorescence, and after background removal, fluorophore levels were calculated as signal/cell. Statistical analysis consisted of ANOVA followed by t-test using Bonferroni multiple-comparison correction.

To evaluate the intensity of fluorescence in the brain tissue, the fluorescent images of the ventral and dorsal regions of interest (ROI) were taken at 20x using standard exposure time by blinded to the experiment observer and processed simultaneously. Using ImageJ software color channels were split and equally thresholded after subtraction of the background and converted into binary images (Iliff et al., 2012). Five ROI were measured in each animal and fluorophore levels were calculated followed by statistical analysis using ANOVA followed by Bonferroni multiple comparison. All data expressed as mean ± SEM.

Human Brain Tissue Sections

Human brain tissue samples were procured, after obtaining signed informed consent and institutional review, from patients undergoing surgically indicated resection of malignant gliomas at the Houston Methodist Hospital. Tissue was collected directly from the operating room, given an identifying code to ensure patient confidentiality, and fixed in ice-cold 4% paraformaldehyde (PFA) within 15 min of removal. For details see Sharpe and Baskin (2016).

The tissue microarray block was sliced into 5-μm sections that were affixed to slides and dried. Slides were dewaxed four times in xylene, twice in isopropanol, and rehydrated using graded ethanol. The slides were washed and permeabilized using PBS (Fisher Scientific, Waltham, MA, United States) containing 0.1% Triton X-100. Epitope retrieval was done by heating the slides in Na-citrate buffer (100 mM, pH 6.0) at $< 100°C$ for 30 min, followed by cooling slowly to bench temperature. After washing in PBS, endogenous peroxidase activity was eliminated using mild conditions: 1.8% H2O2 for 5 min, 1% Periodate for 5 min, 0.02% NaBH4 for 2 min. The slides were blocked using Serum-Free Protein Block (Dako North America, Inc., Carpinteria, CA, United States) and incubated with primary antibodies (same that were used for mouse tissue processing) overnight at room temperature, at 1:100 dilution. After washing in PBS, the HiDefTM HRP-polymer system (Cell Marque, Rocklin, CA, United States) was used to functionalize with peroxidase, and visualization was performed using the Dako DAB chromogen kit according to manufacturer's guidelines. Additional slides

were also incubated with either hematoxylin/100 mM LiOH to render the nuclei blue for visualization of cells using transmission microscopy or 0.1% cresyl violet solution for 3 min, followed by washing (Nissl Staining).

Western Blot

Normal human astrocytes cell cultures were collected at confluence and processed for protein extraction. Cell pellets were lysed with RIPA buffer (Thermo Fisher Scientific) by pipetting them up and down and then placed for 30 min on an orbital shaker at 4°C. Proteins were quantified by Pierce BCA Protein Assay Kit (Thermo Fisher Scientific) and resolved by 4–15% SDS-PAGE Gel (Bio-Rad) according to the manufacturer's instruction.

Antibodies used were: rabbit anti-fibrinogen-Aα, anti-fibrinogen-Bβ and γ (1:1000, respectively H-300, H-270 and C-20; Santa Cruz Biotechnologies, Santa Cruz, CA, United States); anti-goat-HRP (1:2000; 81-1620; Thermo Fisher Scientific) and anti-rabbit-HRP (1:2000, 1706515; Bio-Rad).

RNA Extraction and RT-qPCR

Total RNA was extracted from NHA cell cultures (n = 3) using Aurum Total RNA mini kit (Bio-Rad). RNA concentration was determined using a NanoDrop ND-1000 spectrophotometer (NanoDrop, Rockland, DE, United States). Quantitative RT–PCR was run with 20ng of RNA using the 1-step Rt-qPCR mix from Bio-Rad according to the supplier's protocol. Amplification was done using SYBR green chemistry on CFX96 Real-Time PCR System (Bio-Rad). Each sample was run in duplicate. PCR primers were designed with primer designing tool from NCBI and manufactured by Sigma. Hprt was used as the reference gene. The following primers' sequences were used: FibA-α, 5′-AGA CAT CAA TCT GCC TGC AAA-3′ and 5′-AGT GGT CAA CGA ATG AGA ATC C-3′; FibB-β, 5′-GTC CCA AGG TGT CAA CGA CAA-3′ and 5′-CTC TCT TCT TGT CAA GGG GTC G-3′; Fib-γ 5′-TTA TTG TCC AAC TAC CTG TGG C-3′ and 5′-GAC TTC AAA GTA GCA GCG TCT AT-3′; HPRT, 5′-CCT GGC GTC GTG ATT AGT GAT-3′ and 5′-GGG CTA CAA TGT GAT GGC CT-3′.

Down-Regulation of the FibA-α, FibB-β, and Fib-γ in NHA Cells by siRNA

FGA siRNA (assay# s5115), FGB siRNA (s5119) FGG siRNAs (s5179) and negative control #1 (#4390843) were obtained from Thermo Fisher Scientific. Each siRNA concentration was titrated in 96-well tissue culture plate, in triplicates, with final concentrations ranging from 0 nm to 49 nM, in 7 nm increment. Briefly, each siRNA was dissolved in 200 μl of OPTI-MEM I Reduced Serum Medium (Gibco) mixed in equal volume of Lipofectamine RNAiMAx (Invitrogen, Carlsbad, CA, United States) with a final amount of 0.64 μl/well. siRNA and Lipofectamine were left for 5 min at room temperature for complexes to form, according to manufacturer's instructions, and then were added to each well, mixed gently and incubated at 37°C for 48 h. At 48 h, cells were fixed in ice-cold 4% PFA. Rabbit polyclonal antibodies against human fibrinogen chain Aα antibody (20645-1-AP), fibrinogen chain Bβ antibody (16747-1-AP), and fibrinogen chain γ antibody (15841-1-AP) from Proteintech (Rosemont, IL, United States), were used. Donkey anti-Rabbit IgG H&L (Alexa Fluor®594) (A21207, Invitrogen, Carlsbad, CA, United States) were used as a secondary antibody. Immunofluorescence was processed as described above.

RESULTS

Changes in Fibrinogen Chains Immunofluorescence Following SAH

In the first series of experiments we explored changes in the fibrinogen chains by immunofluorescence (IF) in the superficial layers of the parietal cortex and ventral surface of the mouse brain. We avoided areas on the ventral surface (especially) of the brain with visible signs of blood. Two groups of animals were compared: animals, in which the Circle of Willis was perforated 4 days before euthanasia and sham-operated animals in which no perforation was performed. Four days following SAH fibrinogen chains Aα IF associated with glia limitans and superficial layers of the ventral and dorsal superficial brain parenchyma increased 3.2 and 2.5 times ($p < 0.05$ and $p < 0.01$), respectively; fibrinogen chain Bβ increased by 3 times ($p < 0.01$) on the dorsal surface and fibrinogen chain γ increased by 3 times ($p < 0.01$) on the ventral surface compared to sham animals (**Figures 1A–C**). Importantly the changes in all three fibrinogen chains were un-coordinated suggesting differential distribution of fibrinogen chains in the dorsal and ventral superficial layers of the brain parenchyma.

Besides the increase in the presence of fibrinogen chains in the glia limitans and brain parenchyma, astrocytes and other cells also demonstrated the presence of fibrinogen chains immunoreactivity. Specifically, immunofluorescence of the cell-associated fibrinogen chains changed in the hippocampal dentate gyrus 4 days following the SAH (**Figure 2**).

Human Normal Astrocytes

Next, we explored whether NHA alone are capable of expressing fibrinogen chains. Indeed, immunochemical staining revealed that isolated astrocytes express immunoreactivity of all three fibrinogen chains (**Figure 3**). To determine whether the immunofluorescence was associated with the proteins we performed western blot analysis of the cell, and observed three bands with the molecular weights close to those reported for all three fibrinogen chains (McDonagh et al., 1972) (**Figure 4**).

Effect of siRNA on the Expression of Fibrinogen Chains in Normal Human Astrocytes

Following exploration of the fibrinogen chains proteins immunoreactivity levels in NHA we investigated silencing of the respective genes FGA, FGB and FGG using siRNA will suppress fibrinogen chains proteins immunofluorescence. Lipofection of the NHA with the specific siRNA, known to silence fibrinogen chains genes (Takezawa et al., 2013) we observed significant decrease of fibrinogen chains immunoreactivity in NHA. Specific

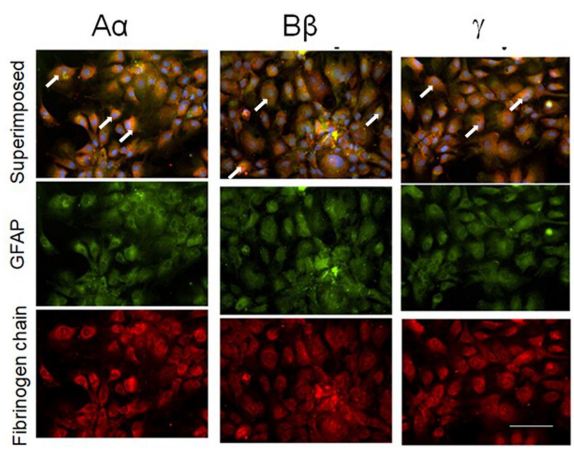

FIGURE 3 | Normal human cultured astrocytes constitutively express all three fibrinogen chains immunofluorescence. Note co-localization (white arrows) of fibrinogen chains immunofluorescence and immunofluorescence of astrocytes labeled with GFAP antibodies. (bar – 100 μm).

siRNA decreased expression immunoreactive of fibrinogen chain Aα by 76%, fibrinogen Bβ by 80% and fibrinogen chain γ by 78%, respectively, at the concentration of siRNA of 49 nM (**Figure 5**).

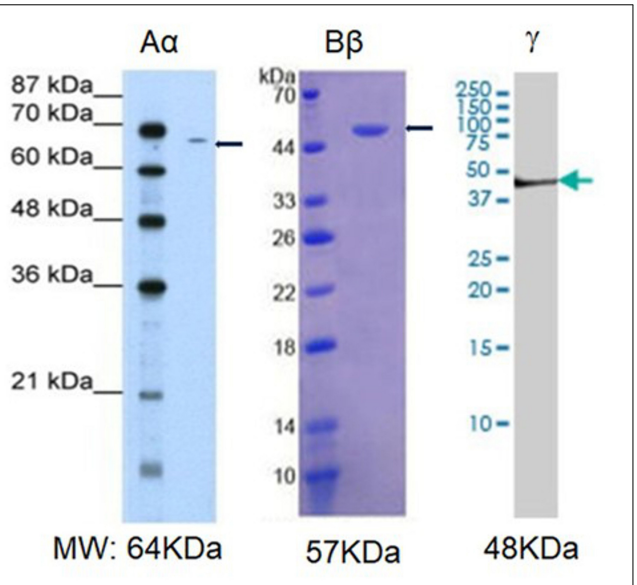

FIGURE 4 | Western blot analysis of the fibrinogen immunopositive chains in normal human astrocytic culture. MW, established molecular weight of fibrinogen chains (Sharpe and Baskin, 2016).

Decrease of the levels of fibrinogen chains after silencing of respective genes strongly suggest that that fibrinogen chains observed in NHA culture are of NHA origin and not resulting from external contamination, e.g., by bovine calf serum.

Reaction to Biologically Significant Stimuli

In the following experiments, we explored whether expression of the fibrinogen chains can be modified by biologically important signals including (i) TNF-α, the cytokine associated with the acute phase reaction of inflammation, (ii) the slow releasing NO donor diethylenetriamine (NOC-18), which is known to participate in various processes, including the inflammatory response, and (iii) stable ATP analog, which is a danger-associated molecule, which initiates protective responses, including the inflammatory response. Expression of the fibrinogen chains differentially changed when exposed for 24 h to these biological stimuli (**Table 1**). Importantly, levels of immunoreactivity of each chain did not correlate. While fibrinogen chain Aα levels, determined by changes in

Red fluorescence, fibrinogen chains; blue, DAPIB. Quantification of the suppression of fibrinogen chains expression by normal human astrocytic culture by siRNA. (**B**, Fluorescence was normalized by the determining the calculation of fluorescence/single cell, see Materials and Methods, all measurements were done in triplicate and three fields of view were taken in each well).

immunofluorescence, increased by ∼50% ($p < 0.01$), fibrinogen chain Bβ levels decreased by almost 50% and did not change significantly to other stimuli. Fibrinogen chain γ also decreased in response to ATP administration. These experiments strongly indicate that fibrinogen chains differentially regulated by biologically significant stimuli (**Figure 6A** and **Table 1**).

RT-qPCR in Astrocytes

The presence of the specific proteins suggested by immunohistochemistry would imply the presence of the specific mRNA if these proteins are being constitutively produced by cultured cells. To establish the presence of the transcription signal we performed RT-qPCR analysis of the presence of specific fibrinogen chain mRNA. Our results demonstrated the presence of the specific mRNA for each chain in the cultured astrocytes suggesting local transcription of the fibrinogen chains. Importantly, the levels of all three fibrinogens chains mRNA not only differed but were modulated differently by different biologically significant stimuli. These experiments strongly suggested that human astrocytes are capable of synthesizing fibrinogen chains, expression of which depends on the specific context (**Figure 6B**).

Human Cortical Neurons

Similarly, we explored constitutive expression and changes in fibrinogen chain immunoreactivities in the culture of human neurons. Human cortical neurons also demonstrated background expression of the fibrinogen chains. Exposure of cortical neurons to pro-inflammatory stimuli (TNF-α and ATP) changed the expression of fibrinogen chains as evaluated by immunofluorescence (**Figure 7A**). These changes were also differential and dependent on the type of stimulus. However, the pattern of the responses to similar stimuli differed from those observed in human astrocyte culture. Fibrinogen chain Bβ level increased by 85%, at the same time fibrinogen chain γ increased by over 100% in response to administration of ATP in neurons, while it decreased in response to ATP in astrocytes (**Figure 7B** and **Table 2**).

Human Tissue

After establishing that cultured human neurons and astrocytes are capable of expressing the three fibrinogen chains and that increases in fibrinogen chain-associated immunofluorescence in the mouse brain, including their intracellular localization, we analyzed whether fibrinogen chains are present in human brain tissue. We analyzed brain parenchyma samples obtained from different human brain structures (amygdala, hypothalamus) and observed that single cell-associated fibrinogen chain–associated immunofluorescence can be observed in human brain cells that displayed neuronal or astrocyte morphology, while there was no fibrinogen chain-related immunoreactivity in the extracellular space (**Figure 8**).

DISCUSSION

We demonstrate, for the first time, that astrocytes and neurons express fibrinogen chains suggesting potential presence of endogenous to the brain fibrinogen chains. Along with others we observed fibrin deposition in the areas remote to hemorrhage following the SAH (Suzuki et al., 1977; Golanov et al., 2017). It is conceivable that in spite of the remote location of the fibrin deposition in the subarachnoid space following the SAH fibrinogen and associated coagulation factors of the extrinsic pathway diffuse there along with CSF and polymerize through the

extrinsic pathway as it is known that the bounding glia limitans contains high levels of TF that can initiate fibrinogen conversion to fibrin (Golanov et al., 2017). In our described experiments cells of the glia limitans also demonstrated high levels of fibrinogen chains, which conceivably could be endocytosed from the CSF. Similarly, increased levels of fibrinogen chains in the parenchyma following the SAH could be due to changes in the permeability barrier of cerebral microvessels following the SAH

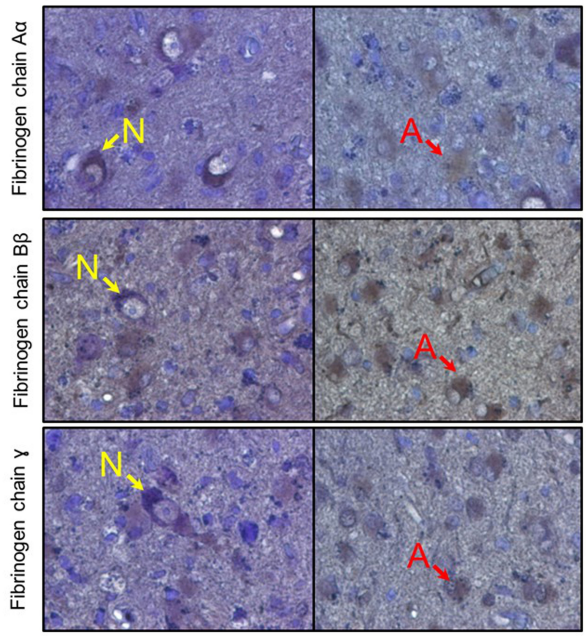

FIGURE 8 | Immunoreactive detection (DAB + hematoxylin) of fibrinogen chains in human brain samples (amygdala). Rows represent respective fibrinogen chains. N, indicate neurons, A, indicate astrocytes.

even in the remote sites, where no blood elements were observed (Davalos and Akassoglou, 2012; Petersen et al., 2018). However, in our experiments changes in the levels of fibrinogen chains were not correlated. Moreover, the fibrinogen chains were also accumulated in the intraparenchymal cells. These observations suggest that fibrinogen chains at least partially can be of local origin, i.e., generated by the glia limitans and other non-vascular brain cells. Furthermore, fibrinogen chain immunoreactivities were also detectable in the hippocampal dentate gyrus, where no blood was observed.

We also explored NHA and cortical human neuron cultures for the presence of the three fibrinogen chains. Immunohistochemistry revealed the intracellular presence of all three fibrinogen chains in human astrocytes and neurons. It can be argued that cultured cells endocytosed fibrinogen from the FBS-containing culture media. Western blot revealed presence of the specific fibrinogen chain proteins with the appropriate molecular weight. Low levels of fibrinogen in calf fetal serum and washing the cells before fixation (Ayache et al., 2006) decrease probability of cell "contamination" with the exogenous fibrinogen chains. However, this does not completely exclude origination of intracellular fibrin chains from the serum fibrinogen. Corroborating are our findings that the astrocyte cultures express the specific mRNAs for each chain, the observation which supports the hypothesis of an intracellular origin of the fibrinogen chains.

Allen atlas also demonstrates possible wide spread expression of fibrinogen chain Aα[1], presence of expression, though much more limited, of fibrinogen chains Bβ[2] and γ[3] (Morris et al., 2010). Expression of fibrinogen γ in the brain was demonstrated earlier (Haidaris and Courtney, 1990). These data provide additional support for the possible fibrinogen chains expression by the mouse brains.

Moreover, immunohistochemically determined levels of fibrinogen chains varied differentially in response to exposure to biologically significant signals. Importantly, responses, for example, of fibrinogen chain γ differed in neurons and astrocytes to the same signal, ATP-γS. These data suggest that the expression of the fibrinogen chains in cultured human neurons and astrocytes is intrinsic and regulated independently of each other.

Taken together these data strongly suggest the possibility that all three fibrinogen chains can be expressed in the brain, by neurons and astrocytes.

Fibrinogen chains appears in numerous brain pathologies: multiple sclerosis, Alzheimer's disease, EAE, posttraumatic demyelination as well as possible involvement in depression (Davalos and Akassoglou, 2012; Chiam et al., 2015; Petersen et al., 2018). In all cases it was suggested that the cause of appearance of fibrinogen in the brain is a "leaky" BBB. Indeed, in most cases the cerebral microvessel permeability barrier is abnormal and allows fibrinogen to enter the brain (Davalos and Akassoglou, 2012; Petersen et al., 2018). Because of fibrin deposits appear in Alzheimer's disease often localized near vessels a role for an altered blood-brain barrier has been suggested (Ryu and McLarnon, 2009; Sagare et al., 2013). However, there are also fibrin deposits in the neuropil without clear BBB disruption (Bien-Ly et al., 2015), which might occur due to the local production of fibrinogen.

Notably, fibrinogen chains as independent units are capable of interacting with various molecules (Weisel, 2005). Fibrinogen chains Aα and γ are capable of interaction with the various integrins such as αMβ2, αIIIβV mostly through their fibrinogen-related domain Arg–Gly–Asp (RGD) (Smith et al., 1990; Suehiro et al., 2000; Lishko et al., 2002; Yakubenko et al., 2002; Podolnikova et al., 2003; Ugarova et al., 2003; Lilja and Ivaska, 2018). The important role of integrins in the regulation of extracellular matrix and synaptic activity is well-established (Wu and Reddy, 2012; Park and Goda, 2016; Lilja and Ivaska, 2018). It is conceivable that fibrinogen chains Aα and γ can play modulatory roles through their interaction with various integrins in neuronal activity and other processes. Longer fibrinogen-related domain (Doolittle et al., 2012) of fibrinogen chain Bβ and fibrinogen chain γ also interacts with TLR-4 (Zuliani-Alvarez et al., 2017) potentially playing important roles in innate immunity and inflammation (Trotta et al., 2014). Fibrinogen chain Aα also interacts with fibronectin and TGF-β playing roles in the neuroinflammation (Engvall et al., 1978; Schachtrup et al., 2010; Webster et al., 2017). Fibrinogen chain Bβ can interact with VE-cadherin and β-amyloid (Yakovlev and Medved, 2009; Ahn et al., 2010). Fibrinogen chain γ is capable of interaction with ICAM-1 (Altieri et al., 1995). As our experiments demonstrated, fibrinogen chains differentially respond to biologically significant

[3]http://mouse.brain-map.org/gene/show/63741

and pro-inflammatory signals. It is conceivable that intrinsic fibrinogens chains play roles in the brain pathology and brain responses to various stimuli. Fibrin(ogen) itself is known to exert damaging effects on brain tissue (Ryu et al., 2009). However, the origin of separate fibrinogen chains could be different, extrinsic and intrinsic. It is conceivable that intrinsic fibrinogen chains can exert pleiotropic effects modulating various processes in norm and pathology.

CONCLUSION

Our data strongly suggest that neurons and astrocytes are capable of production of fibrinogen chains, which may be involved in various normal processes and brain pathology. Additional experiments are necessary to establish (a). whether cell/structure-specific fibrinogen chain genes knock-outs/knock-ins would have specific phenotype; (b) what physiological/behavioral effects fibrinogen chains alone would exercise being introduced directly into the brain; (c) to what extent they are capable to modify synaptic functions; (d) whether they play specific roles in various brain pathologies. The possibility that fibrinogen chains may have intrinsic to the brain origin open new intriguing venues for our understanding of established brain pathologies, including SAH.

CONTRIBUTION TO THE FIELD STATEMENT

Discovery of the expression of all fibrinogen chains by astrocytes and neurons in the brain *in vivo* and *vitro* suggests that fibrinogen observed in various neuropathological conditions can be of endogenous to the brain origin. Demonstration that the fibrinogen chains are differentially regulated by pro-inflammatory stimuli suggests that fibrinogen chains may play different role in brain functioning and brain response to the neuroinflammatory processes occurring during various neurological diseases. Traditionally it is thought that fibrinogen enters brain/subarachnoid space through damaged blood brain barrier. We demonstrate for the first time that mouse and human astrocytes and neurons express fibrinogen chains suggesting potential presence of endogenous to the brain fibrinogen chains differentially changing to biologically significant stimuli. SAH is followed by increased expression of fibrinogen chains associated with glia limitans remote from the hemorrhage. We conclude that brain astrocytes and neurons are capable of production of fibrinogen chains, which may be involved in various normal and pathological processes in the brain.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

AUTHOR CONTRIBUTIONS

EG, MS, and AR-G conceived, planned, and carried out the experiments, processed the data, and wrote the manuscript. GDZ conceived and planned the experiments, analyzed the data, and edited the manuscript. DB and GB planned the experiments, interpreted the data, and edited the manuscript.

Generation of Oligodendrocyte Progenitor Cells From Mouse Bone Marrow Cells

*Yuan Zhang[1†], Xin-Yu Lu[1†], Giacomo Casella[2†], Jing Tian[1†], Ze-Qing Ye[1], Ting Yang[1], Juan-Juan Han[1], Ling-Yu Jia[1], Abdolmohamad Rostami[2] and Xing Li[1]**

Oligodendrocyte progenitor cells (OPCs) are a subtype of glial cells responsible for myelin regeneration. Oligodendrocytes (OLGs) originate from OPCs and are the myelinating cells in the central nervous system (CNS). OLGs play an important role in the context of lesions in which myelin loss occurs. Even though many protocols for isolating OPCs have been published, their cellular yield remains a limit for clinical application. The protocol proposed here is novel and has practical value; in fact, OPCs can be generated from a source of autologous cells without gene manipulation. Our method represents a rapid, and high-efficiency differentiation protocol for generating mouse OLGs from bone marrow-derived cells using growth-factor defined media. With this protocol, it is possible to obtain mature OLGs in 7–8 weeks. Within 2–3 weeks from bone marrow (BM) isolation, after neurospheres formed, the cells differentiate into Nestin$^+$ Sox2$^+$ neural stem cells (NSCs), around 30 days. OPCs specific markers start to be expressed around day 38, followed by RIP$^+$O4$^+$ around day 42. CNPase$^+$ mature OLGs are finally obtained around 7–8 weeks. Further, bone marrow-derived OPCs exhibited therapeutic effect in shiverer (Shi) mice, promoting myelin regeneration and reducing the tremor. Here, we propose a method by which OLGs can be generated starting from BM cells and have similar abilities to subventricular zone (SVZ)-derived cells. This protocol significantly decreases the timing and costs of the OLGs differentiation within 2 months of culture.

INTRODUCTION

Oligodendrocyte progenitor cells (OPCs) are present in both the white and gray matter of the adult central nervous system (CNS); upon oligodendrocytes (OLGs) injury, OPCs contribute to OLGs regeneration and remyelination (Duncan et al., 2018). OPCs are characterized by expression of platelet-derived growth factor receptor alpha (PDGFRα), neural/glial antigen 2 (NG2), and A2B5 (Dietrich et al., 2002; Zhu et al., 2008; Sim et al., 2011); they represent a high proliferative cell population resident in the CNS of adult mammals and humans (Mekhail et al., 2012; Clemente et al., 2013). OLGs derived from OPCs and are the myelinating cells of the CNS. Once OPCs differentiate into mature OLGs, they extend multiple processes that individually ensheath axons and then proceed to generate the concentric layers of the

modified cell membrane that compose myelin (Goldman and Kuypers, 2015). Thanks to their remyelinating ability, several groups used OPCs transplantation as a therapeutic strategy for CNS diseases (Kim et al., 2012; Najm et al., 2013; Yang et al., 2013). Indeed, OPCs can be used as a safe treatment for spinal cord injury (Nori et al., 2018), stroke (Wang et al., 2018), Parkinson's disease (Ahmed et al., 2013), and cerebral palsy (Rumajogee et al., 2018).

The transplantation of exogenous OPCs can represent a suitable treatment for chronic demyelinating disorders (Czepiel et al., 2015). The most common methods for obtaining functional OPCs, use mouse embryonic stem cell (ESCs) or pluripotent stem cells (Li et al., 2013; Wang et al., 2013; Kuai et al., 2015; Manley et al., 2017), or reprogrammed fibroblasts expressing a defined set of transcription factors (TFs) (Najm et al., 2013; Yang et al., 2013; Yamashita et al., 2017). Even if, OPCs transplantation has shown promising result in rodents (Goldman and Kuypers, 2015), its application remains far from the clinic. Several barriers should be overcome such as, whether OPCs can successfully migrate to the lesion (Foster et al., 1995), or their reprogramming can induce aberrant phenotype with consequent side-effects, as reported in some study in which next-generation sequencing was used (Liu et al., 2019). Other well-reported approaches used SVZ, from rodent CNS, as a source for isolating functional OPCs (Dincman et al., 2012; Zhu et al., 2014; Lu et al., 2015); however, due to the low cellular yield these methods have not guaranteed any feasibility for clinical application (Yang et al., 2010). Recently, it has been demonstrated that OPCs can be generated from bone marrow (BM) (Cristofanilli et al., 2011). These bone marrow-derived OPCs, induced with specific growth factor media, have shown similar morphology and cellular markers to canonical OPCs (Nazm Bojnordi et al., 2015).

We describe here a detailed protocol for generating OPCs and mature OLGs from autologous mouse bone marrow-derived neural stem cells (NSCs). Our method consists of two main steps. The first step provides the differentiation and generation of neurospheres from bone marrow-derived NSCs; the second one consists of neurospheres-derived OPCs differentiation within 1 week, using specific media. Respect to a previous report (Douvaras and Fossati, 2015), our protocol enables to produce autologous OLGs in 52 days.

Obtaining a high number of autologous OLGs is relevant to the clinic. For addressing this aspect, we tested the myelination ability of our bone marrow-derived OPCs, in a genetic model of congenital dysmyelination, shiverer (Shi) mice. Bone marrow-derived OPCs induced remyelination and significantly reduced tremor in treated mice. According to our data, this protocol is suitable for producing in large scale autologous OPCs, research aimed at understanding oligodendrocyte biology, and finally, it may represent a screening platform for myelinating compounds.

MATERIALS AND METHODS

Animals

C57BL/6 (The Fourth Military Medical University), SJL, and C3H mouse strains (The Jackson laboratory) are all appropriate for this protocol. Mice were kept in clean cages with a maximum of 5 mice per cage, in a controlled environment with 12/12 h of light/dark cycles and food *ad libitum* throughout the experimental procedures. All experimental procedures and protocols are approved by the Animal Management and Committee of Shaanxi Normal University. At the same time, by the approved institutional guidelines and regulations.

BM-NSCs were given by injection of single cells suspension (2×10^5 cells in 20 μl PBS/each mouse) by intracerebroventricular (i.c.v.) injection, into 1 week-old Shi mice. PBS-treated age-sex- and strain-matched mice were used as controls. All groups of animals were observed for 35 days.

Preparation of Neural Stem Cell Proliferation Media (NSC-PM)

A total of 200 ml of NSC-PM media is prepared mixing 150 ml of DMEM/F12 with 4 ml of B27, 2 ml of Penicillin-streptomycin (50 U/ml), 2 ml of Non-essential amino acid solution (0.1 mM), 2 ml HEPES (10 mM), 2 ml of sodium pyruvate (1 mM; all purchased from Thermo Fisher Scientific), 40 μl of epidermal growth factor (EGF, 20 ng/ml, stock concentration: 100 μg/ml; PeproTech), and 40 μl of basic fibroblast growth factor (bFGF, 10 ng/ml, stock concentration: 50 μg/ml; PeproTech). DMEM/F12 is added to a final volume of 200 ml, filter with a bottle-top filter (0.22 μm) and store at 4°C. We suggest to use complete media within 2 weeks.

Preparation of OPC Proliferation Media (OPC-PM)

A total of 50 ml of OPC-PM is prepared mixing 30 ml of DMEM/F12 with 1 ml of B27, 0.5 ml of N2, 0.5 ml of GlutaMax (2 mM), 0.5 ml of Penicillin-streptomycin (50 U/ml), 0.5 ml of Non-essential amino acid solution (0.1 mM), 0.5 ml of sodium pyruvate (1 mM; all purchased from Thermo Fisher Scientific), 10 μl of platelet-derived growth factor-AA (PDGF-AA, 20 ng/ml, stock concentration: 100 μg/ml; PeproTech), and 20 μl of bFGF (20 ng/ml, stock concentration: 50 μg/ml; PeproTech). DMEM/F12 is added to a final volume of 50 ml, filter with a bottle-top filter (0.22 μm) and store at 4°C. We suggest to use complete media within 2 weeks.

Preparation of Early OLGs Differentiation Media (EOLG-DM)

A total of 25 ml of EOLG-DM is prepared mixing 15 ml of DMEM/F12 with 0.5 ml of B27, 0.25 ml of N2, 0.25 ml of GlutaMax (2 mM), 0.25 ml of Penicillin-streptomycin (50 U/ml), 0.25 ml of Non-essential amino acid solution (0.1 mM), 0.25 ml of sodium pyruvate (1 mM; all purchased from Thermo Fisher Scientific), 50 μl of triiodo-l-thyronine (T3, 40 ng/ml, stock concentration: 20 μg/ml; Sigma-Aldrich), 20 μl of sonic hedgehog (Shh) (40 ng/ml stock, concentration: 50 μg/ml), 20 μl of Noggin (40 ng/ml, stock concentration: 50 μg/ml), 5 μl of insulin-like growth factor (IGF, 100 ng/ml, stock concentration: 500 μg/ml; all purchased from PeproTech), and 25 μl of neurotrophin 3 (NT-3, 10 ng/ml; Sigma-Aldrich). DMEM/F12 is added to a final volume of 25 ml, filter with a bottle-top

filter (0.22 μm) and store at 4°C. We suggest to use complete media within 1 week.

Preparation of Late OLGs Differentiation Media (LOLG-DM)

A total of 10 ml of LOLG-DM is prepared mixing 10 ml of EOLG-DM with 5 μl of 3′,5′-cyclic adenosine monophosphate (cAMP, 50 μM, stock concentration: 50 μg/ml; Sigma-Aldrich). The fresh media should be using within 1 week. For preparing Poly-D-lysine coating solution, stock at 0.1 % (wt/vol) 50 mL of sterile tissue culture grade water to 5 mg of poly-D-lysine (Sigma-Aldrich). Poly-D-lysine solution can be stored at 4°C for 3 months. Coating culture plates with the poly-D-lysine coating solution (0.5 ml per well for 24 well plate) and keep them for 2 h in 37°C incubator or overnight at 4°C. Remove coating solution and wash three times with sterile ddH_2O. After poly-D-lysine coated, add 1 μg/ml laminin (Sigma-Aldrich) solution for 2 h in 37°C incubator or overnight at 4°C. Laminin should be slowly thawed at 2–8°C for avoiding any solidification process. Dilute in a balanced salt solution and coat culture surface with a minimal volume. Remove coating solution, wash three times with sterile ddH_2O and dry completely in a tissue culture hood. Allow to air dry at least 5 min before introducing cells and media. Poly-D-lysine and laminin-coated coverslips: Place sterilized coverslips into the wells of a 24 well plate. The procedure followed the Poly-D-lysine coating and Laminin coating. The coverslips will float on the surface of the solution. Make sure the coverslips are completely immersed in the coating buffer to ensure the coverslips are well coated.

Isolation and Culture of NSCs From Murine SVZ and Bone Marrow

SVZ-derived NSCs were isolated from adult C57BL/6 mice as described previously with minor modification (Yang et al., 2009). Briefly, C57BL/6 mice 8 weeks old were euthanized and the SVZ region was harvested under sterile conditions and placed in DMEM media. After a brief washing with DMEM media, tissues were cut into 1 mm^3 pieces and digested by neural tissue dissociation kits (Miltenyi Biotec). The cells were suspended in serum-free DMEM/F12 (Invitrogen) supplied with 2% B27 supplements (Invitrogen), 20 ng/ml EGF (Peprotech) and 10 ng/ml bFGF (Peprotech), along with 100 IU/ml penicillin and 100 μg/ml Streptomycin (Sigma).

Bone marrow cells were isolated according to a previously described protocol (Swamydas and Lionakis, 2013). Finally, the cells were suspended in NSC-PM media at 10^6 cells/ml, and plated on poly-D-lysine, and laminin coated 24 well plate for 4 days. We suggest to replace half of the media with fresh NSC-PM media every 4 days. The media should be changed softly and slowly to avoid lifting the adhered NSCs (This is the critical step).

The formation of cellular clusters that resemble neurospheres becomes evident after 10–14 days. For cell detachment, aspirate the media, add 500 μl accutase (Thermo Fisher Scientific), and incubate at room temperature (22–25°C) for 2 min. Use 200 μl pipette to carefully suspend the adhered cell and transfer to a 15 ml conical tube. Shake the tube 10 times/min for total 3 min and add 4.5 ml DPBS for centrifuge (300 × *g*, 10 min). Next, suspend the cell pellet in NSC-PM media at 1×10^5 cells/ml, and plate the cell in non-coated 6 cm plate. After 4 days, the neurospheres can observe under the microscope. Collect suspended neurospheres from culture dish and transfer to a 15 ml conical tube. Centrifuge the cell at 100 × *g* for 1 min. Gently aspirate media leaving the neurospheres at the bottom of tube. Resuspend neurospheres in 5 ml DPBS and centrifuge the cell at 100 × g for 1 min to remove the media residues. Gently aspirate media leaving the neurospheres at the bottom of tube and add 1 ml of accutase to the cell culture and incubate 5 min at room temperature. Mildly shake the tube 10 times/min. If any neurosphere remains visible, after 4 min accutase incubation, we suggest to pipette gentle up and down until all the visible neurospheres are in a single cell suspension. The accutase media will change the color from carnation to oyster white. Then, add 4 ml of fresh media to the tube and centrifuge the cells at 200 × *g* for 4 min. Gently aspirate the supernatant and resuspend cells in fresh media. Transfer the cell 1×10^5 cells/ml to a new culture dish and incubate at 37°C for NSCs expanded. Cells can be frozen at this step. For visualization of results, seed the cell at 1×10^5 cells/ml in a poly-D-lysine and laminin coated 24 well plate with coverslips. Cells were fixed using 4% paraformaldehyde for immunocytochemical staining.

Bone Marrow-Derived NSCs Differentiation and Proliferation

To test the proliferation capacity of bone marrow-derived NSCs, growth curve of bone marrow-derived NSCs was determined followed previous method (Yang et al., 2010). Briefly, the newly formed neurospheres were digested to the single cells and plated at a density of 1.0×10^5 cell/ml and cultured in NSC-PM. At days 6, 11, 16 and 21, neurospheres in each well were digested into single cells; cell numbers were counted by hemocytometer. SVZ derived NSCs were used in the parallel experiment to compare the proliferate ratio.

To evaluate the differentiation ability of bone marrow-derived NSCs, single cells were plated on poly-D-lysine/laminin coated coverslip at a density of 1.0×10^4 cells/ml and cultured in specific NSCs differentiation media (Li et al., 2016). In brief, for neuron differentiation, Neurobasal media was supplemented with 2% B27, 2 mM GlutaMax-I and 0.5 mM cAMP. For astrocyte differentiation, DMEM was supplemented with 1% N2, 2 mM GlutaMax-I and 1% FBS. The oligodendrocyte differentiation media requires Neurobasal media supplemented with 2% B27, 2 mM GlutaMax-I and 20 ng/ml T3. Over 2 weeks, NSCs in differentiation media changed morphology and developed markers of neurons, astrocytes, and OLGs as determined by immunocytochemistry staining. To determine the number of cells expressing a specific antigen, five areas of each coverslip were examined, and the percentage of positive cells labeled for a specific neural marker in the total number of $DAPI^+$ cells was expressed as the mean value of specific neural differentiation.

OPCs Differentiation

Once neurospheres reach 100–250 μm of diameter, dissociate the neurospheres with accutase. Start by stepping suspend the cell pellet in NSC-PM media at 1×10^5 cells/ml until transfer the cell 1×10^5 cells/ml to a new culture dish and incubate at 37°C for NSCs expanded to the end. Finally, The cells are seeded on the poly-D-lysine, and laminin coated plate at 5×10^3 cells/ml in the NSC-PM media. After 1–2 days, over 90% cells will be adhered to the bottom, change the media to OPC-PM. Incubate the plate in a 37°C, 5% CO_2 incubator and perform media changes every 2 days for 8 days. Cells can be frozen at this step.

OLGs Maturation

At day 9, aspirate the OPC-PM media, gently rinse with DPBS to remove the growth factor (i.e., PDGF-AA and bFGF), and add fresh EOLG-DM (500 μl/well/24 well plate) for inducing differentiation of OLGs. OPCs will proliferate few times. If the cells reach 90% confluency, it might be necessary to split the cells at a 1:4–6 ratio. After 4 days, the media is changed to LOLG-DM. Adding cAMP will accelerate the branch outgrowth for OLGs differentiation. Repeat these steps for 3 times, after 2 weeks.

Immunofluorescence Staining

For immunocytochemistry, cells were fixed in 4% paraformaldehyde at room temperature for 30 min. Then, incubate with 0.3% TritonX-100 (in PBS) for 15 min at room temperature and wash with PBS. The primary antibody is diluted to a suitable concentration with a blocking solution (10% horse serum in PBS). The following primary antibodies were used: anti-A2B5 (MA1-90445, Thermo Fisher Scientific), anti-CNPase (ab44289, Abcam), anti-Ki67 (ab15580, Abcam), anti-Nestin (MAB353, Milipore), anti-NG2 (MAB5384, Milipore), anti-O4 (NL1326V, R&D), anti-RIP (ab72139, Abcam), and anti-SOX2 (ab97959, Abcam). Primary antibodies were washed out with PBS three times after overnight incubation at 4°C. The corresponding Alexa Fluor 488/594 conjugated secondary antibodies (both from Jackson ImmunoResearch Laboratories) were used for 2 h at room temperature. After wash, the ProLong™ Gold Antifade Mountant with DAPI buffer (P36931, Thermo Fisher Scientific) were used for mounting slides. Results were visualized by fluorescent microscopy (Nikon Eclipse E600; Nikon, Melville, NY, United States). Quantitative image analysis was performed using ImagePro (Media Cybernetics).

Bone Marrow NSC-Derived OPCs Transplantation Into Shi Mice

Newborn double-homozygous Shi (Mbp^{Shi}/Mbp^{Shi}) mice (The Jackson Laboratory, Bar Harbor, ME, United States) were injected with dissociated single OPCs. The protocol followed previous work with minor modifications (Zhang et al., 2019). Briefly, to generate the lentivirus expression of mCherry protein, the backbone of pCDH-CMV-MCS-EF1-copGFP (System Biosciences) was used. Subsequently, the copGFP was replaced by mCherry and puromycin was inserted into the multiple clone sites. The positive plasmid was confirmed by sequencing and using for lentivirus packaging. OPCs were transfected with lentiviral expressed mcherry, and positive cells were selected by puromycin. Then, mcherry $OPCs^+$ were transplanted bilaterally in the corpus callosum of 1 week-old Shi mice (2.0×10^5 cell/mice). PBS-treated age-sex-, strain-matched mice, and sham control mice were used. After 5 weeks from the treatment, mice were anesthetized, and brains were isolated and fixed with 4% paraformaldehyde and cryoprotected using 30% sucrose. CNS coronal sections were stained with myelin basic protein (MBP) antibody (ab40390, Abcam) for evaluating the differentiation process of mcherry $OPCs^+$. Tremor (Trembling time/total time) was analyzed for evaluating disease development. Kaplan-Meier analysis was used to assess the survival rate as described (Shinkai et al., 1992).

Statistical Analysis

Statistical analyses were performed using GraphPad Prism software (GraphPad, La Jolla, CA, United States). Data are presented as mean ± SD. Experiments with 2 groups were tested for statistical significance using unpaired, 2-tailed Student's *t*-tests. When comparing two groups at different time points, data were analyzed by two-way analysis of variance (ANOVA) with Tukey's multiple comparisons test. Comparisons between two groups were carried out with Student's *t*-test. Values of $p < 0.05$ were considered significant.

RESULTS

Timeline of Bone Marrow-Derived Mature Oligodendrocyte Differentiation

The timeline of our protocol is shown in **Figure 1**. In the first step, NSCs are differentiated from BM cells. After BM isolation, the cells are seeded at high density (5×10^5 cell per cm^2) on poly-D-lysine/laminin coated 24-well plate. *In vitro*, the presence EGF and fibroblast growth factor-2 (FGF2) mimic the NSCs culture environment, inducing NSCs proliferation. In the second stage, NSCs are induced to become OPCs. Here, the adherent cultures are dissociated to form spheres in suspension. Although $Sox2^+Nestin^+$ cells can also form spheres, the presence of recombinant protein PDGFα will gradually enrich the $NG2^+A2B5^+$ cell population (Neri et al., 2010). The final stage is the transition from OPCs to mature OLGs, by exposing the cells to T3, NT-3, Noggin, Shh, and IGF (Najm et al., 2013; Douvaras and Fossati, 2015).

Neurosphere Differentiation Step

For NSCs generation, BM from autologous adult mice can efficiency generate neurospheres. During neurosphere differentiation step, we are usually able to observe three stages (**Figure 2A**). (1) After 1 week in culture, individual cells exhibit high proliferative ability. (2) Two weeks later cells form neurospheres. (3) At 3–4 weeks, the neurospheres increased in size and gradually detached from the bottom of the culture plate. To characterize the bone marrow-derived NSCs, we compared the proliferative capacity with the SVZ-derived NSCs. We collected the neurosphere, dissociated, and re-plated at

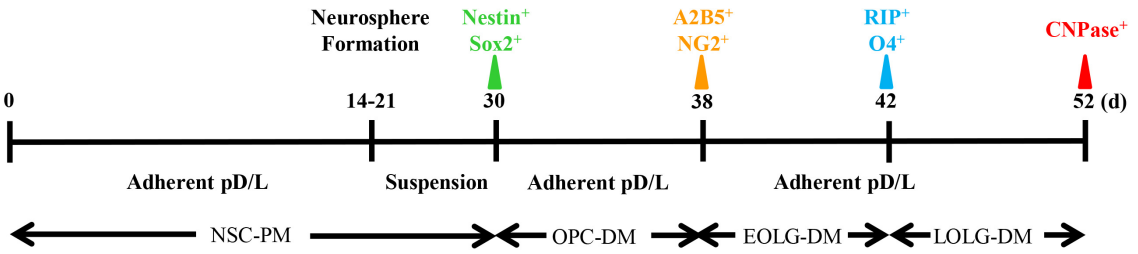

FIGURE 1 | Timeline of oligodendrocyte differentiation. Multicolor triangles represent recommended time points for evaluating the expression of stage-specific markers through immunofluorescence.

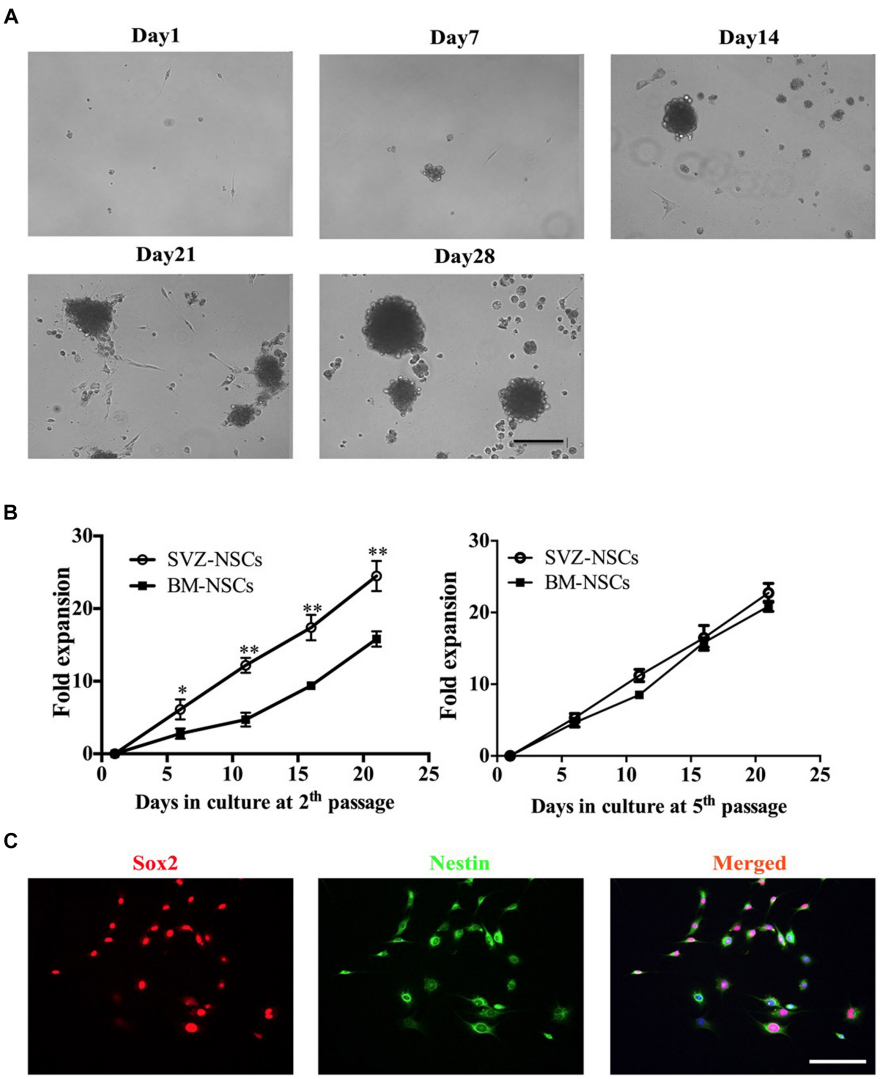

FIGURE 2 | Generation of bone marrow-derived NSCs *in vitro*. BM-NSCs were isolated and expanded from bone marrow of adult C57BL/6 mice and cultured in DMEM/F12 containing 20 ng/ml EGF, 20 ng/ml Bfgf, and 2% B27 supplements. **(A)** Single cells were seeded in poly-D-lysine- and laminin-coated plates. After 7 days, the cells showed obvious proliferation. After 14 days, the NSCs gradually formed neurospheres. After 21–28 days, neurospheres increased size, and detached from the bottom of the culture plate. **(B)** Growth curves of BM-NSCs and SVZ-NSCs. Single cells at the second and fifth passages were seeded at a density of 1.0×10^5 cells/ml and cultured in proliferation media. At days 6, 11, 16 and 21, neurospheres in each well were digested into single cells; cell numbers were counted by hemocytometer. At least 5 wells were evaluated at each time point. Data represent the mean ± SD from three repeated experiments from separately generated cultures, $^*p < 0.05$, $^{**}p < 0.01$, as determined by two-way ANOVA with Tukey's multiple comparison test. **(C)** Neurospheres dissociated with accutase and plated in the coated coverslips were immunostained for NSC markers Sox2 and Nestin. Scale bar = 50 μm.

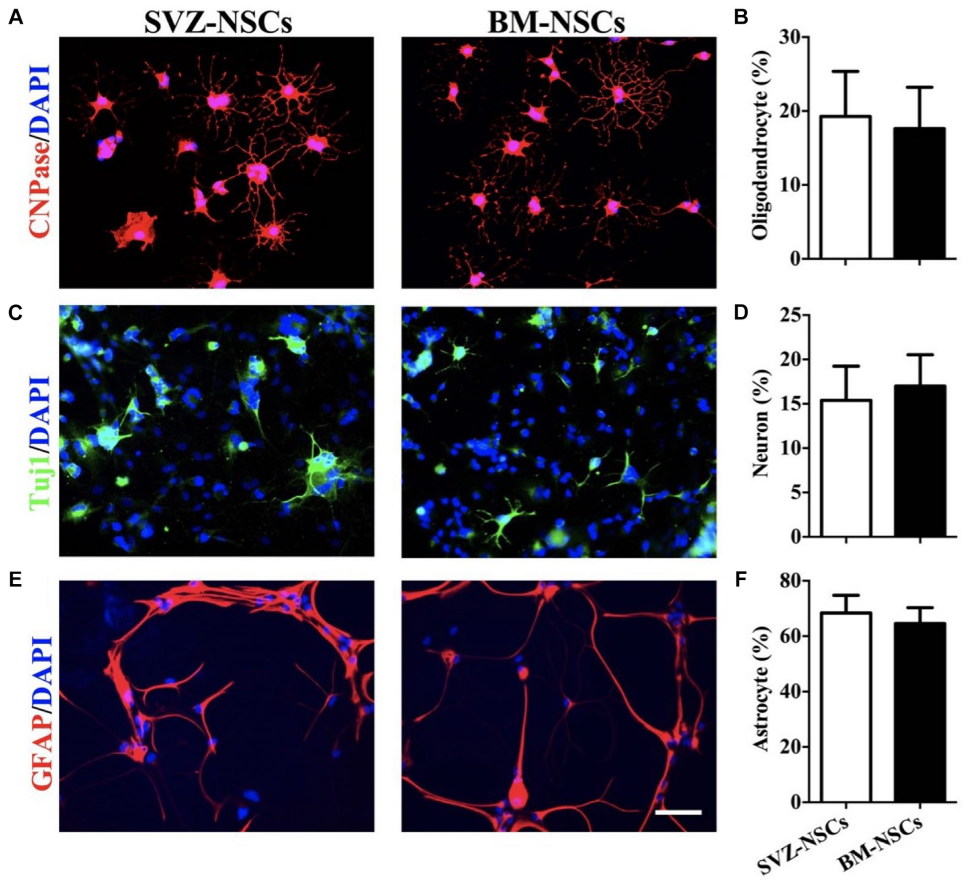

FIGURE 3 | BM-NSCs differentiation *in vitro*. Examples of NSCs that differentiated into **(A)** OLGs (CNPase$^+$), **(C)** neuron (Tuj1$^+$), and **(E)** astrocytes (GFAP$^+$), after 1 week with specific differentiation media. Scale bar = 50 μm. **(B,D,F)** Quantitative analysis of differentiated cells. Data are shown as mean values ± SD (n = 5 each group) and are representative of three experiments. Significance difference was analyzed by Student's t-test.

1.0×10^5 cell/ml for a next round cell expansion. We next compared the proliferation capacity of bone marrow- and SVZ-NSCs. BM and SVZ-NSCs from passages 2 and 5 were seeded and cultured in NSC-PM. At day 6, 11, 16, and 21, the neurospheres formed and re-dissociated to single cells, and the cell number were counted by hemocytometer. The proliferation rate of BM-NSCs was significantly slower than SVZ-NSC at the early stage, whereas there was no obviously difference in proliferation capacity at passage 5 (**Figure 2B**). To identify the BM-NSCs, single cells were transferred onto poly-D-lysine and laminin pre-coated coverslips and used for immunostaining with Sox2 and Nestin. We can observe over 95% cells are Sox2 and Nestin-positive cells at passage 5 (**Figure 2C**).

Differentiation Potential of BM-NSCs

To test the differentiation potential of BM-NSCs *in vitro*, neurospheres were used and cultured in specific neuron/astrocyte/oligodendrocyte differentiation media. After 2 weeks, BM-NSCs, plated in presence of differentiation media, changed morphology and developed markers of neuron, astrocytes, and OLGs, as shown by immunocytochemistry staining. We compared the differentiation capacity of BM-NSCs and SVZ-NSCs. There are no significant difference about the percentage of CNPase$^+$, Tuj1$^+$, and GFAP$^+$ cells between BM-NSCs and SVZ-NSCs. These results indicated that BM-NSCs can differentiate into neural cell lineages (**Figure 3**).

OPCs Differentiation and Oligodendrocyte Maturation Process

To assess whether the enrichment of OPCs obtained by differentiation media could be exploited for increasing the yield of mature OLGs, OPCs grown in EOLG-DM media for 4 days were shift to LOLG-DM media for additional 10 days. Cells grown for 14 days in OPC-PM media were used as control. Cells were then analyzed for the presence of A2B5$^+$, NG2$^+$, RIP$^+$, O4$^+$, and CNPase$^+$ cells. For OPCs differentiation, single NSCs were seed on poly-D-lysine, and laminin coated plates or coverslips in the OPCs differentiation media. Cells exhibited strong proliferation ability and grew faster under the proliferation condition (**Figure 4A**). These OPCs expressed A2B5 and NG2, as shown by immunostaining (**Figures 4B,C**). Moreover, OPC-spheres can be cultured with OPCs media without differentiation.

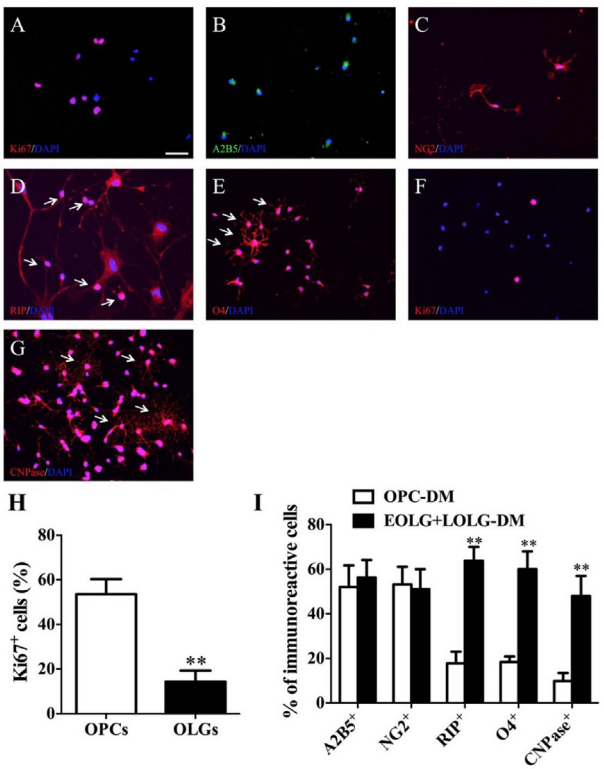

FIGURE 4 | Fundamental steps of BM-NSCs OLGs differentiation. **(A)** Expression of Ki-67 at day 38, as shown by immunofluorescence analysis. **(B,C)** Immunofluorescence staining of progenitor cells at day 38, expressing A2B5, and NG2. **(D,E)** RIP and O4 staining show cells ramified morphology. **(F)** Expression of Ki-67 which in late stage of OLGs differentiation (day 52). **(G)** At the end of differentiation stage, CNPase$^+$ OLGs show typical ramified morphology. **(H)** OPCs and OLGs proliferation **(A,F)** was quantified as percentage of Ki67-positive cells. Scale bar = 50 μm. **(I)** The percentages of A2B5$^+$, NG2$^+$, RIP$^+$, O4$^+$, and CNPase$^+$ cells are present in EOLG+LOLG-DM cultures as compared to OPC-PM cultures. Data are expressed as the mean ± SD, three independent experiments, $^{**}p < 0.01$, Student's *t*-test.

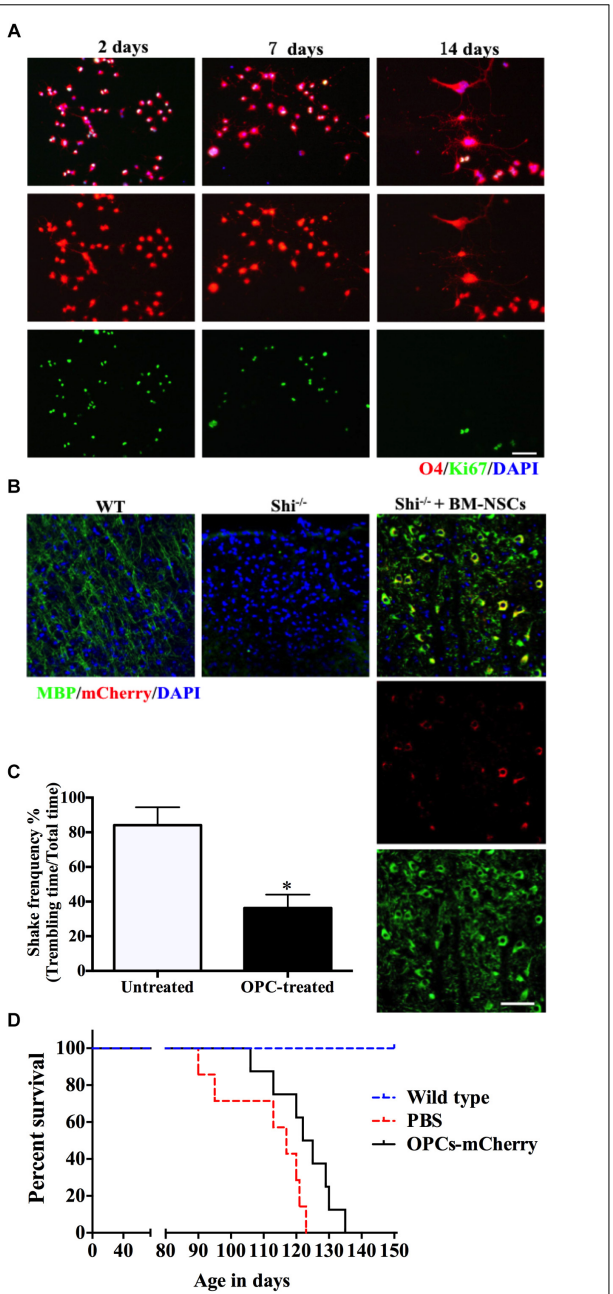

FIGURE 5 | BM-NSCs OLGs differentiation *in vitro* and transplantation in Shi mice. **(A)** BM-NSCs were cultured in oligodendrocyte differentiation media for 48 h, 1 week, and 2 weeks for O4 (differentiation marker) and Ki-67 (proliferation marker) staining. **(B)** Fluorescence staining of BM-NSCs (mCherry$^+$ cells), after 35 days post injection, show myelination (MBP$^+$) in the contralateral striatum. Scale bar = 50 μm. **(C)** Quantification of tremor of Shi mice treated with OPCs. **(D)** Transplanted OPCs prolong the survival of Shi mice compared with PBS-treated ($n = 9$). Symbols represent mean ± SD. $^*p < 0.05$, Student's *t*-test.

They can further form immature OLGs (e.g., RIP$^+$ and O4$^+$) when are grown in OLGs differentiation media for 1 week (**Figures 4D,E**).

For OLGs maturation, OPCs were grown in presence of oligodendrocyte differentiation media. Cells gradually stopped to proliferate (Ki67$^+$) (**Figures 4F,H**) and started to differentiate into mature OLGs (CNPase$^+$). About 50 % of the CNPase$^+$ OLGs exhibited complex membrane morphology indicating OPCs differentiation into mature OLGs successfully (**Figures 4G,I**).

OPCs and Mature OLGs Generation From Autologous Mouse Bone Marrow-Derived NSCs

Our method allows to isolate OPCs, using a selective detachment procedure, generate mature OLGs *in vitro* (**Figure 5A**), and induce remyelination after transplantation into the dysmyelinated Shi mice (**Figure 5B**). Although immunofluorescence analysis showed abundant MBP$^+$mCherry$^+$ cells, the transplanted cells were more like "non-completedly myelinating" cells. We hypothesized that these cells would become mature at later time points and

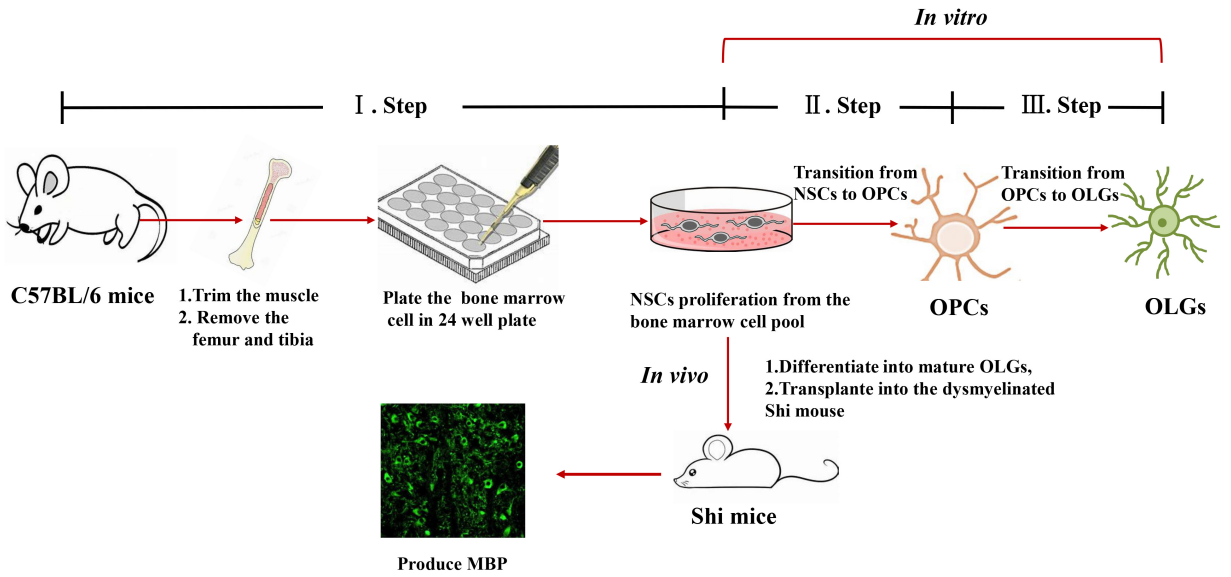

FIGURE 6 | Representative scheme of the protocol for generating OPCs and OLGs from autologous mouse bone marrow-derived NSCs.

express more MBP$^+$ myelin internodes. To define whether our BM-NSCs had the potential to form functional OLGs *in vivo*, the tremor and survival rate were test in the subsequent experiment. After OPCs transplantation, the tremor was significantly decreased compared the untreated Shi mice (**Figure 5C** and **Supplementary Videos 1, 2**). As shown in **Figure 5D**, the survival rate of mice transplanted with OPCs was increased, with a range of 106–135 days. All PBS-treated Shi mice died, over a range of 90–125 days postnatally. These results indicated that BM-OPCs could successfully differentiate into functionally OLGs, induce remyelination, and increase survival rate in Shi mice. The experimental design overview for this protocol is shown in **Figure 6**.

DISCUSSION

Oligodendrocyte progenitor cells can be isolated from the SVZ of adult mammalian and expanded *in vitro* for producing mature OLGs (Chen et al., 2007). However, with this method, a little number of mature OLGs can be obtained. Recent studies showed that it is possible to differentiate OPCs from BM cells (Yang et al., 2010; Nazm Bojnordi et al., 2015). Indeed, bone marrow-derived OPCs showed distinct neural cell markers and morphology (Abbaszadeh et al., 2013). The possibility to get a high number of mature OLGs, starting from bone marrow, represents an accessible, and alternative manner respect to canonical methods in which OPCs are generated from SVZ-derived cells. OPCs transplantation either intravenous (i.v.) or i.c.v. has shown to promote remyelination *in vivo* (Sher et al., 2012; Wu et al., 2012); thus its therapeutic potential is relevant for demyelination disorders.

Currently, there are several methods for obtaining functional OLGs (Garcia-Leon and Verfaillie, 2016). Nazm Bojnordi et al. (2015) used BM stromal cells for producing functional Olig2 and O4$^+$ cells. These OPCs successfully promoted the remyelination, in LPS-induced demyelination model; however, the efficiency was unclear. Further, OPCs isolation from ESCs or induced pluripotent stem cells (iPSCs), is an effective way for repairing and preventing the progression of demyelinating lesions (Douvaras et al., 2014; Thiruvalluvan et al., 2016). However, ESCs-derived OPCs may lack of stability and safety. It has been shown that NSCs possess less risk of potential tumorigenicity than ESCs or iPSCs (Zhao et al., 2015). The generation of OPCs from BM is consistent with what demonstrated so far (Yang et al., 2010; Hojjat-Allah et al., 2013; Nazm Bojnordi et al., 2015). Our method mainly consists of three steps, bone marrow-derived NSCs generation, NSCs-OPCs differentiation, and OLGs maturation. These data also focused on the derivation of OLGs from OPCs using assorted agents. In all of these steps, we use conditioned-media containing essential growth factors such as T3, Shh, IGF, and NT-3. We, also, use Noggin for negatively regulating bone morphogenetic protein (BMP) pathway, which blocked oligodendrocyte maturation (Najm et al., 2013). Although this protocol does not significantly improve the differentiation efficiency, compared with previous work, the timing is shorter (from 75 to 95 and 52 days) (Chen et al., 2007; Douvaras and Fossati, 2015). Our findings provide an alternative, fast strategy for obtaining functional OLGs from BM cells after just 40–50 days of differentiation. Here, we use the congenital dysmyelination model of Shi mice to show that BM-OPCs improved the mice survival. Our protocol can generate OPCs from BM-NSCs providing sufficient cell sources from autologous and inducing remyelination.

One generally OPCs generating strategies is that the cell need transduction of several TFs by lentiviral (Han et al., 2012; Najm et al., 2013). Virus-mediated gene delivery required higher biosafety levels and still need to be considered for

clinical application (Capetian et al., 2016). In our protocol, we choose a well-established, and effective custom differentiation media system (Najm et al., 2013; Baskin et al., 2016). These differentiation media contain several growth factors (EGF, FGF, PDGF, Shh, Noggin, IGF, and NT-3) which used in different proliferation or differentiation stage were sufficient for inducing cell differentiation into mature OLGs. The manner of using growth factor is safer than viral or small molecules to treat cell or neurodegeneration disease (Tuszynski et al., 2015; De et al., 2017). The specificity of growth factors to recognize its target is better than small molecules especially in high dose (such as concentration > 10 μM) (Weiss et al., 2007). Also, when withdrawing the growth factors such as FGF, EGF et al., cell will cease to proliferate and avoid the risk of formation tumor cell. In a previous report, T3 was used as an inducer to differentiate into oligodendrocyte-like cells using autologous BM stromal cells (Kaka et al., 2012; Hojjat-Allah et al., 2013). Compared with their researches, we have demonstrated that mouse OLGs can be produced from bone marrow-derived cells *in vitro*, indicating that our method is more reliable. Together, this protocol indicates that our bone marrow-derived OPCs represent a simple, safe, valuable and promising cell-based therapy strategy for myelin repair and neurodegeneration disease.

ETHICS STATEMENT

All experimental procedures and protocols are approved by the Animal Management and Committee of Shaanxi Normal University. At the same time, in accordance with the approved institutional guidelines and regulations.

AUTHOR CONTRIBUTIONS

YZ and XL conceived and designed the experiments. YZ, X-YL, JT, J-JH, and Z-QY carried out the experiments. TY, L-YJ, and XL analyzed the data. YZ, X-YL, GC, JT, and XL wrote the manuscript. AR and XL supervised the study and revised the manuscript. All authors read and approved the final manuscript.

FUNDING

This study was supported by the Chinese National Natural Science Foundation (Grant Nos. 81771345 and 81501062), the Natural Science Foundation of Shaanxi Province, China (Grant Nos. 2018JZ3001, 2018JQ8033, and 2017043) and the Fundamental Research Funds for the Central Universities (Grant Nos. GK201903062, GK20182010, GK201701009, 2018CSLZ018, 2018CSLZ019, and 2018CSLZ020).

Canine Cognitive Dysfunction and Alzheimer's Disease – Two Facets of the Same Disease?

Sonja Prpar Mihevc[1] *and Gregor Majdič*[1,2]*

[1] Veterinary Faculty, Institute for Preclinical Sciences, University of Ljubljana, Ljubljana, Slovenia, [2] Medical Faculty, Institute for Physiology, University of Maribor, Maribor, Slovenia

Neurodegenerative diseases present a major and increasing burden in the societies worldwide. With aging populations, the prevalence of neurodegenerative diseases is increasing, yet there are no effective cures and very few treatment options are available. Alzheimer's disease is one of the most prevalent neurodegenerative conditions and although the pathology is well studied, the pathogenesis of this debilitating illness is still poorly understood. This is, among other reasons, also due to the lack of good animal models as laboratory rodents do not develop spontaneous neurodegenerative diseases and human Alzheimer's disease is only partially mimicked by transgenic rodent models. On the other hand, older dogs commonly develop canine cognitive dysfunction, a disease that is similar to Alzheimer's disease in many aspects. Dogs show cognitive deficits that could be paralleled to human symptoms such as disorientation, memory loss, changes in behavior, and in their brains, beta amyloid plaques are commonly detected both in extracellular space as senile plaques and around the blood vessels. Dogs could be therefore potentially a very good model for studying pathological process and novel treatment options for Alzheimer's disease. In the present article, we will review the current knowledge about the pathogenesis of canine cognitive dysfunction, its similarities and dissimilarities with Alzheimer's disease, and developments of novel treatments for these two diseases with a focus on canine cognitive dysfunction.

Keywords: brain, neurodegeneration, canine cognitive dysfunction, Alzheimer's disease, amyloid beta, TAU, animal model, treatment

INTRODUCTION

Neurodegenerative diseases such as Alzheimer's disease (AD), Parkinson's disease, Huntington's disease, frontotemporal dementia, amyotrophic lateral sclerosis, and others are a major growing public health problem associated with aging, as aging is the greatest risk factor for neurodegeneration. The global number of people living with dementia more than doubled from 1990 to 2016 (GBD 2016 Dementia Collaborators, 2019). These diseases now affect nearly 50 million individuals, and the incidence is projected to triple by 2050. AD and other dementias are associated with alterations in cell type-specific function, including gliosis, neuronal dysfunction and cell death. The pathognomic cause is the condensation of certain proteins into insoluble aggregates and this aggregates damage vulnerable neurons and glial cells. These inclusions of misfolded proteins build up in the brain during normal aging and during the progression of adult-onset dementias.

Neurodegenerative diseases do not occur spontaneously in laboratory mice and rats, but do occur in several other mammalian species. Studies of neurodegenerative diseases in animals

have shown strong similarities between cognitive dysfunction in dogs and human AD and between AD in humans and most other primates (Cummings et al., 1993; Cummings and Cotman, 1995; Dodart et al., 2002; Chambers et al., 2011; Braidy et al., 2015; Schütt et al., 2016). Canine cognitive dysfunction (CCD), also known as canine cognitive dysfunction syndrome (CDS) or canine dementia affects up to 60% of older dogs, mostly dogs older than 11 years (Fast et al., 2013b). The prevalence of CCD does not differ between breeds (Salvin et al., 2010) and there are no breed specific differences in clinical signs or pathology of the disease. However, as larger dog breeds have shorter life span than the smaller ones (Greer et al., 2007), clinical signs of CCD are more often observed and reported in smaller dogs (Vite and Head, 2014; Schmidt et al., 2015). Due to its similarity with AD, CCD is extremely interesting as a model for human disease. CCD is also a major problem for health of older dogs, and is thus also interesting from the point of view of the development of new veterinary diagnostic procedures/markers and medicines for treating this disease in dogs.

In dogs and humans, dementia often affects cerebral gyri (cerebral atrophy) and shows as widening of sulci together with ventricular enlargement (Borràs et al., 1999; Toepper, 2017). Neuronal loss and cortical atrophy has been described in several brain regions including cortex, hippocampus and parts of the limbic system in cognitively impaired dogs (Tapp et al., 2004; Siwak-Tapp et al., 2008), similarly to human brain affected by AD (West et al., 2000). In human patients, AD has a preclinical stage with the clinical symptoms not yet evident but with pathological changes in the brain already present, which is followed by mild cognitive impairment stage which gradually culminates in dementia due to AD, with severe cognitive and functional decline (Bature et al., 2017). The onset of AD, detected clinically at the mild cognitive impairment stage, is characterized by a subtle decline in memory functions, followed by changes in personality, deterioration of language functions and eventually motor dysfunction (Braak and Braak, 1997). These deficits in cognition and behavior are mirrored in the AD-related regional brain destruction. Similarly to these signs in humans, the most obvious signs of CCD, deduced by standard cognition tests, are loss of memory, poor or completely lost sense of orientation, changes in behavior and confusion (Bain et al., 2001). Most common symptoms include disorientation, anxiousness, dogs get easily scared, do not recognize their owner, become aggressive or apathetic, have difficulty controlling the secretion of body fluids, change circadian rhythms and others.

NEUROPATHOLOGICAL FEATURES OF NEURODEGENERATIVE DISEASES

Role of Protein Aggregates in Neurodegenerative Diseases

Protein aggregation is an established pathogenic mechanism in AD, although little is known about the initiation of this process *in vivo*. As human brain research largely depends on the results of postmortem studies, an insight into the early stages of the disease, when protein aggregates are most likely to occur, is difficult. Novel and better animal models would therefore be very helpful to study the progress of AD in humans. The clinical course of the disease in humans could be monitored by brain imaging (CT, MRI). The exact connection between protein aggregates, such as extracellular amyloid-β (Aβ) plaques and intracellular neurofibrillary tangles (NFTs), the latter composed of hyperphosphorylated microtubule associated protein (TAU), in the brains of patients with AD, and neurodegeneration is therefore still unknown. It does seem that the AD is caused by the accumulation of amyloid plaques and neurofibrillary fibers, although this is not absolutely confirmed and generally accepted (Medeiros et al., 2011). Stronger evidence that aggregates do trigger neurodegeneration (the so-called amyloid hypothesis) and are not just a consequence of the neurodegeneration, is provided by mutations in the gene for the amyloid beta precursor protein (APP) present in some human patients with AD (Selkoe, 1991; Hardy and Higgins, 1992; Hardy and Selkoe, 2002; Lansbury and Lashuel, 2006). Similarly, amyloid plaques are present in different brain regions in dogs with CCD clinical symptoms, and they can be present even before clinical signs of this disease become obvious.

In general, age-related neurodegenerative disorders are complex and multifaceted pathologies, wherein the formation of large aggregates and/or high concentrations of toxic proteins prevent the proper function of neuronal cells, leading to ischemia and eventually tissue removal. The spread of AD pathology follows a characteristic topographic pattern, different for the two proteins involved in the pathology, Aβ and TAU (Brettschneider et al., 2015). TAU aggregates first develop in the locus coeruleus, then in entorhinal cortex followed by hippocampus and neocortex. Aβ plaques firstly appear in the neocortex, and later in allocortical, diencephalic and basal ganglia structures and in the brainstem (Brettschneider et al., 2015; Jucker and Walker, 2018). These aggregates spread in a prion-like manner, forming intracellular and extracellular deposits. TAU, Aβ, and also Parkinson disease associated α-synuclein, exist in different conformational variants ('strains') that show seeding properties and exert different levels of neurotoxicity, which could be the source of heterogeneity of neurodegenerative diseases (Aguzzi, 2014). The seeding potential of these aggregates was recently substantiated by demonstrating propagation of structural variants of Aβ in their distinct conformations through template-directed folding of naïve Aβ peptides (Condello and Stöehr, 2018). Prion-like transmission and seeding has been also observed for TAU (DeVos et al., 2018). Similar mechanism may be involved in young, pre-depositing APP transgenic mice which developed cerebral β-amyloidosis and associated pathology after being intracerebrally injected with Aβ-containing brain extracts from human patients with AD (Meyer-Luehmann et al., 2006; Langer et al., 2011). Interestingly, even intraperitoneal inoculation with Aβ extracts induced β-amyloidosis in the brains of APP transgenic mice after prolonged incubation times (Eisele et al., 2010). Likewise, soluble oligomers from blood and

cerebrospinal fluid (CSF) of an aged dog with CCD were neurotoxic to human neuroblastoma cell line, and canine CSF derived Aβ induced the *in vitro* aggregation of synthetic human Aβ peptides (Rusbridge et al., 2018). Spreading of misfolded Aβ oligomers in a prion-like mechanism might also exploit exosomes, which can seed Aβ not only as vehicles for the neuron-to-neuron transfer (Zheng et al., 2017; Sardar Sinha et al., 2018) but also between distant brain regions (i.e., from the dentate gyrus to other regions of hippocampus and to the cortex) (Zheng et al., 2017).

The Neuropathology in the Brain Parenchyma

The most prominent neuropathological signs of AD are accumulation of Aβ in a form of extracellular plaques in the brain parenchyma and also in the walls of blood vessels (cerebral amyloid angiopathy, CAA), and abnormally phosphorylated protein TAU that accumulates in NFTs (Braak and Braak, 1991; Nelson et al., 2012). These pathological features are believed to cause cognitive and behavioral changes. The amino acid sequence of APP and of the enzymes involved in the processing of Aβ peptides from APP, are highly homologous between humans and dogs (Johnstone et al., 1991; Sarasa and Pesini, 2009; Sarasa et al., 2010). Major canine APP isoforms are APP-770, APP-751, APP-714, and APP-695 (Sarasa et al., 2010). The alignment of the longest canine amyloid-beta precursor protein isoform (APP-770) sequence with protein sequence of human amyloid-beta precursor protein show 96.9% amino acid identity and 98.3% similarity (**Figure 1A**), making them almost identical. The expression patterns of canine APP isoforms are almost similar to the patterns previously detected for human APP isoforms (Yasojima et al., 2001; Sarasa et al., 2010). APP is a single-pass transmembrane protein with a large extracellular domain and a short cytoplasmic tail. The domain structure of APP-770 is shown in **Figure 1B**, the neuronal isoform APP-695 lacks the KPI domain (Müller et al., 2017). In contrary to APP, there is a difference in the TAU protein sequence between dogs and humans. **Figure 1C** shows the longest TAU isoform alignment between dog and human protein sequences with 84% similarity. Interestingly, the four microtubule-binding regions (4R) and the C-terminal regions (**Figures 1C,D**) are identical.

Amyloid-β was found to be present in the form of insoluble plaques in the area of the cerebral cortex in humans and dogs, and cognitive impairment in elderly dogs was in some studies strongly associated with the accumulation of Aβ in the brain (Cummings et al., 1993; Cummings and Cotman, 1995; Pugliese et al., 2006; Rofina et al., 2006; Barnes et al., 2016). However, in two other studies there was no significant correlation between the amount of Aβ brain load and CCD symptoms (Chambers et al., 2011; Ozawa et al., 2016) so the clear connection between Aβ load in the brain and clinical signs of CCD has not been firmly established yet. Although Aβ plaques are generally detected as extracellular deposits of diffuse and neuritic plaques in humans and dogs, some studies also reported the presence of Aβ deposits inside individual neurons in the canine brain (Cummings et al., 1993; Yu et al., 2011). Similarly, intraneuronal Aβ accumulation in human AD brains has been reported by many groups (reviewed in detail by Gouras et al., 2010).

In dogs, formation and maturation of Aβ deposits was observed by immunostaining throughout the canine cortical gray matter layers in a four-stage distribution, which is also characteristic for human AD, and this, according to some studies, correlates with the severity of cognitive deficit in the dog (Bosch et al., 2012) and varies as a function of age and size (weight) in companion dogs (Rofina et al., 2006; Schmidt et al., 2015). The Aβ load was higher in small and medium size dogs, which can be explained by the longer life span of smaller dogs and thus longer time necessary to accumulate these deposits (Schmidt et al., 2015). Most of the studies, on CCD brains, were made on geriatric dogs of different breeds and sizes, hence in this review the pathology is mainly described without further specifications of individual dogs characteristics. The canine prefrontal cortex is normally the site of disease onset (**Figure 2**), which spreads progressively to the parietal, entorhinal and occipital cortices, and lesions in certain brain regions correlate with certain behavioral deficits, as shown in **Table 1**. In separate studies amyloid plaques of mainly diffuse type were detected in several regions of canine brain, in the frontal and temporal cortex (Ishihara et al., 1991; Colle et al., 2000; Pugliese et al., 2006; Schmidt et al., 2015; Ozawa et al., 2016; Schütt et al., 2016; Smolek et al., 2016), in entorhinal cortex and hippocampus (Cummings et al., 1993; Colle et al., 2000; Yu et al., 2011; Schmidt et al., 2015; Borghys et al., 2017) and parietal cortex (Yu et al., 2011). Hippocampal deposits of a subspecies of pyroglutamyl Aβ, the highly neurotoxic pE3AA, were also detected in demented dogs (Schmidt et al., 2015). These plaques were more abundant in small and medium dogs (Schmidt et al., 2015). Studies further suggest that earlier assembly states of Aβ, such as oligomers and protofibrils, may be neurotoxic in the dog's brain (Head et al., 2010). The levels of Aβ soluble oligomers in the CSF correlated inversely with Aβ load in the CCD affected beagle brains (Head et al., 2010). Precipitates from the CSF of demented Samoyed dog with CCD acted highly neurotoxic in *in vitro* tests and were more neurotoxic than the synthetic oligomeric and fibrillary forms of Aβ (Rusbridge et al., 2018).

Besides Aβ plaques, recruitment and activation of astrocytes and microglial cells has been noticed in dogs with CCD (astrocytosis, microgliosis) (Smolek et al., 2016; Rusbridge et al., 2018) along with astrocyte hypertrophy (Borràs et al., 1999). Furthermore, the levels of pathological Aβ in the canine prefrontal cortex were positively correlated with age but neither with the severity of cognitive deficits (Gómez-Pinedo et al., 2016) nor the neuronal cell loss (Cummings et al., 1993). Neprilysin (NEP) mRNA, coding for a pivotal Aβ-degrading protein, was poorly expressed in the prefrontal cortex of aged dogs with CCD (Canudas et al., 2014), similar to human AD brain, where areas with higher Aβ aggregation express lower levels of NEP (Reilly, 2001).

Aged dogs with cognitive impairment exhibit degeneration of noradrenergic neurons, which correlates with higher levels of Aβ deposits in the prefrontal cortex (Insua et al., 2010). Likewise, in human AD, locus coeruleus degeneration and loss of cortical noradrenergic neurons occurs already at early stage (Kelly et al., 2017). The activity of the canine cholinergic system

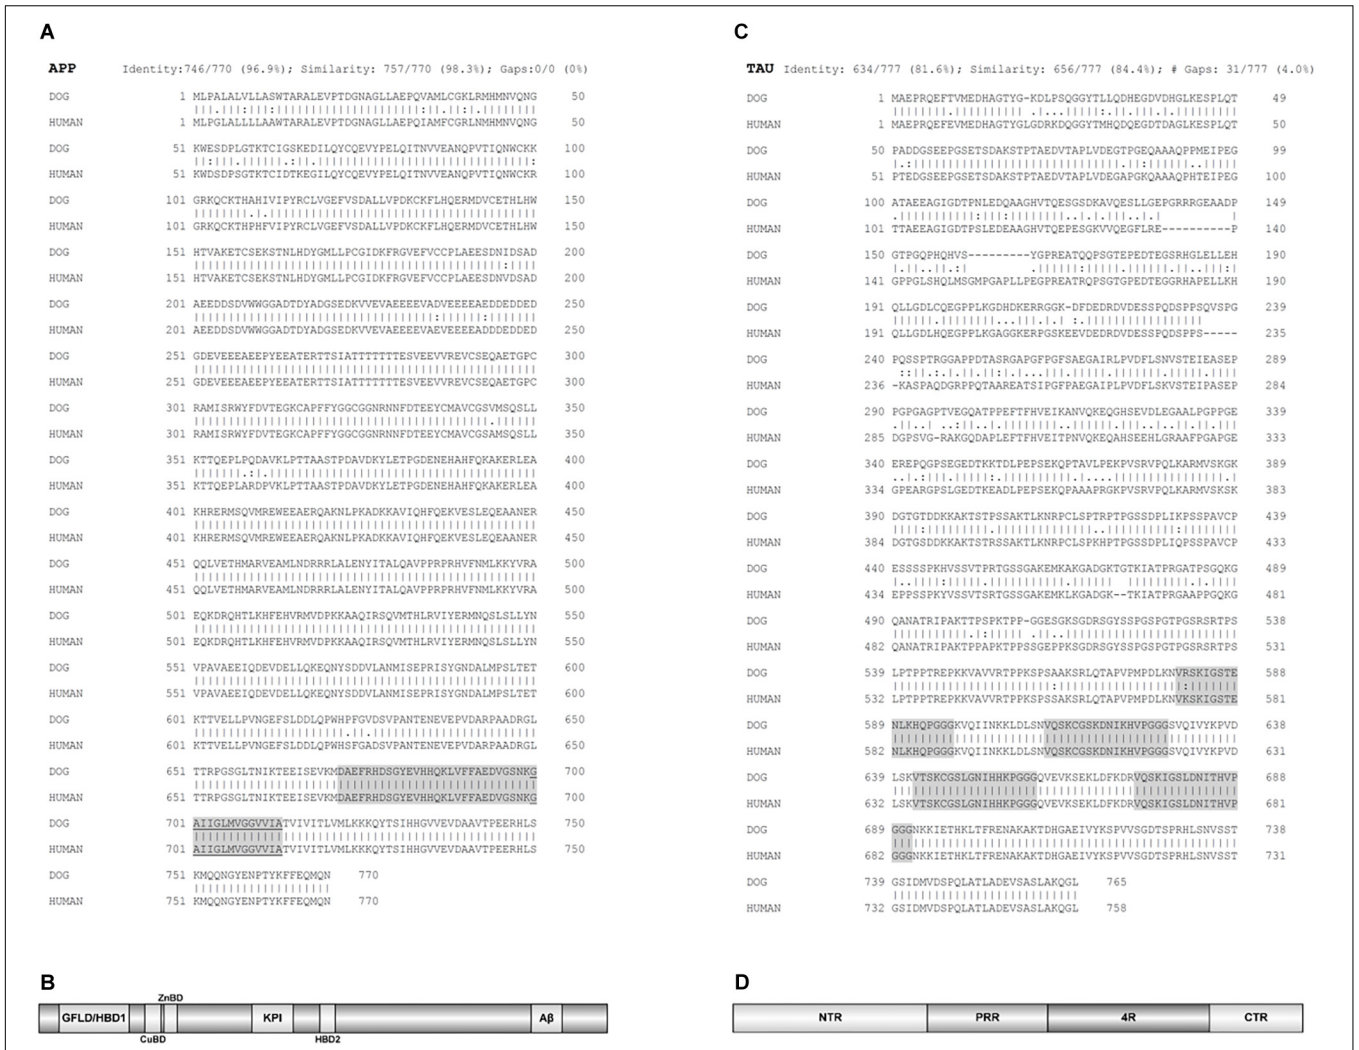

FIGURE 1 | Protein sequences alignments between dog and human amyloid-beta precursor protein (APP) and TAU. **(A)** The alignment of the longest canine APP isoform (APP-770) sequence with protein sequence of human APP. Aligned sequences share 96.9% amino acid identity and 98.3% similarity. Of note, the sequence identity of canine APP-695 isoform, the predominant APP isoform in the canine brain, and human APP is 87.5%. Highlighted is Aβ domain and underlined the membrane bound part of this domain. **(B)** Domain structure of APP. Isoform APP-770 is depicted. HBD1/GFLD, heparin binding domain 1/growth factor like domain; CuBD, copper binding domain; ZnBD, zinc binding domain; KPI, Kunitz-type protease inhibitor domain (not present in APP-695); Aβ, amyloid beta domain, the latter anchors APP in the cell membrane. The α-, β-, and γ-secretase cleavage sites are directly adjacent or inside the Aβ domain region, which is also most mutation prone, thus enabling alternative cleavage of APP and its divergent aggregation propensities. **(C)** Alignment of the longest TAU protein isoform, out of six existing, of dog and human TAU. Aligned TAU sequences share 81.6% amino acid identity and 84.4% similarity. Highlighted are four microtubule-binding regions (4R). **(D)** Domain structure of TAU. The basic organization is shown. NTR, N-terminal region; PRR, proline-rich region; 4R, four microtubule-binding regions (some isoforms have three); CTR, C-terminal region. The PRR and 4R domains are subject of most posttranslational modifications, while the CTR enables interactions with microtubules and plasma membrane. EMBOSS Needle pairwise sequence alignment (Madeira et al., 2019) was performed. A line (|) indicates positions which have a single, fully conserved residue. A colon (:) indicates conservation between groups of strongly similar properties and a dot (.) indicates conservation between groups of weakly similar properties. The domain organization was depicted by software illustrator of biological sequences (IBS) (Liu et al., 2015). Figure made by the authors.

also declines with age (Araujo et al., 2005b). Number of basal forebrain cholinergic neurons was significantly reduced in aged cognitively impaired dogs in comparison to aged cognitive unimpaired and young dogs, but unlike for noradrenergic neurons, this reduction of cholinergic neurons did not correlate with the extent of Aβ cortical load (Insua et al., 2012). As in CCD, cholinergic neurons located in the basal forebrain, including the neurons that form the nucleus basalis of Meynert, are usually lost in AD (Whitehouse et al., 1981). In human patients, the cholinergic neurons appear most vulnerable to Aβ pathology, followed by glutamatergic and GABAergic neurons (Bell et al., 2006). The synaptic loss correlates with the disease progression and destruction of cholinergic neurons contributes to memory and attention deficits in AD (Terry et al., 1991). These alterations in neurotransmitter systems, with reduced neuronal and synaptic function have also been observed in dogs (Landsberg et al., 2012) and result in clinical symptoms of CCD. The employment of the canine

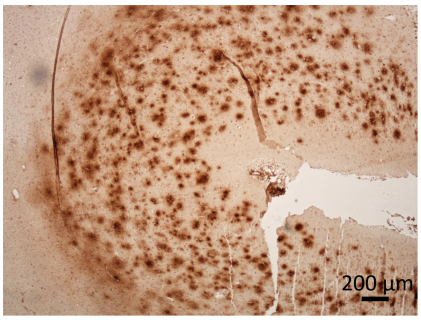

FIGURE 2 | Presence of Aβ in the cerebral cortex of a dog with CCD. The dense plaques detected in superficial cortical layers and diffuse plaques in deeper layers of prefrontal cortex. The dog was 17-years-old of a mixed breed. Immunoperoxidase staining with antibodies against Aβ (purified anti-β-Amyloid, 17-24 Antibody, BioLegend, #800701) with diaminobenzidine (DAB) as chromogen (brown), counter stained with hematoxylin. Original microphotograph made by the authors.

model to examine the effect of the cholinesterase inhibitors in treatment of CCD is described in details under "Treatment and drug development".

TAU protein, another important factor in neurodegenerative diseases, is encoded by *MAPT* (microtubule associated protein tau) gene. Mutations in this gene have not been linked to AD, but cause a familial form of frontotemporal dementia (Olszewska et al., 2016). However, in human AD, intraneuronal NFTs composed of hyperphosphorylated TAU and misfolded insoluble TAU protein aggregates and extracellular Aβ inclusions are both present and necessary for the diagnosis of the disease. In AD NFTs form initially in the locus coeruleus, then entorhinal cortex and further progress to the hippocampus, anterior cingulate cortex, visual association area and finally to the primary visual cortex in the occipital lobe (Ossenkoppele et al., 2016; Hoenig et al., 2018). Interestingly, TAU neurofibrillary inclusions were only rarely identified in canine brain, for instance only in one dog in one study (Smolek et al., 2016) and in three dogs in another study (Schmidt et al., 2015). Increased phosphorylation of TAU was observed at some amino acid sites in canine brain, although no study so far confirmed the presence of vast mature NFTs deposits as are typically observed in human AD. In one study, cytoplasmic deposits of phosphorylated TAU (pTAUThr181) were detected in the prefrontal cortex, but no NFTs were observed (Pugliese et al., 2006). Smolek et al. (2016) detected increased presence of phosphorylated TAU protein (pTAU) in synaptosomes of demented dogs. This could suggest that dementia in dogs might be partially caused by the weakening of the synaptic function, caused by pTAU, and not by the toxic effects of NFTs. This is further supported by the increase in TAU hyperphosphorylation in individual cortical neurons and by pTAU subcellular distribution shift from perinuclear to granular cytoplasmic and nuclear, which correlates with dog's age (Pugliese et al., 2006). Expression of pTAUSer396 and accumulation of ubiquitin were also significantly increased in the parietal cortex and dorsal part of the hippocampus in old dogs when compared to expression in humans (Pugliese et al., 2006; Yu et al., 2011). Specifically, pTAUSer396 expressing astrocytes and neurons with co-localization of pTAUSer396 and ubiquitin were also observed in the parietal cortices and hippocampi of dogs with CCD (Yu et al., 2011). However, cytoplasmic aggregates of normally predominately nuclear proteins, TAR DNA-binding protein (TDP-43) and fused in sarcoma (FUS), which are strongly associated with frontotemporal dementia and amyotrophic lateral sclerosis in human patients, were not detected in the canine brain with CCD (Smolek et al., 2016).

Neurodegenerative diseases occur spontaneously in other domestic animals, especially in cats (Chambers et al., 2015), although brain pathology in these other species is much less studied. In the hippocampi of naturally aged domestic cats, Aβ accumulation, NFTs formation and neuronal loss were observed (Chambers et al., 2015) and this might contribute to cognitive decline in this species, although this has not yet been firmly established. Cognitive deficit may occur in the horse, as clinical signs similar to cognitive impairment have been observed, but no detailed studies focusing on age-related neurologic aberrances have been conducted so far. In one study, TAU protein was shown to be present in equine hippocampal neurons, but no NFTs were detected (Capucchio et al., 2010). Some horses develop equine motor neuron disease, but none have been associated with pathological accumulation of dementia related proteins (El-Assaad et al., 2012; Youssef et al., 2016). Interestingly, a recent study negated the belief that abnormally behaving stereotypic horses (*Equus caballus*) are cognitively impaired (Briefer Freymond et al., 2018).

Neurodegenerative diseases most likely occur in many other mammalian species, but there are very limited reports about these. The reports are focusing on the presence of Aβ deposits and phosphorylated TAU and/or NFTs, which are detected post mortem, not describing the cognitive deficit, this is of course more difficult to observe in wild life animals or in this aspect less characterized species. Diffuse deposits of Aβ were observed in the parietal cortex of dolphins and more compact senile plaques in their cerebellum (Di Guardo, 2018). Sheep and goats (Braak et al., 1994; Nelson et al., 1994; Nelson and Saper, 1995), cheetah (Serizawa et al., 2012), bison (Härtig et al., 2000, 2001), bears (Cork et al., 1988) and most species of nonhuman primates (Schultz et al., 2000a,b; Rosen et al., 2008; Oikawa et al., 2010; Perez et al., 2013, 2016; Rodriguez-Callejas et al., 2016; Reid et al., 2017) also develop amyloid plaques and/or harbor phosphorylated TAU laden neurons, but most of them do not have NFTs present in their central nervous systems (as reviewed in Youssef et al., 2016). However, AT8-immunostained pTAUSer202 and pTAUThr205 were found in the brains of brown lemur, rhesus monkey, baboons, rabbit, guanaco, and bison (Härtig et al., 2000). Furthermore, NFTs were revealed by Gallyas staining in aged bison (Härtig et al., 2001).

There have been speculations on the reasons for the lack of NFTs in the canine brain and in the brains of other animals (Kuroki et al., 1997; Youssef et al., 2016). First possibility

TABLE 1 | Affected brain regions and underlying cognitive deficits in dogs.

Brain region	Pathology	Cognitive decline	References
Prefrontal cortex	Aβ	Executive function, behavioral changes [cognitive performance, loss of previously learned behaviors (e.g., house soiling)], motor skills, attention, emotions and impulse control (fearfulness, aggression, stereotypic pacing or circling)	Bosch et al., 2012
Frontal cortex	Aβ	Changes in executive functions (inhibitory control and complex working memory)	Ishihara et al., 1991; Schmidt et al., 2015; Smolek et al., 2016
Parietal cortex	Aβ	Sensory association, learning and memory	Yu et al., 2011; Nešić et al., 2017
Entorhinal cortex	Aβ, NFTs*	Visual learning, memory	Schmidt et al., 2015; Smolek et al., 2016
Occipital cortex	Aβ	Learning and memory (visual association area, visual cortex)	Martin et al., 2011
Temporal cortex	Aβ, NFTs*	Visual memory (facial recognition), emotions	Smolek et al., 2016
Hippocampus	Aβ, NFTs*	Changes in sleep–wake cycles, appetite control, complex working memory	Colle et al., 2000; Pugliese et al., 2006; Yu et al., 2011; Schmidt et al., 2015; Smolek et al., 2016
Cerebral cortex (not further specified)	Aβ	Disorientation, decrease in social interactions, changes in sleep–wake cycles, loss of prior housetraining, increased anxiety, changes in level of activity	Colle et al., 2000; Pugliese et al., 2006; Yu et al., 2011
Cerebral capillaries and arteries	Aβ - CAA	Lower perceptual speed and episodic memory	Ishihara et al., 1991; Colle et al., 2000; Yu et al., 2011
Meningeal blood vessels	Aβ - CAA		Ishihara et al., 1991; Borràs et al., 1999; Colle et al., 2000; Yu et al., 2011; Nešić et al., 2017

**NTFs are rarely detected in CCD.*

is the dissimilarity between canine TAU protein sequence in comparison to human's. Secondly, the lifespan of dogs might be too short to develop NFTs, as Aβ deposition precedes NTFs formation. Thirdly, although the amyloid protein sequence is highly conserved between species, its N-terminal part is not, which might influence TAU phosphorylation and its subsequent aggregation into NFTs. Therefore, it seems that only humans develop the full blown AD pathology with amyloid plaques, NFTs and dementia. There have been few reports of possible AD in aged great apes (Rosen et al., 2008; Perez et al., 2013, 2016), although also in these the TAU pathology was very limited. Several reasons for this exceptional vulnerability of humans to develop AD have been proposed (Arendt et al., 2017; Walker and Jucker, 2017). Predisposition to develop AD might arise as early as during embryonic development over the period of neurogenesis, this was inferred from the modular deposition of AD related cerebral deposits which mirrors the formation and migration of neurons and on a larger scale development of brain regions (Arendt et al., 2017). In humans, the relative brain size is much larger than in any other animal and this expansion is due to longer duration of brain development as well as higher number of neuronal progenitor cell division cycles, the latter giving rise to genomic aberrations, which in turn can be the origin of AD (Arendt et al., 2017). Furthermore, the neurons display genomic mosaicism, which was detected in neurons of approximately 10% of normally aged people. These neurons were shown to preferentially undergo apoptosis in AD (Arendt et al., 2010). The extent of neuronal genomic mosaicism is brain region specific and correlates with differential vulnerability to neurofibrillary pathology (Arendt et al., 2015). Moreover, the pathological TAU conversion might commence as early as in children (Braak and Del Tredici, 2012), although it has not been firmly established if these processes are transient in nature. The canine model would therefore serve as an accessible and suitable model to further delineate why, except for humans, are other species less susceptible to develop tauopathies.

The Neuropathology of Cerebral Blood Vessels

In patients with AD, accumulation of Aβ is often observed in the walls of blood vessels in the brain. This is called CAA and is caused by pathological deposits of Aβ and other proteins in the cerebral arterioles and capillaries of the leptomeninges and cortex. It is considered as an early and integral part of AD pathogenesis and the prevalence of CAA in AD is over 70% (Attems, 2005). CAA is a risk factor for hemorrhagic stroke and contributes to AD dementia. Atherosclerosis may also cause cerebrovascular dysfunction that may lead to cognitive decline as well as stroke (Shabir et al., 2018). The accumulation of amyloid in the walls of blood vessels is common in elderly people, patients with CAA and in almost all patients with AD (Kumar-Singh, 2008). The most CAA affected brain regions are the leptomeninges and frontal and temporal cortices (Borràs et al., 1999) with Aβ deposits in arteries, arterioles, capillaries, venules, and veins. The CAA disease progresses from mild, to moderate to severe stage, this is from almost intact blood vessels with minor Aβ deposits to extensive vascular Aβ load, which disrupts vessel architecture and exacerbates microangiopathies, microaneurysmal dilatation, and fibrinoid necrosis (Revesz et al., 2002).

In aged dogs Aβ deposits are detected both in the brain parenchyma and in the walls of cerebral blood vessels (Ishihara et al., 1991; Uchida et al., 1992; Borràs et al., 1999;

Colle et al., 2000; Brettschneider et al., 2015; Schmidt et al., 2015; Ozawa et al., 2016; Nešić et al., 2017; Rusbridge et al., 2018), further suggesting similarities between AD in humans and CCD in dogs (**Figures 2**, **3**). The amyloidotic blood vessels in the brains of dogs were observed by Congo red stainings as well as by antibodies directed against Aβ. Vascular Aβ deposition mainly consists of $A\beta_{40}$ in humans, but both $A\beta_{40}$ and $A\beta_{42}$ were detected in dogs (Kumar-Singh, 2008; Chambers et al., 2012). In canine CAA, the most affected region is the frontal cortex, where Aβ is often present in microvascular parenchymal lesions in elderly dogs. In dogs with CCD an overlap between the density and anatomical distribution of CAA and parenchymal plaques was observed (Nešić et al., 2017). The CAA consistently increased with age, but did not correlate with the CCD score (Ozawa et al., 2016). Intracerebral hemorrhages have also been described in association with CAA in dogs (Uchida et al., 1990). A recent case reported multiple infarcts and brain hemorrhages in a dog with CAA and CCD, with cerebral and vascular Aβ deposits (Rodrigues et al., 2018). Pathological hallmarks of CCD and AD are summarized in **Table 2**.

TABLE 2 | Pathological hallmarks of CCD and/or AD.

Abnormality	CCD	AD
Cognitive decline	+	+
Brain atrophy	+	+
Neuronal damage and death	+	+
Aβ accumulation in brain parenchyma	+	+
Diffuse Aβ plaques	+	+
Dense-core Aβ plaques	–	+
Aβ accumulation in blood vessel walls (CAA)	+	+
Neurofibrillary tangles (NTFs) formation	–	+
Microglial dysfunction	+	+
Astrocyte dysfunction	+	+
Astroglial hypertrophy and hyperplasia	+	+
Oxidative brain damage	+	+
Mitochondrial dysfunction	+	+
Cholinergic dysfunction	+	+
Impaired neuronal glucose metabolism	+	+

GENETICS

The incidence of human neurodegeneration and associated dementias is sporadic and is only rarely due to hereditary changes that are linked with genetic mutations. The majority of AD cases are sporadic late-onset (LOAD) with an unknown etiology (Cacace et al., 2016). The other rare AD form is genetically determined familial AD. Known specific gene mutations are the root cause for the development of familial form of AD (Selkoe, 1997). Most of the patients with early onset, familial form of AD have mutations in one of the two presenilin proteins (PSEN1 and PSEN2) (Bekris et al., 2010), which are proteins with a role in Aβ generation. Mutations also occur in *APP* gene (Selkoe, 1997). Polymorphism in APOEε4 allele of apolipoprotein E gene (*APOE*) is the major genetic risk factor for LOAD along with polymorphism in *TREM2* gene, which has a role in maintaining normal immune functions in the brain (reviewed in detail in Wolfe et al., 2018). In population studies, several genetic loci have been identified as risk factors for AD (e.g., *CLU, CR1, APP, PICALM, BIN1, ABCA7, MS4A, MEF2C CD33, EPHA1, CD2AP, APOE, TRIP4, TREM2, SORL1*), although the connection between genes in these loci and pathogenesis of AD has not been established (Ashford, 2004; Karch et al., 2012; Mäkelä et al., 2018). Interestingly, the *APOE4* polymorphism is unique to humans and its evolvement from the presumably ancestral primate form might have been instrumental for the AD pathogenesis (Mahley and Rall, 1999; Walker and Jucker, 2017).

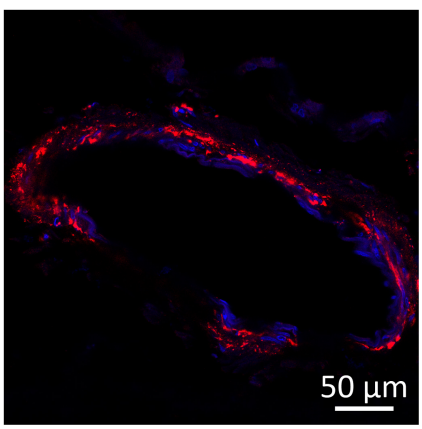

FIGURE 3 | Amyloid beta (red) detected by immunofluorescence staining in the wall of a leptomeningeal blood vessel in the frontal cortex from a 15-years-old Pit Bull Terrier. Nuclei were counterstained with DAPI (blue). The antibody employed is the same as in **Figure 2**. Original microphotograph made by the authors.

Some presenilin mutations and mutations in *APP* have been connected to CAA (Hendriks et al., 1992; Grabowski et al., 2001; Rossi et al., 2004; Bugiani et al., 2010; Sellal et al., 2017) and also a polymorphism in the neprilysin gene was associated with CAA (Kumar-Singh, 2008), although the exact connections between these mutations and AD/CAA symptoms and progression are not yet understood. Furthermore, APOEε4 was shown to be a risk factor for CAA and both APOEε2 and ε4 alleles are associated with more severe forms of CAA (Nelson et al., 2013; Yu et al., 2015).

No mutations in specific genes have been reported in dogs with CCD so far. The only neurodegenerative disease in dogs that has been linked to specific mutation is degenerative myelopathy (DM), a condition caused by both demyelination and axonal loss in the canine spinal cord. In dogs with this disease, mutations have been found in a gene SOD1, coding for superoxide dismutase enzyme (Nakamae et al., 2015; Kobatake et al., 2016). Interestingly, this gene is in human patients associated with some forms of familial amyotrophic lateral sclerosis (Rosen et al., 1993). Beside mutations in SOD1 gene, risk for developing DM in dogs, as well as onset of disease, seem to be partially modulated by gene encoding SP110 nuclear body protein (SP110) at least in Pembroke Welsh Corgis (Ivansson et al., 2016). No other

mutations or disease modifying loci related to neurodegeneration have been detected in dogs so far and thus, little is known about the potential genetic risks or genetic predisposition for CCD and CAA.

BIOMARKERS

Neurodegenerative diseases are particularly challenging diseases, as they are difficult to diagnose in the initial stages. Although many years of research have been devoted to the identification of suitable biomarkers, preferably in blood, that would allow early diagnosis or even prediction of AD in humans, such markers remain elusive. Numerous candidates have been identified in both blood and CSF, but none of the markers identified so far have been used routinely in the clinics. CSF levels of Aβ, total TAU and hyperphosphorylated TAU are the most often monitored variables, along with PET molecular imaging of amyloid and TAU deposition, in diagnosis of early stages of AD (McKhann et al., 2011).

In dogs there are no biological markers that would allow accurate and early diagnosis of CCD. In most cases assessment of cognitive functions through several neuropsychological tests and excluding other conditions with overlapping symptoms is sufficient to confirm diagnosis when the disease has progressed, but markers for detecting disease in early stages would be very useful in veterinary medicine.

In dogs with CCD, plasma $A\beta_{42}$, a longer Aβ isoform which is more fibrillogenic and associated with disease, was monitored as a biomarker potentially linked to CCD (González-Martínez et al., 2011; Schütt et al., 2015). One study showed highest $A\beta_{42}$ plasma levels in younger healthy dogs, and significantly higher $A\beta_{42}$ plasma levels in mildly cognitively impaired dogs in comparison to severely impaired dogs (González-Martínez et al., 2011). However, another study reported the opposite with highest $A\beta_{42}$ plasma levels in CCD dogs (Schütt et al., 2015). Plasma ratio of $A\beta_{40}$ and $A\beta_{42}$, was shown to be similar in human AD and CCD as in healthy individuals (Mayeux et al., 2003; Lopez et al., 2008; González-Martínez et al., 2011) although in some studies decreases in plasma $A\beta_{42}$ were an indicator of faster progression of CCD and AD (Pesini et al., 2009; González-Martínez et al., 2011). This points to a possible disease mechanism wherein aggregation and accumulation of Aβ in the brain results in lower levels of Aβ in plasma and CSF. A more recent human study showed decrease in plasma Aβ during the dementia stage of AD and increased levels of Aβ in plasma during vascular disease (Janelidze et al., 2016).

In healthy aged dogs with age related Aβ deposits, a decrease in levels of $A\beta_{42}$, but not $A\beta_{40}$ was detected in CSF (Head et al., 2010). Similarly, in elderly people $A\beta_{42}$ has been monitored in CSF and the decrease in $A\beta_{42}$ is suggested as biomarker for Aβ deposition in the brain and has been observed alongside brain atrophy (Fagan et al., 2009; Racine et al., 2016). Although CSF Aβ content decreased in the aging dog (Head et al., 2010), high levels of Aβ in the CSF of young and middle-aged dogs also correlated with impaired learning (Borghys et al., 2017). This infers high CSF Aβ levels in younger dogs, which are not likely to harbor depositions of amyloid in their brains yet, as an early biomarker for the development of cognitive impairment. One study also reported an increase of lactate, pyruvate and potassium concentrations in CSF of dogs correlating with severe cognitive impairment (Pugliese et al., 2005), but this has not been firmly established or confirmed. Therefore, there are no biomarkers available to monitor and predict CCD progress in dogs. Future studies aiming to develop such biomarkers would be needed, hoping to provide biomarkers for early detection of this disease.

DIAGNOSIS OF CCD

Although CCD is highly prevalent the disease is severely under-diagnosed, affecting a growing population of aged dogs. The diagnosis of CCD is a diagnosis of elimination. The illness exacerbating symptoms, commonly also observed in CCD, must be excluded, such as brain tumors, hypertension, other neurological conditions, metabolic and hormonal imbalances, etc. Screening and diagnosis of CCD is primarily based on observation of clinical signs which are summarized by the acronym DISHAA [Disorientation, altered social Interactions, altered Sleep–wake cycles, House soiling and loss of other learned behaviors, altered Activity levels and increasing Anxiety (Ruehl et al., 1995; Neilson et al., 2001; Azkona et al., 2009; Rosado et al., 2012; Fast et al., 2013b; Madari et al., 2015)]. Sleeping during the day and restless at night, decreased interaction, disorientation at home and anxiety are common symptoms (Fast et al., 2013b).

The diagnosis depends largely on the owners and the veterinarians to observe and diagnose the disease, which is in most cases overlooked and symptoms attributed to the aging of dogs. To facilitate the detection of CCD, veterinarians can use a screening questionnaire that includes a list of possible signs. Several questionnaires are available and based on the scores the stage of dog's cognitive decline can be identified (Colle et al., 2000; Neilson et al., 2001; Osella et al., 2007; Azkona et al., 2009; Golini et al., 2009; Salvin et al., 2011; Landsberg et al., 2012; Rosado et al., 2012; Fast et al., 2013b; Madari et al., 2015). Madari et al. (2015) have proposed criteria for discrimination of three stages of the disease, these are mild cognitive impairment, moderate cognitive impairment, and severe cognitive impairment. The severity and progression of CCD disease is identified by Canine Dementia Scale (CADES), which contains 17 items distributed into four domains related to changes in dogs' behavior (spatial orientation, social interactions, sleep–wake cycles, and house soiling) (Madari et al., 2015). The Canine Cognitive Dysfunction Rating Scale (CCDR) is another questionnaire (Salvin et al., 2011), which is comprised of 13 behavioral items distributed into four domains, namely orientation, memory, apathy, impaired olfaction, and locomotion (Salvin et al., 2011). The cognitive deficits in dogs with CCD with regards to affected brain regions are summarized in **Table 1**. Cognitive impairment parallels the symptomology of AD. Performance on tasks involving complex learning and working memory are impaired first, along with executive function, visuospatial ability and complex learning deficits, with disease progression impairments in discrimination learning and behavioral

changes are common (Neilson et al., 2001; Tapp et al., 2003; Studzinski et al., 2006; Madari et al., 2015).

MRI diagnosis is only rarely performed in dogs, due to possible complications during anesthesia and cost restraints. In dogs with CCD, as in humans with AD, MRI shows brain atrophy and include ventricular enlargement as well as widened and well-demarcated cerebral sulci. Measuring the thickness of the interthalamic adhesion in CCD was employed as a parameter for quantifying canine brain atrophy (Hasegawa et al., 2005; Noh et al., 2017). In demented canine brain MRI can be a useful tool to detect other abnormalities of the brain, possibly causing dementia such as leukoaraiosis (periventricular white matter hyperintensities) and brain microhemorrhages (Dewey et al., 2019). In human brain imaging a variant of amyloid-binding histological dye Thioflavin T, [^{11}C]PiB, has been used as a tracer to detect Aβ using PET (positron-emission tomography) scans. In dogs this compound failed to detect the full amyloid load in the brain, established by *ex vivo* histopathological investigation (Fast et al., 2013a).

In general, the diagnosis of human AD is set similarly. First by ruling out other possible causes for symptoms and then by detection of CSF and plasma biomarker levels, tests of memory, problem solving, attention, counting, and language, which can be followed by MRI and PET scans (Hane et al., 2017). As in dogs, the cause of dementia can only be confirmed with certainty postmortem.

TREATMENT AND DRUG DEVELOPMENT

Current treatment approaches for AD in humans are focused on helping people maintain mental function, manage behavioral symptoms, and slow or delay the symptoms of the disease. Unfortunately, there is no effective treatment for AD. Drugs that are used today in the management of AD can only alleviate the symptoms, and even that only temporarily. Cholinesterase inhibitors (donepezil, rivastigmine, and galantamine) have been approved for the management of AD in humans. Drugs acting as acetylcholinesterase inhibitors reduce the activity of the acetylcholine esterase which degrades acetylcholine, thus increasing the amount of acetylcholine available in the brain and therefore stimulate brain cells which receive more synaptic inputs (reviewed in Winblad et al., 2016). This very unspecific treatment can slow the disease progression for 6–12 months, and even achieve temporary improvement as shown for donepezil (Birks and Harvey, 2018), but does not cure the disease which will eventually progress. Another drug used for the treatment of AD is memantine that acts on the glutamatergic system by blocking NMDA (*N*-methyl-D-aspartate) receptors. A recent random-effects network meta-analysis of 41 randomized controlled trials reveled the most suitable dosages of cholinesterase inhibitors and memantine to treat patients with mild, moderate and severe AD (Dou et al., 2018). Although these pharmacological interventions have beneficial effects on cognition, function and global clinical impression, these treatments do not alleviate the neuropsychiatric symptoms (Dou et al., 2018). Unfortunately, there have been numerous clinical trials with many candidate drugs, but most of these had negative outcomes (Cummings et al., 2018).

Treatment of Canine Dementia

Current treatment options for CCD target prevention, slowing and/or improving the cognitive decline in dogs. Some drugs or food supplements are available for senior dogs and might act neuroprotective. Some enhance the blood flow into the brain, others work as antioxidants and more effort is now directed to slowing the progression of the disease instead of providing only symptomatic treatment. One commonly prescribed drug for cognitive impaired dogs is selegiline, which acts as an inhibitor of monoamine oxidase B (MAOB), thus reducing degradation of several neurotransmitters in the brain, and may have neuroprotective effects on dopaminergic, noradrenergic and cholinergic neurons (Landsberg, 2005; Magyar, 2011). Another drug that is occasionally used is nicergoline, which increases the blood flow through the brain. It may enhance neuronal transmission and act neuroprotective, increase dopamine and noradrenaline turnover and inhibit platelet aggregation (Landsberg, 2005). Propentofylline also has a neuroprotective role as it inhibits the production of free radicals and reduces the activation of microglial cell, thus acting anti-inflammatory (Frampton et al., 2003). Antidepressants such as selective serotonin reuptake inhibitors fluoxetine and sertraline, amitriptyline, paroxetine and anxiolytics benzodiazepines, gabapentin, valproic acid and buspirone can also be used to treat the anxiety and aggression which may accompany CCD. Clomipramin is an antidepressant commonly prescribed for dogs with anxiety (Landsberg, 2005), but these are all symptomatic treatments and do not treat the disease itself. *S*-adenosylmethionine tosylate supplementation was reported to be safe and effective in improving signs of age-related mental decline in dogs (Rème et al., 2008).

There are also some nutraceutical preparations available for dogs, which are based on natural products and/or supplement formulations. Behavioral enrichment alongside with antioxidant-rich diet and exercise is an approach for maintaining cognitive function and slowing the progression of CCD in senior pets. As means of preventative intervention, aging beagles were fed a diet rich in antioxidant, which improved cognition, maintained cognition and reduced oxidative damage and Aβ pathology in treated dogs (Milgram et al., 2004; Dowling and Head, 2012). Another longitudinal survey in beagles looked at the proteomic changes following administration of antioxidant-rich diet in combination with behavioral enrichment (Opii et al., 2008). Following treatment, the levels of oxidative stress biomarkers decreased and the increased expression levels of Cu/Zn superoxide dismutase, fructose-bisphosphate aldolase C, creatine kinase, glutamate dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase correlated with improved cognition (Opii et al., 2008). In addition, some other studies implicated the nutrition as cognition modifying factor in dogs (Araujo et al., 2005a; Siwak et al., 2005; Osella et al., 2007; Christie et al., 2009; Head et al., 2009; Snigdha et al., 2011, 2012; Katina et al., 2016;

Chapagain et al., 2018), highlighting combination of nutraceutical supplements directed at several mechanisms of pathological aging, in combination with behavioral enrichment, as more effective (Araujo et al., 2005a, 2008). Dogs receiving both an antioxidant-rich diet and environmental enrichment showed increased levels of brain-derived neurotrophic factor (BDNF) mRNA when compared to untreated aged dogs. As a result of increase in BDNF mRNA, the cognitive performance improved and the amount of cortical Aβ deposits decreased (Fahnestock et al., 2012). Interesting is the finding that neuronal loss in the hippocampus, occurring in the aged dogs, could be partially reversed by more engagement with the dog, i.e., with stimulation of brain function (Siwak et al., 2000).

Animal Models for Developing Novel Treatments

In comparison to transgenic mouse models, natural animal models better represent the pathophysiology of AD. Models of "physiologically" aged rats, degus and dogs are useful for studying mechanistic aspects of AD, which are also very valuable in the development of therapeutics that would alleviate age-related declines in cognitive function. Mouse models for AD research carry mutations, found in familial AD, and are artificially accumulating Aβ plaques and NFTs. Whether mice are good models have been thoroughly discussed elsewhere (Götz et al., 2018). Several drugs have cleared the amyloid load in mice but failed to do so in people with AD. Recently the genetic background and environmental factors have been demonstrated as the variability in AD development, which was partially recognized by incorporating genetic diversity into mouse models of AD (Neuner et al., 2018). Transgenic minipigs expressing *APP695* or *PSEN1* have also been developed but have not shown the histopathological nor the cognitive impairment signs (Holm et al., 2016). Therefore, natural animal models of species with spontaneously occurring neurodegeneration are potentially more useful in developing and testing novel treatments for such diseases.

To date, most of the drugs in development for AD treatment have been directed toward the removal of amyloid plaques or NFTs, not taking into the account the multifactorial causation of the disease. Several experimental drugs that have successfully removed plaques from mouse brains have not lessened the symptoms of AD in people. For instance, drugs acting as BACE1 (beta-site amyloid precursor protein cleaving enzyme-1) inhibitors had failed in Phase II/III clinical trials (Hawkes, 2017; Dobrowolska Zakaria and Vassar, 2018; Egan et al., 2018). A BACE1 inhibitor verubecestat successfully blocked the accumulation of amyloid protein in mice (Villarreal et al., 2017), rats and monkeys (Kennedy et al., 2016), but did not reduce cognitive or functional decline in patients with mild to moderate AD (Egan et al., 2018). Although decrease in Aβ biomarkers in CSF and brain has been noticed after treatment with BACE1 inhibitors, the failure to prevent cognitive decline might have been due to irreversible neurotoxic accumulation of Aβ that occurred prior to the start of the treatment. For this reason, focus is on the development of therapies that commence at presymptomatic stage (preclinical stage and the stage of mild cognitive impairment) although for this, development of novel, useful biomarkers, is also crucial.

As canine cognitive decline and human Alzheimer's disease show neuropathological, cognitive and behavioral parallels, the testing of products for the treatment of AD in canine model could be useful to determine the efficacy of these compounds in humans, and also to develop novel therapeutic agents for the treatment of senior dogs. Several drugs have been tested in elderly dogs and their suitability and effectiveness correlated with results obtained in human trials, when available. Drugs tested in dogs are listed in **Table 3**.

BACE1 is a protease that controls the formation of Aβ and most likely plays an important role in the development of pathogenesis in AD. The usefulness of BACE1 small-molecule inhibitor LY2886721 has been tested in a dog model and in humans in the first clinical phase (May et al., 2015). It significantly reduced plasma and CSF Aβ levels both in dogs and healthy volunteers (May et al., 2015). After administration of two BACE1 inhibitors (cyclic sulfoxide hydroxyethylamine NB-B4 and oxazine derivative NB-C8) a unique pattern of secreted Aβ peptides was observed in canine CSF (Mattsson et al., 2012). Besides the expected reduced levels of $A\beta_{40}$ and $A\beta_{42}$, reduced levels of $A\beta_{1-34}$ and increased levels of $A\beta_{5-40}$ were detected, which were proposed as prognostic markers of BACE1 inhibition therapies (Mattsson et al., 2012). A recent survey, using BACE1 inhibitor CNP520, demonstrated reduced brain and CSF Aβ in rats, dogs, and reduced CSF Aβ in humans and was assessed to be well tolerated in healthy adults and further clinical trials are ongoing (Neumann et al., 2018). A cardiovascular disease drug, atorvastatin, has been investigated in a canine model of dementia whether it could reduce Aβ plaques, BACE1 protein levels and oxidative stress (Barone et al., 2012). It does offer some neuroprotective role through the up-regulation of enzyme biliverdin reductase-A (Barone et al., 2012). Selegiline (L-deprenyl), a type B monoamine oxidase inhibitor, has been reported to prolong the survival of aged dogs (Ruehl et al., 1997) and in some cases improve visuospatial working memory (Head et al., 1996). However, in subsequent studies only a small subset of dogs seemed to show improvement, pointing to a minor clinical relevance of selegiline administration (Campbell et al., 2001). Furthermore, several human AD trials provided no evidence of clinically meaningful benefits of selegiline administration for people with AD (Birks and Flicker, 2003). Interestingly, although selegiline was shown to be fairly ineffective in the treatment of CCD, it is still the only FDA-approved treatment for CCD.

Testing the same compounds in dogs and humans provided similar findings also in other studies. CP-118,954, an acetylcholinesterase inhibitor, showed minimal cognitive enhancing effects in dogs and human clinical trials were discontinued (Studzinski et al., 2005). Donepezil administration enhanced memory in dogs (Araujo et al., 2011a). Phenserine, an acetylcholinesterase inhibitor which also inhibits synthesis of Aβ and acts as a cognitive enhancing therapeutic, improved learning and working memory in geriatric dogs (Studzinski et al., 2005; Araujo et al., 2011a). Its administration showed

TABLE 3 | Pharmacological interventions tested in dogs with cognitive decline.

Name/type	Mode of action	Testing in dog	Results/outcomes	References
LY2886721	BACE1 inhibitor	Pharmacology study in dogs and clinical trial in healthy volunteers	Aβ lowering in plasma and CSF	May et al., 2015
Selegiline (L-deprenyl)	MAOB inhibitor	Longitudinal study	Higher life expectancy (cognitive status not monitored)	Ruehl et al., 1997
Selegiline (L-deprenyl)	MAOB inhibitor	Performance studies	Improved visuospatial working memory (in only a subset of dogs)	Head et al., 1996; Campbell et al., 2001; Studzinski et al., 2005
Atorvastatin	Reduction of Aβ and BACE1	Longitudinal study	Neuroprotective	Barone et al., 2012
Adrafinil	A wakefulness-promoting agent (eugeroic) with nootropic effects	Longitudinal study; pharmacological study	A significant increase in locomotion; improved learning; impaired working memory	Siwak et al., 2000; Studzinski et al., 2005
Ampakine	Positive modulator of AMPA receptors (enhance excitatory glutamatergic neurotransmission)	Pharmacological study	Decrease of performance accuracy; may have memory impairing effects	Studzinski et al., 2005
CP-118,954	Acetylcholinesterase inhibitor	Pharmacological study	Minimal cognitive enhancing effects	Studzinski et al., 2005
Phenserine	Acetylcholinesterase inhibitor	Pharmacological study; performance study	Enhancing effects on memory and learning; improved performance (only in a subset of dogs treated)	Studzinski et al., 2005; Araujo et al., 2011a
Donepezil	Acetylcholinesterase inhibitor	Performance study	memory enhancement	Araujo et al., 2011a
CNP520	BACE1 inhibitor	Dogs, human	Safe to use in dogs; tolerated in healthy humans; ongoing clinical trials	Neumann et al., 2018
Antioxidant-rich diet with cognitive enrichment	/	Dogs	Improved cognition	Opii et al., 2008; Dowling and Head, 2012
Anti-Aβ immunotherapy	Passive vaccination with injections of antibodies against $A\beta_{42}$	Dogs	Reduced amyloid plaques and reduced astrogliosis	Head et al., 2008; Neus Bosch et al., 2015; Davis et al., 2017

similar results in Phase II human clinical trials, suggesting its effectiveness in improving memory in AD patients, but in Phase III human clinical trial, with patients with mild to moderate AD, no significant differences between the phenserine treated and placebo groups were noticed and the trial was discontinued (Thatte, 2005). There has been further discussions if this trial, and several other AD trials, failed due to procedural errors rather than due to a lack of drug efficacy (Winblad et al., 2010). In more recent studies patients with mild AD showed improvement in cognition following phenserine treatments, this was mirrored also by an increase in CSF $A\beta_{40}$ (Kadir et al., 2008; Nordberg et al., 2015). There is another mode of action of phenserine in AD, namely inhibition of neuronal self-induced preprogrammed cell death, which further clinical trials might pursue (Becker et al., 2018). Ampakine (drug that alters the glutaminergic system) also failed in human AD trials and in dogs with age-associated memory disorder and dementia showed insignificant memory-enhancing effects after treatment with ampakine (Studzinski et al., 2005). Dogs, treated with adrafinil, a mild central nervous system stimulant used to relieve excessive sleepiness and inattention in elderly patients, were more attentive (Siwak et al., 2000). Cholinergic hypofunction might play a role in age-dependent cognitive decline in dogs (Araujo et al., 2011b), this was determined by administration of muscarinic cholinergic receptor antagonist scopolamine, which induces transient memory impairment. Similar findings were presented for aged and demented humans (Schliebs and Arendt, 2011). All these suggest that dogs might be a very good preclinical model for developing and testing new drugs for AD in humans.

Besides BACE1 and cholinesterase inhibitors several attempts have been made to develop immunotherapy treatments directed against Aβ or TAU (Bittar et al., 2018). A range of TAU-targeted immunotherapies have entered clinical development (recently reviewed in Novak et al., 2018). Clinical trials in patients with AD, which were administered Aβ peptide with conjugate to stimulate the immune response (i.e., active immunization) or anti-Aβ antibodies (i.e., passive immunization) have shown modest results and also serious side effects (reviewed in detail in Wisniewski and Drummond, 2016).

In dogs, Aβ immunotherapy could reduce the presence of amyloid plaques and astroglial reaction in aged individuals (Neus Bosch et al., 2015). A vaccine directed against fibrillary Aβ (anti-$A\beta_{42}$) reduced the presence of Aβ plaques in canine prefrontal cortex and improved the function of the frontal cortex, thus resulting in cognitive benefits (Head et al., 2008). Anti-$A\beta_{42}$ vaccination of dogs with CCD, in combination with behavioral enrichment, resulted in reduced presence of Aβ plaques in the brain, a significant maintenance of learning abilities over time

and cognitive maintenance with no improvement in cognition (Davis et al., 2017). This anti-Aβ vaccine, however, also increased the frequency of brain microhemorrhages (Davis et al., 2017) which is commonly observed in the development of these immunotherapies also in human trials and could be very serious side effect. Similarly to pharmacological compounds, immunotherapies in both dogs and humans have provided modest improvements at most, yet similarities between human and canine patients again highlight the parallels between diseases and usefulness of dogs as a preclinical model for AD.

CONCLUSION

Risks for age-related AD and CCD are a complicated interplay between aging, genetic risk factors and environmental influences. CCD in dogs is similar to human AD with respect to APP processing, amyloid plaque deposition and cognitive dysfunction. As dogs age, they have been shown to accumulate amyloid plaques, but, dissimilar to human AD patients, dog brain rarely contains NFTs. Aβ peptide accumulates in the canine brain extracellular space in the form of soluble oligomers, fibrils and Aβ plaques. Its toxic accumulation is believed to be responsible for the neuronal dysfunction and degeneration although the severity of the disease does not always correlate with amyloid burden, but might correlate with toxic fibril polymorphs.

Dogs over 7–8 years seem to be interesting, naturally occurring model organism for aging/dementia that fairly faithfully recapitulate human disease. They are potentially much more useful as rodent models as in laboratory rodents neurodegenerative diseases do not occur spontaneously. Furthermore, genetically modified mice used in research often show very different neurodegeneration courses, as seen in humans. Dogs also spontaneously develop vasculopathies, such as CAA, and perhaps vascular dementia although this has not yet been truly studied, and are therefore also valuable as models to decipher the age and/or dementia related cerebrovascular changes that often accompany or even precede neurodegeneration in human patients.

There are no effective treatments for neurodegenerative disorders, practically all currently available treatments are symptomatic. This is partially related to the poor understanding of the pathogenesis of these diseases, and partly due to the lack of good animal models. Cholinesterase or secretase inhibitor therapy or immunotherapy has been attempted in dogs with CDD, with overlapping results to human AD trials. The neuroprotective effects of cognitive enrichment, alongside with antioxidant-rich diet, show benefits in managing the disease progression and severity in both humans and dogs. Similar results with various drugs do suggest that dogs are useful model to study both pathogenesis and novel treatments for AD in the future.

Taken together, animal studies are important to dissect the molecular and cellular processes specific to AD pathology. Dogs with CCD not only develop isomorphic changes in human cognition and brain pathology, but also accurately predicted the efficacy of known AD treatments and would be therefore good models for testing new substances that affect the lowering of Aβ levels or the reduction or degradation of aggregates associated with AD. This would benefit human patients, but could also help dog patients as any successful treatments could be also introduced into clinical veterinary medicine with the aim to successfully treat this debilitating disease in canine patients.

Stroke is one of the leading causes of death and disability worldwide. Age is associated with increased risk of stroke, while telomere length shortening plays a pivotal role in the process of aging. Moreover, telomere length shortening is associated with many risk factors of stroke in addition to age. Accumulated evidence shows that short leukocyte telomere length is not only associated with stroke occurrence but also associated with post-stroke recovery in the elderly population. In this review, we aimed to summarize the association between leukocyte telomere length and stroke, and discuss that telomere length might serve as a potential biomarker to predict the risk and prognosis of stroke.

Keywords: telomere, telomerase, telomere length, risk of stroke, prognosis of stroke

INTRODUCTION

Stroke is an acute cerebrovascular disease caused by the disruption of blood supply. As the second leading cause of death and the third leading cause of disability worldwide (1), stroke brings heavy burden to both family and health care system. The incidence of stroke is increased with age and ∼65% of stroke cases occur in individuals older than 65 years. In addition to age *per se*, various risk factors of stroke are age-related, including hypertension, atherosclerosis, atrial fibrillation, high cholesterol, and diabetes. Telomere length (TL) shortening is associated with age and many other risk factors of stroke. Consistently, a number of studies indicated that stroke occurrence is associated with short leukocyte telomere length (LTL) (2–4). Moreover, accumulated evidence indicates that short LTL is also associated with the post-stroke recovery. Therefore, we aimed to summarize the association between LTL and stroke, and discuss the potential of TL as a biomarker to predict the risk and prognosis of stroke.

TL MAINTENANCE

Telomeres

Human telomeres are specialized structure of DNA-protein complex, capping the end of linear chromosomes. Human telomeric DNA consists of a variable number of tandem repeats of double-stranded TTAGGG and a 3′ G-rich single-stranded overhang, known as the G-tail (5). The length of double-stranded repeats ranges from 2 to 30 kb, while the length of 3′ overhang is around 150 nt. The invasion of 3′ G-tail into the double-stranded region forms a high order structure and a triple-stranded structure, called T-(telomere) loop and D-(displacement) loop, respectively

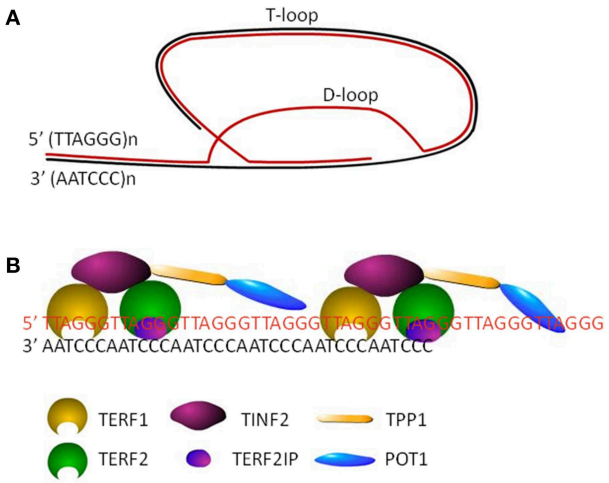

FIGURE 1 | The structure of telomeres. **(A)** Cap structure of telomeres consists of a T-loop and a D-loop. **(B)** The shelterin complex, including TERF1, TERF2, TINF2, TERF2IP, TPP1, and POT1, maintains the stability of loop structures by binding to the telomeric DNA.

(6) (**Figure 1A**). Shelterin complex, the protein components of telomere, includes six subunits, telomeric repeat binding factor 1 (TERF1), telomeric repeat binding factor 2 (TERF2), TERF2 interacting protein (TERF2IP), TERF1-interacting nuclear factor 2 (TINF2), tripeptidyl peptidase I (TPP1), and protection of telomeres 1 (POT1) (**Figure 1B**). TERF1/TERF2 and POT1 bind directly to double-stranded and single-stranded telomeric DNA, respectively (**Figure 1B**). TERF2IP, the partner of TERF2, interacts solely with TERF2, while TINF2 connects TERF1, and TERF2. POT1 is tethered to TERF1 and TERF2 via an interaction between TPP1 and TINF2 (7). Telomeric DNA along with the shelterin protein complex maintains the specialized telomere structure and protects the ends of chromosomes from degradation, fusion, and recombination for maintaining genomic integrity (8). Moreover, mammalian CTC1-STN1-TEN1 (CST) complex does localize to telomeres, which resembles the Cdc13-Stn1-Ten1 complex from *Saccharomyces cerevisiae* in that the STN1 and TEN1 subunits are conserved. CST complex binds to single strand DNA in a non-sequence specific manner and plays a key role in telomere replication (9–11). In addition, various DNA repair proteins contribute to telomere maintenance including TL maintenance via interacting with telomere proteins or modifying telomere proteins, including Polβ, FEN1, APE1, XPF-ERCC1 complex, and MRN complex which are involved in base excision repair pathway, nucleotide excision repair pathway and double strand break repair pathway, respectively (12–15).

Telomerase

Inability of DNA polymerase complex to replicate the 3′-end of the lagging strand in linear chromosomes leads to telomere shortening by each cycle of DNA replication during cell division, so-called end replication problem. As the number of cell division increases, TL is gradually shortened. When TL is reduced to the critical length, cells stop dividing and may enter cellular senescence or apoptosis (16). To counter this issue, human telomerase is responsible for synthesizing telomeric DNA to compensate the erosion of TL during DNA replication. Telomerase is a unique ribonucleoprotein enzymatic complex consisting of a RNA component and a protein component, telomerase RNA component (TERC), and telomerase reverse transcriptase (TERT). TERC is a non-coding RNA which is essential for telomere synthesis by serving as a template for the elongation of telomere 3′ overhang of the telomeric G-rich strand, while TERT catalyzes the process by its reverse transcriptase activity (17). In mammalian, telomerase is active only in germ cells, some types of stem cells and cancer cells, while most human somatic cells lack telomerase activity. Moreover, the activity of telomerase is regulated by the shelterin complex, CST complex, and telomeric repeat containing RNA (TERRA) which is transcribed from telomeric DNA. For example, shelterin complex control telomerase-dependent telomere elongation through a TERF1-mediated negative regulatory pathway, i.e., the more TERF1 is binding to telomeres, the less telomerase accesses to the ends of telomeres leading to less telomere elongation (13, 18, 19). In addition, the phosphoryaltion and PARylation of TERF1 promotes the release of TERF1 from telomeres contributing to telomere lengthening (13, 20, 21). Recently, the structure of telomerase with telomeric DNA has been resolved, which will promote the understanding the function of telomerase (22).

TL AND STROKE

TL maintenance is critical for human health as telomere shortening is associated with aging and various age-related diseases. Leukocyte telomere length (LTL) is served as a marker in a number of association studies of aging and age-related diseases (3, 23–26). The alteration of LTL has been observed in patients with stroke, which is one of the most common age-related diseases leading to death and disability. The positive association between short LTL and the risk of stroke was reported in the case-control studies from China, while the short LTL was also associated with post-stroke death (2, 25, 27, 28). In a 10-year prospective study from the United States, the positive association between short LTL and increased risk of stroke was only existed in the population ranging from 65 to 73 years old, but not in the population beyond 73 years old (29). A study from Europe showed that short LTL was associated with cerebrovascular accidents in the hypertensive patients with left ventricular hypertrophy aged 55–80 years (30). Moreover, short LTL was associated with higher mortality rate in patients with cardiovascular diseases aged 60 years or older (31). However, two nested case-control studies from the United States have not found the positive association between LTL and stroke (32, 33). In addition, no association between short LTL and stroke was found in a 29-year cohort study from Denmark (34). It has to be noted that the participants aged 30–55, 40–84, and 30–60 years, respectively, in the three studies when the blood samples were collected. It highly suggested that the positive

association between short LTL and the risk of stroke or post-stroke death might only exist in the aged population although further validation is necessary. Recently, two meta-analysis have been performed to investigate the association between TL and stroke. First, a meta-analysis including 11 studies showed that shortened TL is significantly associated with stroke, even though subgroup analysis showed equivocal results for both prospective ($n = 7$, $p = 0.051$) and retrospective ($n = 4$, $p = 0.067$) studies (35). The high heterogeneity, particularly age difference, and reduced sample size might contribute the equivocal results of the subgroup analysis. Another meta-analysis based on causal inference approaches using TL-related SNPs as instrumental variables did not support the causal effect of shorter TL on ischemic stroke (36). It has to be noted that age, one of the most important covariates, was not considered in this study. As previous studies do indicate that the positive association between short LTL and the risk of stroke or post-stroke death might only exist in the aged population, the effect of age might need to be taken into consideration in future studies. Currently, although mechanisms of the positive association between short LTL and stroke in the elderly remain elusive, multiple signaling pathways may contribute the positive association, e.g., apelin-apelin receptor mediated signaling pathway, histone deacetylases mediated epigenetic regulation (37, 38).

RISK FACTORS OF STROKE AND TL

Age

Age is one of the major risk factors of stroke (39). The incidence of stroke is increased with age, and the mean age at first-ever stroke was more than 68 years (40). TL is considered as a marker of the biological aging process because it shortens with each cell division. The estimated shortening rate is about 25–27 base pairs per year with individual difference (23, 41, 42). However, the actual LTL shortening rate is about 31–72 base pairs per year (23, 43). It suggests that many factors may contribute to LTL shortening in addition to end replication problem. For example, oxidative stress-induced oxidative DNA damage could lead to telomere uncapping and subsequent telomere shortening, while telomere shortening further enhances oxidative stress forming a vicious cycle (44–47). Age-related increase of oxidative damage is observed in human (48, 49). Moreover, increased evidence suggests that reduction of mitochondria function contributes to the aging process (50). Dysfunction of mitochondria contributes to age-related increase of oxidative stress, which in turn leads to TL shortening (51). Furthermore, multiple molecules (e.g., apelin, HDAC4, RCAN1, α-synuclein), altered in stroke are implicated in aging process, premature disorders (e.g., Down syndrome, Werner syndrome) and age-related disorders (e.g., Alzheimer's disease, Parkinson's disease, Huntington's disease) (37, 38, 52–66). Thus, age-related physiological or pathological alterations may also contribute to TL shortening.

Genetic Factors

Growing evidence indicates that genetic factors play a major role in stroke and family history of stroke is associated with increased stroke risk (67–69). Genomewide association study (GWAS) showed that the heritability for all ischemic stroke was 37.9%, while the heritability varied markedly in different subtypes of stroke, 32.6% for cardioembolic stroke, 40.3% for large-vessel stroke and 16.1% for small-vessel stroke (70). It was also reported that genetic factors appeared to be more important in large-vessel and small-vessel strokes than in cardioembolic stroke (71). Moreover, various genetic variants associated with short telomeres also contribute to the risk of stroke. For example, genetic variants of *ACYP2* and *TSPYL6* were associated with shorter telomere, which did contribute to the increased risk of stroke (72, 73).

Obesity

Obesity is associated with elevated risk of stroke. A number of studies showed that obesity is consistently associated with increased inflammation and oxidative stress, which promotes telomere shortening (74–80). Valdes et al. found that LTL of obese women was 240 bp shorter than that of age-matched lean women (41). A couple of cross-sectional studies showed a negative correlation between LTL and obesity (81, 82), whereas others did not show significant associations between LTL and obesity (83, 84). A recent meta-analysis showed there is a tendency toward demonstrating negative correlation between obesity and TL. Although 39 of 63 studies showed either weak or moderate correlation between obesity and TL, heterogeneity among the selected studies made the relationship of obesity and TL still open (85).

Smoking and Alcohol Intake

Smoking is a well-established risk factor for all forms of stroke (86–88). Even passive smoking significantly increases the risk of stroke (89–91). Meta-analysis including 30 studies showed that shorter LTL was among ever smokers compared to never smokers, while the dosage of smoking was negatively associated with LTL (92). Moreover, Valdes et al. showed that each pack-year smoked caused an additional loss of 5 base pairs of LTL per year (41). Babizhayev et al. reported that telomere attrition can serve as a biomarker of the oxidative stress and inflammation induced by tobacco smoking (93). In addition, heavy alcohol consumption was strongly associated with a reduced LTL in participants aged ≥65 years (94).

Psychological Stress and Depression

Numerous studies demonstrated that psychological stress caused by negative life event, work stress, illness etc. has significant effect on the risk of stroke (95–98). Accelerated LTL shortening was associated with psychological stress, which might be caused by psychological stress-induced higher oxidative stress and lower telomerase activity (99, 100). In addition, depression is a strong risk factor for stroke, while long-term stress could lead to depression (101, 102). Although the association between LTL and depression was inconsistent, two meta-analyses showed that short LTL was associated with depression (103, 104).

Age-Related Diseases

Hypertension

Hypertension is one of the most important modifiable risk factors for stroke. The strong, direct, linear, and continuous association between increased blood pressure and stroke risk was observed, while intensive blood pressure lowering appears to be beneficial for the reduction of stroke incidence (105–109). Two studies showed that LTL was negatively associated with pulse pressure and hypertension (110, 111). Importantly, meta-analyses from 3,097 participants showed that LTL of hypertensive patients was significantly shorter than that of controls (112).

Diabetes

Diabetes is an independent risk factor for stroke with a 2-fold increased risk in stroke for diabetic patients (113). Compared with control individuals, TL is significantly shorter in patients with type 1 diabetes or type 2 diabetes (114–121). For example, LTL was significantly shorter in type 2 diabetes cases compared with controls over a wide age range in a retrospective case-control study comprising 4,016 subjects (121). Moreover, the escalated telomere attrition was associated with insulin resistance in young adults aged from 21.0 to 43.5 years, which might be caused by increased oxidative stress, metabolic and inflammatory factors (122). In addition, the inverse association between LTL and body mass index (BMI)was observed (120).

Cardiovascular Diseases

Short LTL are associated with various cardiovascular diseases (CVD) including atherosclerosis, myocardial infarction, coronary artery disease (CAD) and atrial fibrillation (AF) (123–129). For example, short TL was associated with severe CAD adjusting for age and sex (123). A recent systematic review and meta-analysis from 43,725 participants and 8,400 patients suggested that LTL was inversely associated with the risk of coronary heart disease independent of conventional vascular risk factors (26). LTL was shorter in patients with myocardial infarction than that in age-matched control individuals (124). In a prospective study, Chen et al. examined LTL at baseline to predict the incidence and progression of carotid atherosclerosis (130). Compared to participants in the highest LTL tertile, those in the lowest tertile had significantly elevated risk for both incident plaque and plaque progression (130). A recent study indicated that telomere shortening may constitute a novel factor for cardioembolic stroke in patients with AF (129).

Although the underlying mechanism of the relationship between short LTL and CVD remains elusive, booming studies have provided a number of hypotheses (131–133). First, genomic evidence showed that inheritance of shorter telomere might act as a cause of CVD. Genome-wide association studies (GWAS) identified a small set of loci, including SNPs within *TERT* and *TERC*, but all with very small R^2 values (<0.5%) (72, 134). Moreover, it has been reported that cardiovascular risk-related systemic oxidative stress and inflammation might accelerate telomere attrition (135). In addition, the attrition-rate hypothesis implies that variation in adult telomere attrition rates might be more important than TL inheritance (136), indicating that telomere attrition rate could serve as a clinical atherosclerosis CVD biomarker. However, a smaller longitudinal study did not show and so on an association between leukocyte telomere attrition rate and atherosclerosis (137).

CONCLUSIONS

Short LTL is positively associated with stroke in the elderly population. In addition, multiple risk factors of stroke are associated with shortened LTL, e.g., age, smoking, alcohol intake, psychological stress, while the possibility of short LTL as an independent risk indicator of stroke still remains. It indicates that LTL might serve as a potential biomarker to evaluate the risk of stroke in the elderly. Moreover, short LTL was also positively associated with the mortality of stroke and cardiovascular diseases, indicating that LTL might be a potential biomarker to predict the prognosis of stroke.

Despite the high prevalence and devastating outcome, only a few treatment options for cerebral ischemic stroke exist. Based on the nitric oxide (NO)-stimulating capacity of Non-pulsed Sinusoidal Electromagnetic Field (NP-SEMF) and the possible neuroprotective role of NO in ischemic stroke, we hypothesized that NP-SEMF is able to enhance survival and neurological outcome in a rat model of cerebral ischemia. The animals, in which ischemic injury was induced by occlusion of both common carotid arteries, received 20 min of NP-SEMF of either 10 or 60 Hz daily for 4 days. NP-SEMF dramatically increased survival, reduced the size of the infarcted brain area and significantly improved the neurological score of the surviving rats. Corresponding to previous reports, NP-SEMF was able to induce NO production *in vitro*. The importance of NO as a key signaling molecule was highlighted by inhibition of the NP-SEMF beneficial effects in the rat stroke model after blocking NO synthase (NOS). Our results indicate for the first time that NP-SEMF exposure (13.5 mT at 60 and 10 Hz) improves the survival and neurological outcome of rats subjected to cerebral ischemia and that this effect is mediated by NO, underlining the great therapeutic potential of NP-SEMF as a therapy for ischemic stroke.

Keywords: cerebral ischemia, nitric oxide, electromagnetic field, endothelial cell, neuroprotection

INTRODUCTION

Cerebral ischemic stroke is caused by the occlusion of a major artery in the brain, which results in extensive brain tissue loss. Cerebral ischemic stroke is a major cause of mortality and disability worldwide (Kissela et al., 2009; Feigin et al., 2014). Currently, the only available treatment options are tissue plasminogen activator and thrombectomy, which have significant effectivity after stroke. However, these therapies can only be used in a small subset of cases, indicating the clear need for new interventions (Zhang et al., 2013).

Nitric oxide (NO) is an important signaling molecule that is synthesized from its precursor L-arginine by nitric oxide synthase (NOS). Following stroke, NO produced by the neuronal and

inducible isoforms of NOS exerts neurotoxic effects, while NO supplied by endothelial NOS (eNOS) is beneficial by stimulating several mechanisms such as vasodilation, angiogenesis, and neurogenesis. As a consequence of these later positive effects, NO donors display therapeutic effects in animal stroke models (Terpolilli et al., 2012; Garry et al., 2015). Extremely low frequency electromagnetic field (ELF-MF) has been shown to induce NO production (Jelenkovic et al., 2006; Bragin et al., 2015). ELF-MF is defined by a magnetic flux below 20 mT with a frequency range of 1 to 300 Hz and is applied in a pulsed or non-pulsed fashion. Pulsed ELF-MF is intensively investigated and used in the clinic to treat delayed union bone fractures and wounds (Pesce et al., 2013). Furthermore, pulsed ELF-MF is beneficial in preclinical models of hind limb ischemia (Li et al., 2015), myocardial infarction (Yuan et al., 2010; Hao et al., 2014) and traumatic brain injury (Rasouli et al., 2012). In contrast, NP-SEMF is less studied but shows clinical promise in a rat model of Huntington's disease (Tasset et al., 2012). Although the precise cellular mechanism activated by ELF-MF is poorly characterized, NO is induced by both pulsed ELF-MF and NP-SEMF in the brains of healthy rats (Jelenkovic et al., 2006; Bragin et al., 2015).

Because of the promising preclinical data of NO donors as a stroke therapy and the ability of NP-SEMF to induce NO production, we investigated the effect of NP-SEMF in a rat model of cerebral ischemia. We also studied the influence of NOS inhibition on NP-SEMF-induced neuroprotective effects. To our knowledge, this study is the first to show the therapeutic effect of NP-SEMF in brain ischemia and its NO-dependence.

MATERIALS AND METHODS

Generation of NP-SEMF

Based on our previous results using NP-SEMF for pain relief (Niubó Elías et al., 2010), we used an electromagnetic field strength of 13.5 mT and a non-pulsed sinusoidal frequency of 10 and 60 Hz during a short application of 20 min. NP–SEMF was generated using a coil (ferromagnetic core radius 16 mm; wire diameter 0.20 mm; 950 turns) connected to a Magnetic Stimulator NaK-02. The NaK-02 function generator was coupled to a power amplifier (high fidelity amplifier; bandwidth 10 Hz–20 kHz; output 60 W) to generate a continuous sinusoidal current source (for detailed specifications see **Supplementary Data S1**). The resulting magnetic field showed a sinusoidal distribution in function of time as exemplified in **Figure 1A**. During the exposure time, a continuous sinusoidal current was applied without intervals, which is in contrast to pulsed ELF-MF.

Permanent Bilateral Common Carotid Arteries Occlusion (2CCAO Model) in Rats

Cerebral ischemia was induced in Wistar rats (6–8 weeks old), in which both common carotid arteries were permanently occluded with 5-0 silk suture (Yamaguchi et al., 2005). Animals that died immediately after the procedure or demonstrated bleeding during surgery were excluded. Treated groups (10 and 60 Hz both 13.5 mT) were repeatedly exposed to NP-SEMF during 20 min on 4 subsequent days, with first exposure 3 h after injury (experimental setup, see **Figure 1B**). A group of sham operated animals, which were subjected to the same surgical intervention but without vessel occlusion, was also included. Survival was evaluated daily for 7 days. The open field test was performed to assess general locomotor activity (measuring the number crossing the fourth quadrant) and spontaneous exploratory activity (measuring the number of rears, thus the frequency at which the rodent stands on its hind legs). This was done before surgery (baseline level) and 7 days after surgery. Neurological outcome was scored double blindly 24 h and 7 days after surgery (**Supplementary Table S1**) (Menzies et al., 1992). Experimental procedures were approved by the "Scientific and Ethic Council of the CNEA." All conducted experiments were performed according the standard biosecurity and UHasselt (BIOMED), and CNEA safety procedures.

Staining of Brain Sections With 2,3,5-Triphenyltetrazolium Chloride (TTC)

Seven days after surgery, animals were sacrificed. Brain slices of 1 mm were made and stained for 30 min in a 2% TTC solution (Sigma, St. Louis, MO, United States). TTC stains non-damaged tissue in red, while death tissue remains white. Infarct quantification was performed on digital photographs using ImageJ (NIH, Bethesda, MD, United States).

NO Production by HMEC-1 Cells After NP-SEMF

Human immortalized microvascular endothelial cells (HMEC-1) were seeded in 24 well plates (40,000 cells/well). 24 h later, the medium was replaced and cells were treated with NP-SEMF (13.5 mT, 20 min. 10 or 60 Hz) with or without the NOS inhibitor L-NMMA at different concentrations (1.5 mM, 150 μM, 15 μM and 1.5 μM). L-NMMA was added 15 min before NP-SEMF (A scheme of the experimental setup is provided in **Supplementary Figure S2**). 1 h or 24 h later, medium was collected and the amount of nitrite (a non-volatile breakdown product of NO) was measured using Griess assay (Promega, Leiden, Netherlands).

In vivo Inhibition of NO After NP-SEMF Treatment

Cerebral ischemia was induced in male Wistar rats by 2CCAO. The NOS inhibitor (L-NAME) was injected intraperitoneally (20 mg/kg) (Delwing et al., 2005) once 15 min before surgery and daily 15 min before NP-SEMF treatment. Untreated animals received an intraperitoneal saline injection. Survival was monitored daily. At day 7, the rats were sacrificed and TTC staining was performed.

Statistical Analysis

Statistical analysis was done with Graphpad Prism software (Graphpad, San Diego, CA, United States). Statistical significance was set at $p < 0.05$.

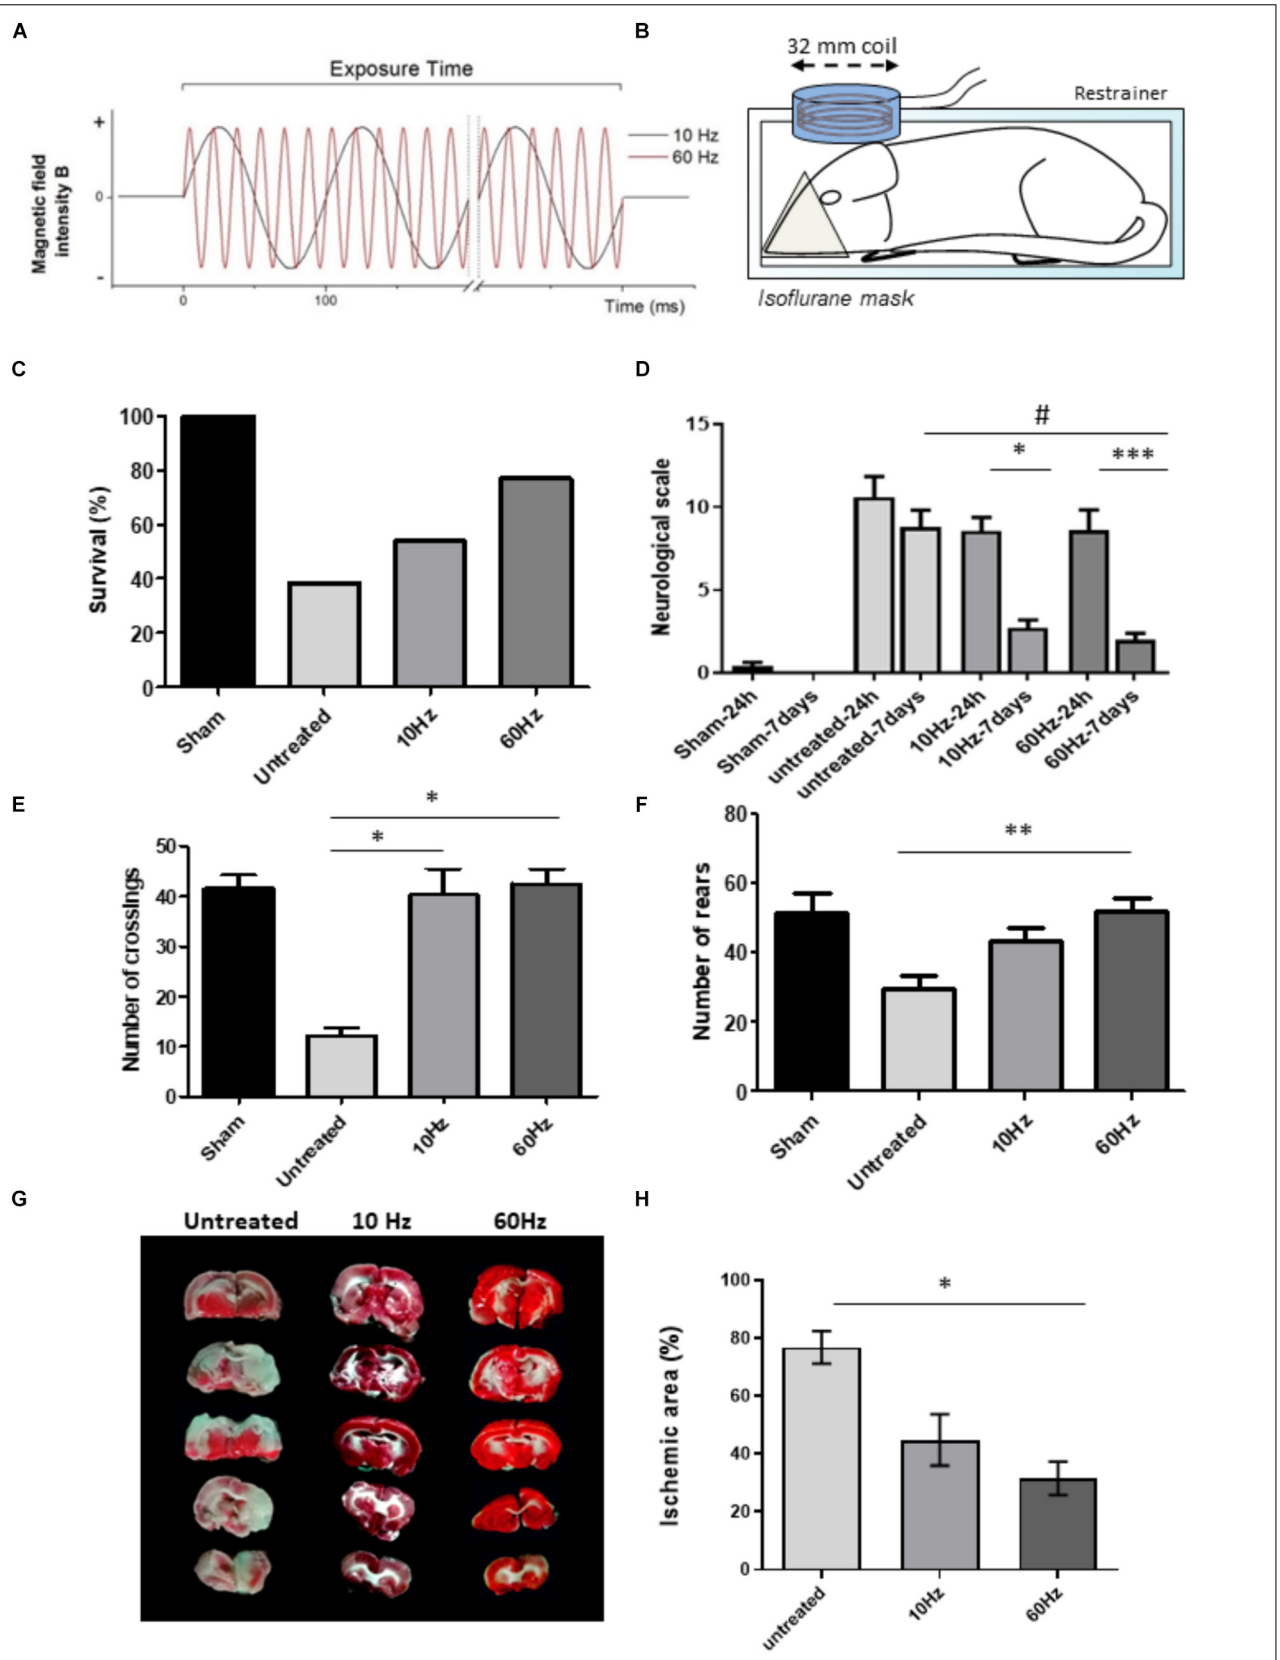

FIGURE 1 | Continued

FIGURE 1 | Beneficial effects of NP-SEMF in a rat model of ischemic stroke. Cerebral ischemia was induced by using the standard two-vessel occlusion (2CCAO) protocol in Wistar rats. Treated groups (10 and 60 Hz both 13.5 mT; n = 13/group) were repeatedly exposed to non-pulsed sinusoidal electromagnetic field (NP-SEMF) during 20 min on 4 subsequent days. The first exposure was performed 3 h after injury. **(A)** Graph showing the properties of the applied NP-SEMF. Sinusoidal magnetic waves were generated at either 10 or 60 Hz in a continuous fashion during the exposure time. **(B)** Scheme of the experimental set-up for the rat study. Rats were restricted in a plastic restrainer while receiving the anesthetic isoflurane during the NP-SEMF treatment. The plastic enclosed coil which has a diameter of 32 mm generates the NP-SEMF and is placed on top of the skull. **(C)** Survival was evaluated 7 days following stroke induction. Only 38% of the untreated animals survived 7 days after surgery while survival rates were substantially higher after NP-SEMF treatment (54% for 10 Hz and 77% for 60 Hz). **(D)** Neurological score was determined 24 h and 7 days after injury on the surviving animals. A higher score represents a higher number of deficits. n = 5/sham group and n = 13/untreated and treated groups. $^{*}p \leq 0.05$ and $^{***}p \leq 0.001$ 24 h vs. 7 days; $^{\#}p \leq 0.001$ 60 Hz NP-SEMF 7 days vs. untreated 7 days post-surgery. All calculated with a Kruskall–Wallis test and Dunnett's *post hoc* test. **(E)** Open field test was assessed before surgery (baseline) and 7 days after surgery. The frequency to cross the fourth quadrant was measured to assess the effect on locomotion. $^{*}p \leq 0.05$ vs. untreated, as analyzed with a Kruskal–Wallis test with a Dunnett's *post hoc* test. **(F)** In the open field tests, the number of rears (i.e., animal raises his forepaws) was measured as an indication of spontaneous exploratory behavior. $^{**}p \leq 0.01$ as analyzed with a Kruskal–Wallis test with a Dunnett's *post hoc* test. **(G)** Brain slices were stained with TTC to determine infarct size in 2CCAO animals. **(H)** The damaged area as well as the whole brain area was quantified using ImageJ. For every animal, the area of affected brain tissue was quantified and calculated as % of total brain area. Next, the averages of all animals of the same experimental group were made (5 sections/brain, n = 8/group, data represent average ± standard deviation). TTC was performed 7 days after surgery, on animals without treatment and animals which received 10 Hz or 60 Hz NP-SEMF. $^{*}p \leq 0.05$, $^{***}p \leq 0.001$ vs. control, as analyzed with a Kruskal–Wallis test with a Dunnett's *post hoc* test.

RESULTS

NP-SEMF Has Beneficial Effects in a Rat Model of Stroke

Cerebral ischemia was induced in rats by permanent occlusion of the two common carotid vessels. Animals where either untreated or received NP-SEMF treatment (10 or 60 Hz both 13.5 mT; n = 13/group) for 20 min during 4 subsequent days. Without treatment, the surgery causes death of 62% of the animals after 7 days (**Figure 1C**). NP-SEMF considerably improved the survival rates by 1.4-fold for 10 Hz and by 2.0-fold for 60 Hz. The neurological scale was assessed after 24 h and 7 days post-surgery (**Figure 1D**). For the untreated group, no statistical differences were found between 24 h and 7 days. In contrast, in both NP-SEMF groups, a significant improvement was evident after 7 days (from 8.6 ± 1.2 to 2.7 ± 0.5 for 10 Hz, and from 8.6 ± 0.8 to 2.0 ± 1.1 for 60 Hz). Functional outcome was measured with the open field test (**Figures 1E,F**). NP-SEMF treatment induced a significant improvement of locomotion as shown by a rescued frequency of crossing the fourth quadrant: from 12.2 ± 1.5 (untreated) to 40.2 ± 5.2 (10 Hz) and 42.5 ± 3.0 (60 Hz). The number of rears was significantly increased for the 60 Hz treated group (29.6 ± 3.8 in untreated animals versus 51.7 ± 4.1 in 60 Hz).

During NP-SEMF, animals are anesthetized with isoflurane and placed in a restrainer. To rule out any effect of this procedure, we studied animals (with 2CCAO) placed in the restrainer but without switching on the magnetic flux (= sham exposed animals) (**Supplementary Figure S1**). No amelioration in survival nor neurological outcome were observed.

NP-SEMF reduced the severity of the ischemic brain damage (**Figures 1G,H**). TTC staining 7 days after injury revealed that untreated animals displayed large white infarcted areas in both the cortex and the striatum as quantified with ImageJ. The infarcted brain area was reduced by more than 50% after 60 Hz NP-SEMF treatment and the remaining lesions were mainly located in the striatum. The percentage of ischemic brain area in control animals was significantly reduced from 76.9 ± 5.6% toward 31.5 ± 5.8% in animals treated with 60 Hz. 10 Hz application did lead to a slight reduction in lesion size, although this difference was not statistically significant.

Inhibition of NOS Decreased NP-SEMF-Induced NO Production *in vitro*

To verify that NP-SEMF acts via NO, the NO production was indirectly measured with the Griess assay in HMEC-1 cells (**Figure 2A**). Nitrite concentration (and thus NO) was significantly increased 24 h after 60 Hz NP-SEMF (3.9 ± 1.3 μM in 60 Hz vs. control). The involvement of NOS was studied using the general NOS inhibitor L-NMMA, which was able to dose-dependently inhibit the NP-SEMF-triggered NO production (**Figures 2B,C**). The IC_{50} for 10 Hz was estimated 59.88 μM after 1 h and 85.53 μM after 24 h; The IC_{50} for 60 Hz was 7.3 μM after 1 h and 2.7 μM after 24 h.

NOS-Derived NO Was Essential for NP-SEMF-Effectivity *in vivo*

To prove the involvement of NO in the neuroprotective action of NP-SEMF after ischemic stroke, the general NOS blocker L-NAME was injected in 2CCAO rats to inhibit NO formation. The beneficial effect of NP-SEMF at 60 Hz on survival 7 days after ischemic stroke disappeared when NO-synthesis was blocked (**Figure 2D**). Inhibition of NOS with L-NAME inhibited the protective effect of NP-SEMF on tissue damage as the lesion size (in % of total area) was significantly increased (NP-SEMF+L-NAME 69.1 ± 3.4 vs. NP-SEMF alone 34.5 ± 6.2). The tissue damage in animals treated with both NP-SEMF and L-NAME were similar in size compared to the untreated group (**Figure 2E**). These results indicate that NO is a key signaling molecule by which NP-SEMF protects the brain from tissue damage after ischemic stroke.

DISCUSSION

As several studies have demonstrated the ability of ELF-MF to alter NO production and since NO has been suggested to be beneficial in stroke, we explored the use of NP-SEMF in a rat

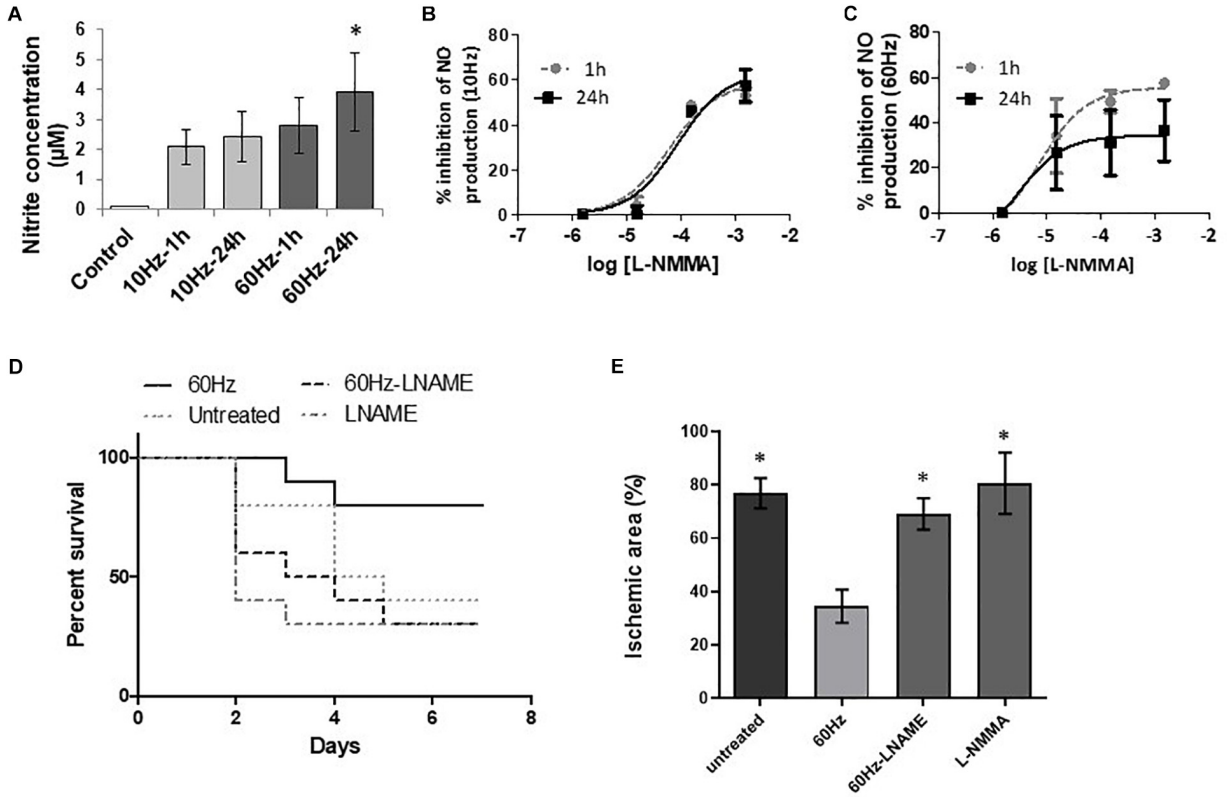

FIGURE 2 | Involvement of NO as key mediator of the beneficial effects of NP-SEMF. **(A)** Nitrite concentration (as an indirect measure for the NO concentration) induced by NP-SEMF was measured by Griess reaction, 1 h or 24 h after treatment of NP-SEMF for 20 min (13.5 mT at 10 or 60 Hz). Values are expressed as mean ± SD, $n = 4$, $^*p \leq 0.05$, as calculated with Kruskal-Wallis ANOVA test with a Dunnett's *post hoc* test. **(B)** Inhibitor effect of L-NMMA (1.5 mM, 150 μM, 15 μM, 1.5 μM) on NO production by HMEC-1 subjected to 10 Hz NP-SEMF for 20 min, $n = 4$. NO production was measured 1 h or 24 h after treatment. **(C)** Inhibitor effect of L-NMMA on NO release by HMEC-1 subjected to 60 Hz NP-SEMF. NO production was measured 1 h or 24 h after treatment, $n = 4$. **(D)** Rats were subjected to 2CCAO and received either no treatment, L-NAME injections, 60 Hz NP-SEMF or combination of L-NAME and NP-SEMF. L-NAME was injected at a dose of 20 mg/kg, 15 min before surgery and before each NP-SEMF treatment (13.5 mT for 20 min at 10 or 60 Hz). Kaplan-Meier graph shows the survival rates of these four groups during 7 days after surgery ($n = 10$/group). The percentage of surviving animals was higher after NP-SEMF treatment. L-NAME injection inhibited the beneficial effect of NP-SEMF on survival. **(E)** The ischemic area in the brain of the surviving rats was measured by TTC staining 7 days after surgery and calculated as ischemic area (in % of total area). Treatment of L-NAME obliterates the neuroprotective effect of NP-SEMF. $n = 4$/group, $^*p \leq 0.05$ vs. 60 Hz, according to a Kruskal–Wallis ANOVA test with a Dunnett's *post hoc* test.

model of severe cerebral ischemic stroke. Daily applications of 20 min of NP-SEMF (10 and 60 Hz) significantly improved survival, locomotion, and neurological outcome. The lesion size was dramatically reduced in rats treated with 60 Hz NP-SEMF. Our study confirmed that NO is the key player in this beneficial effect of NP-SEMF. NP-SEMF increased NO production in HMEC-1 cells, which was inhibited by the NOS-inhibitor L-NMMA. Moreover, the NOS blocker L-NAME reversed the beneficial effects of NP-SEMF in rats subjected to 2CCAO. This is in line with previous findings which showed that L-NAME prevents blood flow induction by pulsed ELF-MF in healthy rat brains (Bragin et al., 2015). Accordingly, L-NAME also reduced the angiogenic effects of endothelial cells induced by pulsed ELF-MF (Li et al., 2015).

We postulate that NP-SEMF is effective by inducing NO. In the acute phases of stroke, relative NO depletion occurs, leading to a reduction of cerebral blood flow (CBF) and the development of secondary damage. Therefore, increasing post-ischemic NO content to augment CBF toward the lesion is considered to be a promising treatment strategy for ischemic stroke. Indeed, numerous animal studies demonstrate the efficacy of NO donors or inhaled gaseous NO as an ischemic stroke therapy (Garry et al., 2015). Nevertheless, in the clinic, application of the NO precursor L-arginine or the NO donor glyceryl trinitrate has no beneficial effects in ischemic stroke (Bath et al., 2000), while other strategies based on NO (such as NO inhalation) are still in the experimental stage (Terpolilli et al., 2016). It is highly likely that NP-SEMF has a similar effect as NO donors or gaseous NO. An additional advantage of NP-SEMF is that it locally induces NO production in regions with interrupted blood flow, whereas gaseous NO or NO donors are administered systemically so might not reach the damaged regions and may provoke unwanted side effects (Garry et al., 2015). Possibly, NP-SEMF also activates other pathways independent of NO.

The mechanism by which NP-SEMF stimulates NO production remains to be investigated in detail. Previous studies

on healthy brains show enhanced NO levels in the brain but the underlying mechanism could not be revealed. NP-SEMF induces eNOS and iNOS expression in human keratinocytes (Patruno et al., 2010), while pulsed ELF-MF enhances phosphorylation of eNOS in a mouse hindlimb ischemia model (Li et al., 2015).

Taken together, our data clearly show the high potential of NP-SEMF to improve neurological outcome, lesion size and survival in a rat model of stroke. The fact that an electromagnetic field of low frequency during short time frames causes such a tremendous improvement sparks hope to translate this new "electroceutical" into the clinic.

The datasets generated for this study are available on request to the corresponding authors.

ETHICS STATEMENT

This study was carried out in accordance with the regulations of Scientific and Ethic Council of the CNEA (Centro Nacional de Electromagnetismo Aplicado), Santiago de Cuba, Cuba. The protocol was approved by the "Scientific and Ethic Council of the CNEA" (Centro Nacional de Electromagnetismo Aplicado), Santiago de Cuba, Cuba.

AUTHOR CONTRIBUTIONS

LF carried out the *in vivo* experiments and wrote the first draft of the manuscript. LF, HK, and AB carried out the *in vitro* experiments, histology, and prepared the figures. LF, MC, AB, and BB were involved in data interpretation. MC designed the NP-SEMF equipment. FG was responsible for device calibration. LF, AB, BB, HK, MC, RM, FG, OS, IL, and J-MR contributed to the project design and reviewed the manuscript. All authors who contributed to manuscript revision, read, and approved the submitted version.

FUNDING

This work was supported by the Belgian Development Cooperation through VLIR-UOS (Flemish Interuniversity Council-University Cooperation for Development) in the context of the Institutional University Cooperation Program with Universidad de Oriente and the Institutional Research Founds of the Centro Nacional de Electromagnetismo Aplicado, Cuba, and through BOF-BILA, doctoral grants in the framework of the bilateral cooperation, University Hasselt. AB benefits from a research grant of the FWO (Research Foundation – Flanders-Grant Nos. 1266015N and 1522518N).

ACKNOWLEDGMENTS

We would like to acknowledge Petra Bex and Neldris Zamora Suárez for their excellent technical assistance. HMEC-1 were a kind gift of the Centers for Disease Control and Prevention (Atlanta, GA, United States).

Cerebral ischemia is a complex pathology involving a cascade of cellular mechanisms, which deregulate proteostasis and lead to neuronal death. Proteostasis refers to the equilibrium between protein synthesis, folding, transport, and protein degradation. Within the brain proteostasis plays key roles in learning and memory by controlling protein synthesis and degradation. Two important pathways are implicated in the regulation of proteostasis: the unfolded protein response (UPR) and macroautophagy (called hereafter autophagy). Both are necessary for cell survival, however, their over-activation in duration or intensity can lead to cell death. Moreover, UPR and autophagy can activate and potentiate each other to worsen the issue of cerebral ischemia. A better understanding of autophagy and ER stress will allow the development of therapeutic strategies for stroke, both at the acute phase and during recovery. This review summarizes the latest therapeutic advances implicating ER stress or autophagy in cerebral ischemia. We argue that the processes governing proteostasis should be considered together in stroke, rather than focusing either on ER stress or autophagy in isolation.

Keywords: stroke, autophagy, ER stress, proteostasis, mTOR

INTRODUCTION

Cerebral ischemia is a major cause of adult mortality and disability in developed countries. It is characterized by a reduction of cerebral blood flow, leading to a dramatic drop of energetic supply, altered cellular homeostasis and finally cell death (Doyle et al., 2008; Yepes et al., 2009). Several pathways leading to neuronal death are activated during ischemic events. Historically, glutamate receptor-mediated excitotoxicity, apoptosis and inflammation have been shown to be important parts of ischemia-mediated neuronal death (Dirnagl et al., 1999). More recently, ER stress via the UPR (Roussel et al., 2013) and autophagy (Liu et al., 2010) pathways, either at the acute phase or during recovery, has received much attention in the stroke research field.

To date, only two therapeutic approaches are available to promote reperfusion during ischemic stroke: the recent mechanical clot removal (endovascular thrombectomy), and thrombolysis by tPA (Thiebaut et al., 2018). Of note, tPA administration is often combined with endovascular thrombectomy, especially in patients with large vessel occlusion (Berkhemer et al., 2015). However, both treatments have their own limits: tPA has a narrow therapeutic window (4.5 h after stroke onset) (Hacke et al., 2008), presents a risk of hemorrhagic transformation and has a low recanalisation rate (National Institute of Neurological Disorders and Stroke rt-Pa Stroke Study Group, 1995; Thiebaut et al., 2018); while endovascular thrombectomy is restricted to large vessel occlusions (Berkhemer et al., 2015). Several strategies of neuroprotection have been tested in stroke, but no clinical trials have demonstrated any beneficial effect in patients (Young et al., 2007). To overcome this challenge, better stroke models and trial designs are required, and integration of multiple complex signaling pathways will be necessary to provide a complete understanding of stroke (Karsy et al., 2017).

Among such pathways, those maintaining proteostasis appear especially relevant as they encompass many responses, from changes in protein synthesis and folding to secretion and degradation. Moreover, altered proteostasis is implicated in both the acute and recovery phases of stroke (Wang and Yang, 2018). The UPR, which is the proteostasis control system affecting the ER, maintains the balance between protein synthesis, folding and degradation within the organelle (Roussel et al., 2013). On the other hand, protein or organelle degradation during stroke is mainly driven by autophagy (with ubiquitination and SUMOylation), and more particularly, macroautophagy (called hereafter autophagy) (Liu et al., 2010).

AUTOPHAGY AND CEREBRAL ISCHEMIA

Autophagy is a protein degradation system highly conserved in all eukaryotes. Its name comes from Greek roots: "auto" which means "self" and "phagy" which means "eating." This self-protecting catabolic process is required for restoring cellular homeostasis under nutrient starvation or metabolic stress by degrading or recycling long-lived or misfolded proteins and damaged organelles (Klionsky et al., 2016). Depending on the mode of cargo delivery, three types of autophagy have been described: microautophagy, CMA and macroautophagy.

Microautophagy is a non-selective lysosomal degradative process referring to as the direct engulfment of cytoplasmic materials by the lysosome. In microautophagy, the lysosomal membrane is randomly invaginated to trap portions of the cytosol (**Figure 1A**). Microautophagy is known to play several roles, such as the regulation of the ratio of lipid to protein at the lysosomal surface, the maintenance of organelle size, the membrane composition and lipid metabolism. It can occur simultaneously with macroautophagy or simply be a constitutive method to degrade long-lived proteins and membrane proteins (Iwata et al., 2005; Krick et al., 2009).

Chaperone-mediated autophagy is a selective lysosomal degradative process requiring the presence within the substrate protein of a specific amino acid motif recognized by the chaperone hsc70. All cargo recognized by hsc70 are delivered to lysosomes where they bind to the LAMP2A (Bandyopadhyay et al., 2008; **Figure 1B**). Then, they are translocated one-by-one into lysosomes assisted by a chaperone located in the lysosomal lumen. CMA contributes to protein quality control through selective removal of altered or damaged proteins (Zhang and Cuervo, 2008).

In contrast to microautophagy and CMA, macroautophagy involves sequestration of the cargo away from the lysosome. Macroautophagy requires the synthesis of an autophagosome, a double-layered membrane structure, to transport cellular cargo targeted for degradation. Autophagosomes then fuse with lysosomes to form autophagolysosomes resulting in the degradation of their contents (**Figure 1C**). Because macroautophagy is the most abundant and characterized form of autophagy, our review will primarily focus on its mechanisms and effects in cerebral ischemia.

Autophagy occurs at a basal level in all mammalian cells and is regulated by conditions such as starvation, oxidative stress or hypoxia, and can also be triggered by obesity, diabetes, inflammation and cancer. The induction of autophagy appears as a promising therapeutic strategy for neurodegenerative diseases with protein misfolding and aggregation (Alzheimer's diseases, Parkinson's disease, Tauopathies, Huntington's disease, and various spinocerebellar ataxias) (Rubinsztein et al., 2012).

Autophagy Mechanisms in Physiopathological Conditions

Autophagy Processes and Signaling Pathway

The most common experimental approaches to induce autophagy are either nutrient starvation and or the use of rapamycin to inhibit the mTOR. Autophagy activates the ULK1 complex (ULK1, also known as Atg1 for intervention of autophagy-regulated 1), Atg13, and FIP200 (Noda and Ohsumi, 1998). The ULK1 complex also regulates the activation of a class III PI3K complex formed by Beclin-1, VPS34, and VPS15. When phosphorylated by ULK1, Beclin-1 promotes the generation of PI3P by VPS34, which upgrades autophagosomal

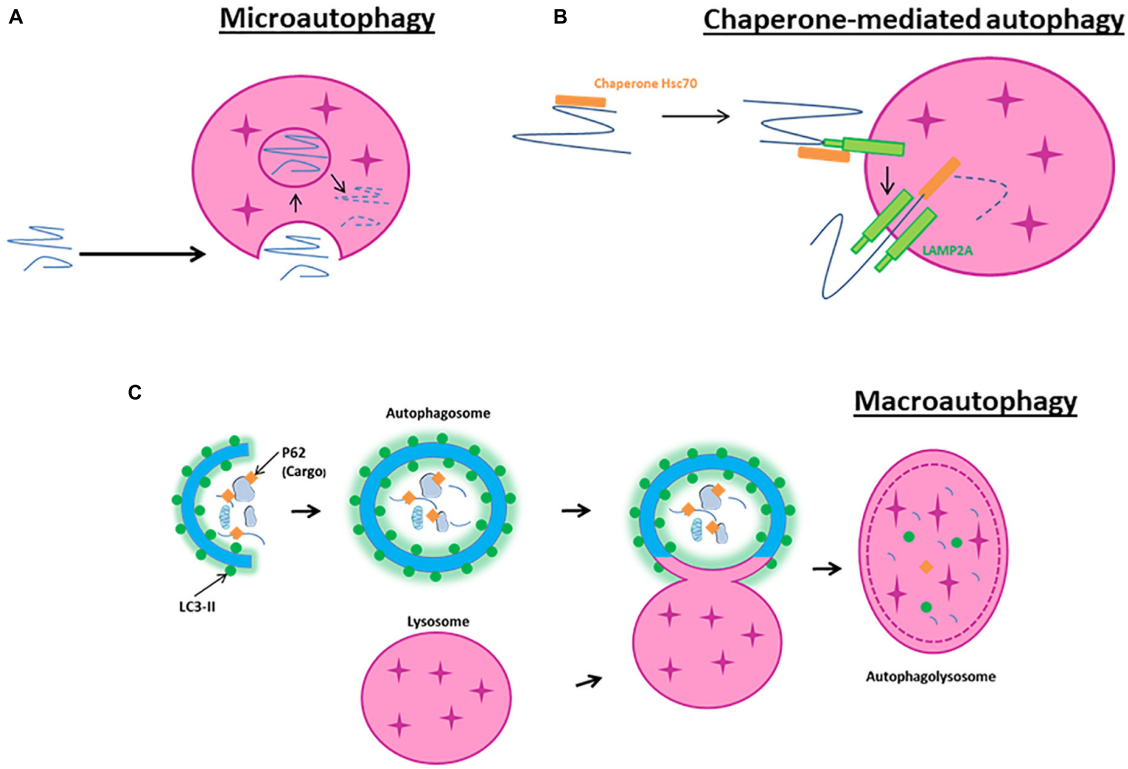

FIGURE 1 | Schematic model of autophagy. **(A)** Macroautophagy is the result of the fusion of an autophagosome, a double membrane vacuole transporting cellular cargo that has been targeted for degradation, with a lysosome. **(B)** Microautophagy is a non-selective lysosomal degradative process that involves direct engulfment of cytoplasmic materials by the invagination of the lysosome. **(C)** Chaperone-mediated autophagy involves the direct translocation, through LAMP2A, of specific proteins containing a motif recognized by a chaperone named hsc70 (heat-shock cognate protein of 70 kDa).

membrane nucleation (Russell et al., 2013; **Figure 2A**). On the other hand, Beclin-1 can bind to the anti-apoptotic protein Bcl-2 leading to the inhibition of autophagy (Pattingre et al., 2005). In response to starvation, JNK1 phosphorylates Bcl-2 allowing its release from Beclin-1 and the induction of autophagy (Pattingre et al., 2009; **Figure 2B**).

In addition to these two complexes, other Atg proteins are hierarchically required for the biogenesis of autophagosomes. Atg5 and Atg12, co-operate with Atg7, to promote the formation of an Atg5-Atg12- Atg16L1 complex, and thus facilitate the cargo recruitment and autophagosomes membrane elongation. The microtubule-associated protein light chain 3 (LC3, also named Atg8) is cleaved by Atg4 to yield LC3-I, then, LC3-I is conjugated to PE by Atg7 and Atg3 to become LC3-II (Mizushima et al., 2011). p62, also called SQSTM1, binds to ubiquitinated proteins, targeting them for degradation into autolysosomes through its binding to LC3-II in the autophagosome (Myeku and Figueiredo-Pereira, 2011). LC3-II is essential for phagophore formation, with the participation of GABARAP/GATE-16 subfamily members in later stages of autophagosome formation, in particular for phagophore elongation, closure and fusion (Weidberg et al., 2010). Autophagosome can acquire membranes from multiple sources including the ER, the Golgi apparatus, the plasma membrane and the mitochondrial outer membrane. This process requires the involvement of the only transmembrane Atg protein, Atg9, which is present in single-membrane vesicles providing membranes for early autophagosome formation (Yamamoto et al., 2012). The fusion between the autophagosome and the lysosome requires the recruitment from the ER and mitochondria of the SNARE protein STX17. STX17 interacts with SNAP29 and VAMP8 to form a *trans*-SNARE complex and mediates autophagosome-lysosomes fusion (Itakura et al., 2012).

Autophagy Activation in Brain Ischemia

Nitatori et al. (1995) were the first to demonstrate, by electron microscopy, an increase in cathepsin B-immunopositive lysosomes, in the CA1 pyramidal neurons 3 days after an ischemic insult. Since then, the evidence for activation of autophagy has continued to accumulate. For example, beclin 1 is activated and associated to a LC3-II increase following neonatal hypoxia-ischemia (HI) (Carloni et al., 2008) and focal cerebral ischemia (Rami et al., 2008). In neonatal cerebral HI, in addition to the increase in autophagosomal formation (characterized by an increase of LC3-II), there is also an increase of lysosomal activity in damaged cortical and CA3 neurons, suggesting an increase in the autophagic flux (Ginet et al., 2009). These results are confirmed in a pMCAO. Moreover, immunofluorescence shows strong co-localisation of autophagosomal puncta (LC3-II) and lysosomes (cathepsin D and LAMP1) (Puyal et al., 2009).

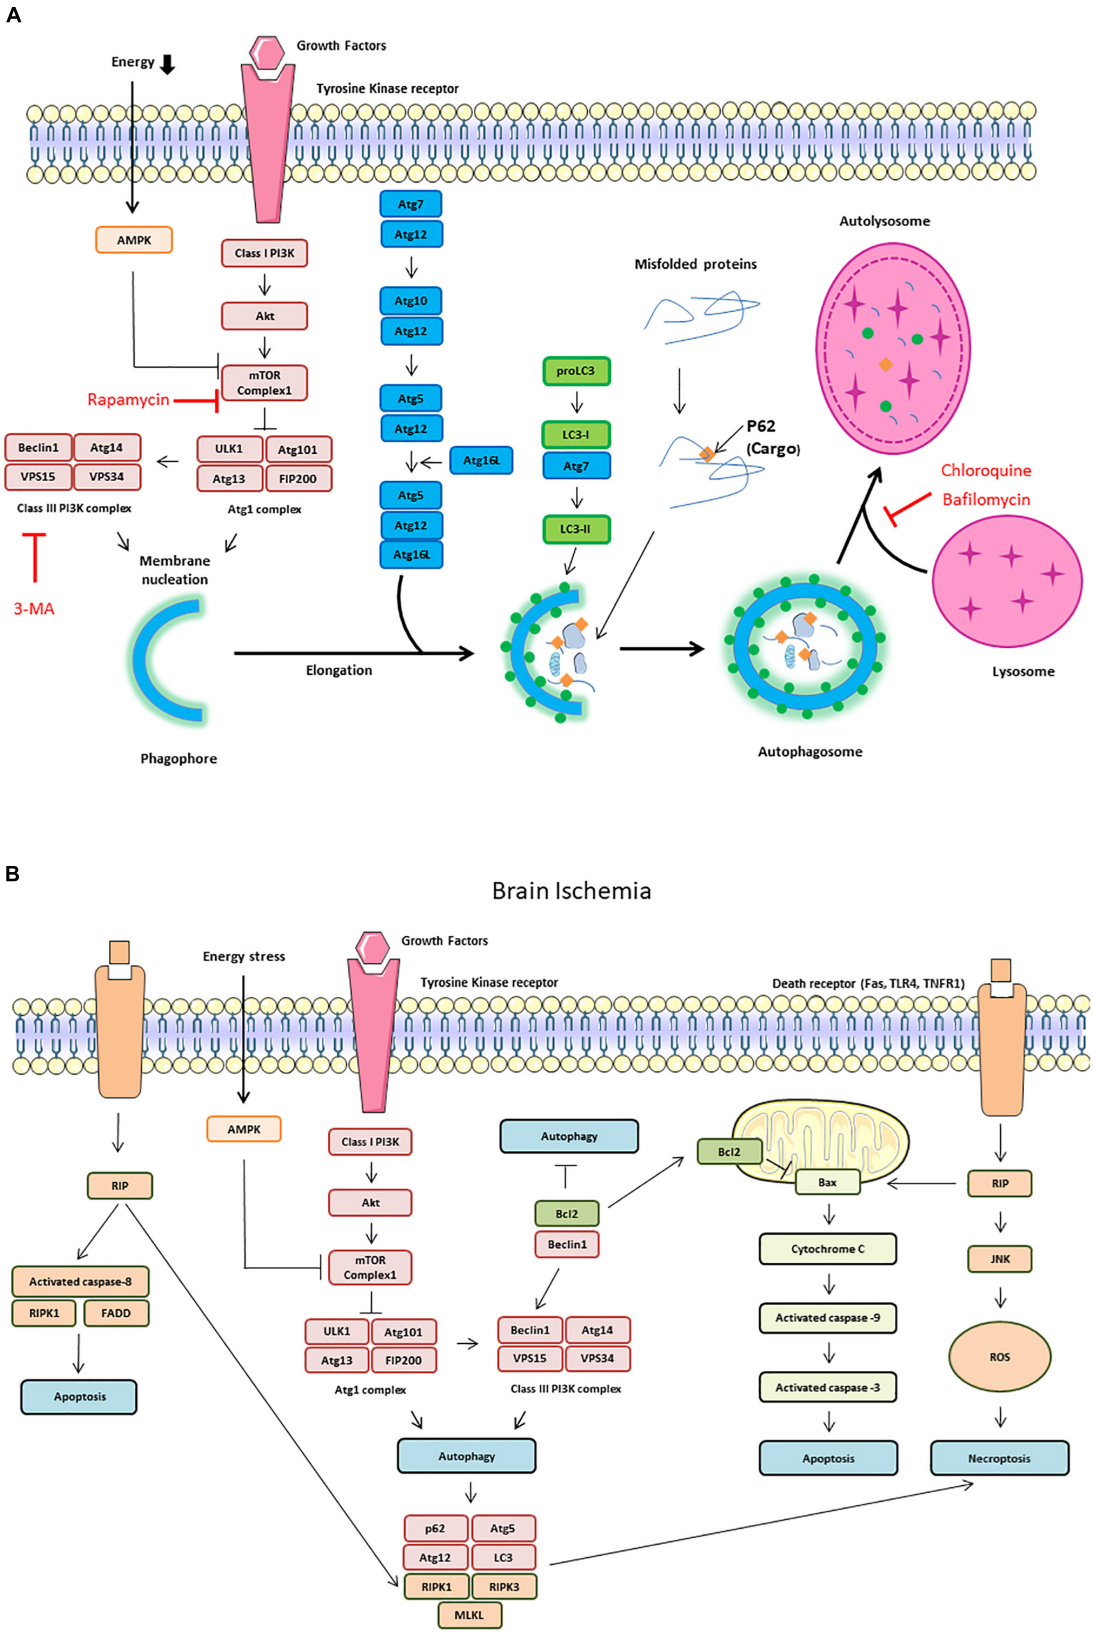

FIGURE 2 | Continued

FIGURE 2 | Autophagy signaling pathway. Autophagy is induced by an energetic stress, leading to AMPK activation; or by growth factors starvation, leading to the inhibition of the class I phosphatidylinositol 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR) pathway. Two complexes can be involved in autophagy induction: ULK1 complex composed of autophagy-regulated 101 (Agt1), Atg101, FIP200, and ULK1 and class III PI3K complex form by Beclin-1, vacuolar protein sorting 34 (VPS34) and vacuolar protein sorting 15 (VPS15). **(A)** Schematic illustration of autophagy initiation and autophagosome formation. Different Atg proteins including Atg5-Atg12-Atg16L and the microtubule-associated protein LC3-II are involved in double membrane elongation and in autophagosome-lysosome fusion. P62 binds to ubiquitinated proteins targeting them for degradation in the autolysosomes. Rapamycin can activate autophagy by inhibiting mTOR Complex 1. Both 3-MA (3-methyladenine), chloroquine and Bafilomycin are autophagy inhibitors by, respectively, inhibiting Class III PI3K complex and autophagosome/lysosome fusion. **(B)** Schematic illustration of cross talk and interaction among autophagy, apoptosis and necroptosis during brain ischemia. The dissociation of Beclin1 and Bcl-2 is also responsible of autophagy increase. The receptor interacting protein (RIP) Kinase 1 activation by death receptors, such as Fas, TLR4 and TNFR1, is responsible of Jun N-terminal kinase 1 (JNK1) pathway activation, ROS (reactive oxygen species) release and necroptosis. RIP1 interacts with FADD (Fas-Associated protein with Death Domain) and TRADD (Tumor necrosis factor receptor type 1-associated DEATH domain protein) to induce extrinsic apoptosis. RIP1 is also involved in intrinsic (mitochondrial) apoptosis through cytochrome C release which activates caspase-9 and capase-3.

Furthermore, a study with 37 acute ischemic stroke patients revealed that CSF and serum levels of both Beclin-1 and LC3 are increased compared to control patients (Li et al., 2015), suggesting that autophagic cells die and release these markers in the circulation. Levels of Beclin1 and LC3 in CSF are positively correlated with infarct volumes and the severity of neurological deficits (NIHSS and Modified Rankin Scale) (Li et al., 2015). In addition, the expression of autophagic and apoptotic genes is increased in blood samples of ischemic stroke patients (Guo et al., 2017). However, Liu et al. (2010) reported that autophagy pathway is up-regulated after cerebral ischemia/reperfusion, but fails to operate correctly. They propose the idea that at least a part of the accumulation of protein aggregate-associated organelles seen following ischemia is due to the failure of autophagosomes to fuse with lysosomes (Liu et al., 2010).

After brain ischemia, autophagy-related signaling pathways are dramatically activated. In neonatal HI, Akt and CREB are activated in neurons and both phospho-Akt and phospho-CREB colocalized with Beclin-1. In this model, it has been shown that activation of autophagy activated by rapamycin was neuroprotective, and this was associated with the activation of Akt/CREB signaling (Carloni et al., 2010). During ischemia, a decrease in ATP concentration increases the AMP/ATP ratio and activates AMPK. Active AMPK leads to phosphorylation of TSC1/2 (tuberous sclerosis proteins 1 and 2) and inhibition of mTORC1 activity through Rheb. Several groups have reported the involvement of AMPK signaling pathway in the mediation of autophagy-related neuroprotection in brain ischemia (Wang et al., 2012; Gabryel et al., 2014; Jiang et al., 2014; Dai et al., 2017). Conversely, a study has shown that inhibition of AMPK activity inhibits autophagy and alleviates focal cerebral ischemia injury in mice by restoring mTORC1 activity (Fu et al., 2016). Autophagy may also be increased by the HIF-1α, a key transcription factor activated by the low oxygen conditions observed during cerebral ischemia (Xin et al., 2011; Yang et al., 2014; Zhang et al., 2018).

Role of Autophagy in Cerebral Ischemia

While brain ischemia is known to induce autophagy, its protective or deleterious role remains unclear. Indeed, *in vitro* and *in vivo* studies report contradictory effects of autophagy induction during ischemia.

Neuronal Autophagy in the Ischemia Brain

Neuronal autophagy occurs early during cerebral ischemia, with autophagosomes and autolysosomes detectable just 1 h after pMCAo, and increasing up to 12 h thereafter (Wen et al., 2008). In line with this, Tian et al. (2010) showed, using GFP-LC3 transgenic mice, increased levels of autophagosomes in the ipsilateral hemisphere at 1, 3, and 6 days following tMCAo, with a peak at 1 day. The cells containing GFP-LC3-punctae were mostly neurons (Tian et al., 2010). Indeed, during cerebral ischemia, autophagy is predominantly a neuronal phenomenon (Carloni et al., 2008; Rami et al., 2008; Ginet et al., 2009; Puyal et al., 2009).

Autophagy and Neuronal Death in Brain Ischemia

After cerebral ischemia, the number of GFP-LC3-punctae/TUNEL (terminal deoxynucleotidyl transferase-mediated dUTP-digoxigenin nick end labeling) double-positive cells increases in both the core and the peri-ischemic area (Tian et al., 2010). In addition, dying neurons displaying intense vacuolisation and numerous autophagosomes are detected 6 h after HI in neonatal rats, with a peak at 24 h. These dying neurons display some features of apoptosis such as chromatin condensation, cytoplasmic shrinkage, and relatively well-preserved organelles, suggesting that autophagy could precede apoptosis (Ginet et al., 2009). Uchiyama (2001) have shown that inhibiting autophagy protects neuron-like differentiated PC12 cells from apoptosis following serum deprivation, suggesting that autophagy is involved in neuronal cell death *in vitro*. This association between neuronal death and autophagy has led to the term "autophagic death" (**Figure 2B**). Beclin 1 has been reported to be involved in autophagic death. RNAi against Beclin-1 reduces neuronal autophagy and apoptosis in tMCAo model (Zheng et al., 2009). In addition, Beclin 1 knockdown inhibits autophagosomal formation and alleviates apoptotic neurodegeneration in the ipsilateral thalamus following focal ischemia (Xing et al., 2012).

Apoptosis is not the only mechanism involved in ischemia-induced cell death. In 2005, a study shown that an intracerebroventricular injection of necrostatin-1, an inhibitor of necroptosis (programmed necrosis), decreases the infarct volume in a mouse MCAo model (Degterev et al., 2005). A recent work demonstrates in a pMCAo model, that the RIP1K-regulated necroptosis contribute to ischemia-mediated neuronal and astrocytic cell death through the activation of autophagic pathways (Ni et al., 2018). Furthermore, necrostatin-1 decreases LC3-II level and autophagy (Ni et al., 2018). On the other hand, pre-treatment with 3-MA, an inhibitor of autophagy and PI3K,

prevents neuronal necroptosis at 7 days of reperfusion in a severe model of global cerebral ischemia (Wang et al., 2011).

Despite controversial findings suggesting that ischemia induces autophagy only in the hippocampal CA1 region (Gao et al., 2015), it has been suggested that hippocampal CA1 and CA3 regions present a differential response to ischemia-induced autophagy, with CA1 neurons mostly undergoing apoptosis without autophagy, while CA3 neurons mostly undergo autophagic death (Ginet et al., 2009; Papadakis et al., 2013). The reasons for these subpopulation differences remain to be established.

Deleterious Autophagy in Brain Ischemia

In both primary cultures of neurons and SH-SY5Y cells subjected to OGD, autophagic cell death occurs and can be reversed by 3-MA, a PI3Ks inhibitor (Shi et al., 2012). Bao et al. (2017) suggest that this effect is dependent of autophagy-induced AMPAR subunits GluR1, GluR2, and GluR3 upregulation during OGD, leading to an increase of cytoplasmic Ca^{2+} levels. In rats subjected to transient focal cerebral ischemia, intraventricular injection of 3-MA dramatically reduces the lesion volume (by 46%) whereas an inhibitor of apoptosis does not provide protection (Puyal et al., 2009). Several inhibitors of autophagy (3-MA, bafilomycin, and the cathepsin B inhibitor Z-FA-fmk) significantly reduce the increase of autophagosome and autolysosome, the downregulation of Bcl2, infarct volume, brain oedema and motor deficits in a rat model of pMCAO (Wen et al., 2008). Thus, it seems that decreasing autophagy both *in vitro* and *in vivo* during cerebral ischemia is beneficial (Cui et al., 2013; Jiang et al., 2017; Ryan et al., 2018).

Knocking down Beclin1 and Atg7 with siRNA reduce autophagy and excitotoxic cell death induced by both kainate and hypoxia in primary neurons (Ginet et al., 2014). Atg7 deficient mice show nearly complete protection from HI-induced caspase-3 activation and hippocampal pyramidal neuronal death (Koike et al., 2008). Furthermore selective neuronal deletion of Atg7 reduces autophagy and infarct volume by 42% in neonatal mice subjected to HI (Xie et al., 2016). Overexpression of microRNA-9a-5p (miR-9a-5p) decreases Atg5 protein level, leading to a decrease of infarct volume and neurological deficit in a rat model of MCAo (Wang et al., 2018).

Protective Autophagy in Brain Ischemia

In Wang et al. (2012) have shown that 3-MA pre-treatment is deleterious in a rat model of MCAo. The inhibition of autophagy by 3-MA or wortmannin, both PI3Ks inhibitor, accelerates the progression toward necrotic cell death in neonatal HI model. Conversely, rapamycin, increases Beclin 1 expression and reduces necrotic cell death and brain damage (Carloni et al., 2008). Both ischemic preconditioning (IPC) and permanent focal ischemia induce autophagy activation by up-regulating LC3-II and Beclin-1. IPC treatment significantly reduces infarct volume, brain oedema and motor deficits, whereas 3-MA and bafilomycin suppress IPC-induced neuroprotection (Sheng et al., 2010). The neuroprotective action of rapamycin has been confirmed in several models of MCAo (Chauhan et al., 2011; Buckley et al., 2014). Finally, neuronal autophagy upon brain ischemia seems to be a part of pro-survival signaling pathway, that involves PI3K/Akt/TSC2 /mTOR/P70S6K signaling pathway (Wang et al., 2012; Papadakis et al., 2013) and Akt/CREB pathway (Carloni et al., 2010). IPC-induced autophagy is also neuroprotective and this effect has been suggested to be dependent of the amelioration of ER stress (Sheng et al., 2012). Inhibition of autophagy with Atg7 knock down increase ischemia-induced neuronal apoptosis in OGD and MCAo model. Mitochondrial clearance is reversed by 3-MA and Atg7 silencing, suggesting that mitophagy underlies the neuroprotection by autophagy (Zhang et al., 2013). Moreover, Atg7 silencing reverses the neuroprotection induced by an ER stress activator (Zhang et al., 2014). In fact both tunicamycin and thapsigargin protect against ischemic brain injury by activating mitochondrial autophagy during reperfusion. Interestingly, this effect is reversed by the inhibition of autophagy (Zhang et al., 2014). Knocking out arrestin-β1, which is upregulated after cerebral ischemia, protects neurons from OGD by impairing the interaction between Beclin-1 and PIK3 catalytic subunit type 3, thus decreasing autophagy (Wang et al., 2014). Beclin-1 seems central, as caveolin1, an integral membrane protein, is able to activate autophagy through its binding to Beclin-1/VPS34 complex: in Caveolin1 knock out mice, autophagy is impaired, leading to greater tMCAo-induced cerebral infarct (Nah et al., 2017).

Endothelial Autophagy in Brain Ischemia

In Engelhardt et al. (2015) have published a comparative study to characterize BBB-associated cells responses to HI. BMVECs exhibit greater responsiveness and sensitivity to OGD than astrocytes and pericytes. This is associated with the stabilization of HIF-1α, early disruption of cellular cytoskeleton and metabolism impairment, but unlike perivascular cells, BMVECs appear unable to induce autophagy. BMVECs are specialized endothelial cells, connected by tight junction and display intimate contact with supporting pericytes, astrocytes, microglia, and neurons in order to maintain the structural and functional integrity of the BBB. Brain ischemia and thrombolysis therapy with tPA induce BBB disruption, brain oedema and neuronal injury (Thiebaut et al., 2018). Several groups support the idea that autophagy induces endothelial cell injury and BBB disruption. Indeed focal ischemia, in NF-κB p50 knockout mice, induces autophagy like-injury in BMVECs together with a disruption of BBB integrity (Li et al., 2013). It appears that autophagy is beneficial for BMVECs and BBB integrity. In Li et al. (2014) shown that enhancing autophagy by rapamycin and lithium reverses OGD-induced collapsing of tight junction and decreases tMCAo-induced BBB leakage and brain oedema; while 3-MA intensifies BMVECs apoptosis. Supporting these results, the knockdown of Beclin-1 attenuates autophagy processes and reduces the viability of endothelial cells subjected to OGD, while treatment with rapamycin increases cell viability (Urbanek et al., 2014). Similarly, chloroquine-induced autophagy inhibition enhances BBB permeability during pMCAo in diabetic rats. By opposition to the results of Engelhart and collaborators, this group observed autophagy activation in BMVECs after ischemia (Fang et al., 2015).

Astrocytic Autophagy in Brain Ischemia

During brain ischemia, glial cells, especially astrocytes, play a crucial role. They are involved in water transport, ion homeostasis, glutamate uptake, cerebral blood flow regulation, cerebral inflammation, maintenance of the BBB integrity, modulation of neuroplasticity and the secretion of neurotrophic and neuroprotective factors (Nedergaard et al., 2003).

In Tian et al. (2010) have shown, in a mouse model of MCAo, that GFP-LC3-punctae positive cells were mostly neurons rather than astrocytes or microglial cells in the peri-ischemic area, suggesting that glial cells may be more resistant to brain ischemia-induced autophagy than neurons. Nonetheless, a few groups report that ischemia induces an increase of astrocytic autophagy (Qin et al., 2010; Zhang et al., 2010; Engelhardt et al., 2015). Autophagosomes start to appear in the cytoplasm of astrocytes within the ischemic cortex 1 h after pMCAo and in the cytoplasm of primary astrocytes 1 h after OGD, with a peak at 3 h (Qin et al., 2010). The number of lysosomes significantly increases 6 h after pMCAo and OGD. In addition, they observe an increase of LC3-II, Beclin-1, LAMP2 and lysosomal cathepsin B expression. 3-MA and bafilomycin decrease ischemia-induced autophagy, apoptosis and necrosis, suggesting that autophagic/lysosomal activation may contribute to ischemic injury of astrocytes (Qin et al., 2010). This is partially confirmed by the fact that RIP1K knockdown decreases autophagy, increases GFAP levels, and attenuates astrocytic necrotic cell death in the ischemic cortex (Ni et al., 2018). RIP1K-mediated necroptosis may play important roles in ischemia-induced neuronal and astrocytic cell death through the activation of autophagic-lysosomal pathway (Ni et al., 2018). In the same line, breviscapine provides neuroprotection in the penumbra by decreasing both astrocytic and neuronal autophagy induced by tMCAo (Pengyue et al., 2017).

In contrast, inhibition of AMPK, by siRNA targeting AMPKα1 or by a pharmacological inhibitor, attenuates autophagy and astrocyte viability following OGD. This work supports the idea that during ischemia AMPK is involved in the induction of protective autophagy in astrocytes (Gabryel et al., 2014). Furthermore, when the astrocytic autophagy is specifically enhanced, by using AAV-GFAP-ATG7, it leads to neuroprotection in astrocytes/neurons co-cultures exposed to OGD and improves neurological outcome following tMCAo (Liu et al., 2018).

It is important to mention that many inhibitors used in the autophagy field are not always selective. For example, 3-MA and wortmannin inhibit both class I and class III PI3K, and each class of PI3K has its own, and sometimes opposite, effect on autophagy (Petiot et al., 2000). Furthermore, the use of rapamycin to inhibit mTORC1 does not only affect autophagy, as mTORC1 is involved in cell growth, cell survival protein synthesis and ribosomes biogenesis (Boutouja et al., 2019). Rapamycin can also inhibit mTOR complex 2, a complex known to have pro-survival and pro-proliferation effect by increasing Akt and SGK (Boutouja et al., 2019). The use of these poorly selective autophagy inhibitors could explain some of the discrepancies observed in the literature.

ER STRESS AND CEREBRAL ISCHEMIA

Another important consequence of cerebral ischemia is ER stress. The ER is an important organelle for the folding of all secreted and membrane proteins. In stress conditions, such as ischemia, the ER cannot assume correctly its functions and triggers an adaptive program called the UPR, leading to two distinct actions: (i) an early inhibition of protein synthesis; (ii) a delayed upregulation of genes that promote protein folding and degradation (Marciniak and Ron, 2006).

In Def Webster and Ames (1965), it was first noted that neurons of the rabbit retinas show swelling of their ER when subjected to OGD. Although initially reversible, this change becomes irreversible when OGD lasts more than 30 min. Similar distension of the ER was subsequently reported in neurons in a rat model of MCAo reperfusion injury (Dietrich et al., 1989), implicating ER dysfunction in the complex process of ischemic neuronal damage.

The threat of ER is detected in cells by three sensors that are present at the ER membrane, PERK, IRE1, and ATF, each mediating a separate branch of the UPR (**Figure 3**).

The PERK branch: the inhibition of protein synthesis is an early response to ER stress mediated by PERK (PKR-like endoplasmic reticulum eIF2α kinase) (Harding et al., 1999). Under physiological conditions, PERK is held inactive by its binding to the chaperone BiP (binding immunoglobulin protein, also known as Grp78). Upon stress, the kinase is activated by the release of BiP and phosphorylates its sole cytoplasmic target, eIF2α (Marciniak et al., 2006). This is a regulator of the initiation of protein synthesis. In teleological terms, a "goal" of the PERK branch activation is to prevent the further accumulation of misfolded proteins (Roussel et al., 2013). However, despite a global shutdown of protein translation due to the phosphorylation of eIF2α, some mRNAs are translated more efficiently (Harding et al., 2003). This is the case of ATF4, leading to a transcriptional program of stress-responsive genes including CHOP (C/EBP homologous protein) (Harding et al., 2003). The observation that Chop−/− animals and cells are resistant to ER stress, led some to suggest CHOP functions to promote ER stress-induced cell death. This is not fully supported, however, by analysis of the genes regulated by CHOP (Marciniak et al., 2004). Instead, CHOP appears to regulate a program that promotes the recovery of protein synthesis and secretion following the recovery of ER stress. For example, CHOP induces expression of GADD34 (protein phosphatase 1 regulatory subunit 15A), which is responsible for the dephosphorylation of eIF2α and thus the recovery of normal protein translation (Roussel et al., 2013). In this light, the ATF4-CHOP-GADD34 axis can be viewed as a negative feedback loop opposing the effects of PERK. It is therefore likely that the apparent "pro-death" role that has been attributed to CHOP is too simplistic. The recovery of translation is essential for normal functioning of

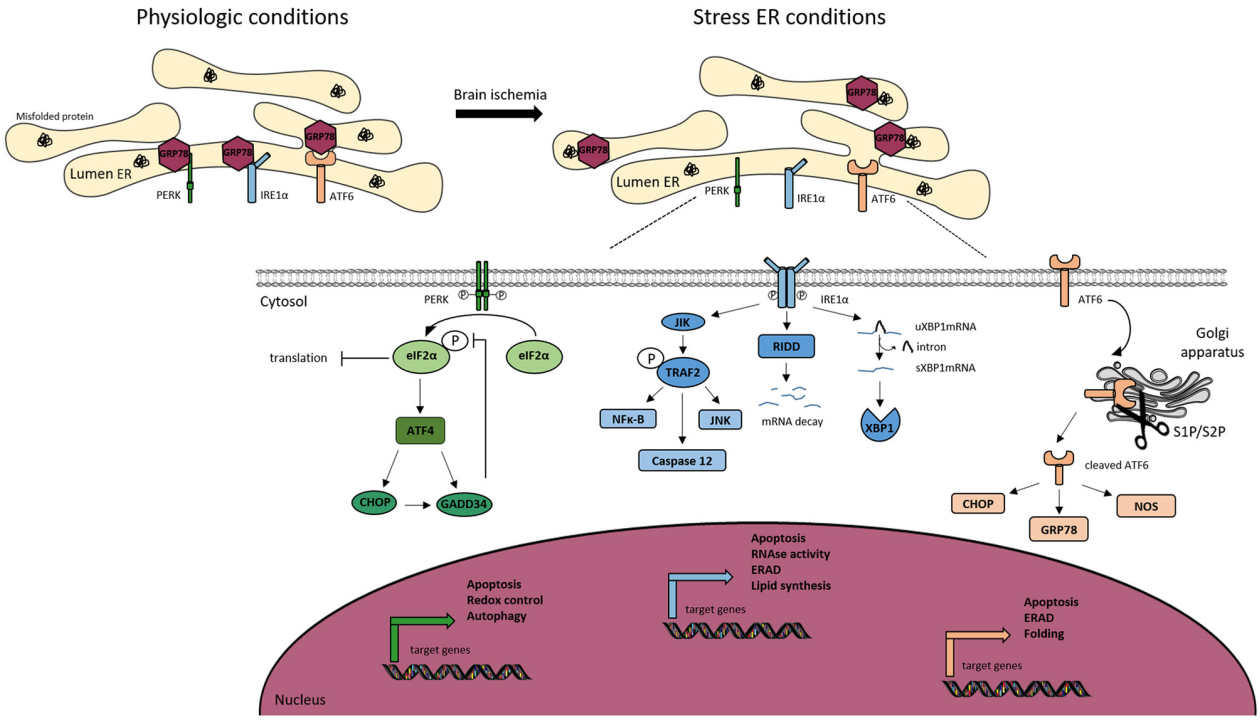

FIGURE 3 | Endoplasmic reticulum (ER) stress signaling. Under physiological conditions, the Glucose Related Protein 78 (GRP78) binds to the three ER transmembrane sensors; protein kinase RNA-like ER kinase (PERK), inositol-requiring kinase 1α (IRE1α) and activating transcription factor 6 (ATF6), and maintains them inactive. Ischemic stroke induces ER stress, leading to the activation of the UPR. Under stress conditions, GRP78 dissociates from the ER sensors to bind to misfolded proteins, allowing the *trans*-autophosphorylation of PERK. P-PERK phosphorylates the eukaryotic translation initiation factor 2α (eIF2α), which decreases the global protein translation. Paradoxically, P-eIF2α allows the transcription of activating transcription factor 4 (ATF4), CCAT/enhancer binding protein homologous protein (CHOP). Both P-eIF2α and CHOP can activate the translation of growth arrest and DNA damage inducible gene/protein 34 (GADD34). The latter creates a feedback mechanism by dephosphorylating eiF2α. PERK is associated to apoptosis, autophagy and redox control. IRE1α dimerizes and *trans*-autophosphorylates, to splice the unspliced mRNA XBP1 (uXBP1) into spliced XBP1 (sXBP1). IRE1α activates c-jun-N-terminal-inhibiting kinase (JIK) and allows the recruitment of TNF receptor-associated factor 2 (TRAF2), leading to the activation of nuclear factor κ-B (NFκ-B), caspase 12 and c-jun-N-terminal kinase (JNK) pathway. IRE1α activates Regulated IRE1-Dependent Decay (RIDD) leading to the degradation of selected mRNAs. IRE1α is also involved in apoptosis, ER-associated degradation (ERAD) and lipid synthesis. The activation of ATF6 is dependent of its cleavage by S1P and S2P endopeptidases in the Golgi apparatus. Cleaved ATF6 induces the transcription of GRP78, nitric oxide synthase (NOS) and CHOP. Moreover, cleaved ATF6 controls ERAD, apoptosis and protein folding.

the cell following mild ER stress, but perhaps in pathology, for example cerebral ischemia, there are benefits from disabling the normal rapid recovery of protein synthesis. This clearly has exciting therapeutic implications and many groups are currently developing approaches to antagonize the ATF4-CHOP-GADD34 axis for therapeutic benefit.

The ATF6 branch: like PERK, ATF6 is held inactive by the binding to BiP. Under stressed conditions, ATF6 is free to traffic to the Golgi apparatus where it is cleaved to release a soluble transcription factor for protein folding and degradation genes (Hillary and Fitzgerald, 2018).

The IRE1 branch: the activation of IRE1 is similar to that of ATF6 and PERK, but IRE1 is an endoribonuclease that triggers the splicing of the mRNA XBP1 (Calfon et al., 2002). The splicing induces a frameshift, allowing the active form of the protein. Proteins that fail to fold in the ER are eventually returned to the cytoplasm and targeted for degradation by the proteasome in process called ERAD. Many proteins of the ERAD machinery are induced by XBP1 (Yoshida et al., 2003). During intense ER stress, IRE1 also degrades many mRNAs located at the ER membrane through a mechanism called regulated IRE1-dependent decay (RIDD) (Hollien and Weissman, 2006). This helps further to reduce the load of new proteins entering the ER to be folded.

UPR in Cerebral Ischemia

The ER is the main storage site for intracellular calcium, a central second messenger mediating diverse physiological processes in neurons, including secretion, synaptic plasticity and cell death (Zundorf and Reiser, 2011). Molecular chaperones that reside within the ER require high calcium concentrations to function efficiently (Michalak et al., 2002). This high calcium environment is maintained by the constant pumping of calcium from the cytosol into the ER by the SERCA (Doutheil et al., 1999b). Release of calcium back into the cytosol happens through the IP3R channel, which can be triggered by extracellular signals, or by the ryanodine receptor, activated by cytosolic calcium itself during CICR. Both lead to signaling but, if sustained, they deplete ER calcium stores and can induce chaperone dysfunction (Szydlowska and Tymianski, 2010). During cerebral ischemia, the

influx of extracellular calcium via the NMDA receptor mediates glutamate-dependent neurotoxicity (Lopez-Atalaya et al., 2008). The rise in intracellular calcium triggers the release of ER calcium from ryanodine-sensitive stores, which is known to exacerbate CA1 hippocampal neuronal damage during global cerebral ischemia-reperfusion (Xing et al., 2004; Bull et al., 2008). Accordingly, inhibition of calcium release with the ryanodine receptor antagonist dantrolene decreases brain injury in animal models of both neonatal and adult HI (Wei and Perry, 1996; Gwak et al., 2008). While commonly attributed to the effects of cytosolic calcium, it is likely that effects on ER protein folding will also be important in these pathological conditions. Moreover, during cerebral ischemia, lack of ATP affects protein maturation (Kumar et al., 2003), and at the same time energy depletion leads to failure of the SERCA pumps (Doutheil et al., 1999b), contributing to the global ER calcium depletion and causing chaperone failure. Thus, the redistribution of calcium from ER to cytosol delivers a double blow to neurons, which exacerbates neurotoxicity (Paschen and Doutheil, 1999; Parsons et al., 1999).

The deregulation of ER-calcium homeostasis causing chaperone failure and activation of the UPR is readily apparent in many animal models of cerebral ischemia, including mice with BCAo (Kumar et al., 2001) or MCAo (Mengesdorf et al., 2002), rats with middle carotid artery occlusion with (Nakka et al., 2010) or without (Rissanen et al., 2006) reperfusion, cardiac arrest with reperfusion (Kumar et al., 2003) and a model of cortical spreading depression in rats (Schneeloch et al., 2004). This induction of ER stress during cerebral ischemia is responsible for the shutdown of protein translation seen during stroke (Burda et al., 1994; DeGracia et al., 1996; Hayashi et al., 2003; Kumar et al., 2003). It involves the activation of the stress-sensing PERK (Kumar et al., 2001; Li et al., 2005; Rissanen et al., 2006) that phosphorylates the translation initiation factor eIF2α, leading to the attenuation of new protein synthesis and disaggregation of polyribosomes (Althausen et al., 2001; Nakka et al., 2010).

Also, CHOP expression is elevated in several animal models of cerebral ischemia, including MCAo (Qi et al., 2004) and BCAo in mice (Tajiri et al., 2004; Osada et al., 2009), as well as MCAo and global ischemia in rats (Hayashi et al., 2005). Chop knockout (−/−) mice are more resistant to a BCAo type of ischemia than their wild-type littermates (Tajiri et al., 2004), and depletion of CHOP using RNA-interference in primary cultures of astrocytes partially prevents cell death in response to OGD (Benavides et al., 2005), suggesting that CHOP regulates a genetic program that is toxic in the context of cerebral ischemia. It has been shown that GADD34 is a target gene of CHOP responsible for some of the tissue damage seen in animal models of ER stress (Marciniak et al., 2004). This phosphatase is induced under conditions of cerebral ischemia (Doutheil et al., 1999a; Paschen et al., 2004; Li et al., 2005; Owen et al., 2005) and is detectable by immunostaining in the peri-infarct penumbra up to 24 h following the induction of stroke in rats (Imai et al., 2002; McCaig et al., 2005). As discussed already, it is therefore plausible that the toxicity attributed to CHOP is in fact the result of re-established protein translation mediated by GADD34 (Marciniak et al., 2004): it might be a mechanism implicated in reperfusion-mediated damage in cerebral ischemia. If this is the case, attenuation of protein translation should protect neurons from accumulating misfolded proteins. Consistent with this theory, salubrinal, a putative GADD34 inhibitor, has been shown to decrease ER stress and kainate-induced neurotoxicity *in vitro* (Sokka et al., 2007). However, the specificity of salubrinal has been questioned many times, since it was first demonstrated to work only *in vivo* (Boyce et al., 2005), and more recently its inhibitory effect has been shown to be really limited (Crespillo-Casado et al., 2017). IRE1, which splices the mRNA encoding the transcription factor XBP1, also shows activation during cerebral ischemia, for example in the cortex of mice after MCAo (Paschen et al., 2003; Morimoto et al., 2007) and BCAo (Tajiri et al., 2004). By contrast, ATF6 signaling remains a subject of debate: ATF6 expression was increased following MCAO in rats (Rissanen et al., 2006), but activation could not be demonstrated in an ischemia-reperfusion model by cardiac arrest in rats (Kumar et al., 2003).

CROSSTALK BETWEEN AUTOPHAGY AND ER STRESS

Autophagy and ER stress are important signaling pathways, but when dysregulated can lead to cell death, such like during cerebral ischemia. A well-balanced activation of these processes allow the maintenance or the recovery of proteostasis. However, their over-activation, by duration or intensity, tips the scale from a protective to a deleterious role (Roussel et al., 2013; Chen et al., 2014).

Although, as mentioned in the introduction, several interactions exist between ER stress and autophagy, in particular when misfolded proteins accumulate within the ER and activate PERK to induce autophagy (Kouroku et al., 2007). Moreover, downstream targets of PERK, like ATF4 and CHOP, induce the transcription of genes related to autophagy in response to both ER stress and amino acid starvation (B'Chir et al., 2013). During hypoxia, ATF4 facilitates autophagosome expansion through a binding to a cAMP response element-binding site within the *LC3b* promoter (Rzymski et al., 2010). Other sensors are also involved in autophagy induction, such as IRE1 by dissociating Beclin1 from its binding with Bcl2 (Wei et al., 2008). In addition, IRE1 also induces autophagy by activating AMPK in response to nitric oxide (Meares et al., 2011). XBP1, the mRNA processed by IRE1, is important for the negative feedback of ER stress-mediated autophagy, especially via its interaction with FOXO1 (Zhou et al., 2011). Interestingly, a genetic screen in *Drosophila* shows that both XBP1 loss of function and spliced-XBP1 overexpression lead to the induction of autophagy (Arsham and Neufeld, 2009). Finally, ATF6 has also been implicated in ER stress-mediated autophagy. By increasing the expression of DAPK1 (Gade et al., 2014), ATF6 promotes the dissociation of Beclin1 from Bcl2, leading to autophagy activation (Zalckvar et al., 2009).

In a mouse model of tMCAo, both ER stress and autophagy markers increase, suggesting a dual activation of ER stress and autophagy (Feng et al., 2017). It seems then important when

studying proteostasis in cerebral ischemia, to pay attention to both phenomena and not only ER stress or autophagy.

Some studies also demonstrate an action of autophagy on ER stress. Indeed, the use of 3MA in a rat model of MCAo alters the ER stress response and leads to the stimulation of apoptosis and the enlargement of the cerebral infarct (Zhang et al., 2018). Similarly, Carloni et al. (2014) show a reduced ER stress activation and a better protection after neonatal HI when they increase autophagy with rapamycin. A possible explanation might be that CHOP induces death by inhibiting autophagy (Lei et al., 2017). This has been demonstrated in hepatocellular carcinoma cells, where ER stress inducer increases apoptosis and autophagy, while autophagy inhibitor promotes apoptosis and autophagy activator decreases ER stress-induced apoptosis (Lei et al., 2017). However, this hypothesis needs to be confirmed in neurons under ischemic/hypoxic challenge.

Finally, ER stress has been reported to cause the translocation of ER chaperones to the cell surface. BiP is the best described chaperone at the cell surface, and can act as a general co-receptor (Gonzalez-Gronow et al., 2009), with roles in autophagy, cancer and neuroprotection (Casas, 2017). Interestingly, cell-surface BiP can regulate autophagy by at least two mechanisms: by activating the PI3K/AKT pathway (Liu et al., 2013); and by associating to α2-macroglobulin receptor to activate mTOR signaling (Misra and Pizzo, 2012). Under OGD conditions, BiP is also at the neuronal surface (Louessard et al., 2017), and its binding to tPA results in a decrease in ER stress activation and neuroprotection (Louessard et al., 2017). In another model of hypoxia-induced apoptosis, the activation of neuronal-surface BiP by a synthetic peptide is also protective (Goldenberg-Cohen et al., 2012), reinforcing its role in neuroprotection during cerebral ischemia.

CONCLUSION

Many neurological diseases, including cerebral ischemia, are associated with complete or partial activation of the UPR, perturbations in calcium homeostasis, autophagy dysfunctions, and finally cell death. Both an appreciation of the crucial role for ER homeostasis, the multiple forms that ER dysfunction can take, the regulation and the consequences of autophagy are now providing novel therapeutic strategies.

We propose a model in which proteostasis dysfunction spans a continuous spectrum from the UPR to autophagy, with probably a direct regulation of autophagy by the UPR as mentioned above. In cerebral ischemia, both pathways will be triggered to a greater or lesser degree, depending of stroke intensity, itself depending of the occlusion type and localisation. In each case, the relative contribution of each response and their interactions would need to be determined if rational approaches to therapy are to be developed.

Also, special attention should be given to studies using pharmacological approaches. As scientists, we all know that pharmacological treatments are really convenient, but we have to keep in mind that a "specific" drug has a lot of off targets actions. For example, it has been recently shown that GSK2606414, a PERK inhibitor, and KIRA6, an IRE1 inhibitor, are not only UPR specific (Mahameed et al., 2019). In fact they also inhibit KIT (also called CD117), a receptor tyrosine kinase involved in signal transduction pathways such as ERK and PI3K/AKT, upstream of mTOR and autophagy. In fact, many pharmacological activators and inhibitors are not as specific as they are supposed to be, and thus participate to discrepancies.

AUTHOR CONTRIBUTIONS

AT and EH did the research and wrote the autophagy and the ER stress part, respectively, and made the figures. SM has actively participated to the writing of the ER stress section and made useful comments on the whole manuscript. DV made corrections and comments on the manuscript. BR organized the review, wrote the introduction and the last section on the interactions between the autophagy and the ER stress, and made final corrections.

Infections in the post-acute phase of cerebral ischaemia impede optimal recovery by exacerbating morbidity and mortality. Our review aims to reconcile the increased infection susceptibility of patients post-stroke by consolidating our understanding of compartmentalised alterations to systemic immunity. Mounting evidence has catalogued alterations to numerous immune cell populations but an understanding of the mechanisms of long-range communication between the immune system, nervous system and other organs beyond the involvement of autonomic signalling is lacking. By taking our cues from established and emerging concepts of neuro-immune interactions, immune-mediated inter-organ cross-talk, innate immune training and the role of microbiota-derived signals in central nervous system (CNS) function we will explore mechanisms of how cerebral ischaemia could shape systemic immune function. In this context, we will also discuss a key question: how are immune requirements critical for mediating repair of the ischaemic insult balanced by the need for anti-microbial immunity post-stroke, given that they are mediated by mutually exclusive immune networks? Our reformed understanding of the immune landscape post-stroke and novel mechanisms at play could guide targeted therapeutic interventions and initiate a step-change in the clinical management of these infectious complications post-stroke.

Keywords: cerebral ischaemia, post-stroke infection, systemic immunity, innate immune training, neuroimmunology

Ischaemic stroke imposes a significant burden on health-care systems and societies across the globe as a consequence of the morbidity and mortality associated with the condition (1, 2). In addition to neurological deficits, infectious complications such as pneumonia and urinary tract infections post-stroke also pose a hurdle to optimal recovery, affecting a significant proportion of patients and exacerbating mortality risk (3–7). Despite significant leaps in our understanding of key players in the immune response post-stroke (8–19) and biomarkers of infection (4, 20, 21), therapy using statins (for immunomodulation), prophylactic beta-blockers (to target sympathetic activation), and antibiotics (to control infection) have proved ineffective in treating infection (22–26). Equally, attempts to improve stroke outcome using neuroprotective therapies to harness the immune system such as dexamethasone, erythropoietin, and many others have been met with limited success in the clinic; in part, due to undesirable effects on systemic immunity. Yet, the

question of whether drugs that possess immunomodulatory properties can be purposed for stroke patients remains to be resolved (27). What is clear, however, is the onset of a plethora of immunological alterations involving diverse immune cells and tissues that is essential for both neurological recovery as well as the occurrence of systemic infections through impairments in anti-microbial immunity (13). In this review, we collate previously described alterations to systemic immunity, and delineate how long-range communication between the CNS and the periphery shapes immune control by taking our cues from data that does not examine stroke. We will finally examine whether the cost of tissue repair (of the ischaemic damage) is impairment in anti-microbial immunity and consequently, increased infection susceptibility.

THE SYSTEMIC IMMUNE LANDSCAPE OF STROKE

To date, there is a wealth of information surrounding the spectrum of immune alterations that ensue following a stroke in both patients as well as models of experimental stroke. The onset of immunological alterations in the central nervous system (CNS) is sequential; neutrophils are recruited hours after stroke by activated microglia and endothelial cells, followed by monocytes a few days following the insult, whilst T and B cells infiltrate the ischaemic tissue in the succeeding weeks (28–32). This contrasts immune alterations in peripheral tissues where stroke drives alterations to the hepatic cytokine networks as early as 6 h post-stroke whilst other systemic immune effects present 24 h post-stroke, affecting both myeloid and lymphoid populations (12, 14, 17, 33–35). However, the mechanisms by which these rapidly-elicited immune changes morph into immune suppression remain poorly defined.

As well as directly altering immune networks, stroke-driven systemic cytokine signals have also emerged as key players that have been implicated to have divergent effects on outcome following stroke (16, 36, 37). Importantly, hepatic interleukin (IL)-6 and chemokine (C-X-C motif) ligand 1 (CXCL1) drive a rapid and transient inflammatory response (35, 38) whilst primed splenocytes secrete tumour necrosis factor (TNF)-α, interferon (IFN)-γ, chemokine (C-C motif) ligand 2 (CCL2) and IL-2 (39); and granulocyte colony stimulating factor (G-CSF) mobilises monocytes and neutrophils from the bone marrow following experimental stroke (40, 41). Moreover, stroke has also been shown to compromise humoral responses through the induction of hypogammaglobulinaemia via the excretional loss of immunoglobulin (Ig) G and impairments in innate-like B cell responses facilitating IgM loss (12, 42).

Many groups have implicated the loss of lymphocytes (T and natural killer (NK) cells), termed lymphopenia, in circulation as a central feature of stroke-induced immune suppression in patients (43–45), a hallmark also replicated in experimental stroke (14, 45, 46). It is thought that the remaining T lymphocytes are also fundamentally altered, being primed to mount a type-1 response through increased IFN-γ and IL-2 production even years after the ischaemic insult (47). In fact, experimental models of stroke have also demonstrated that $CD4^+$ T cells in Peyer's patches (lymphoid tissue in the small intestine) of mice are primed to secrete increased levels of IL-17 and IFN-γ (15). Similarly, there is also an activation of innate lymphocytes such as invariant natural killer T cells (iNKT) cells in the liver in tandem with a cessation of their patrolling behaviour in the sinusoids (48). Additionally, stroke also leads to the apoptotic loss of splenic marginal zone B cells (12) whilst their loss in the blood and bone marrow is predominantly driven by alterations in lymphopoiesis (49).

As such, even innate immune responses are compromised in stroke patients with impairments in the oxidative burst of neutrophils (34) as well as shifts in the proportions and properties of monocyte populations (9, 17, 50, 51). Specifically, as classical and intermediate monocytes expand within the circulating monocyte pool (50, 51) they accrue deficiencies in their anti-microbial immunity as evidenced by their shedding of CD163, tolerance to endotoxin and their inability to secrete key cytokines such as TNF-α, IL-6, and CCL2. These monocytes, also through their increased secretion of IL-10 and downregulation of human leukocyte antigen-DR isotype (HLA-DR) thus acquire an immune suppressed state (16, 17, 33, 46, 52–54). That said, CD74, the invariant polypeptide chain associated with the HLA complex is upregulated in the peripheral blood mononuclear cells of patients (55). Despite being capable of processing and transporting antigens, monocytes, nevertheless, are not professional antigen-presenting cells (56, 57). Consequently, it remains to be determined if the loss of HLA-DR functionally impacts these monocytes in their ability to prime T cell responses post-stroke. Indeed, murine models of experimental stroke have also implicated impairments in monocyte function with an increase in splenic monocytes; both macrophages and monocytes in the spleen downregulate their expression of major histocompatibility complex II (MHCII) (58, 59). By contrast, the role of non-classical monocytes following stroke is less clear in both patients and experimental models of stroke (60, 61).

THE DYNAMIC INTERACTIONS BETWEEN THE CNS AND SYSTEMIC IMMUNITY IN STROKE

Thus far, we have discussed compartmentalised alterations to systemic immunity post-stroke. In this section, we shall highlight how recruited immune cells interface with locally resident cells and the milieu of cytokines following ischaemic injury in stroke. The identification of meningeal lymphatics in the dural sinuses of the CNS (62, 63) as well as previously undescribed subsets of CNS-resident immune cells such as type 2 innate lymphoid cells (ILC2) (64) has reformed our understanding of immunity in the CNS and its frontiers. It is particularly salient to probe the role of these ILC2s post-stroke given their established function in mediating type 2 immunity (65–69) and the critical role of type 2 immunity in mediating tissue repair (70–73). Essentially, type 2 immunity is an ancient arm of the immune system that is mobilised during infection by multicellular metazoan parasites such as helminths that can drive tissue injury as they develop in the host (70, 74, 75). Characterised by the cytokines IL-3,

IL-4, IL-5, IL-9, IL-10, and IL-13, it can be orchestrated by a large repertoire of cells including expanded populations of macrophages, T cell, ILCs, and other sentinels of tissue injury to mediate tissue repair in parallel with parasite expulsion (73, 76, 77). As a result, it becomes important to appreciate the reciprocal regulation that exists between the CNS and systemic immunity in homeostasis (78–80) and how injury to the brain modulates this cross-talk during stroke.

Local cytokine cues facilitate neutrophil recruitment to the ischaemic hemisphere as early as 6 h post-stroke in an intercellular adhesion molecule-1-dependent manner (28, 81). Neutrophils are thought to exacerbate the initial injury through the release of proteases and neutrophil extracellular traps (NETs) that exert neurotoxic effects (82, 83). In particular, the release of matrix metalloproteinase-9, a gelatinase, is thought to compromise the integrity of the blood-brain barrier (BBB) (84, 85) and promote the development of oedema (86). Despite being short-lived, it is thought that neutrophils can take on polarisation states through the acquisition of Ym1 and CD206 expression which has been suggested to be important for their clearance and the resolution of inflammation post-stroke (87).

The role of microglia through their interaction with peripherally-derived leukocytes adds an extra layer of complexity as they are double-edged swords with the capacity to propagate and curtail inflammation, and support neurogenesis (88, 89). Through the acquisition of a classically activated state as a result of astrocytic signals and/or microglial CD8 signalling, they secrete pro-inflammatory cytokines including TNF-α, IL-1α that induce neurotoxic astrocytes (90) and disrupt the integrity of the BBB post-stroke (91). By contrast, they are also capable of limiting neuroinflammation by restraining neutrophil recruitment through the effects of transforming growth factor (TGF)-β on astrocyte-derived CXCL1 (92), limiting neuronal excitotoxicity (93) as well as myelin auto-reactivity (94).

Being one of the first responders to injury or infection (95–97), it comes as no surprise that monocytes are rapidly recruited from the periphery to the ischaemic brain post-stroke (9, 19, 31, 79). Whilst they can infiltrate the brain parenchyma through a breached BBB (98), studies have also demonstrated that the choroid plexus is another means of access to the CNS (95, 99). By employing the CD73 enzyme for extravasation and transmigration, monocytes are thought to infiltrate the CNS via the choroid plexus through interactions between the vascular cell adhesion molecule 1 (VCAM-1) and very late antigen-4 (VLA-4). In the CNS, monocytes are an acute source of pro-inflammatory cytokines that drive neuroinflammation following which the milieu of cytokines directs their differentiation into macrophages with features of alternative activation such as arginase-1 and Ym1 expression to mediate tissue repair (61, 100–103). Nevertheless, the interactions between microglia and monocyte-derived macrophages are indispensable for restraining and resolution of long-term microglial inflammation (61, 104) and promoting neurological recovery in diverse settings of CNS injury (95, 99). Despite their ability to engraft in this niche and mediate repair in contexts of inflammation, studies have shown that these monocyte-derived macrophages maintain a distinct transcriptional identity and cannot replenish microglia (105–107). Although this has been ascribed to the embryonic origins of microglia that are seeded from the yolk sac (108–110), the dynamics of this niche remain unclear in stroke.

Amongst leukocytes recruited to the infarcted brain, T cells are one of the last responders and their dynamics are equally complex with studies suggesting that their functions *in situ* are influenced by not just the subset but also the route of entry into the CNS (8, 111, 112). It is thought that γδ T cells gain access to the injured brain through the leptomeninges in a C-C chemokine receptor (CCR) type 6-dependent manner (8, 113, 114) meanwhile other T cells can access the CNS through the choroid plexus (112) in addition to migrating across a breached BBB (111). Consequently, γδ T cells exacerbate ischaemic damage through their production of IL-17 (8, 113, 114) whilst $CD4^+$ T cells can take on a type 2 activation state and mediate tissue repair through the production of IL-4 in synergy with macrophages (72, 73, 111).

In conjunction with the previously described alterations to systemic immunity it can thus be observed that stroke initiates a complex cycle of events in the ischaemic brain that shapes immunity and inflammation at distal sites. The notion that inflammation at one site can affect other sites is not a new concept as studies have demonstrated that infection-driven inflammation or antigenic challenges in the lungs are capable of promoting the homing of $CD4^+$ T cells to the gastrointestinal tract where they can drive pathology or protective immunity (115, 116). In this paradigm, it is worth noting that γδ T cells are recruited from the intestinal tract (8) where stroke also modulates inflammation in the Peyer's patches whilst driving shifts in microbial communities (15). It can therefore be observed that by fuelling neuroinflammation, ischaemic damage concurrently shapes immune networks in peripheral tissues such as the blood, bone marrow, and spleen that in turn amplify neuroinflammation and inter-organ cross-talk.

THE REACHES OF STROKE: MEANS OF IMMUNE CONTROL

Given the diverse range of immune alterations elicited by stroke, it is conceivable that long-range communication mechanisms between the CNS and the peripheral immune system is a prerequisite to mediating these effects. By employing established and emerging immunological data that does not investigate stroke, we will outline plausible mechanisms of how inflammation and injury in the brain in the context of stroke can shape immune networks at distal sites. Thus, we will highlight possible mechanisms that cerebral ischaemia could utilise to effect compartmentalised changes to systemic immunity and add to the concepts of autonomic dysfunction by suggesting avenues of research (**Figure 1**).

Autonomic Signalling

Mounting evidence has ascribed the alterations in systemic immunity to be consequence of increased autonomic signalling, particularly an over activation of the sympathetic nervous system (SNS) through the excessive release of catecholamines, in both

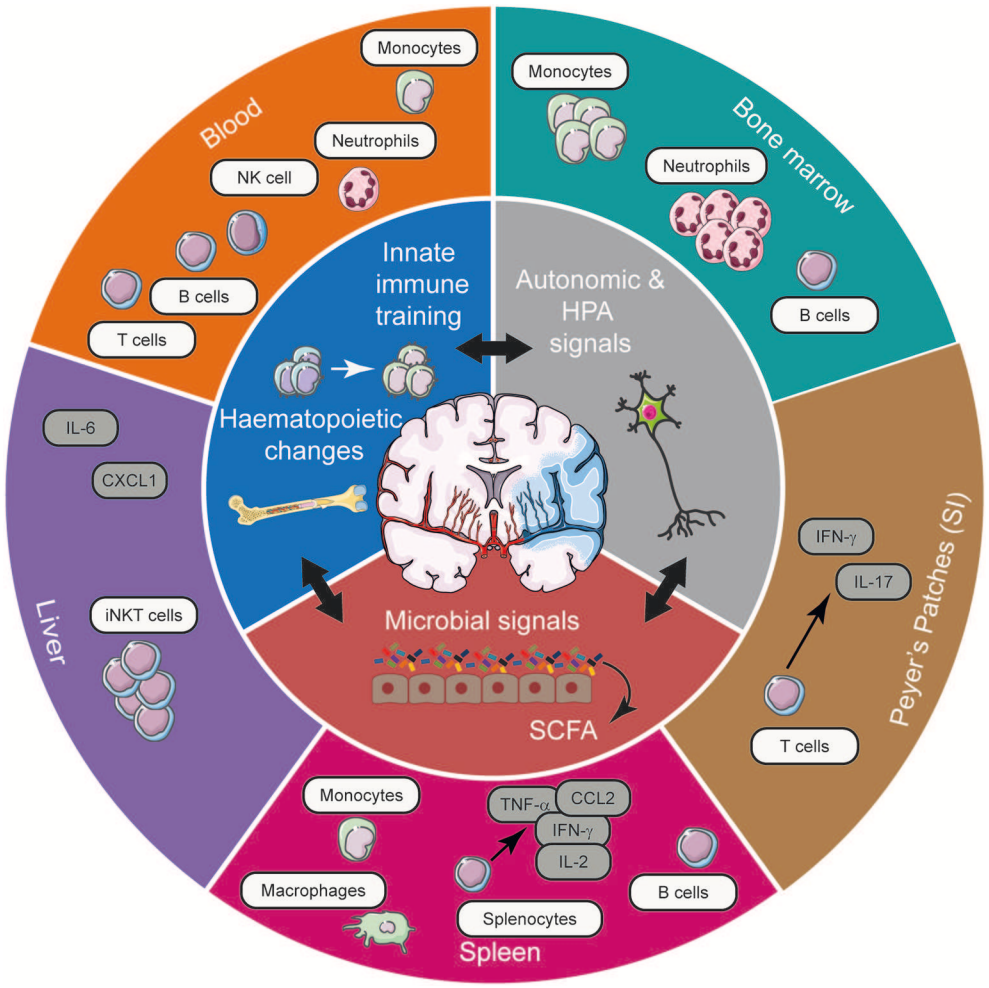

FIGURE 1 | The spectrum of systemic immune alterations post-stroke and the potential mechanisms exploited by stroke to mediate these long-range effects. Stroke, through its effects on autonomic and HPA axis activation, innate immune training, and microbial communities in the gut can gain access to various tissues to shape the systemic immune landscape, affecting cellular, and cytokine networks. Acting in synergy, these means of long-range communication modulate the frequency and functional responsiveness of a plethora of immune cells, tuning the quality of the immune response elicited in various tissues in response to CNS injury. CCL2, chemokine (C-C motif) ligand 2; CXCL1, chemokine (C-X-C motif) ligand 1; IFN-γ, interferon- γ; HPA, hypothalamic-pituitary-adrenal; IL, interleukin; iNKT cell, invariant natural killer T cell; NK cell, natural killer cell; SCFA, short chain fatty acids; SI, small intestine; TNF-α, tumour necrosis factor-α.

patients (43, 117, 118) and experimental stroke (12, 14, 48). Studies have also implicated aberrant cholinergic input (45, 119, 120) and glucocorticoid signalling via the hypothalamic-pituitary-adrenal (HPA) axis (14, 49, 121) in mediating systemic immune dysfunction; again through the excessive release of stress mediators such as cortisol and glucocorticoids into the circulation. In addition to being shaped by circulating catecholamines, many tissues that exhibit altered immune profiles post-stroke such as the gut, lung, spleen, and bone marrow are in fact hard-wired to the SNS (39, 122–125). Mechanistically, it has been posited that neurogenic input from autonomic signals as well as the HPA axis could calibrate systemic immunity by the direct effects of stress mediators on immune cells through adrenergic (126, 127), cholinergic (128, 129) and glucocorticoid receptor signalling (130, 131). Intriguingly, the phenomenon of immunosuppression driven by autonomic and HPA axis-derived signals is not restricted to stroke but is also observed in the broader context of CNS injury such as traumatic brain and spinal cord injury (132–134). Hence, a broader understanding of fundamental neuronal pathways linking the CNS and immune system could guide therapeutic interventions to alleviate infectious complications driven by CNS injury.

Innate Immune Training

Emerging evidence has highlighted the training of innate immune responses by diverse stimuli such as pathogen-associated molecular patterns or cytokines and consequently, the development of immunological memory, a concept traditionally confined to the realms of adaptive immunity (135–144). Given the transient existence of innate cells such as monocytes and neutrophils, it is thought that trained innate immunity is a means to elicit a targeted and enhanced immune reaction

to suit host requirements. This has been shown to drive immunometabolic reprogramming via epigenetic rewiring (139, 141) or the replacement of these cells *en masse* through the generation of functionally poised ones via alterations in haematopoietic output (135, 144). To put this in the context of stroke, recent work has demonstrated that microglial training resulting from repeated administration of bacterial endotoxin is capable of curtailing IL-1β secretion as well as microglial activation (and hence neuroinflammation) following cerebral ischaemia (136). Equally, it is plausible that stroke itself could elicit the training of immune cells in the periphery through its effects on the bone marrow. For example, it has been shown that stroke increases the generation of classical monocytes as a consequence of altered myelopoietic output post-stroke (40). As the bone marrow receives rich sympathetic innervation, it can be envisaged that stroke-driven autonomic signals could tune myelopoiesis to facilitate tissue repair by transducing signals through distinct adrenergic receptor subtypes (125, 145–148). Therefore, the predisposition to repair and replace the entire pool of monocytes and the duration of these changes could impact infection susceptibility as well as the response to a subsequent stroke.

Microbiota-Derived Signals

The interaction of stroke with the commensal microbiota in the gastrointestinal tract is extremely nuanced. Not only does the commensal microbiome play a role in shaping stroke outcome (despite the precise effect being unclear) (8, 15, 18, 149–152) but stroke also mediates shifts in key microbial communities like Firmicutes and Bacteroidetes (153). In homeostasis, the microbiome itself calibrates immunity within the gut microenvironment as well as distal sites through the symbiotic relationship of diverse microbial communities with immune networks by means of microbial metabolites (154–157). In light of data suggesting a detrimental effect of the gut microbiota on stroke outcome (assessed by infarct volume) as well as their role in seeding bacteria that drive pneumonia (8, 149), it therefore becomes difficult to reconcile how commensal bacteria mediate such effects given their indispensable roles in calibrating immunity in homeostasis and injury (158–163). Nevertheless, it is conceivable that the leakiness of the gut barrier induced by stroke (15) could promote the systemic dissemination of pathobionts such as *Enterococcus* spp., *Escherichia coli,* and *Morganella morganii* (149) or result in shifts in key microbial communities that could directly impact systemic immune networks and consequently, stroke outcome (153). Equally, microbial metabolites such as short-chain fatty acids for example, butyrate and propionate are capable of modulating myelopoietic output (increasing the generation of functionally poised monocytes, macrophages and dendritic cells), indicating their ability to train innate immune responses as well (156, 157). In light of these data, it is reasonable to hypothesise that stroke, by shaping gut microbial communities, could also train myeloid responses through the generation of primed progenitors, simultaneously influencing immune networks, shaping both infarct repair and infection susceptibility in distal tissues such as the lungs and bone marrow. However, the precise contributions of stroke in driving shifts in microbial communities and innate immune training remain to be elucidated.

A BALANCING ACT: ISCHAEMIC INJURY REPAIR VS. ANTI-MICROBIAL IMMUNITY

Thus far, we have summarised the plethora of effects that stroke has on systemic immunity as well as the means it employs to shape immune function, taking our cues from established and emerging immunological evidence. Taken together, the net effect of the immune alterations elicited by stroke appear to facilitate the repair of the ischaemic insult given that both mononuclear phagocytes as well as T cells appear to adopt an alternatively activated state (14, 31, 61). This is unsurprising as a large body of evidence has identified critical roles for type 2 immunity in mediating tissue repair, a response conserved across vertebrates (74, 75, 164–166). Studies have shown that type 2 cytokines such as IL-4 and IL-13 promote the alternative activation of macrophages via the expression of molecules such as arginase and Ym1 and facilitate collagen fibril assembly (70, 72, 73, 167). However, mononuclear phagocytes with the predisposition to take on an alternatively activated fate remain in circulation and police the immune responses in various tissues but their plasticity, and hence ability, to classically activate and then mediate antimicrobial immunity is questionable. This is due to the fact that the transcriptional and epigenetic landscapes that drive classical and alternative activation, at least in macrophages, are mutually opposing (168). Although tissue-resident macrophages can reversibly polarise in a GATA6-dependent manner (169), whether these principles apply to monocytes and in the context of stroke requires further investigation.

Viewing the paradigm from the vantage point of an immunologist raises some pertinent questions. Is the cost of repairing the ischaemic damage an impairment of antimicrobial defences? Are the various effects on systemic immunity a means to dampen immune responses to antigens that are now exposed to the immune system through a breached BBB following a stroke? Intriguingly, studies have identified that some contexts of stroke (170–174) and other settings of spinal cord (132) and traumatic brain injury (175–177) could also initiate auto-immunity through antibodies to myelin-derived proteins. As a result, immunosuppression post-stroke could be construed as a means to dampen debilitating auto-immunity post-stroke by skewing immunity towards a type 2 phenotype and limiting the splenic B cell pool to constrain humoral and T cell-mediated immunity towards exposed brain antigens. The simultaneous autonomic activation could educate monocytes to take on features of alternative activation in order to augment repair of the injured brain tissue prior to entry though alterations in haematopoiesis in the bone marrow. An inadvertent consequence of this cascade could be increased infection susceptibility due to inadequate plasticity in the polarisation fate acquired during generation. Thus, the systemic availability of poised mononuclear phagocytes could underpin impaired antimicrobial defences in the lungs but it remains to be determined if this is indeed the case.

CONCLUDING REMARKS

Data from clinical and pre-clinical paradigms of stroke highlight a diverse range of effects on systemic immunity that can be mediated directly and indirectly by the ischaemic damage. An appreciation of not just the changes themselves but the means employed to elicit them could inform the choice of viable therapies to mitigate infections post-stroke by digressing from traditional choices of antibiotics and beta-blockers. It is therefore imperative we re-examine data from clinical trials of immunotherapy in settings of auto-immunity and cancer to appreciate the remit of immunotherapy. By taking cues from these studies, the clinical trials of immunomodulatory therapies in stroke could provide insight into the fundamental mechanisms at play and more importantly, the suitability of immunotherapies for bolstering neuroprotection and antimicrobial immunity in stroke. This in turn could guide approaches for targeted therapies in the clinical management of neuroprotection and infection to improve outcome following stroke.

Background and Purpose: The morbidity and early mortality associated with stroke is largely attributable to cerebral edema and elevated intracranial pressure (ICP). Existing pharmacotherapies do not target the underlying pathophysiology and are often ineffective in sustainably lowering ICP, whilst decompressive craniectomy (DC) surgery is life-saving yet with surgical/peri-operative risk and increased morbidity in the elderly. Accordingly, there is an urgent need for therapies that directly target the mechanisms of edema genesis. Neurogenic inflammation, mediated by substance P (SP) binding to the tachykinin NK1 receptor (NK1-r), is associated with blood-brain barrier (BBB) disruption, cerebral edema and poor outcome post-stroke. NK1-r antagonist treatment ameliorates BBB dysfunction and cerebral edema in rodent stroke models. However, treatment has not been investigated in a large animal model, an important step toward clinical translation. Consequently, the current study compared the efficacy of NK1-r antagonist treatment to DC surgery in reducing ICP post-stroke in a clinically relevant ovine model.

Methods: Anesthetized female Merino sheep (65 ± 6 kg, 18–24 months) underwent sham surgery (n = 4) or permanent middle cerebral artery occlusion (n = 22). Stroke animals were randomized into one of 5 treatments: 1×NK1 bolus (4 h), 2×NK1 bolus (4 h;9 h), 3×NK1 bolus (4 h;9 h;14 h), DC surgery (performed at 4 h) or saline vehicle. ICP, blood pressure and blood gasses were monitored for 24 h post-stroke. At 24 h post-stroke anesthetized animals underwent MRI followed by perfusion and brains removed and processed for histological assessment.

Results: 2×NK1, 3×NK1 administration or DC surgery significantly ($p < 0.05$) reduced ICP compared to vehicle. 1×NK1 was ineffective in sustainably lowering ICP. On MRI,

midline shift and cerebral edema were more marked in vehicles compared to NK1-r treatment groups.

Conclusion: Two or three boluses of NK1-r antagonist treatment reduced ICP comparable to DC surgery, suggesting it may provide a novel alternative to invasive surgery for the management of elevated ICP.

Keywords: intracranial pressure, cerebral edema, substance P, decompressive craniectomy, blood-brain barrier, stroke

INTRODUCTION

Elevated intracranial pressure (ICP) arising as a result of malignant cerebral edema is the leading cause of death in the first week following stroke (Hacke et al., 1996). Despite the devastating impact of elevated ICP on patient outcome, clinical management remains sub-optimal. Pharmacological interventions for ICP management are limited, and while osmotic therapies (including mannitol and hypertonic saline) are used in some centers (Zhang et al., 2018), there is no evidence that these therapies are independently effective in improving outcome. Furthermore, the efficacy of other pharmacotherapies including corticosteroids and barbiturates remains ambiguous for the treatment of post-stroke cerebral edema (Brogan and Manno, 2015). In selected patients with malignant middle cerebral artery (MCA) territory infarction, surgical intervention with decompressive craniectomy (DC) may be required. This procedure rapidly alleviates pressure by removing a large portion of the skull and opening the dura overlying the brain, thereby providing space for the edematous brain to swell freely until cerebral edema resolves, typically beyond the first week following stroke (Xiao-feng et al., 2005). However, although this procedure reduces compression on cerebral structures and the risk of life-threatening tonsillar herniation, it is also associated with increased morbidity in those aged greater than 60 years, the patient population in which stroke is most prevalent (Jüttler et al., 2007; Das et al., 2019). It is clear that current pharmacological and surgical interventions are inadequate as they target the symptoms, rather than the underlying cause of cerebral edema and concomitant rise in ICP (Bardutzky and Schwab, 2007; Simard et al., 2007). An enhanced understanding of the mechanisms that underlie the genesis of cerebral edema and raised ICP is critical for the development of more targeted and effective treatments.

Although factors associated with the pathogenesis of cerebral edema are not completely understood, neurogenic inflammation has been identified as a potential therapeutic target (Stumm et al., 2001; Turner et al., 2006; Corrigan et al., 2016a). Neurogenic inflammation is a neurally mediated process involving the release of neuropeptides, including substance P (SP) and calcitonin gene-related peptide, which initiate vasodilation, increased microvascular permeability and edema (Hokfelt et al., 2000). Although well established as a precipitant of edema development within peripheral tissues such as the skin and lungs (Alves et al., 1999), neurogenic inflammation remained largely unexplored as a potential mechanism of cerebral edema development (Lewis et al., 2013; Sorby-Adams et al., 2017). This was until studies depleting neuropeptides or blocking the action of SP at the tachykinin NK1 receptor (NK1-r), to which SP binds preferentially, showed a ubiquitous role for this process in the genesis of cerebral edema following stroke and traumatic brain injury (TBI) (Vink et al., 2003; Nimmo et al., 2004; Turner et al., 2006, 2011; Donkin et al., 2009; Turner and Vink, 2012, 2014; Corrigan et al., 2016a). Specifically, increased SP immunoreactivity within the penumbral perivascular tissue is associated with profound BBB disruption and cerebral edema at 24 h post-stroke and poor functional outcomes up to 7 days following middle cerebral artery occlusion (MCAO) in rats, with NK1-r blockade ameliorating these effects (Turner et al., 2011; Turner and Vink, 2012, 2014; Corrigan et al., 2016a). Increased plasma SP levels have also been reported clinically following severe acute ischemic stroke, elevated levels of which were associated with increased mortality (Lorente et al., 2016). Comparable alterations in SP levels have also been observed in clinical TBI correlating with injury severity and mortality (Lorente et al., 2015).

The cumulative evidence from these studies suggests an important role for SP in the development of cerebral edema and poor outcome following acute CNS injury. However, pre-clinical stroke evaluation of the NK1-r antagonist has been limited to small animal stroke models, with the most extensive screening to date performed in small and large animal models of TBI. Whilst rodent species are essential for establishing basic biological processes, it is often difficult to obtain clinically relevant outcome measures, thereby limiting clinical translation. Given the extremely poor translation of stroke neuroprotection from the laboratory to the clinic (Xu and Pan, 2013), evaluation of promising therapies in a large, intermediate species is essential. Species such as sheep are an ideal candidate for such studies due to the ability to utilize clinically relevant outcome measures in addition to similarities in neuroanatomical structure, including gyrencephalic cerebral organization and significant portion of white matter (Sorby-Adams et al., 2018). Of particular relevance when investigating elevated ICP, however, is the strong tentorium cerebelli of the sheep, separating supra- and infratentorial compartments, bearing structural similarity to that of the human (Dostovic et al., 2016). In the setting of clinical malignant cerebral edema, this leads to compartmentalization of pressure within the supratentorial space, tonsillar herniation, and ultimately often fatal compression of the brain stem as the brain attempts to alleviate dangerously elevated ICP. Indeed, ovine stroke models replicate key clinical hallmarks following

stroke including elevated ICP, cerebral edema, midline shift and tonsillar herniation (Wells et al., 2012; Wells et al., 2015; Sorby-Adams et al., 2018).

As such, the aim of the present study was to determine the effect of inhibition of SP with an NK1-r antagonist, compared to DC surgery, on ICP following permanent ischemic stroke in an ovine model.

MATERIALS AND METHODS

Animals and Experimental Design

Female Merino sheep ($n = 26$) aged 18–24 months old (65 ± 6 kg) were allocated to the study. Animals were randomized into either sham surgery or permanent MCA occlusion (MCAO). Following induction of stroke animals were then randomized into one of the following groups: (1) saline vehicle treatment at 4 h post-stroke ($n = 6$); (2) 1× bolus NK1 antagonist at 4 h post-stroke ($n = 3$); (3) 2× boluses of NK1 antagonist at 4 h and 9 h post-stroke ($n = 3$); (4) 3× boluses of NK1 antagonist at 4, 9 and 14 h post-stroke ($n = 6$); or (5) decompressive craniectomy ($n = 5$) at 4 h post-stroke. Note that the dose for the NK1-r antagonist treatment was the same across all the NK1-r treatment groups, the only difference was the number of boluses that each group received, either one (1×NK1), two (2×NK1), or three (3×NK1) boluses. The NK1-r antagonist used in the study was a test compound supplied by PresSuraNeuro prepared at a concentration of 1 mg/ml in warmed saline (37°C) and administered at a dose of 1 ml/kg via an indwelling jugular venous catheter, as per previous studies in our laboratory (Vink et al., 2017).

Anesthesia and Physiological Monitoring

Anesthesia was induced with intravenous thiopentone (1000 mg in 20 mL, Jurox Pty Ltd., Australia) and maintained with 1.5% inhalational isoflurane (Veterinary Companies of Australia Pty Ltd., Australia) in a mixture of oxygen and room air (500:5000 ml/min), plus intravenous ketamine (Parnell Australia Pty Ltd., Australia) infusion at 4 mg/kg/hr via a femoral venous line. These two anesthetic agents were used in combination to avoid the intrinsic neuroprotective properties of either above certain doses, and to maintain a twilight general anesthesia (Hudetz and Pagel, 2010; Schifilliti et al., 2010). With the animal supine, an arterial catheter was placed in the right femoral artery for continuous blood pressure monitoring and periodic arterial blood gas sampling, and a venous catheter inserted for anesthetic and fluid administration. The animal was then placed prone in the sphinx position, a burr hole drilled in the right parietal bone posterior to the coronal suture and approximately 20 mm from the sagittal suture, dura perforated, and skull bolts secured. A Codman microsensor ICP probe (Codman & Shurtleff Inc., MA, United States) was introduced into the bolt, calibrated and inserted intraparenchymally to measure ICP within the supratentorial compartment. Using LabChart Reader (v 8.1.1), mean arterial blood pressure (MABP) and ICP were continuously recorded through the 24 h monitoring period. Arterial blood gas sampling was conducted prior to MCAO or sham surgery and at hourly intervals throughout the monitoring period until the completion of the experiment to maintain physiological pO_2, pCO_2, and pH.

Surgical Approach to MCAO

We have previously described the surgical approach to proximal MCAO in detail (Wells et al., 2012, 2015). Briefly, a 50 mm vertical incision was made posterior to the right eye, terminating at the zygomatic arch. The underlying muscle was retracted, coronoid process removed, and the skull revealed. A small craniotomy was performed at the junction of the parietal and squamous temporal bones with a high-speed pneumatic drill using a 5 mm cutting burr (Midas Rex, Medtronic, MN, United States). All intra-dural work was carried out with loupe magnification and a head mounted light source (Surgical Acuity, WI, United States). A horse-shoe shaped durotomy was performed with an inferiorly based flap allowing for gentle upward retraction of the anterior temporal lobe to achieve visualization of the proximal MCA. Animals then either underwent sham surgery in which the proximal MCA was dissected but not occluded, or permanent MCA in which the proximal MCA was occluded via Malis bipolar diathermy forceps (Valleylab Inc., CO, United States). The exposed brain was irrigated with saline during surgery to prevent dehydration of the cerebral cortex. After completion of sham or MCAO surgery the dura was approximated and synthetic dura (Durepair, Medtronic) interleaved under the existing dura (in the case of dural retraction following incision) and closed watertight with ethyl cyanoacrylate (Bostik, Australia). Once dural closure was confirmed and no leakage of CSF observed, the craniotomy site was reinforced with dental acrylic cement (Lang Dental, IL, United States) that was manipulated into the edge of the craniotomy and the wound closed in layers, maintaining the shape of the cranial cavity and importantly, the homeostasis of ICP dynamics. For animals allocated to the DC group, at 4h following stroke the wound was opened, dental acrylic removed, and the craniotomy site widened (3 cm × 6 cm) to allow for decompression. A dural pouch was created using Durepair to expand the intracranial cavity, after which the bone was left off and the overlying skin sutured closed, simulating clinical DC and expansile duraplasty. For all groups, the head was then returned to a neutral position for monitoring under general anesthesia.

Magnetic Resonance Imaging

At 24 h following stroke or sham surgery onset animals were placed under general anesthesia (3% isoflurane) in a 1.5 Tesla Siemens Sonata (Siemens AG, Munich, Germany) magnetic resonance imaging (MRI) scanner. The scanning sequence included time-of-flight magnetic resonance angiography (TOF MRA; TR 26.0 ms, TE 3.69 ms, slice thickness 0.50 mm, slices per slab 48), diffusion weighted imaging (DWI; TR 5600.0 ms, TE 80 ms, slice thickness 3.0 mm, slices per slab 25), fluid attenuated inversion recovery (FLAIR; TR 5000.0 ms, TE 386 ms, slice thickness 0.9 mm, slices per slab 96), T1 (TR 2300.0 ms, TE 2.58 ms, slice thickness 0.9 mm, slices per slab 96) and T2 (TR 3200 ms, TE 410 ms, slice thickness 0.9 mm, slices per slab 96) weighted images.

The degree of midline shift on MRI was used as a marker of the amount of expansion of the infarcted hemisphere, indicative of cerebral edema. Extent of shift from the midline was assessed using axial T2-weighted scans and measured in mm from the septum pellucidum at the level of the foramen of Monro (Horos DICOM image viewer v3.1.1). To calculate cerebral edema, coronal FLAIR images were analyzed using Horos (v3.1.1). After optimal adjustment of brightness and contrast, edema volume was determined from sequences using computer-aided manual tracing of the hyperintense lesion by a blinded assessor. The areas were then summed and multiplied by the slice thickness to give a total volume in cm^3.

To calculate infarct volume, segmentation tools in ITK-SNAP (v 3.7) were used to perform semi-automated segmentation of the MRI diffusion lesions using diffusion-weighted images (Yushkevich et al., 2006). A combination of "three-dimensional active contour segmentation" and subsequent manual post-processing of the segmentation while adjusting image thresholds was performed to maximize reproducibility whilst excluding artifacts. The "three-dimensional active contour segmentation" consisted of multiple steps: First, in the pre-segmentation phase, independent component analysis automatically segmented parts of the DWI image and these were manually identified as foreground or background. To obtain an optimal distinction between foreground and background, thresholds of the image windows were adjusted. After thresholding, a "speed image" with a separate foreground and background was created. Next, in the active contour phase, seed regions were manually placed within the region of interest (ROI). These seeds were then automatically grown within the ROIs to form the temporary segmentation. Subsequently, areas that were not automatically included in the "active contour segmentation," were manually included in the follow-up infarct segmentation. The total volume of the segmentation was exported and reported in cm^3 for analysis.

Histological Examination

Following MRI, intravenous heparin (5000I.U./5 ml; Pfizer, NY, United States) was administered and animals euthanized via common carotid perfusion fixation with cold Tris–buffered saline under Isoflurane anesthesia. The brains were subsequently removed and sliced into 10 mm coronal slices using a custom-made matrix. Sections were then immersion fixed in 10% neutral-buffered formalin for a minimum of 14 days prior to being processed, embedded in paraffin wax and sectioned coronally at 5 micron intervals for histological examination by hematoxylin and eosin (H&E), albumin (1:2000, Dako Pty Ltd., A0001), SP (1:5000 citrate retrieval, Abcam Pty Ltd., ab14184), NKI-r (1:1000 citrate retrieval, Advanced Targeting Systems Pty Ltd., AB-N-33AP) and caveolin-1 (cav-1; 1:1000 EDTA retrieval, Cell Signaling Technologies Pty Ltd., 3238) immunohistochemistry.

Statistical Analysis

All data are expressed as mean ± SD. Physiological data (arterial blood pressure, pH, pO_2, pCO_2) were analyzed using one-way analysis of variance (ANOVA) followed by Tukey's *post hoc* tests (Prism v.8.0.1, Graphpad, CA, United States). Values were averaged for each treatment group across all time points and reported as a single value. Raw ICP and MABP data underwent a logarithmic exponential transformation as previously described and were expressed as geometric mean ± SD (Matthews et al., 1990; Wells et al., 2015). ICP was analyzed by two-way ANOVA and lesion volume, cerebral edema and midline shift data were analyzed by one-way ANOVA, all followed by Tukey's *post hoc* tests. A p-value of < 0.05 was considered significant. Correlations were performed between cerebral edema and midline shift and ICP and cerebral edema to determine the relationship between these variables.

RESULTS

Surgery, Mortality and Physiological Parameters

All experimental procedures were carried out without complication and there was no premature mortality or unexpected events in any of the groups. Basic physiological parameters are expressed in **Table 1**. For all groups, there was no statistically significant difference in pO_2, pCO_2, or pH at any of the time-points following stroke. However, there was a statistically significant difference in MABP between sham, 1×NK1 (p = 0.02) DC (p = 0.02) and 3×NK1 (p = 0.006) treatment groups.

Intracranial Pressure

Intracranial pressure remained physiologically stable across all time points in sham animals (9 ± 3 mmHg). At both 4 and 9 h post-stroke, there was no significant difference in ICP between sham or any of the stroke groups. By 14 h following injury, ICP in vehicle animals was significantly elevated (24 ± 11 mmHg) compared to shams (10 ± 3 mmHg) (p = 0.019). However, no difference in ICP was seen between vehicle or any of the treatment groups at this time-point (**Figure 1**).

Intracranial pressure in vehicle animals continued to rise and by 19 h post-stroke measured 32 ± 11 mmHg, which was significantly elevated (p = 0.0002) compared to shams recording an ICP of 13 ± 6 mmHg. By 19 h there was a significant reduction in ICP seen in 2×NK1 (18 ± 4 mmHg; p = 0.013), 3×NK1 (17 ± 7 mmHg; p = 0.015), and DC (19 ± 11 mmHg; p = 0.042) treated animals compared to vehicle. Conversely, there was no reduction ($p > 0.05$) in ICP seen following 1×NK1 treatment

TABLE 1 | Basic physiological parameters.

Group	pCO_2 (mmHg) ± SD	pO_2 (mmHg) ± SD	MABP (mmHg) ± SD	pH (−log $[H^+]$) ± SD
Sham	43 ± 8.41	113 ± 14.09	79 ± 8.78	7.48 ± 0.039
Vehicle	40 ± 6.09	127 ± 31.28	104 ± 10.17	7.46 ± 0.062
1×NK1	36 ± 2.55	138 ± 25.06	112 ± 10.18	7.51 ± 0.033
2×NK1	43 ± 6.56	149 ± 33.99	98 ± 5.81	7.45 ± 0.031
3×NK1	37 ± 2.34	135 ± 20.53	111 ± 15.66	7.52 ± 0.018
DC	42 ± 3.78	150 ± 17.22	108 ± 10.65	7.45 ± 0.082

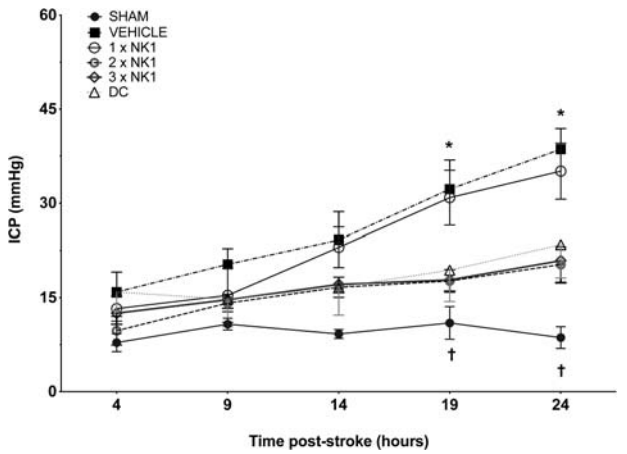

FIGURE 1 | 24 h ICP following MCAO. There was no significant difference in sham ICP across any of the time points. At 14 h post-stoke ICP was elevated in vehicle animals compared to sham ($p < 0.05$) and by 19 h post-stroke, ICP was significantly elevated in vehicle ($p < 0.001$) and 1×NK1 ($p < 0.01$) treated animals when compared to 2×NK1 ($p < 0.05$), 3×NK1 ($p < 0.05$) and DC treatment groups ($p < 0.05$). By 24 h, ICP remained significantly elevated in vehicle animals compared to sham ($p < 0.0001$), 2×NK1 ($p < 0.01$), 3×NK1 ($p < 0.01$) and DC ($p < 0.05$) treatment groups. ICP also remained elevated at 24 h post-stroke in 1×NK1 treatment groups compared to sham ($p < 0.001$) and 2×NK1 ($p < 0.05$). Data presented as mean ± SD. *$p < 0.05$ compared to sham; †$p < 0.05$ compared to vehicle.

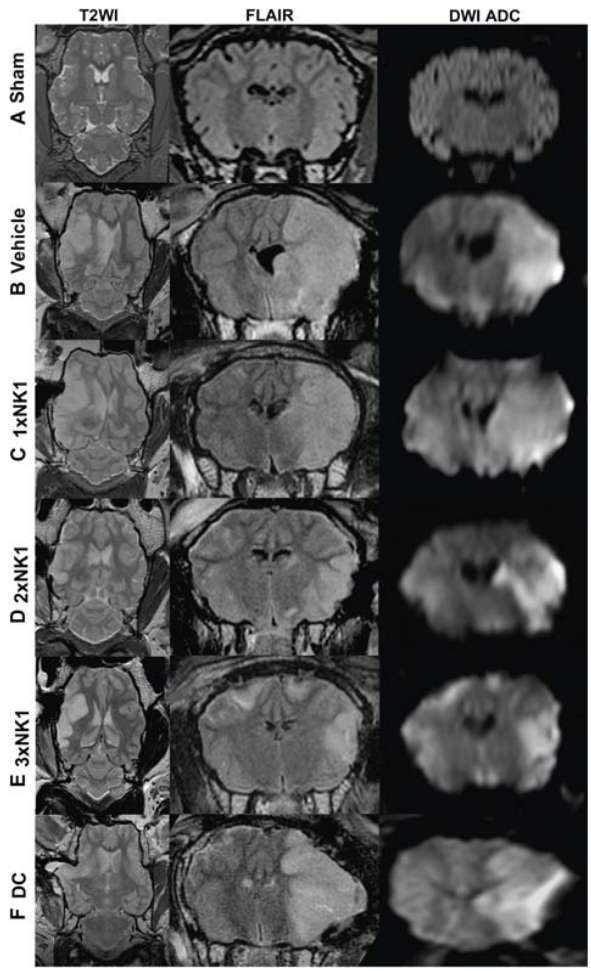

FIGURE 2 | MRI findings 24 h post-MCAO. There was no evidence of hyperintensity or tissue deformation seen in sham animals **(A)**. Midline shift was evident in all stroke animals as seen on axial T2-weighted images **(B–D)**. Cerebral edema as shown in coronal FLAIR MRI images was greater in vehicle **(B)**, DC **(F)** and 1×NK1 **(C)** groups compared with 2×NK1 **(D)** and 3×NK1 **(E)** groups. This was associated with a smaller diffusion lesion volume as shown in DWI ADC images in the coronal plane. Note the transcalvarial herniation through the craniotomy site in DC treated animals **(F)**.

(31 ± 9 mmHg) compared to vehicle, with ICP remaining significantly elevated compared to sham ($p = 0.002$).

By 24 h post-stroke, ICP in vehicle animals had continued to rise (39 ± 7 mmHg) and remained significantly elevated compared to shams (12 ± 8 mmHg; $p < 0.001$), DC (23 ± 12 mmHg; $p = 0.013$), 2×NK1 (20 ± 6 mmHg; $p < 0.001$), and 3×NK1 (19 ± 7 mmHg; $p < 0.005$) treated animals. ICP continued to rise in the 1×NK1 treatment group (35 ± 9 mmHg) and remained significantly elevated compared to both shams ($p < 0.001$) and 2×NK1 ($p = 0.029$) treatment groups. ICP in 2×NK1 and 3×NK1 treatment groups was comparable ($p > 0.05$) to DC across all time points following stroke. No rebound increases in ICP were observed following 2×NK1 or 3×NK1 treatment at any time-point post-stroke.

MRI

Magnetic resonance imaging was unremarkable in sham animals ($n = 4$) with no evidence of cerebral edema, midline shift or infarction (**Figure 2A**). All stroke animals showed evidence of hyperintensity on T2-weighted and FLAIR images in the territory MCA, indicative of the infarct core and surrounding vasogenic edema (**Figure 2**). In addition, DC treated animals showed evidence of transcalvarial herniation through the craniectomy site (**Figure 2D**). No animals showed evidence of tonsillar herniation or brain stem compression on MRI (data not shown).

Cerebral edema calculated on FLAIR MRI (**Figure 3** and **Table 2**) was reduced in DC ($p = 0.012$) and 1×NK1 treatment groups ($p = 0.042$) when compared to vehicle (**Figure 3A**). However, treatment with 2×NK1 ($p = 0.001$) and 3×NK1 ($p = 0.001$) was associated with a more significant reduction in cerebral edema volume compared to vehicle (**Figure 3A**). Midline shift was evident in all stroke animals (**Table 2**) with no statistical significance seen between groups ($p = 0.2$; **Figure 3B**). Nevertheless, there was a moderate positive relationship between the volume of cerebral edema and the degree of midline shift ($r = 0.46$; **Figure 3C**). No significant differences ($p = 0.17$) were observed in infarct volume across any of the treatment groups following stroke, as measured on DWI MRI (**Figure 3D**).

Histological Analysis

H&E

There was no evidence of tissue injury or infarction in sham tissue (**Figure 4A**). Following stroke (**Figure 4B**) there was marked tissue pallor and loss of gray-white matter differentiation,

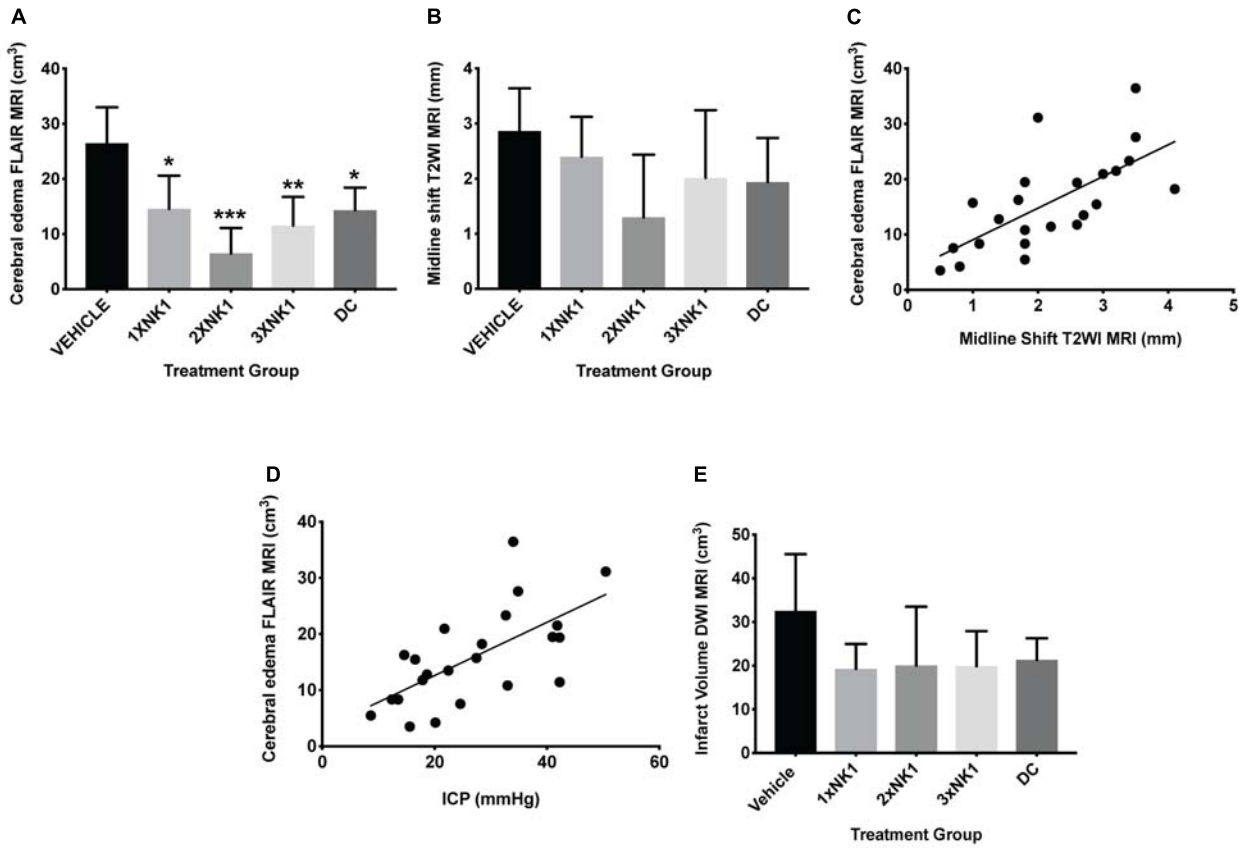

FIGURE 3 | Cerebral edema and infarct volume findings at 24 h post-MCAO. Cerebral edema volume, as measured on FLAIR MRI **(A)**, was decreased in 1×NK1 ($p < 0.05$), 2×NK1 ($p < 0.001$), 3×NK1 ($p < 0.01$), and DC ($p < 0.05$) treatment groups when compared to vehicle. There was no difference in midline shift in any of the vehicle or treatment groups post-stroke **(B)**. Despite this, there was a relative moderate positive correlation between cerebral edema and midline shift **(C)**. There was also a moderate positive correlation between cerebral edema and ICP measured at 24 h post-stroke **(D)**. There was no significant difference in infarct volume **(E)** as measured on DWI MRI between any treatment groups. *$p < 0.05$, **$p < 0.01$ and ***$p < 0.001$ compared to vehicle.

indicative of infarction within the MCA territory of the right hemisphere. 1×NK1 (**Figure 4C**) treatment tissue was comparable to vehicles, however, there was an increased preservation of tissue, in particular the sub-cortical white matter, in the 2×NK1 (**Figure 4D**), 3×NK1 (**Figure 4E**) and DC (**Figure 4F**) treated groups.

Albumin

There was minimal evidence of albumin extravasation in sham tissue (**Figure 4A**). Following stroke, marked albumin extravasation, indicative of BBB breakdown and subsequent vasogenic cerebral edema formation, was observed both macroscopically within the infarcted territory and microscopically in the perivascular tissue of the infarct in vehicles (**Figure 4B**), 1×NK1 (**Figure 4C**) and DC (**Figure 4F**), when compared to shams (**Figure 4A**), 2×NK1 (**Figure 4D**) and 3×NK1 (**Figure 4E**) treatment groups.

SP

There was low to no observable immunoreactivity of SP in sham tissue (**Figure 5A**). Furthermore, similarly low levels of SP immunoreactivity were observed in the infarcted hemisphere of vehicle and each of the treatment groups following stroke.

NK1-r

Low levels of perivascular NK1-r immunoreactivity were observed in sham tissue (**Figure 5B**). Following stroke, an increase in perivascular NK1-r immunoreactivity was observed in vehicle and DC treated groups, which was not observed in any of the NK1 treatment groups.

Cav-1

Little to no perivascular cav-1 immunoreactivity was observed in sham tissue (**Figure 5C**). Following stroke, a marked increase in perivascular cav-1 immunoreactivity was observed in vehicles (E), 1×NK1 (F) and DC (L) tissue when compared to sham (D), 2×NK1 (J) and 3×NK1(K) tissue.

DISCUSSION

In this study we have demonstrated that administration of two or three boluses of an NK1-r antagonist is effective

in reducing ICP following stroke in a clinically relevant ovine model. This reduction in ICP following treatment was associated with improved BBB integrity, as shown by albumin immunohistochemistry, and a trend toward reduction in the volume of cerebral edema in the infarcted hemisphere. These findings corroborate previous experimental (Vink et al., 2003; Nimmo et al., 2004; Turner et al., 2006, 2011; Donkin et al., 2009; Corrigan et al., 2012, 2016b; Turner and Vink, 2012, 2014) and clinical (Lorente et al., 2015, 2016) studies to further support the role of SP in the pathogenesis of elevated ICP, cerebral edema and increased permeability of the BBB following acute CNS injury. Indeed, the reduction in ICP following treatment observed in this study is consistent with findings in an ovine model of TBI (Vink et al., 2017). Taken together, we have now successfully demonstrated the efficacy of NK1-r antagonist treatment for the reduction of cerebral edema and its consequences in both rodent and sheep models of stroke (Turner et al., 2006, 2011; Turner and Vink, 2012, 2014) and TBI (Donkin et al., 2009; Corrigan et al., 2012, 2016b; Vink et al., 2017). Taken together these findings clearly demonstrate that SP release is a ubiquitous feature of acute CNS injury and that blockade of this pathway is able to preserve BBB integrity and halt the development of cerebral edema and subsequent rise in ICP.

Despite the clear treatment effect of blocking the NK1-r to reduce ICP in this study, we did not observe a significant increase in perivascular SP immunoreactivity within the infarcted territory in any of the treatment groups following stroke. This is in keeping with our previous findings in a rodent model of MCAO (Turner, 2007), where minimal SP immunoreactivity was observed following permanent MCAO, yet profound perivascular staining was identified following transient MCAO with reperfusion. These observations are most likely due to the fact that in the setting of permanent MCAO, the release and peak in SP occurs acutely due to the severity of the ischemic insult. As such, SP has likely been degraded by the time of tissue harvest at 24 h post-stroke. In comparison, in previous rodent transient MCAO studies, perivascular SP immunoreactivity was observed primarily in the penumbral tissue. The relative proportion of penumbra to ischemic core is likely to be much less following permanent compared to transient MCAO due to the extensive collateral failure with longer durations of ischemia. Not surprisingly, this suggests that the magnitude and timing of SP release in the neurogenic inflammatory response is dependent upon the duration and severity of the ischemic insult (Corrigan et al., 2016b). Indeed, following vascular occlusion, temporary changes in transient receptor potential channels of c-fibers as a result of alterations in temperature, pH and ligand binding instigates release of SP (Hokfelt et al., 1975). When there is no reperfusion, compromised cells undergo ischemic necrosis quickly with associated acute changes in cellular function, leading to a rapid return of receptor channel potential and decrease in SP release. Comparatively, in the setting of transient MCAO, compromised cells in the penumbra experience long durations of electrical silence and alterations in neuronal function, leading to sustained activation of c-fibers and persistent SP release (Astrup et al., 1981; Turner, 2007; Hofmeijer and Van Putten, 2012). Taken together, these findings may provide an explanation as to why SP was not observed on IHC in this study.

We did not observe any effect on infarct volume following NK1-r antagonist treatment, irrespective of the number of boluses administered. This is not surprising considering that we used a permanent stroke model and given that the NK1-r antagonist is targeting BBB disruption and not other pathways in the ischemic injury cascade. Indeed, a transient stroke model with reperfusion followed by delivery of an NK1-r antagonist may yield different results on infarct volume. Nevertheless, we also did not observe an effect on infarct volume at 24 hrs following 2 h MCAO thread occlusion in our rodent studies (Turner et al., 2011). In these previous rat studies, however, we did demonstrate that increased perivascular SP immunoreactivity was associated with increased BBB permeability, profound cerebral edema and persistent functional deficits (Turner et al., 2006, 2011; Turner and Vink, 2012, 2014).

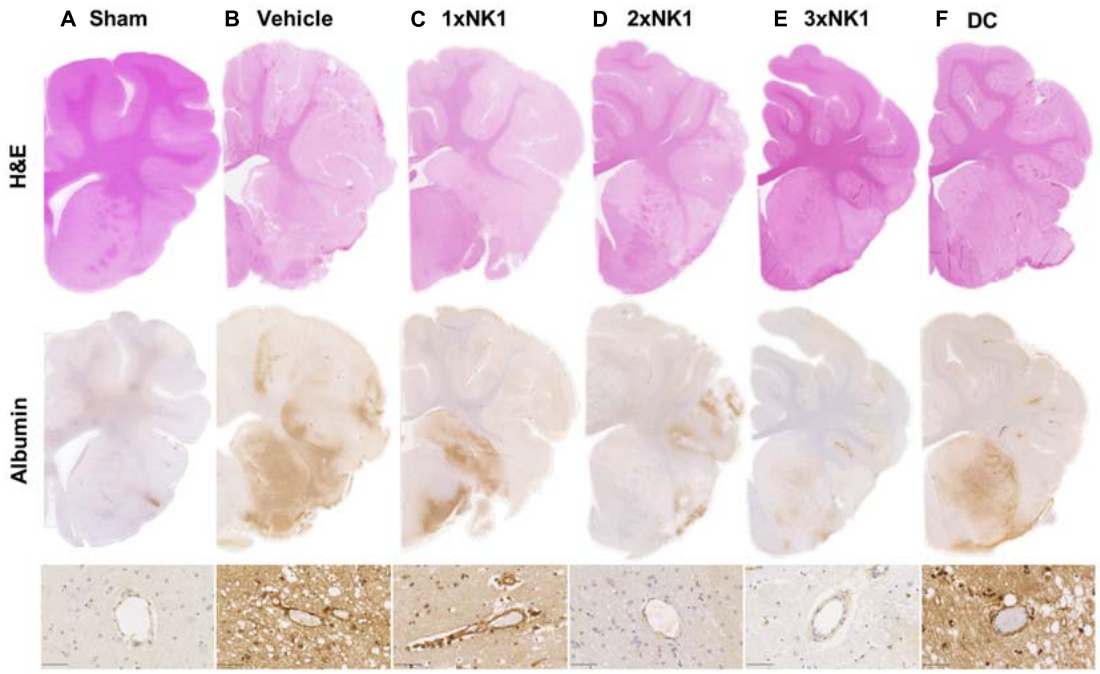

FIGURE 4 | Hematoxylin and Eosin staining and albumin immunoreactivity in **(A)** sham, **(B)** vehicle, **(C)** 1×NK1, **(D)** 2×NK1, **(E)** 3×NK1, and **(F)** DC animals. H&E staining shows evidence of pallor and reduced gray white matter differentiation, which is especially prominent in vehicles and 1×NK1 treated animals. Enhanced albumin extravasation was seen macroscopically in vehicle, 1×NK1 and DC treated animals compared to sham, 2×NK1 and 3×NK1 treatment groups. This pattern of albumin staining is consistent with the perivascular staining seen in microscopic images. Scale bar 50 μm, 40× magnification.

In this study we have identified that increased BBB permeability was sustained to 24 h post-stroke in vehicle-treated animals, as identified by the increased albumin extravasation. Furthermore, the corresponding increase in perivascular caveolin-1 immunoreactivity in the vehicle group may provide an explanation for persistent changes barrier permeability seen. Caveolae are invaginations of the plasma membrane present in endothelial cells, including those that comprise the BBB, with a key role in regulating transcytosis of large molecules, including albumin, across the barrier (Abbott et al., 2006). Cav-1 is an integral protein for caveolae formation, with upregulation associated with enhanced albumin extravasation and the development of vasogenic cerebral edema (Nag et al., 2007). Furthermore, cav-1 is shown to be upregulated following rodent cortical-cold injury and feline TBI, despite maintenance of tight junction (TJ) integrity (Povlishock et al., 1978; Nag et al., 2007), suggesting that physical breakdown of the barrier through loss of TJ is not necessary for the development of cerebral edema. The NK1-r is located within caveolae, suggesting that its activation may play a role in regulating transcytosis (Monastyrskaya et al., 2005; Kubale et al., 2007). Indeed, this is consistent with the observation of reduced barrier permeability following NK1-r antagonist administration (Donkin et al., 2007; Turner et al., 2011; Turner and Vink, 2012, 2014; Corrigan et al., 2016a; Vink et al., 2017). It is proposed that SP release following acute CNS injury leads to NK1-r activation, including those located within the caveolae of endothelial cells. This precipitates enhanced transcytosis of albumin across the barrier, altering the osmotic gradient leading to the development of vasogenic edema. Inhibition of transcytosis-mediated albumin extravasation through administration of the NK1-r antagonist attenuates unfavorable alterations in osmotic gradient across the barrier, thus preventing the abnormal accumulation of water in the parenchyma and subsequent development of edema and rise in ICP.

As previously mentioned, in this study we were able to reliability measure changes in ICP throughout the 24 h monitoring period. Clinical studies investigating fluctuations in ICP following malignant MCA stroke have recorded pressures as high as 43 mmHg in patients that died, compared with 28 mmHg in survivors (Hacke et al., 1996). In the present study pressures as high as 50 mmHg were recorded in vehicle animals, however, two or three boluses of the NK1-r antagonist were sufficient to sustainably reduce ICP to less than 30 mmHg. Furthermore, 2×NK1 treated animals recorded pressures of less than 20 mmHg throughout the 24 h monitoring period, with the exception of one animal, and 3 boluses of the antagonist was sufficient to maintain pressures below 25 mmHg, again with the exception of one animal who recorded a maximum pressure of 28 mmHg. One dose of the NK1-r antagonist, however, was insufficient to produce a treatment effect with pressures averaging 35 mmHg. These findings suggest that multiple boluses of the NK1-r antagonist is a potentially viable therapeutic strategy to reduce elevated ICP following stroke, with the ability to bring about a clinically meaningful and sustainable reduction

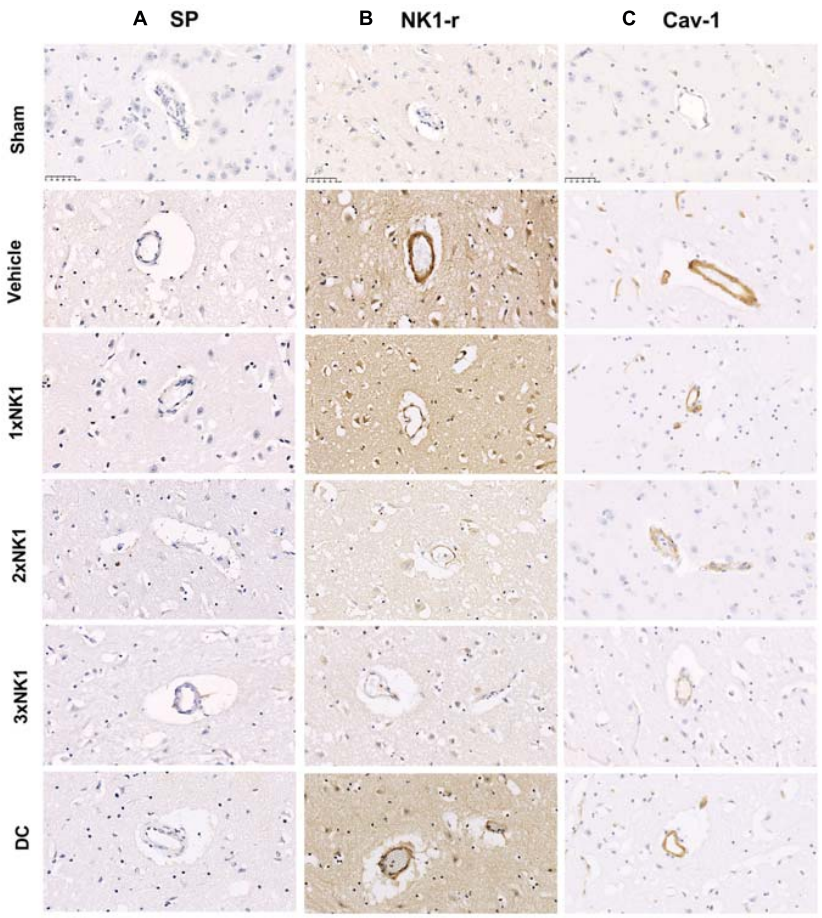

FIGURE 5 | SP, NK1-r and caveolin-1 immunoreactivity. There was no identifiable increase in SP, NK1-r or cav-1 immunoreactivity in sham animals. Low levels of SP immunoreactivity were seen perivascularly in vehicle, 1×NK1, 2×NK1, 3×NK1 and DC groups **(A)**. This was concordant with an increase in NK1-r immunoreactivity, which was most prominent in vehicle, 1×NK1 and DC animals **(B)**. Cav-1 immunoreactivity was significantly enhanced in 1×NK1, 2×NK1 and DC treatment groups when compared to vehicle and 1×NK1 **(C)**. Scale bar: 50 μm, 40× magnification.

in pressure comparable to that observed in surviving patients (Hacke et al., 1996).

Furthermore, the reduction in ICP we observed with repeated NK1-r boluses was comparable to surgical decompression, which is encouraging given the limitations of current available pharmacotherapies used for ICP management, often necessitating early DC. Indeed, DC performed before clinical signs of herniation is shown to improve functional outcomes however surgery performed after onset of clinical deterioration may be too late to yield beneficial outcomes (Shah et al., 2019). Furthermore, although DC is the most powerful tool currently available to combat elevated ICP, the procedure is highly invasive, benefits remain controversial and the long-term implications of the procedure on ICP dynamics are not well understood (Funchal et al., 2018; Lilja-Cyron et al., 2019; Shah et al., 2019). A pooled analysis of the randomized control trials DECIMAL, HAMLET, and DESTINY, compared early DC with best available conventional medical management in patients with evidence of MCA territory hypersensitivity and a National Institute of Health Stroke Scale (NIHSS) > 15/20 (Jüttler et al., 2007; Vahedi et al., 2007a,b; Hofmeijer et al., 2009; Geurts et al., 2013). These studies found that that DC significantly reduced fatality rates and improved functional outcome compared with conventional pharmacotherapy alone. However, whilst some studies report reduced mortality and improved survival, it is at the cost of a higher number of individuals that are moderately severely disabled following the procedure (Vahedi et al., 2007a; Kurland et al., 2015). This becomes an issue of increasing concern given that DC is associated with higher mortality rates in those aged greater than 60 years of age, the most prevalent stroke patient population (Hofmeijer et al., 2009; Benjamin et al., 2018). The correlation between age and functional outcome remains an extremely important pre-treatment prognostic factor in deciding if patients should undergo DC (Chen et al., 2007), further highlighting the need for development of new therapies that can be administered to a wider patient population in a safe and timely manner, eliminating the need for surgical decompression and risk of associated morbidity. In this study we have demonstrated that repeated dosing of NK1-r antagonist treatment was able

to reduce ICP comparable to DC surgery, thus providing an alternate treatment strategy, circumventing the need for invasive surgery.

Limitations

Although we have established that the NK1-r antagonist is an effective strategy to lower ICP and we have previously determined that the ovine model is viable candidate for the screening of promising novel therapeutics, we must acknowledge the limitations of the study.

Due to the invasive nature of the surgery and significant deficits that ensued following permanent MCAO, animals were required to be maintained under anesthesia for the duration of the experiment. We recognize that human patients are rarely under the influence of anesthesia on stroke onset, and that the use of anesthetic agents may affect outcome measures. Despite this, the agents used for induction and maintenance were chosen to reduce any potential neuroprotective or damaging effects, as previously described in detail (Wells et al., 2015). Indeed, as ketamine is known for its neuroprotective properties, and inhalation isoflurane for its sub-neuroprotection and association with reduced blood pressure, the combination was used to bring about a countering effect. The synergistic use of these agents permitted adequate anesthesia with controlled MABP whilst preventing inadvertent neuroprotection as a confounding factor, an important consideration when modeling acute ischemic stroke. It must be acknowledged, however, that we did observe significant differences in MABP across several of the groups. Nevertheless, these alterations in MABP did not follow the same pattern as the alterations in ICP so it is therefore unlikely that they significantly contributed to the observed treatment effects. The differences in MABP observed between groups most likely reflects both the within group and between group heterogeneity in the amount of isoflurane required to maintain twilight anesthesia during surgery whilst balancing with ketamine to maintain adequate blood pressure.

Furthermore, only female animals were used in the present study due to the inherent need for catheterization of animals during long-duration anesthesia. Females were selected preferentially over males upon veterinary advice given the difficulty in catheterizing the highly convoluted male urethra.

Though we were able to establish a significant increase in ICP following ovine stroke, MRI findings were not strongly correlated with ICP. Although the relationship between ICP and cerebral edema well established and promising in this study, we acknowledge that the small sample sizes in this study may have led to a low statistical power. Furthermore, it must be noted that this is frequently seen in clinical stroke cases, where MRI and computed tomography (CT) findings are not always a good predictor of ICP. Due to facility access, MRI was not possible in the entire cohort, leading to uneven group sizes. Despite a larger cohort available for ICP in both treatment and vehicle groups, only animals with matching ICP/MRI data were included, leading to variations in group sizes. Furthermore, the reliable measurement of cerebral edema on MRI at a single time-point is somewhat contentious, as the hyperintensity of vasogenic edema is difficult to distinguish from the lesion itself. The measurement of the entire FLAIR lesion volume therefore includes areas of infarction as well as edema, and is thus an indirect measure of edema volume. A more robust approach to measuring edema evolution would be to perform sequential MRI's and evaluate the change in diffusion lesion volume between 2 times points following reperfusion, which was not possible in this study due to cost. It should also be acknowledged that whilst MRI findings did not correlate with ICP, we were able to observe MRI features similar to that seen clinically, including transcalvarial herniation in DC treated animals and reduced midline shift. Finally, testing of multiple NK1-r antagonists was not feasible in this study given the time and cost involved in conducting sheep experiments. However, in our rodent studies of TBI we have previously tested 2 different NK1-r antagonists and recorded comparable results (Donkin, 2006) which provided the basis for the use of the agent in the present study.

For future studies we will work alongside the animal ethics committee of the South Australian Health and Medical Research Institute (SAHMRI) to develop a survival model of transient MCAO which obviates the need for long duration anesthesia, allowing for the study of conscious animals following induction of stroke and assessment of long-term functional changes.

CONCLUSION

Multiple boluses of an NK1-r antagonist is effective in lowering ICP following ovine stroke, producing a reduction in ICP that is comparable to decompressive surgery. We propose that the mechanism by which the NK1-r antagonist is exerting its effect is largely via caveolae mediated albumin transcytosis. Administration of the NK1-r is thus preventing abnormal albumin extravasation from the vasculature to the brain parenchyma and ameliorating the subsequent development of vasogenic edema and rise in ICP. These findings suggest that NK1-r antagonist treatment may represent a novel intervention for the management of elevated ICP following stroke.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the supplementary files.

ETHICS STATEMENT

All experimental procedures were approved by the Animal Ethics Committees of the University of Adelaide (M-2011-240) and the South Australian Health and Medical Research Institute (SAHMRI; SAM104/11) and conducted according to guidelines established for the use of animals in experimental research as outlined by the Australian National Health and Medical Research Council code of practice for the care and use of animals for scientific purposes (8th edition, 2013).

AUTHOR CONTRIBUTIONS

AW, RV, RT, and AL conceived and designed the experiments. AW, RT, and AL carried out the experiments. AS-A, NY, JH, and RT analyzed the data. AS-A, RT, and AL wrote the manuscript.

FUNDING

This work was supported by the National Health and Medical Research Council (NHMRC; Project grant GNT1082556) and by the Neurosurgical Research Foundation (Adelaide, SA, Australia). RT was supported by the NHMRC Post-Doctoral Training Fellowship. AW was supported by the NHMRC Post-Graduate Fellowship.

ACKNOWLEDGMENTS

We would like to thank Sunthara Rajan Perumal for the acquisition of the MRI and Shenyi Peng, Tony Nguyen, and Martina Kontos for their contribution to the MRI analysis. We would also like to acknowledge the facilities and scientific and technical assistance of the National Imaging Facility, a National Collaborative Research Infrastructure Strategy (NCRIS) capability, at LARIF and SAHMRI.

Background and Purpose: Cerebral edema and elevated intracranial pressure (ICP) are the leading cause of death in the first week following stroke. Despite this, current treatments are limited and fail to address the underlying mechanisms of swelling, highlighting the need for targeted treatments. When screening promising novel agents, it is essential to use clinically relevant large animal models to increase the likelihood of successful clinical translation. As such, we sought to develop a survival model of transient middle cerebral artery occlusion (tMCAO) in the sheep and subsequently characterize the temporal profile of cerebral edema and elevated ICP following stroke in this novel, clinically relevant model.

Methods: Merino-sheep (27M;31F) were anesthetized and subject to 2 h tMCAO with reperfusion or sham surgery. Following surgery, animals were allowed to recover and returned to their home pens. At preselected times points ranging from 1 to 7 days post-stroke, animals were re-anesthetized, ICP measured for 4 h, followed by imaging with MRI to determine cerebral edema, midline shift and infarct volume (FLAIR, T2 and DWI). Animals were subsequently euthanized and their brain removed for immunohistochemical analysis. Serum and cerebrospinal fluid samples were also collected and analyzed for substance P (SP) using ELISA.

Results: Intracranial pressure and MRI scans were normal in sham animals. Following stroke, ICP rose gradually over time and by 5 days was significantly ($p < 0.0001$) elevated above sham levels. Profound cerebral edema was observed as early as 2 days post-stroke and continued to evolve out to 6 days, resulting in significant midline shift which was most prominent at 5 days post-stroke ($p < 0.01$), in keeping with increasing ICP. Serum SP levels were significantly elevated ($p < 0.01$) by 7 days post-tMCAO.

Conclusion: We have successfully developed a survival model of ovine tMCAO and characterized the temporal profile of ICP. Peak ICP elevation, cerebral edema and

midline shift occurred at days 5–6 following stroke, accompanied by an elevation in serum SP. Our findings suggest that novel therapeutic agents screened in this model targeting cerebral edema and elevated ICP would most likely be effective when administered prior to 5 days, or as early as possible following stroke onset.

Keywords: intracranial pressure, cerebral edema, stroke, large animal model, blood-brain barrier

INTRODUCTION

Worldwide, over 15 million people suffer a stroke each year, of which one third will die and one third will remain permanently disabled as a result (Feigin et al., 2017). Cerebral ischemia initiates a cascade of interrelated events precipitating brain tissue injury and cell death (Ayata and Ropper, 2002). Of these secondary injury processes, increased microvascular permeability and loss of structural integrity of the blood-brain barrier (BBB) are key to the development of cerebral edema, a pathological state in which fluid abnormally accumulates in the extracellular space of the cerebral parenchyma, resulting in an overall increase in brain volume. This leads to a subsequent rise in intracranial pressure (ICP), which has devastating consequences including infarct expansion, displacement of brain tissue, tonsillar herniation, and death (Steiner et al., 2001; Raslan and Bhardwaj, 2007; Battey et al., 2014; Kim et al., 2015).

Stroke patients often exhibit a progressive and slow evolution of brain injury, with cerebral edema and elevated ICP presenting some days following initial insult to tissue, most commonly around 3–5 days following onset (Hewitt and Ellory, 2012). Despite the devastating impact of cerebral edema and elevated ICP, however, existing treatments fail to address the underlying pathophysiology, thereby limiting their efficacy (Battey et al., 2014). Novel therapies that target the underlying cause of swelling and prevent the evolution of cerebral edema and elevated ICP are urgently required to improve post-stroke outcomes. To this end, our laboratory has identified that the tachykinin neuropeptide substance P (SP) is a key mediator in BBB dysfunction and development of cerebral edema following stroke (Turner et al., 2006, 2011; Turner and Vink, 2012) and traumatic brain injury (TBI) (Vink et al., 2003; Nimmo et al., 2004; Donkin et al., 2009; Corrigan et al., 2012). Specifically, SP release leads to neurogenic inflammation, manifesting following acute central nervous system (CNS) injury as increased BBB permeability and the development of cerebral edema. Furthermore, we have established that blockade of the receptor for SP, the tachykinin NK1 receptor (NK1-r), reduces both BBB permeability and cerebral edema in rodent models of stroke (Turner et al., 2011; Turner and Vink, 2012, 2014) and TBI (Donkin et al., 2009; Corrigan et al., 2012, 2016), suggesting that this is a common feature of acute brain injury.

An enhanced understanding of the underlying pathophysiology of cerebral edema and elevated ICP following stroke is essential in guiding the development of more effective therapies, and pre-clinical stroke studies are an essential step in this process. However, the poor clinical translation of stroke therapies from the laboratory to the clinic to date has emphasized the importance of appropriate species and model selection (Casals et al., 2011). The use of large intermediate species for these studies is paramount in the pre-clinical phase to improve translation to the clinic due to similarities in neuroanatomical structure, such as a large gyrencephalic brain that is closer in similarity to that of the human compared with many widely adopted small animal models. In light of this, a number of large animal species are used as pre-clinical stroke models, including sheep (Boltze et al., 2008; Wells et al., 2012, 2015), dogs (Qureshi et al., 2004; Cameron et al., 2008; Boulos et al., 2011; Christoforidis et al., 2011), pigs (Sakoh et al., 2000; Watanabe et al., 2007; Platt et al., 2014), and non-human primates (Nehls et al., 1986; Tagaya et al., 1997; Yuji et al., 2001; D'Ambrosio et al., 2004; Furuichi et al., 2007), each with their own inherent advantages and disadvantages (Sorby-Adams et al., 2018). Although gyrencephalic non-human primates are of great value in modeling the human condition, the cost, housing requirements and ethical considerations may preclude their use in large scale studies. Pigs are a widely used experimental species in models of cardiovascular (Suzuki et al., 2011; Kamoi et al., 2014) and TBI studies worldwide (Lighthall, 1988; Pfenninger et al., 1989; Ross et al., 1994; Duhaime et al., 2000; Manley et al., 2006), however, the Yucatan mini-pig is not available in Australia, and the rapidly increasing bodyweight of other strains can make long-term studies difficult. Sheep are an accessible experimental species and have been used extensively to model a number of neurological conditions, including non-accidental head injury (Sandoz et al., 2012; Anderson et al., 2014), TBI (Vink et al., 2008; Vink et al., 2017), and Huntington's Disease (Reid et al., 2013; Morton et al., 2014). Although sheep have earned a reputation as unintelligent animals, the evidence is quite to the contrary, as sheep demonstrate excellent facial recognition, executive decision making and emotional processing, often comparable to humans on equivalent tasks (Tate et al., 2006; Keith et al., 2007; Morton and Avanzo, 2011). Specifically, the high proportion of white to gray matter in the sheep brain is of particular benefit when studying the pathophysiology of edema and ICP, given that edematous fluid accumulates in the white matter following ischaemic stroke (Jha, 2003; Mahajan and Bhagat, 2016). The strong fibrous tentorium cerebelli of the sheep, comparable with that of the human, also prevents the brain from moving downward to accommodate increased volume of the edematous brain, resulting in persistent elevations in ICP, midline shift and tonsillar herniation all of which are seen clinically. Additional advantages of large animal models, is the ability to take multiple serum and cerebrospinal fluid (CSF) samples from an individual animal over time which is not possible in rodents, as well as using clinical physiological monitoring equipment and magnetic resonance imaging (MRI). As such, large animal stroke models, including the sheep, are

an excellent additional screening tool following evaluation in rodents prior to progression to clinical trials.

There are two models of ovine middle cerebral artery occlusion (MCAO) currently in use (Boltze et al., 2008; Wells et al., 2012) both of which involve permanent occlusion of the MCA. In the Boltze model (Boltze et al., 2008) the craniotomy is left open so that animals are effectively given decompression at the time of stroke, allowing for the investigation of long-term time-points without premature mortality, although intracranial pressure dynamics cannot be investigated. Conversely, in the Wells model (Wells et al., 2012, 2015) the craniotomy is closed following MCAO so that the evolution of ICP can be accurately studied. However, survival time-points beyond 24 h are not possible in this model due to the resulting malignant MCA infarction and ethical requirement to maintain animals under anesthesia for the duration of the experiment. As such, there is a clear requirement for an ovine MCAO stroke model where the MCA is temporarily occluded to study the effects of reperfusion injury and longer time-points following stroke onset. Furthermore, there is an increasing incidence of patients who successfully recanalize following stroke onset. This is largely due to the increased use of endovascular clot retrieval for reperfusion of large strokes, such as occlusion of the internal carotid artery (ICA) or M1 segment of the MCA (Goyal et al., 2016). The mechanical recanalization of the MCA able to be produced in a transient MCAO model closely aligns with the vascular reperfusion achieved with endovascular thrombectomy, and thus may be more representative of the human condition.

Accordingly, the aims of the present study were to: (1) develop a survival model of ovine MCAO stroke with reperfusion; (2) characterize the temporal profile of intracranial pressure changes following stroke; and (3) determine the contribution of SP to BBB permeability and cerebral edema that develops in this model. By determining the clinical course of ICP in this model, an optimal time window for administration of novel therapeutic agents targeting elevated ICP due to cerebral edema can be established.

MATERIALS AND METHODS

Experimental Design

A total of 58 (n = 27M;31F) merino sheep (weight range 65 ± 7 kg; age 18–36 months) were used in this study. Animals (3M and 3F/time point) were pre-operatively randomized to daily post-stroke survival time points ranging from 1–7 days. Animals allocated to the post-stroke time-points underwent two surgeries: tMCAO surgery with recovery, and ICP monitoring on the designated day post-stroke. An additional group of animals underwent the surgical procedure without MCAO and acted as sham controls (n = 4F). These animals had ICP continuously recorded for 4 h immediately following the sham surgical procedure. Finally, an additional follow up cohort of 12 animals (n = 6F;6M) underwent stroke surgery and were included to obtain serum and CSF samples over the 7-day post-stroke time-course. This was not possible in the main stroke cohort due to the risk that repeat CSF sampling might potentiate changes in intracranial dynamics leading to inaccurate measurements of ICP. All animals were group housed in conventional sheep paddocks for a minimum of 2 weeks prior to surgery to allow for acclimatization. Animals were then moved to individual indoor pens 48 h prior to surgery and fasted over night for a minimum of 12 h prior to the procedure.

Experimental Procedure

Animal Preparation and Anesthesia

Anesthesia was induced with a combination of intravenous ketamine (0.05 ml/kg, 100 mg/kg Injection, CEVA, Australia) and diazepam (0.08 ml/kg, 5 mg/ml Injection, Pamlin, CEVA, Australia). Following induction, animals were intubated via endotracheal tube insertion to ensure airway patency for ventilation. Animals were then positioned on the operating table on their left side, with hind limbs exposed for arterial access. An arterial catheter was inserted in the left hind leg for blood gas sampling and a cannula inserted into the external jugular vein for fluid and drug administration. Intraoperative anesthesia was maintained via a combination of inhalational isoflurane (Henry Shein, Australia; 1.5–2.0%) in 100% oxygen and intravenous (jugular) ketamine at an infusion rate of 4 mg/kg/h. Crystalloid fluids were administered throughout surgery via continuous intravenous infusion with compound sodium lactate (Baxter Health, Australia) to assist hydration and ionic balance. In addition, intraarterial sodium chloride (Baxter Health, Australia) was infused at a rate sufficient to ensure arterial catheter patency. Following surgery, animals were recovered and treated with subcutaneous antibiotic Rilexine (1 ml/10 kg every 12 h, 15 g/100 ml Cephalexin, VIBRAC, Australia), NSAID Carprieve (0.7 mg/kg, 50 mg/ml every 12 h, Carprofen, Norbrook, Australia) and opioid Temgesic (1.0 ml, 324 ug/ml Buprenorphine hydrochloride, one dose post-operatively, Reckin Benckiser, Australia) for pain relief. Antibiotic and NSAID treatment was continued for a minimum of 3 days following surgery, with additional opioid and/or NSAID administered as required thereafter for pain management.

Surgical Approach

A model of ovine stroke was modified from previously published works (Wells et al., 2012, 2015) in order to achieve tMCAO with reperfusion (**Figure 1**). This modification enabled the recovery of animals from surgery and the study of longer time-points (beyond 24 h) following stroke. In this particular approach, it was necessary to keep the coronoid process of the mandible intact and preserve the surrounding temporalis muscle to ensure animals were able to masticate following surgery. To achieve this, a 50 mm curved horizontal incision was made posterior to the orbital rim of the right eye and terminating anterior to the ear. Upon incision, the temporalis muscle was retracted and the coronoid process elevated to expose the underlying skull. Cervical retractors (Codman) were inserted and blades adjusted to provide space for a small craniotomy to be drilled at the junction of the parietal and squamous temporal bones with a high-speed pneumatic drill using a 5 mm cutting burr (Midas Rex, Medtronic, MN, United States). Following craniotomy, a horse shoe durotomy was performed, the brain exposed and the anterior temporal lobe gently retracted to expose the right

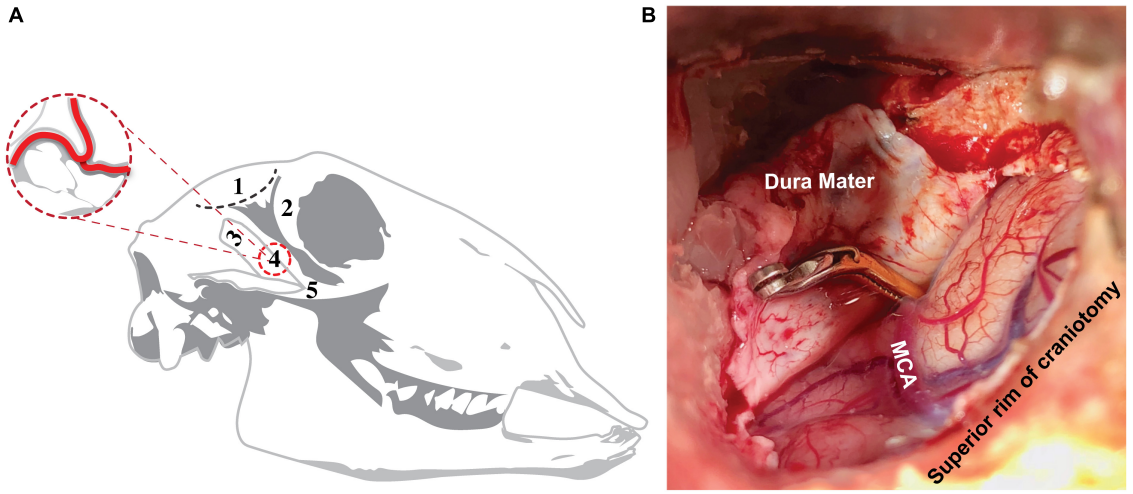

FIGURE 1 | Surgical approach to ovine transient MCAO. Surgical approach **(A)**, showing site of incision (1; black dashed line) posterior to the orbital rim (2) and superior to the coronoid process (3). This approach enabled the skull base to be accessed without disrupting the coronoid process or zygomatic arch (5), allowing for craniotomy (4) and direct access to the MCA, whilst ensuring post-operative recovery of the animal and the ability to masticate following the procedure. Superior view of craniotomy site **(B)** showing the aneurysm clip applied to the proximal MCA.

proximal MCA. A small amount of CSF was aspirated to ensure sufficient visualization of the proximal MCA, however, this was kept to a minimum to reduce the impact on intracranial volume. Gentle dissection of the MCA from the arachnoid mater was performed to allow for a temporary aneurysm clip (Aesculap) to be applied proximal to the MCA bifurcation using a clip applicator (YASARGIL Aneurysm clip system, Aesculap). Successful clipping of the MCA resulted in an immediate decrease in vessel caliber, confirming reduced blood flow. The dura was then gently re-opposed onto the brain and the craniotomy site filled with sterile saline to prevent dehydration of the underlying cortical tissue and the surgical site draped. The clip was left *in situ* for 2 h and subsequently removed with clip applicators to achieve reperfusion. Visual confirmation of reperfusion was noted when the caliber of the vessel increased and blood returned to the distal MCA. Successful reperfusion also was confirmed on magnetic resonance angiography (MRA) MRI performed at the pre-selected timepoints.

Following reperfusion, the dura was approximated and interleaved with synthetic dura (Durepair, Medtronic, Australia) to cover the exposed brain. Dural closure was then achieved with ethyl cyanoacrylate (Bostik, Australia), and the bone previously removed reinserted into the craniotomy site and reinforced with dental acrylic cement (Sledgehammer, Keystone, Germany) to create a watertight seal, thus restoring intracranial dynamics. The surgical site was then treated with 1.0 ml 0.5% local anesthetic Marcain (bupivacaine hydrochloride 5 mg/ml, AstraZeneca, Australia) and closed using a 0.1 Vicryl braided polyglactin Suture (ETHICON, Australia) using the horizontal mattress suture technique of wound closure to minimize risk of infection. The animal was removed from anesthesia, extubated and pain relief administered prior to transfer into a post-operative recovery pen. Mean arterial blood pressure (MABP) was monitored at 5-min intervals throughout surgery via application of a pediatric blood pressure cuff (Delfi Medical, Canada) on the upper left front limb. Blood gas samples (Machine AVL Scientific Corporation United States, Manufactured by Hersteller, OPTI Critical Care Analyzer–Model OPTI3, Serial No. OP3-2759) were acquired hourly via arterial catheter sampling to determine pO_2, pCO_2, hematocrit, hemoglobin, pH, Na^+ and K^+ levels. End tidal CO_2 was also recorded at regular intervals. Animals were maintained on a heating pad throughout all surgical procedures and rectal temperature checked hourly to ensure maintenance of body temperature within normal ovine limits (37.5–39.0°C).

ICP Measurement

At 4 h prior to the pre-determined post-stroke time-point, or immediately following surgery in shams, anesthetized (using aforesaid isoflurane and ketamine maintenance protocols) animals were placed prone in the sphinx position on the operating table. Bilateral burr holes were drilled into the left and right parietal bones, posterior to the coronal suture and approximately 20 mm from the sagittal suture. The dura was perforated and skull bolts secured, following which Codman microsensor ICP probes (Codman Neuro, DePuy Synthes, Australia) were inserted to an approximate depth of 15 mm into the brain parenchyma and ICP recorded continuously for a period of 4 h post-MCAO induction or sham surgery (LabChart Reader, ADInstruments, v. 8.1.1). Two-point calibration (0 and 100 mmHg) was performed prior to insertion of probes and at the end of the recording period to confirm measurement accuracy. ICP readings selected for final analysis (left or right) were based on calibration data, with readings preferentially selected from the right hemisphere probe. Raw ICP data underwent a logarithmic exponential transformation as previously described and was expressed as geometric mean ± SEM (Matthews et al., 1990; Wells et al., 2015).

MRI

Following the 4-h ICP monitoring period, animals were moved to a 1.5T Siemens Syngo2004A (Siemens AG, Munich, Germany) MRI scanner, during which they were maintained under general anesthesia (3% isoflurane). Sequences were acquired including time-of-flight MRA (TOF MRA; TR 26 ms, TE 3.69 ms, slice thickness 0.50 mm), diffusion weighted imaging (DWI; TR 5600 ms, TE 80 ms, slice thickness 3.0 mm), fluid attenuated inversion recovery (FLAIR; TR 5000 ms, TE 386 ms, slice thickness 0.9 mm), T1-weighted imaging (TR 2300 ms, TE 2.58ms, slice thickness 0.9 mm) and T2-weighted imaging (TR 3200 ms, TE 410 ms, slice thickness 0.9 mm). T1-weighted post-contrast images were also acquired following intravenous administration of 1 mL/kg gadolinium-diethylene-triamine-pentaacetic acid (GAD) (Magnevist, Bayer HealthCare, Germany) to determine the extent of BBB breakdown on MRI.

The degree of midline shift was used as a surrogate marker for the anatomical sequalae of cerebral edema. Shift from the midline was assessed using axial T2-weighted scans and measured in mm from the septum pellucidum at the level of the foramen of Monro (Horos DICOM image viewer v3.1.1). To calculate cerebral edema, coronal FLAIR images were analyzed using Horos DICOM image viewer (v3.1.1). After optimal adjustment of brightness and contrast, edema volume was determined from sequences using computer-aided manual tracing of the hyperintense lesion by a blinded assessor. The areas were then summed and multiplied by the slice thickness to give a total volume in cm^3.

To calculate infarct volume, segmentation tools in ITK-SNAP (v3.7) were used to perform semi-automated segmentation of the MRI diffusion lesions using diffusion-weighted images (Yushkevich et al., 2006). A combination of "three-dimensional active contour segmentation" and subsequent manual post-processing of the segmentation while adjusting image thresholds was performed to maximize reproducibility whilst excluding artifacts. The "three-dimensional active contour segmentation" consisted of multiple steps: First, in the pre-segmentation phase, independent component analysis automatically segmented parts of the DWI image and these were manually identified as foreground or background. To obtain an optimal distinction between foreground and background, thresholds of the image windows were adjusted. After thresholding, a "speed image" with a separate foreground and background was created. Next, in the active contour phase, seed regions were manually placed within the region of interest (ROI). These seeds were then automatically grown within the ROIs to form the temporary segmentation. Subsequently, areas that were not automatically included in the "active contour segmentation," were manually included in the follow-up infarct segmentation. The total volume of the segmentation was exported and reported in cm^3 for analysis.

Perfusion and Histological Examination

Following MRI, intravenous heparin (5000 I.U./5 ml; Pfizer, NY, United States) was administered and animals humanely euthanized via common carotid perfusion fixation with cold TRIS-buffered saline under isoflurane anesthesia. The brains were subsequently removed and sliced into 10 mm coronal slices using a custom-made sheep brain matrix. Sections were then immersion fixed in 10% neutral-buffered formalin for a minimum of 14 days prior to being processed, embedded in paraffin wax and sectioned coronally at 5-micron intervals to identify albumin, SP, and caveolin-1 via immunohistochemistry (**Table 1**).

Serum and CSF Collection

Blood samples were collected (BD-Vacutainer®-SST™-II-Advance-Tube) from animals (n = 12, 6M;6F) pre-injury and at 4, 8, 12, and 16 h post-stroke and on days 1, 3, 5, and 7 via jugular venipuncture. Following collection, samples were centrifuged (10 min at 2000g) and serum extracted into 10 × 500 µl aliquots and stored at −80°C. CSF was collected via lumbosacral tap prior to induction of stroke and on days 1, 3, and 6 thereafter. Note that this was performed in the follow up cohort, and these animals did not undergo ICP monitoring so there were no concerns regarding multiple CSF draws and the associated effects on ICP measurement accuracy. Prior to collection, animals were induced with combination diazepam and ketamine as previously described. The animals were then placed in the prone position on a surgical table and the sagittal plane of the animals vertebrae manipulated so that it was perpendicular with the horizontal plane of the bench. The animal was shaved to allow for clear access to the lumbosacral joint and appropriate visualization for landmarks. Palpation of the hips was performed to determine the correct sagittal plane orientation of the spine and the optimal site for CSF collection was determined via identification of the midline depression between the last lumbar and first sacral vertebrae. The area was cleaned using a 4% chlorhexidine preoperative surgical scrub brush (BD E-Z Scrub™), povidone-iodine applied and site surgically prepared. A steriseal spinal needle with stylet (Becton Dickinson Medical Technology) was inserted perpendicular to the skin and the needle advanced slowly through the subcutaneous tissue and interarcuate ligament until a sudden drop in resistance was felt indicating the advancement through the dural membrane and entry into the subarachnoid space. The stylet was then removed and 2 ml of CSF aspirated via a syringe and deposited into a 3 ml container; sample placed immediately on ice for 20 min, centrifuged (15 min at 3000g), extracted into 3 × 500 µl aliquots and stored at −80°C.

Analysis of Serum and CSF

Serum and CSF samples were used to quantify expression of SP using enzyme-linked immunosorbent assay (ELISA)

TABLE 1 | Immunohistochemistry protocols.

Antibody	Dilution	Retrieval	Brand	Catalog no.
Albumin	1:2000	No retrieval	Dako	A0001
SP	1:5000	Citrate	Abcam	ab14184
Caveolin-1	1:500	EDTA	Cell Signaling Technologies	3238

according to the manufacturer's instructions (Abcam; KIT-ab133029). All samples were diluted 1:4 in assay buffer for appropriate compliance with each individual plate standard curve. Standards, serum and CSF test samples were run and the plate immediately analyzed following addition of the stop solution using a spectrophotometric microplate reader (Synergy HTX, multi-mode reader). At optical density of 405 nm light absorbance was calculated to give an inverse reading of SP proportional to its captured measure on the plate.

Statistical Analysis

All data are expressed as mean ± SEM. Physiological data (MABP, pH, pO_2, and pCO_2) were analyzed using one-way analysis of variance (ANOVA) followed by Tukey's *post hoc* tests (Prism v.8.0.1, Graphpad, CA, United States). ICP, infarct volume, cerebral edema and midline shift data were analyzed by one-way ANOVA with multiple comparisons followed by Tukey's *post hoc* tests. ELISA evaluation was performed for each plate using individually generated standard curves and an R-value of 0.9709 was accepted to improve the efficacy of inter-plate accuracy. ELISA values were then analyzed via one-way ANOVA with Tukey's *post hoc*. Pearson's correlations were run between midline shift and cerebral edema, cerebral edema and ICP and midline shift and ICP to determine the relationship between variables. A two-way ANOVA with Sidak's multiple comparison test was run to determine gender differences in physiological variables during both surgery and ICP monitoring. Gender discrepancies were also established for infarct volume, cerebral oedema, midline shift and ICP in addition to CSF and serum SP via two-way ANOVA with Sidak's *post hoc*. A p-value < 0.05 and R-value > 0.04 was considered significant.

RESULTS

Surgery, Mortality, and Post-operative Course

There was no premature mortality of animals in the present study. One animal was excluded due to insufficient reperfusion following MCAO as seen on MRA, resulting in a permanent rather than a transient occlusion (**Figure 2**). In all other temporary occlusions of the MCA reperfusion was successfuly achieved and confirmed on MRA. A further four animals were excluded due to significant anesthetic difficulties which confounded the experimental course (n = 2 in 2 days group; n = 2 in 3 days group). Specifically, the excluded animals were unstable throughout the induction of stroke surgery, necessitating repeat boluses of ketamine and diazepam and an increased rate of isoflurane to maintain surgical levels of anesthesia, which resulted in significantly lowered MABP, decreased cerebral perfusion pressure and ultimately profound infarct expansion.

All animals were able to use their jaw and masticate to eat following surgery. A comprehensive behavioral analysis was beyond the scope of this study, however, all animals in the ICP cohort were observed for jaw alignment and eating behavior, the presence/absence of fetlock weakness and demeanor throughout the post-stroke period. A total of 9/42 animals demonstrated evidence of jaw misalignment following stroke surgery, which persisted to the end of the experiment in 3/9 animals. Although 25/42 animals showed reduced food intake post-stroke when compared to their pre-stroke daily intake, body weight remained within acceptable limits (< 15% reduction from pre-stroke weight). A total of 14/42 animals showed fetlock weakness following stroke, manifesting as knuckling of the distal forelimb which was most commonly observed on day 1 and typically resolved by day 4 post-stroke.

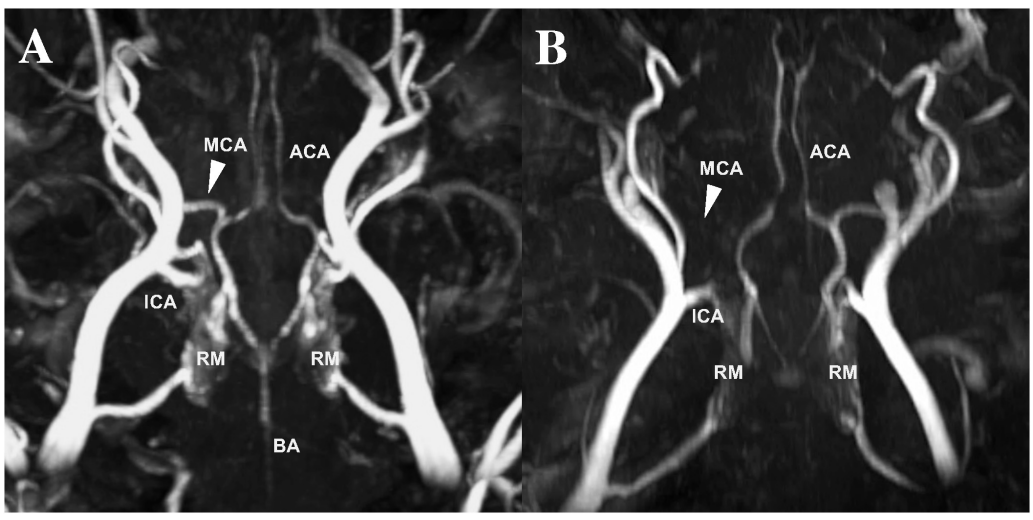

FIGURE 2 | MCA reperfusion following transient MCAO **(A)** compared to permanent MCAO **(B)** on time-of-flight MRA. Evidence of vessel patency, indicated by the white arrow, following clip removal in transient MCAO animals compared to permanent MCAO animals, where the vessel cannot be visualized MRA (data not reported). MCA, middle cerebral artery; ACA, anterior cerebral artery; ICA, internal carotid artery; BA, basilar artery; RM, rete mirabile.

A decline in demeanor, as demonstrated by a lowered head position and droopy ears, was observed in 26/42 animals and was most prevalent at days 5–7 post-stroke, coinciding with elevated ICP.

Physiological Parameters

Physiological variables for pCO_2, MABP, and pH were within normal limits for all groups throughout the duration of the experiment (**Table 2**). As animals were maintained on 100% oxygen (oxygen 6.0 L/min) through the course of surgery and ICP monitoring this resulted in pO_2 values that were significantly above the normal clinical range of 90–100 mmHg. These observations, however, were observed across all experimental groups. No significant difference ($p > 0.05$; **Table 1**) in pO_2, pCO_2, or pH were observed amongst groups during stroke surgery or the 4-h period of ICP monitoring. There was however a statistically significant decrease in MABP during the ICP monitoring period seen at 1-day post-stroke compared with 4 ($p = 0.04$) and 7 ($p = 0.01$) days.

Intracranial Pressure

Intracranial pressure remained within normal limits for the duration of the 4-h monitoring period in sham animals (8 ± 2 mmHg). From 1 to 4 days following tMCAO, ICP levels were comparable to sham ($p > 0.05$; **Figure 3**). However, by 5 days post-stroke, ICP was significantly elevated (28 ± 10 mmHg; $p < 0.0001$) from sham levels and post-stroke days 1–4 ($p < 0.0001$). ICP remained significantly elevated out to 6 days post-stroke when compared to shams (25 ± 5 mmHg; $p = 0.0001$) and 1 ($p = 0.0001$), 2 ($p = 0.0003$), 3 ($p = 0.03$) and 4 day ($p = 0.0007$) post-stroke time points. By 7 days, ICP began to decline (18 ± 2 mmHg; $p = 0.02$ when compared to 5 days), but remained significantly elevated compared to sham ($p = 0.04$), although not significantly different ($p > 0.05$) from recordings on days 1, 2, 3, 4, and 6 post-stroke.

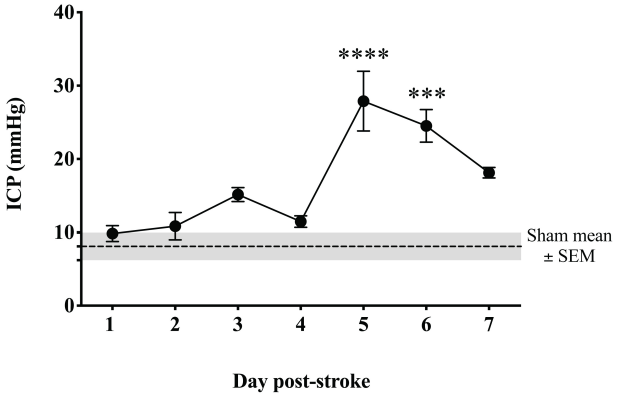

FIGURE 3 | Temporal profile of ICP following transient MCAO. ICP was significantly elevated at 5 days ($p < 0.001$) and 6 days ($p < 0.05$) post-stroke when compared to sham. By 7 days, ICP began to resolve though remained elevated compared to sham ($p < 0.05$). ****$p < 0.0001$; and ***$p < 0.001$ compared to sham. $n = 6$/time-point, $n = 4$ sham.

MRI

Magnetic resonance imaging was normal in sham animals, with no evidence of infarction, cerebral edema or midline shift (data not shown). At each time-point following stroke there was evidence of MCA recanalization following clip removal as seen on MRA, with the aforementioned exception of one animal that was excluded due to persistent MCAO (**Figure 3**). All stroke animals showed evidence of hyperintensity on T2-weighted and FLAIR images in the territory MCA, indicative of the infarct core and surrounding extracellular edema (**Figure 4**). There was no significant difference in infarct volume at any of the time points post-stroke as measured on DWI MRI (**Figure 5A**).

Cerebral edema evolved over time from 1 to 6 days post-tMCAO, with the largest volume of cerebral edema seen at 5 (8.86 ± 2.03 cm^3) and 6 days (7.01 ± 0.9 cm^3). This increase in the volume of edema was accompanied by increased extravasation of GAD across the barrier, as seen in T1 post-contrast sequences, indicative of BBB breakdown (**Figure 4**). However, although a qualitative evolution of cerebral edema post-stroke was apparent (**Figure 4**), accompanied by increased GAD contrast, there was no statistically significant difference between time-points (**Figure 5B**; $p > 0.05$). Midline shift was evident in all stroke animals, the degree of which evolved over time following stroke (**Figure 5C**) and was most prominent at 5 days post-stroke (3.92 ± 0.59 mm) when compared to 1 ($p = 0.002$) and 7 days ($p = 0.04$), in keeping with ICP findings. No animals showed evidence of tonsillar herniation or brain stem compression on MRI (data not shown).

Despite the fact that cerebral edema findings were not significantly different between time points, there was a moderate positive correlation seen between midline shift and cerebral edema calculations ($r = 0.49$; **Figure 6A**). However, there was no positive correlation seen between ICP and cerebral edema ($r = 0.23$; **Figure 6B**) or ICP and midline shift ($r = 0.20$; **Figure 6C**).

SP ELISA

A reduction in serum SP was observed between 4 and 16 h following transient MCAO, however, changes were not significant ($p > 0.05$; **Figure 7**). At 7-days post-stroke, SP levels were significantly elevated compared to 16 h ($p = 0.002$) and days 1 ($p = 0.04$), 4 ($p = 0.04$), 8 ($p = 0.008$) and 12 ($p = 0.003$) following occlusion. Despite a qualitative increase, the concentration of serum SP at day 7 was not significantly elevated ($p > 0.05$) when compared to pre-stroke measurements. Furthermore, despite a relative increase in SP seen in the serum post-stroke, no significant changes ($p > 0.05$) in SP levels in the CSF (**Figure 7**) were observed at any time-point following MCAO.

Gender Comparisons

No differences in pCO_2, pO_2, MABP or pH were seen between sexes during either stroke surgery or ICP monitoring ($p > 0.05$; **Table 2**). There was no significant difference in ICP between male and female animals at any of the post-stroke time-points ($p = 0.93$; **Figure 8A**). Furthermore, there was no significant difference in infarct volume ($p = 0.79$; **Figure 8B**), cerebral edema ($p = 0.41$; **Figure 8C**) or midline shift ($p = 0.39$; **Figure 8D**)

*$p < 0.05$ compared to day 1.

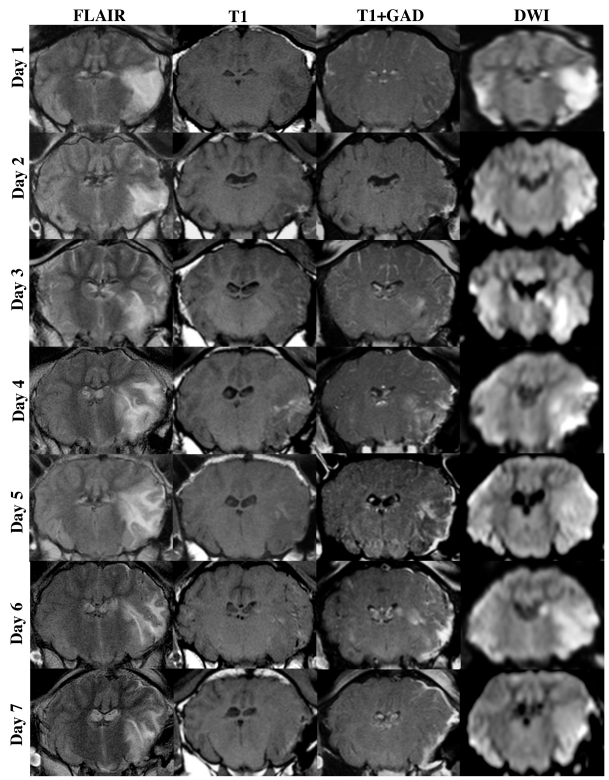

FIGURE 4 | MRI findings following transient MCAO. Cerebral edema, as shown in coronal FLAIR MRI images, evolved from 1–6 days following stroke, beginning to resolve by 7 days. This evolution in cerebral edema was associated with enhanced extravasation of GAD across the BBB as seen on T1 weighted post-contrast series (T1+GAD) when compared to pre-contrast T1 series. Lesion volume, as shown in DWI MRI images, was comparable across time-points following stroke.

seen between sexes following stroke. SP levels in the serum were not significantly different between males and females ($p = 0.41$; **Figure 8E**). However, there was a significant increase in SP seen in the CSF (**Figure 8F**) of females when compared to males pre-stroke ($p = 0.002$), and at 1 ($p < 0.0001$), 3 ($p < 0.0001$) and 6 ($p = 0.002$) days post-stroke although there were no significant within group differences observed in the females at any time-point pre- or post-stroke ($p = 0.18$).

Immunohistochemistry

Albumin

There was minimal evidence of albumin extravasation in sham tissue (**Figure 9**). Following stroke, marked albumin extravasation, indicative of BBB breakdown and subsequent vasogenic cerebral edema formation, was observed both macroscopically within the infarcted territory and microscopically in the perivascular tissue of the infarct, most prominent of which was at 5 and 6 days post-stroke.

SP

Little to no perivascular SP immunoreactivity was observed in sham tissue (**Figure 10**, Substance P, S). Following stroke, a marked increase in perivascular SP immunoreactivity was observed in tissue at 5 and 6 days, which was still evident at 7 days, although less pronounced.

Cav-1

Low levels of caveolin-1 immunoreactivity were observed in sham tissue (**Figure 10**, Caveolin-1, S). Following stroke, an increase in perivascular caveolin-1 immunoreactivity was identifiable which was particularly evident at 5 and 6 days post-stroke.

DISCUSSION

This study is the first to describe a surgical approach to ovine tMCAO with reperfusion. Through this study we have successfully developed a model that conserves tissue and permits post-operative recuperation, allowing for investigation into the pathophysiology of ischemic stroke, in particular post-stroke complications such as BBB disruption, development of cerebral edema and elevated ICP. This method of transient stroke induction provides a clinically relevant model in which promising novel treatments targeting stroke and its complications can be screened.

Although a number of studies have reported raised ICP following stroke in small animal models (Beard et al., 2015; Murtha et al., 2015) and large animal species at early time-points (Wells et al., 2015) this study is the first in which ICP was recorded out to 7 days post-stoke in a large gyrencephalic species. Using this model we have successfully characterized the temporal profile and established that ICP peaks at 5–6 days following ovine transient MCAO. These findings are comparable to the human patients, where ICP is shown to peak 3–5 days post-stroke, indicating that our model reliably replicates the clinical situation (Battey et al., 2014). The modest difference in the time course between the ovine model and humans may reflect the additional time taken to restore intracranial dynamics following surgery due to CSF aspiration required for optimal visualization of the proximal MCA. Indeed, a closed skull approach to MCAO where ICP dynamics are maintained through the induction of stroke may yield a timeline of ICP changes that directly align with clinical pathogenesis, however, this was not possible due to the complex ovine extracranial cerebrovasculature, in particular the rete mirabile, which precludes vascular access via the ICA for insertion of a balloon catheter, autologous clot or other occlusive agent.

Regardless, at 5–6 days post-stroke we consistently observed elevated ICP readings above 20 mmHg. In the clinic, ICP readings of ≥20 mmHg warrant investigation for possible treatment and intervention (Lavinio and Menon, 2011; Battey et al., 2014), as persistently elevated ICP is associated with poor outcome following ischemic stroke, widely accepted as being attributable to the development of edema in the cerebral parenchyma (Ayata and Ropper, 2002). Despite this, conflicting studies have reported an elevation of ICP in the absence of cerebral edema following small ischemic stroke in rats (Beard et al., 2015;

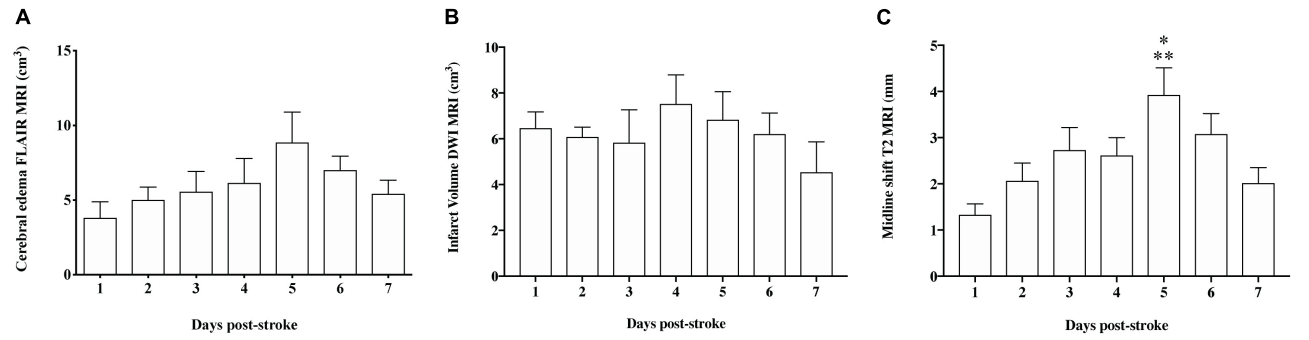

FIGURE 5 | Quantification of infarct volume, cerebral edema, and midline shift on MRI. **(A)** There was no significant difference ($p > 0.05$) in infarct volume at any of the time-points following stroke. **(B)** The evolution of cerebral edema showed a similar pattern to ICP, however, changes were not significant ($p > 0.05$). **(C)** Midline shift was significantly greater at 5 days when compared to 1 (<0.01) and 7 ($p < 0.05$) days post-stroke. Data shown as mean ± SEM. *$p < 0.05$ compared to 7 days, **$p < 0.01$ compared to 1 day. n = 6/time-point.

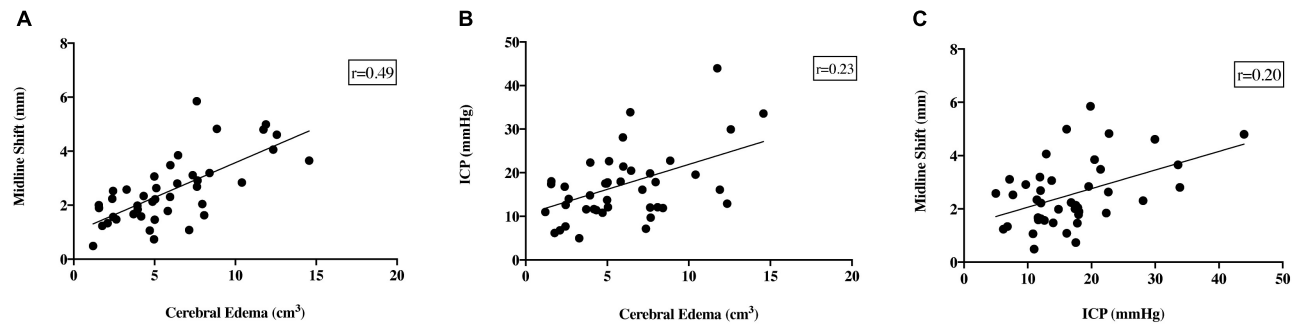

FIGURE 6 | Relationship between ICP, cerebral edema, midline shift and infarct volume. There was a moderate positive correlation seen between cerebral edema and midline shift (r = 0.49, **A**). Despite this, there was no correlation seen between ICP and cerebral edema (r = 0.23, **B**), or ICP and midline shift (r = 0.20, **C**). NB data from all time points was used for comparison between variables.

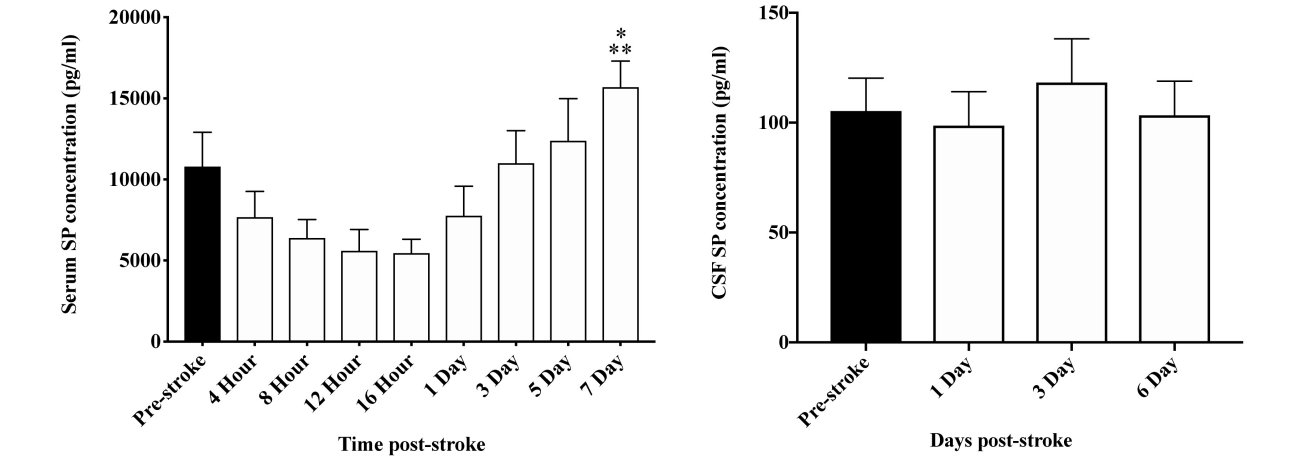

FIGURE 7 | Temporal profile of serum and CSF SP levels following stroke. At 7 days post-stroke, SP in the serum was significantly elevated compared with levels seen at 4 h ($p < 0.05$), 8, 12, and 16 h ($p < 0.01$), and 1 day ($p < 0.05$) following stroke. Furthermore, despite a qualitative increase, SP concentration pre-stroke was comparable to day 7 post-stroke. In the CSF, there was no significant difference seen in SP levels at days 1, 3, and 6 post-stroke ($p > 0.05$). Data shown as mean ± SEM. *$p < 0.05$ compared to 4 h and 1 day; **$p < 0.01$ compared to 8, 12, and 16 h. n = 12/time-point serum; n = 8/time-point CSF.

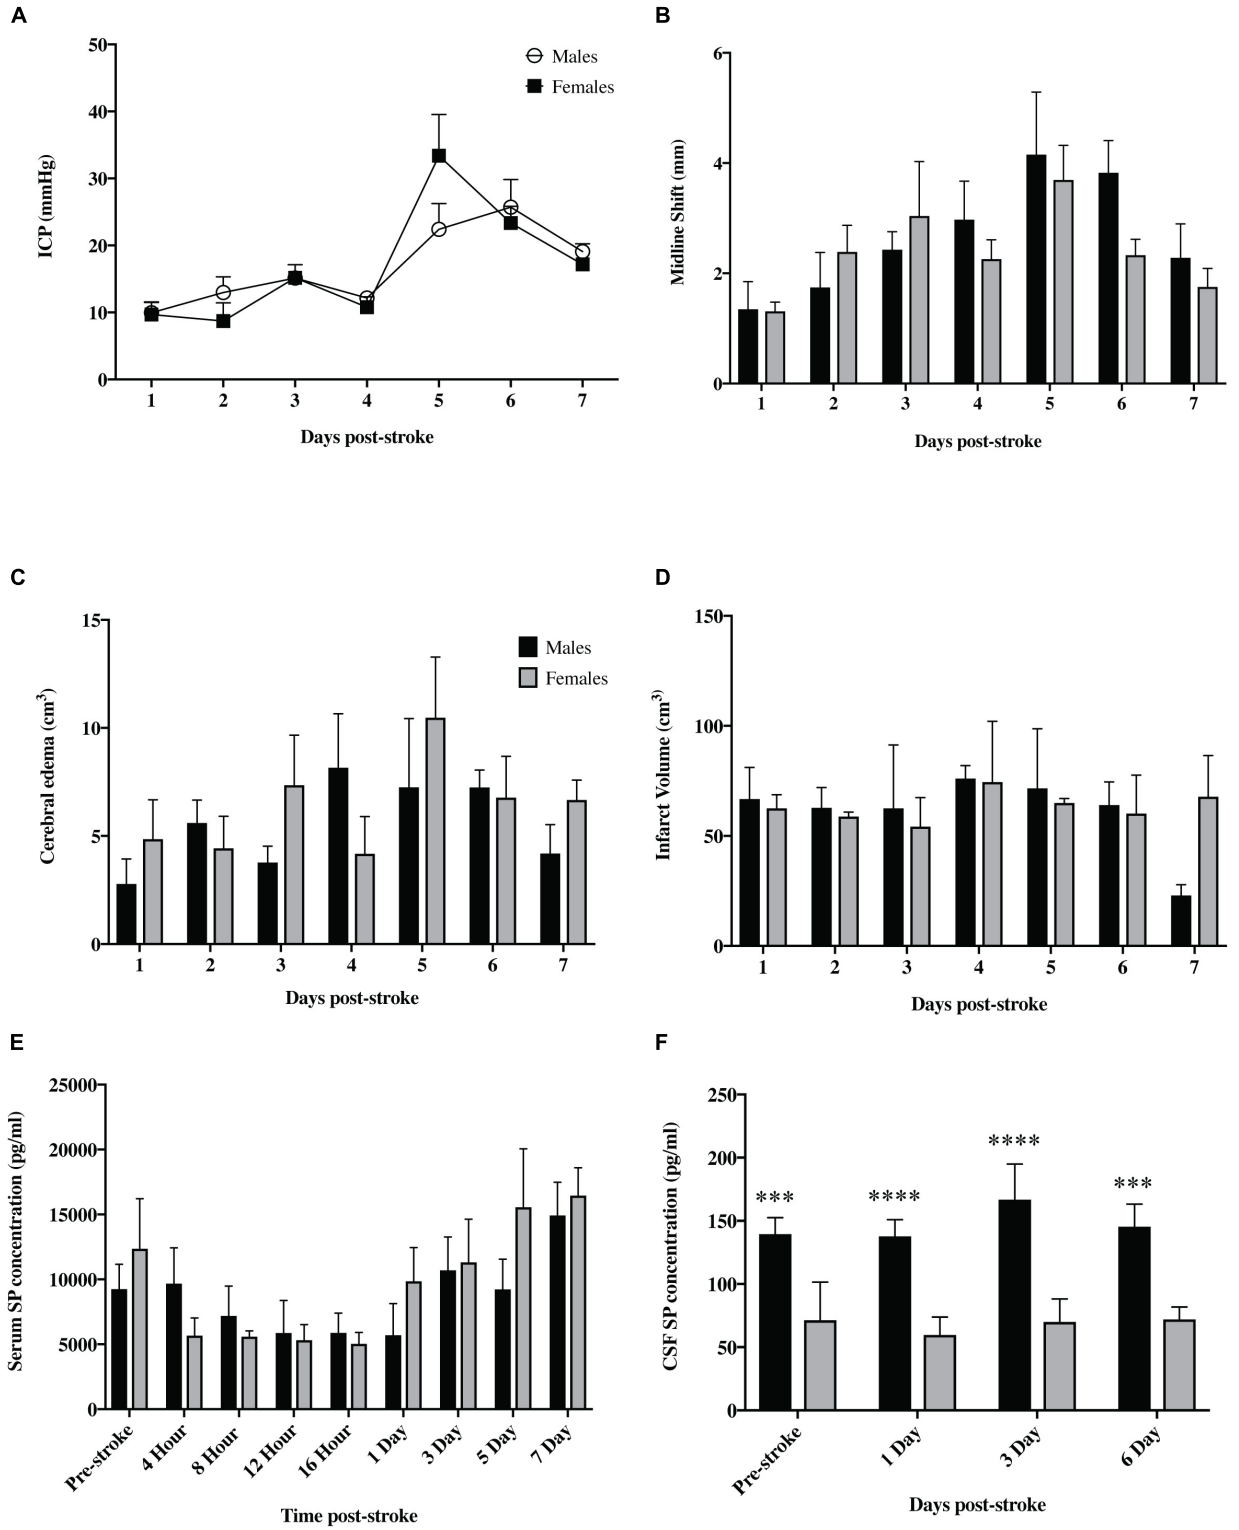

FIGURE 8 | Sex differences following tMCAO. There was no significant difference in ICP **(A)** seen between sexes at any of the post-stroke time points ($p > 0.05$). Furthermore, there was no significant difference seen between males and females in infarct volume **(B)**, cerebral edema **(C)**, or midline shift **(D)** ($p > 0.05$). SP levels in the serum **(E)** were not significantly different between sexes ($p > 0.05$) but were significantly elevated in the CSF **(F)** of female animals compared to males at both pre and post-stroke time points ($p < 0.01$). Data shown as mean ± SEM. ***$p < 0.01$ and ****$p < 0.0001$ females compared to males. n = 3/time-point ICP infarct volume, midline shift and edema; n = 6/time-point for serum; n = 4/time-point CSF.

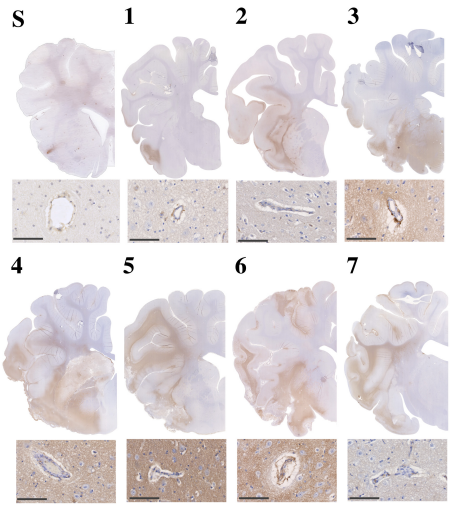

FIGURE 9 | Albumin immunoreactivity in sham (S) and post-stroke animals at 1 (1), 2 (2), 3 (3), 4 (4), 5 (5), 6 (6) and 7 days (7) post-stoke. Enhanced albumin extravasation evolved over time following stroke and was most prominent at 4–6 days following tMCAO. This pattern of albumin staining was consistent with perivascular staining seen microscopically. Microscopic images scale bar 100 μm, 40× magnification.

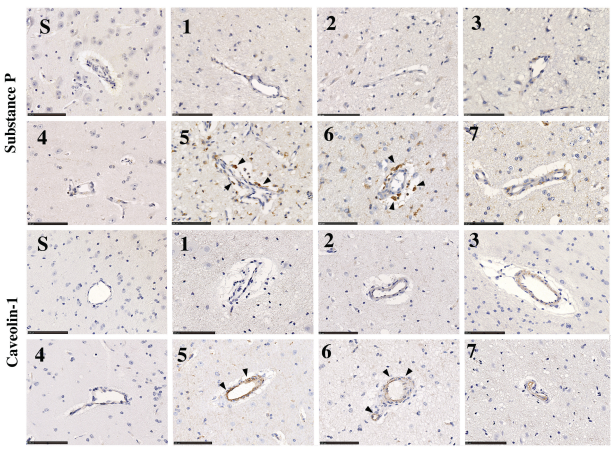

FIGURE 10 | SP and caveolin-1 immunoreactivity in sham (S) and post-stroke animals at 1 (1), 2 (2), 3 (3), 4 (4), 5 (5), 6 (6), and 7 days (7) post-stoke. There was no identifiable immunoreactivity of SP or caveolin-1 in sham animals (S). Low levels of SP immunoreactivity were seen perivascularly at 1–4 days post-stroke. At 5 and 6 days following transient MCAO, there was an increase in SP seen in the perivascular tissue of the ischemic penumbra in the affected hemisphere. This increase in SP was concordant with an increase in caveolin-1 immunoreactivity perivascularly, which was most evident at 5–6 days. Arrows indicate increased immunoreactivity of SP and cav-1 seen surrounding vessels. Scale bar 100 μm, 40× magnification.

Murtha et al., 2015). However, the underlying pathophysiology of increased ICP was not reported and requires further investigation. Furthermore, in the case of larger hemispheric strokes seen clinically, such as that of proximal MCAO or ICA occlusion, there is a positive correlation between cerebral edema and elevated ICP (Engelhorn et al., 2002). However, we did not observe such a relationship in this study, which may reflect the within group variability and different cohorts that were required to populate the time course. Furthermore, when measuring elevated ICP following stroke, the influence of autoregulation must also be taken into consideration. The ability to maintain cerebral homeostasis plays an important role in moderating the pathogenesis of elevated ICP. A loss of autoregulation has been shown to enhance the progression of ischemia and development of cerebral edema, and thus plays an important role during MCA reperfusion (Dohmen et al., 2007). It is proposed that autoregulation may be enhanced quite early following stroke, and become dampened at 6 days post-stroke (Reinhard et al., 2012), in keeping with our observations of significantly elevated ICP at 6 days post-stroke. Furthermore, elevated ICP is associated with a decreased ability to autoregulate following head injury, indicating a strong positive correlation between the two (Reinhard et al., 2012).

We observed an evolution of cerebral edema over time following stroke, although changes were not significant between time-points. Nevertheless, it is widely accepted that the increased volume of the brain as a result of cerebral edema positively correlates with subsequent elevations in ICP (Battey et al., 2014; Beard et al., 2015; Brogan and Manno, 2015). The development of vasogenic cerebral edema in particular occurs following loss of integrity of the BBB, permitting the abnormal extravasation of proteins across the damaged barrier. This creates an osmotic drive pulling water from the vasculature into the extracellular cerebral parenchyma, leading to an overall increase in brain volume and concomitant rise in ICP (Battey et al., 2014). Our study was able to confirm that there was disruption to BBB via visualization of the GAD contrast medium within the brain parenchyma, suggesting that the cerebral edema seen was vasogenic in nature. This finding was substantiated by the increased extravasation of albumin following tMCAO, which was most prominent at 5–6 days post-stroke. Albumin is unable to cross the intact barrier under physiological conditions due to its large size and structure (Quinlan et al., 2005). Previous studies have established that albumin crosses the barrier via the transcellular pathway, facilitated by caveolae (Abbott et al., 2006), of which caveolin-1 (cav-1) is an integral component (Nag et al., 2007). Indeed, increased barrier permeability in association with caveolin-1 upregulation was observed in the absence of tight junction breakdown, confirming the integral role of caveolae in the maintenance of barrier integrity (Povlishock et al., 1978; Nag et al., 2007). Our IHC findings of increased cav-1 immunoreactivity at 5–6 days post-stroke corroborate this, providing a potential mechanism driving sustained barrier permeability and the evolution of cerebral edema. Furthermore, the volumetric enlargement of the brain as a result of vasogenic edema leads to displacement of cerebral tissue and subsequent shift of the midline, a critical state in which compression of adjacent brain structures precedes potentially fatal tonsillar herniation (Huttner and Schwab, 2009). We observed significant midline shift at 5 days following stroke in keeping with elevated ICP. As such, our findings of enhanced GAD, albumin and cav-1 immunoreactivity at 5–6 days post-stroke suggest a loss of barrier integrity at this time-point, precipitating the development

of vasogenic cerebral edema, extensive midline shift and the subsequent rise in ICP seen in this model.

We also demonstrated that serum SP levels were increased at 7 days following stroke when compared to pre-stroke values. This followed a non-significant decline in serum SP at 4 h which continued to decline out to 16 h following injury. This suggests a peak increase in the levels of serum SP may occur ahead of the 4 h-post-stroke sampling time-point. Indeed, rodent TBI studies have reported an early peak in plasma SP levels at 30 min post-injury but a decline by 5 h post-injury (Donkin and Vink, 2010) Similarly, SP levels were increased in serum samples obtained within 12 h following the onset of both clinical stroke (Bruno et al., 2003; Lorente et al., 2016) and TBI (Lorente et al., 2015), with higher levels associated with early mortality. Although some discrepancy between experimental and clinical time-points exists, it is important to acknowledge that it is difficult to draw firm comparisons given the complications in obtaining clinical samples at acute time-points. We also examined SP levels in the CSF following stroke, though observed no differences at 1, 3, or 6 day time-points. Although females consistently had higher CSF SP levels compared to males at all post-stroke time-points, there was no significant change in these levels post-stroke. This suggests that females have higher baseline levels of SP. Indeed, gender differences in the SP response have previously been observed (Pittenger et al., 2016; Simões et al., 2018). A comprehensive sampling regime, including sampling at 4 and 6 days post-stroke for serum and 4 and 5 days post-stroke for CSF, would be required to populate a detailed time-course of changes in SP in the serum and CSF in the setting of ischemic stroke, and may reveal changes beyond those observed in the current cohort. Nevertheless, the increase in serum SP levels we observed, in conjunction with the increased barrier permeability and vasogenic edema seen with albumin IHC and MRI, support a potential role for SP in the genesis of cerebral edema and development of elevated ICP in this model. Indeed, our rodent stroke studies support this (Turner et al., 2006, 2011; Corrigan et al., 2012, 2016; Turner and Vink, 2012, 2014) and corroborates our recent work demonstrating the efficacy of NK1-r antagonist treatment in reducing ICP in an ovine model of permanent MCAO (Sorby-Adams et al., 2019). Taken together, these findings suggest that neurogenic inflammation occurs following ischemic stroke and may contribute to the increased BBB permeability and elevated ICP observed, suggesting that blocking the action of SP with a tachykinin NK1-r antagonist may be an effective strategy to mitigate these post-stroke complications and thus improve outcome.

LIMITATIONS AND FUTURE DIRECTIONS

Although the findings of this study demonstrate successful model development and clearly show the evolution of ICP following stroke, limitations must be acknowledged. It must firstly be recognized that human patients are rarely under anesthesia when suffering a stroke. This is of particular importance due to the implied effects of anesthesia, both protective and deleterious. Ketamine has been shown to have neuroprotective effects (Hudetz and Pagel, 2010), whilst isoflurane is associated with respiratory depression, decreased MABP and thus diminished oxygen supply to neuronal cells (Murr et al., 1993), exacerbating cerebral ischemia. These limitations have been discussed in detail in our previous studies (Wells et al., 2012, 2015), however, due to the nature of the surgical procedure, anesthesia is unavoidable (Lin et al., 1997). The decision to maintain animals on a combination of ketamine and isoflurane was made on the basis of prolonged duration (4–5 h) of surgical procedures. The anesthetic combination produces a countering effect, eliminating the neuroprotective effect of pure ketamine and the respiratory distress associated with pure isoflurane, thus reducing confounding factors of anesthetic agents administered alone (Schifilliti et al., 2010).

There was a large within group variability, particularly for the MRI parameters, seen at each of the time-points following stroke. This may reflect differences in collateral flow or autoregulation capacity within the individual animals. Indeed, there is a considerable degree of variation in the severity and timing of cerebral edema in human patients following stroke. Furthermore, there may be some variability due to the severity of stroke in addition to the relative age of the sheep compared with the greater stroke population. In this study we used sheep aged 18–24 months, which are the equivalent to mid-adulthood in humans, whereas clinical stroke most commonly occurs in those over 60 years of age. Furthermore, the exclusion of experimental animals due to anesthetic complications or lack of reperfusion decreased the total sample size. This could be addressed by increasing the overall sample size for each group to increase statistical power. It must also be acknowledged that we used different cohorts of animals to generate the stroke ICP data, sham ICP data and serum/CSF for the ELISAs. This led to an inability to run true correlations between groups, for example between the SP and ICP datasets, limiting the conclusions we can draw regarding the potential relationship between serum/CSF SP and ICP. Furthermore, there was some discrepancy seen between elevated ICP and edema at 5–6 days in the first cohort and elevated serum SP seen at 7 days in the second cohort. Our findings suggest that SP is involved in the evolution of edema, however, given that different cohorts used in this study it was difficult to establish a definitive relationship between the two. As such, the differences in the time course of SP elevations and increased ICP are most likely attributable to the different cohorts used for each of these outcome measures.

In order to reduce the number of animals required we utilized a cohort of sham animals that underwent sham surgery immediately followed by ICP monitoring. We acknowledge that we would have preferentially used the same regime as the stroke cohort but it was not possible to generate an additional sham control cohort for this study alone. When measuring ICP, values would ideally be obtained from the same animal from 1–7 days post-stroke to look at the evolution of pressure individual

to that animal. This could be addressed through the use of a telemetric system to remotely and non-invasively measure ICP. As sheep are quadrupeds however, some question remains regarding the impact of head position, in particular when feeding, on ICP measurements obtained using this method. Furthermore, the use of individual cohorts of animals benefited this study by allowing us to harvest the brain at specific time-points following stroke and perform IHC accordingly, an important aspect to understanding the evolution of the injury. The reliable measurement of cerebral edema on MRI at a single time-point is somewhat contentious, as the hyperintensity of vasogenic edema is difficult to distinguish from the lesion itself. The measurement of the entire FLAIR lesion volume therefore includes areas of infarction as well as edema and is therefore an indirect measure of edema volume. A more robust approach to measuring edema would be to undergo sequential MRI's and evaluate the change in diffusion lesion volume between 2 time points following reperfusion, which was not feasible in this study due to cost. Furthermore, although GAD was utilized, T1 weighted MRI images were only taken at a single time-point following administration. As such, it is difficult to obtain a quantitative measure of GAD extravasation across the barrier. A more robust approach to this would be to obtain dynamic contrast enhanced (DCE) and dynamic susceptibility contrast (DSC) sequences to generate clinically relevant measurements of barrier permeability. Finally, although gender differences were examined in this study the hormonal status of the female animals at the time of stroke and monitoring period was not known.

CONCLUSION

In this study, we have successfully developed a surgical approach to tMCAO with reperfusion in the sheep that permits recovery and the examination of long-term time-points following stroke. In this novel model we have determined the temporal profile of ICP, showing that ICP peaks at 5–6 days following stroke, in conjunction with midline shift, an evolution of cerebral edema, increased serum SP levels, enhanced SP immunoreactivity and increased albumin extravasation. These results suggest a role of SP in BBB disruption and the subsequent genesis of cerebral edema and associated rise in ICP following stroke. As such, agents targeting elevated ICP and cerebral edema would be most effective when administered prior to 6 days post-stroke, or as early as possible following stroke-onset. We conclude that this ovine model provides a promising platform to screen novel treatments targeting post-stroke complications and verify treatment efficacy prior to clinical assessment.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the supplementary files.

ETHICS STATEMENT

All experimental procedures were approved by the Animal Ethics Committees of The University of Adelaide (M-2014-015) and South Australian Health and Medical Research Institute (SAHMRI SAM 3; SAM 141). Experiments were conducted in accordance with the Australian National Health and Medical Research Council code of practice for the care and use of animals for scientific purposes (8th edition, 2013).

AUTHOR CONTRIBUTIONS

AS-A, RV, RT, and AL conceived and designed the experiments. AS-A, RT, ET, OM, and LE performed the experiments. AS-A, LE, JH, and NY analyzed the data. AS-A and RT wrote the manuscript.

FUNDING

This study was supported by funding from the National Health and Medical Research Council (NHMRC; Project Grant 1082556) and the NeuroSurgical Research Foundation (Australia).

ACKNOWLEDGMENTS

We would like to thank Sunthara Rajan Perumal for the acquisition of the MRI. We would also like to acknowledge the facilities and technical assistance of the National Imaging Facility, a National Collaborative Research Infrastructure Strategy (NCRIS) capability, at LARIF, SAHMRI.

Mangin G, Cogo A, Moisan A, Bonnin P, Maïer B and Kubis N (2019) Intravenous Administration of Human Adipose Derived-Mesenchymal Stem Cells Is Not Efficient in Diabetic or Hypertensive Mice Subjected to Focal Cerebral Ischemia. Front. Neurosci. 13:718. doi: 10.3389/fnins.2019.00718

As the second cause of death and cognitive decline in industrialized countries, stroke is a major burden for society. Vascular risks factors such as hypertension and diabetes are involved in most stroke patients, aggravate stroke severity, but are still poorly taken into account in preclinical studies. Microangiopathy and sustained inflammation are exacerbated, likely explaining the severity of stroke in those patients. We sought to demonstrate that intravenous administration of human adipose derived-mesenchymal stem cells (hADMSC) that have immunomodulatory properties, could accelerate sensorimotor recovery, prevent long-term spatial memory impairment and promote neurogenesis, in diabetic or hypertensive mice, subjected to permanent middle cerebral artery occlusion (pMCAo). Diabetic (streptozotocin IP) or hypertensive (L-NAME in drinking water) male C57Bl6 mice subjected to pMCAo, were treated by hADMSC (500,000 cells IV) 2 days after cerebral ischemia induction. Infarct volume, neurogenesis, microglial/macrophage density, T-lymphocytes density, astrocytes density, and vessel density were monitored 7 days after cells injection and at 6 weeks. Neurological sensorimotor deficit and spatial memory were assessed until 6 weeks post-stroke. Whatever the vascular risk factor, hADMSC showed no effect on functional sensorimotor recovery or cognitive decline prevention at short or long-term assessment, nor significantly modified neurogenesis, microglial/macrophage, T-lymphocytes, astrocytes, and vessel density. This work is part of a European program (H2020, RESSTORE). We discuss the discrepancy of our results with those obtained in rats and the optimal cell injection time frame, source and type of cells according to the species stroke model. A comprehensive understanding of the mechanisms preventing recovery should help for successful clinical translation, but first could allow identifying good and bad responders to cell therapy in stroke.

Keywords: stroke, cell therapy, adipose tissue, cognitive decline, inflammation, behavior

INTRODUCTION

Stroke is currently the second cause of death and cognitive decline worldwide (Snyder et al., 2015; World Health Organization [WHO], 2018). Recanalization treatments, either by rtPA (recombinant tissue plasminogen activator) or thrombectomy, can only be used at the acute phase, with less than 10% of patients being concerned (Bhaskar et al., 2018). In that context, cell therapy, using stem cells/progenitors or differentiated cells, was developed in order to potentially repair tissue damage and improve neurological outcome taking advantage of a wider therapeutic window (Mangin and Kubis, 2018).

Among them, mesenchymal stem cells (MSCs) are particularly attractive. They are multipotent cells capable of differentiating into at least one differentiated cell type depending on environmental conditions (Chamberlain et al., 2007). These cells improve neurological deficit after stroke in both mice (Chen et al., 2003) and rats (Li et al., 1999; Cho et al., 2012) but their mechanism of action is still poorly understood, although neurogenesis, angiogenesis and immunomodulation, all contributing to new neuronal networks formation, have been associated to improved neurological recovery (Chen et al., 2014).

Mesenchymal cells derive from multiple sources such as bone marrow, cord blood, or adipose tissue, this last one offering numerous advantages. A large number of cells can be easily collected by liposuccion. Expansion of cells is easier than when MSC are derived from bone marrow (BM-MSC), the other largest source of MSC and they could be more effective than BM-MSC (Mangin et al., 2019). Indeed, they proliferate better *in vitro* and further reduce the cerebral ischemic-related damage in a mouse model of transient middle cerebral artery occlusion (tMCAo) compared to cells isolated from bone marrow (Ikegame et al., 2011). In addition, they showed an excellent safety profile in 8 clinical trials representing 321 patients (Lalu et al., 2012) and their low immunogenicity after allogeneic administration (Pers and Jorgensen, 2013) make them a likely "ready-to-use" therapeutic product.

Up to date, few studies have considered the impact of vascular risk factors on stroke outcome. This is quite surprising since hypertension, the first leading vascular risk factor for stroke, is still dramatically underdiagnosed, with only 32.5% of hypertensive patients being pharmacologically treated and controlled (Chow et al., 2013). Diabetes is another independent risk factor for stroke, tripling its incidence (Mankovsky and Ziegler, 2004). These data are particularly alarming since the diabetic population will double by 2030 (Shaw et al., 2010). These two vascular risk factors are associated with increased disability, death (Knopman et al., 2001; Ettehad et al., 2016) and post-stroke cognitive decline (Gorelick et al., 2011). As hypertensive and diabetic patients are at higher risk of stroke and therefore potential candidates for cell therapy, understanding how vascular risk factors influence donors' cells properties and efficiency is therefore mandatory (Mangin and Kubis, 2018).

This work if part of a H2020 program (RESSTORE) that includes clinical and preclinical work-packages, and whose aim is to assess the efficiency of cell therapy in stroke taken into account vascular risk factors. Preclinical evaluation complied with the STAIRS (Liu et al., 2009) and STEPS II (Savitz et al., 2011) recommendations. Mesenchymal stem cells derived from human adipose tissue (hADMSC) obtained from healthy donor, were injected intravenously 2 days after induction of a focal cerebral ischemia in mice in which hypertension or diabetes had been previously induced. The primary objective of our work was to evaluate the short (1 week) and long-term (6 weeks) consequences on neurological sensorimotor and cognitive decline and on stroke volume. Neurogenesis, inflammation, and angiogenesis were secondarily evaluated.

MATERIALS AND METHODS

All experiments and surgical procedures were performed according to the European Community Directive (2010/63/EU), the ARRIVE (Animal Research Reporting In Vivo Experiments) guidelines, and the French national guidelines for the care and use of laboratory animals. The study was specifically approved by our local institutional ethics committee (CE121#/17581v6) and by the French ministry of Higher Education for Research and Innovation (APAFIS#5431-2016031912549126 v2).

Experimental Design

The experimental design is summarized in **Figure 1**. Experiments were performed on male adult C57/BL6 mice (Janvier Labs, Le Genest-Saint-Isle, France) housed in a 12 h/light/dark cycle with food and water *ad libitum*. Prior to stroke, either hypertension or diabetes was induced. The duration of sustained hyperglycemia and elevated blood pressure were determined to be the minimal duration to induce an increased sensorimotor deficit compared to age-matched mice without vascular risk factors. Because timing differed between diabetic (2 months) and hypertensive mice (4 months), control groups were matched with age. At day 0 (D0), permanent occlusion of middle cerebral artery was performed. At day 1 (D1), mice undergone cerebral MRI to be randomized in treated or untreated groups, according to the infarct volume and IV hADMSC or PBS were intravenously (IV) delivered the day after (D2). Sensorimotor evaluation was conducted from D-1 until D14, open field at D28 and cognitive assessment between D30 and D38. Stroke volume measured after Cresyl violet staining was assessed at day 9 (7 days after hADMSC delivery) and neuroblasts density, microglia/macrophages cells density, T-Lymphocytes density, astrocytes density, and vessels density assessment were performed 1-week post-hADMSC delivery (9 days post-stroke, D9) or 40 days post-stroke (D40), i.e., at the end of the cognitive assessment period, to evaluate the histological consequences of hADMSC injection. Thus, a subset of mice was sacrificed at D9 and another at D40 for histological and immunohistochemical analyses.

The following groups were evaluated: untreated non-diabetic (ND-PBS) and diabetic (D-PBS) mice and treated non-diabetic (ND-hADMSC) and diabetic (D-hADMSC) mice; untreated non-hypertensive (NHT-PBS) and hypertensive (HT-PBS) mice and treated non-hypertensive mice (NHT-hADMSC) and hypertensive mice (HT-hADMSC).

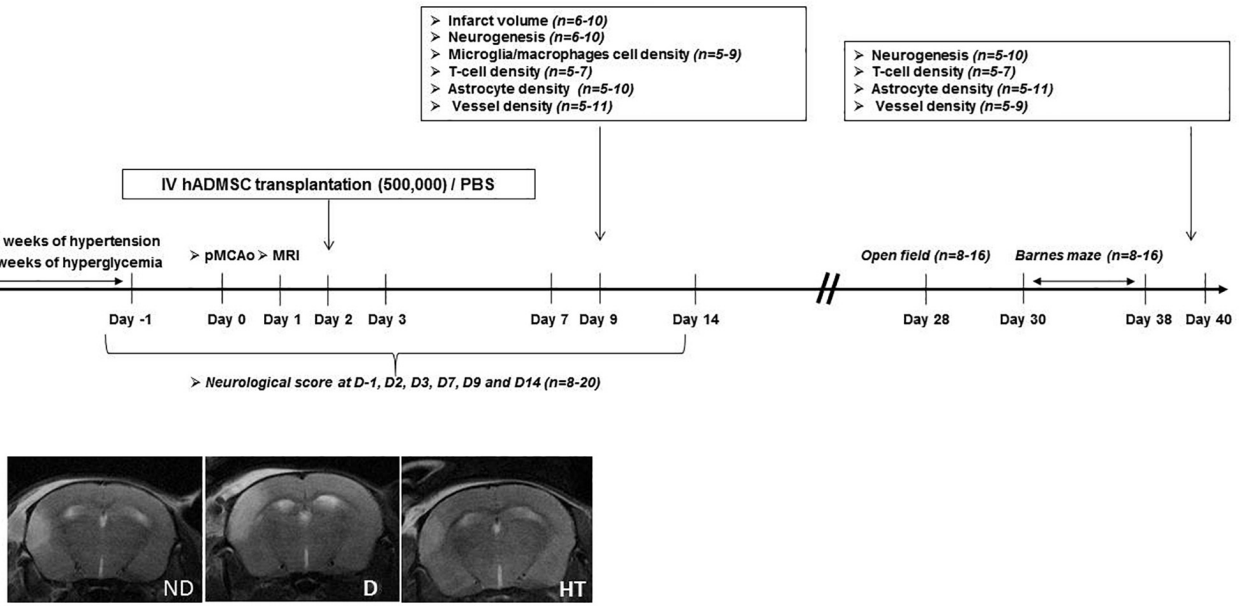

FIGURE 1 | Experimental protocol and time schedule for hypertensive and diabetic mice. hADMSC, human adipose derived mesenchymal stem cells; pMCAo, permanent, middle cerebral artery occlusion; n, number of mice.

In a separate set of diabetic and hypertensive mice, vasoreactivity was assessed after 8 weeks of diabetes and hypertension induction, by measuring with Doppler ultrasound the variations of mean blood flow velocity at the basilar trunk after CO_2 inhalation.

All experiments were conducted by investigators blinded to the status (diabetic and non-diabetic, hypertensive, and non-hypertensive) and the treatment (hADMSC or PBS).

Diabetes Induction

At 6 weeks of age, C57Bl6/J mice were randomized to receive for five consecutive days intraperitoneal (IP) injections of STZ (60 mg/kg in 100 μL of citrate buffer) to induce diabetes or 100 μL of citrate buffer for non-diabetic mice. To ensure that mice became diabetic, blood glucose levels were monitored once a week by collecting blood through a skin incision at the tail. Only mice with sustained hyperglycemia above 300 mg/dL were considered as diabetic (90% of treated mice).

Hypertension Induction

At 6 weeks of age, C57Bl6/J mice were randomized to receive during 16 weeks L-NAME [*N*(G)-nitro-L-arginine methyl ester, 60 mg/kg/day] in drinking water to induce hypertension, or without L-NAME for the non-hypertensive mice. Systolic and diastolic blood pressure and heart rate were measured after 2 weeks of habituation once a week until sacrifice, using a tail-cuff plethysmograph connected to a computerized system (BP-2000 computerized system, Visitech Systems, Apex, NC, United States). Measurements were performed in vigil mice, placed on a heating blanket. All mice became hypertensive.

Doppler Imaging of Cerebral Vasoreactivity to Inhaled CO_2

Cerebral vasoreactivity was assessed in all groups after 8 weeks of hyperglycemia and hypertension induction as previously described (Poittevin et al., 2015). This time point was previously determined in preliminary studies to be the shortest time to impair vasoreactivity. Ultrasound measurements were performed under 0.5% isoflurane anesthesia, using an echocardiograph (Acuson S3000, Siemens, Erlangen, Germany), equipped with a 14-MHz probe (14L5 SP). As previously described, time-averaged mean blood flow velocities were measured at the basilar trunk under air and after 5 min of breathing a gas mixture of 16% O_2, 5% CO_2, and 70% N_2.

Permanent Middle Cerebral Artery (pMCAo) Induction

This procedure has already been fully described (Poittevin et al., 2013). Briefly, at D0, mice were anesthetized by isoflurane (initially 2%, followed by 1.5 to 1.8% in O_2) and body temperature was continuously maintained at 37 ± 0.5°C during the whole procedure using a heating blanket (Homeothermic Blanket Control Unit; Harvard Apparatus Limited, United Kingdom). The permanent focal cerebral ischemia was induced by electrocoagulation of the left middle cerebral artery. The whole procedure did not exceed 10 min.

Cerebral MRI

MR examinations were performed at D1 at the FRIM plateform using a 7.0 Tesla MR unit (PharmaScan, Bruker Biospin, Ettlingen, Germany) equipped with a surface coil with an internal diameter of 10 mm, in thermoregulated and anesthetized

(2% isoflurane in O_2) mice. T2-weighted imaging [Rapid Imaging with Refocused Echoies (RARE) sequence was used with the following parameters: effective TE: 33 ms, TR: 2742 ms, NEX: 1, Flip angle: 180°] was performed in order to measure infarct volume (Medical Image Processing, Analysis and Visualization or MIPAV software, NIH, Bethesda, MD, United States) and T2*-weighted imaging [a Fast Low Angle Shot (FLASH) sequence was used with the following parameters: 15 axial slices 1 mm thick, TE: 8 ms, TR: 600 ms, NEX: 2, Flip angle: 30°, FOV: 2 cm × 2 cm, MTX: 256 × 256] to verify that there was no hemorrhage in any of these mice.

hADMSC Collection

Adipose tissue was harvested from the subcutaneous abdominal adipose tissue by lipo-aspiration from one young healthy female then transferred to the cell therapy unit for digestion. Negativity of the donor for HIV1/2, HBV, HCV, HTLV1/2, HSV1/2, Syphilis, CMV, and EBV serology was verified in order to be compliant with the Directive 2006/17/EC. At the end of the aspiration procedure, adipose tissue was transferred to the Etablissement Français du Sang (EFS) cell therapy unit for digestion according to an internal procedure. The adipose tissue stem cell line RESSTORE01 (Master Cell Bank/Stock no. 1—Donor RESSSTORE01, Batch no. 591133643763) was cultured in the growth medium Alpha MEM (Macopharma) supplemented with 5% human platelet lysate (Stemulate, Cook Medical, United States). The medium was changed twice each week and cells were passaged when they reached (85%) confluence. The cells were detached with TrypLE Select (Life Technologies) for 7–10 min. The RESSTORE01 cell phenotype was analyzed with flow cytometry (FACS Canto II, BD Biosciences) at passage P1. The BD Stemflow hMSC Analysis kit (ref: 562245, Becton Dickinson) was used to phenotype the ADSC that were characterized by the expression of the surface markers CD73, CD44, CD105, and CD90. In addition, in order to identify non-mesenchymal cell contamination, specific markers of monocytes/macrophages (CD11b), lymphocytes (CD19), pan-leucocytes (CD45), hematopoietic stem cells (CD34), and HLA-DR were performed. The expression of these positive markers should be ≥90% and ≤5% for the negative markers. These specifications have been established based on the recommendations of the International Society for Cellular Therapy. These hADMSC were harvested after expansion in MEMα medium (Thermofisher) and human platelet lysate 5% (Cook Regentec). At D2 post-stroke 500,000 cells in 0.2 mL PBS were administered through the retroorbital vein.

Sensorimotor Deficit Assessment

Mice underwent a neurological evaluation consisting of five tests: neurological score, grip and string test, beam walking test and pole test, currently used in our laboratory (Poittevin et al., 2013, 2015; Hilal et al., 2018) and that have been fully described elsewhere (Frechou et al., 2019). The maximum global score was 19, with the lower neurologic score corresponding to a more severe deficit. The assessment was performed at D-1 (habituation stage, the mouse being its own control), D2 (just before cell infusion), D3, D7, D9, and D14 in all groups.

Cognitive Assessment

Before testing spatial memory (Barnes maze), we evaluated the sensorimotor deficit as well as spontaneous locomotor activity (open field) at D28, since residual neurological sensorimotor deficit or anxiety could otherwise introduce a bias in the interpretation of the Barnes maze. Cognitive assessment was performed in a dedicated room where mice were placed 2 weeks before in order to acclimate to the room where they were subjected to a 12 h night-day cycle with food and water provided *ad libitum*.

Open Field

Residual sensorimotor deficit and potential anxiety likely to cause the mice to "freeze," could interfere with the Barnes maze evaluation thus skewing the results. We used the open-field as previously described (Cifuentes et al., 2015). Spontaneous activity (distance traveled in cm and mean velocity in cm/s) was measured automatically for 30 min by an EthoVision XT system and analyzed by EthoVision XT 11.5 tracking software (Noldus, Wageningen, Netherlands). Open field activity was assessed at D28 in all groups that were then tested on the Barnes Maze platform.

Barnes Maze

The Barnes maze is an open space 1 m in diameter, consisting of 20 holes spaced equidistantly around the circumference; one escape box is placed under one of the holes that the mouse will learn to find using visual cues placed in the behavior room. Mice are trained three times a day with a 15-min rest between each trial and recorded with a camera.

As previously described (Cifuentes et al., 2017), at D30, the mouse has to learn the location of the escape box on four consecutive days, named the training phase (1st day to 4th day of evaluation). After 2 days of resting (7th day of evaluation), mice are tested on their ability to recall the place of the escape box, named the retention phase. The next day (8th day), the escape is box is changed from its original location and mice have to adapt, learn and memorize the new location during 2 days (8th day and 9th day). During this last phase or reversal phase, brain plasticity is evaluated. During each phase, the latency to escape (seconds) is measured.

Assessment of Infarct Volume

At D9, 1 week after hADMSC IV administration, mice were transcardiacally perfused with heparinized saline, followed by 4% paraformaldehyde (PFA). Brain was removed, post-fixed overnight in PFA and cryoprotected in 20% sucrose. Coronal 30 μm-thick sections were cut frozen using a cryostat CM 1950 (Leica Biosystems, Nußloch, Germany). Every eight 30 μm-thick floating section was stained with Cresyl violet. Using ImageJ software (National Institutes of Health, Bethesda, MD, United States), the cortical infarct area was measured to calculate the stroke volume (mm^3) by integrating measured areas and distances between sections. Measured infarct volume was corrected for edema with the following formula: corrected infarct volume = measured infarct volume × (contralateral

hemisphere volume/ipsilateral hemisphere volume) as already described (Poittevin et al., 2013).

Assessment of Histological Response to hADMSC

Thirty μm-thick coronal floating sections were incubated with primary antibody overnight at 4°C to detect neuroblasts using anti-doublecortin (DCX) (1:4000, Abcam, Cambridge, United Kingdom); microglial cells using anti-Iba1 (1:200, Wako, Japan), T-lymphocytes using anti-CD3 (1/200, Dako, Santa Clara, United States), astrocytes using anti-GFAP (1:200, Millipore, Burlington, MA, United States) and vessels using the anti-glucose transporter-1 (Glut-1) (1:500, Millipore, Burlington, MA, United States). Appropriate fluorescent-labeled secondary alexa fluor 594 or 488 antibodies (Molecular Probes, Eugene, OR, United States 1:400) were applied for 1 h at room temperature. Specificity was checked by omitting the primary antibody. As doublecortin is expressed in newborn and migrating neurons, we assumed that DCX+ cells reflect neurogenesis (Brown et al., 2003; Jin et al., 2010).

Morphological Analysis

Cells density assessments were conducted blindly (vascular risk factor and treatment) at D9 and D40 and performed on three coronal brain sections at +0.80, −0.80, and −1.20 mm relative to bregma, that consistently contained the infarct area.

Neuroblasts density was assessed by calculating the DCX-positive area (X10) using NIH ImageJ software, in the whole ipsilateral hemisphere to stroke, actually only found in the subventricular zone and along the corpus callosum along which they migrate toward the lesion.

Microglial/macrophage density was assessed by calculating the Iba1-positive area (X5) using NIH ImageJ software in the peri-infarct area.

T-cell density was manually assessed by counting CD3+ cells in each section, actually only present in the infarct area, and expressed as the number of CD3+ cells per section.

Astrocytes density was assessed by calculating the GFAP-positive area in 2 R.O.I (X40) using NIH ImageJ software in the peri-infarct area.

Vessel density was assessed by calculating the GLUT-1-positive area (X20) using NIH ImageJ software in the peri-infarct area.

All calculated areas were expressed as arbitrary units.

Statistical Analysis

Statistical analyses were performed using Prism 7.02 software (GraphPad, San Diego, CA, United States). The data are expressed in mean ± SD. The Shapiro–Wilk normality test was used to assess whether the data corresponded to a Gaussian distribution. Comparisons between the four groups of diabetic mice or of hypertensive mice were analyzed using either ANOVA or a Kruskal–Wallis test. Two-way ANOVA for repeated measures was used to analyze data of the training (1^{st} to 4^{th} days) and reversal (8^{th} to 9^{th} days) phases in the Barnes maze. *Post hoc* analyses were performed using Bonferroni's multiple comparison tests. A value of $p < 0.05$ was considered statistically significant.

RESULTS

Mean glycemia was not significantly different at D-1 between D-PBS (451.7 ± 59.7 mg/dl) and D-hADMSC mice (431.8 ± 50.1 mg/dl). No mice died whatever the group during surgery and during follow-up. hADMSC did not significantly modify glycemia in diabetic mice during follow-up until D40 (460.3 ± 56.6 mg/dl) compared to untreated D-PBS mice (493.3 ± 70.9 mg/dl) (n = 13–14).

Before stroke, systolic and diastolic blood pressure were significantly higher in HT mice (134.9 ± 5.9/89.0 ± 7.2 mmHg) compared to NHT mice (114.0 ± 7.0/78.6 ± 6.2 mmHg) ($p < 0.0001$). After stroke and during follow-up, hADMSC did not significantly modify systolic blood pressure (NHT-PBS: 104.9 ± 14.1 mmHg vs. NHT-hADMSC 111.7 ± 6.3 mmHg; HT-PBS: 138.3 ± 7.2 mmHg vs. HT-hADMSC: 136.2 ± 11.2 mmHg), or diastolic blood pressure (NHT-PBS: 82.1 ± 9.5 mmHg vs. NHT-hADMSC: 80.9 ± 6.5 mmHg; HT-PBS: 86.3 ± 7.3 mmHg vs. HT-hADMSC: 90.1 ± 6.6 mmHg). Heart rate (beats per min) did not differ significantly between groups (NHT-PBS: 536 ± 10 vs. NHT-hADMSC: 522 ± 17 vs. HT-PBS: 518 ± 36 vs. HT-hADMSC 507 ± 35) (n = 18–20). No mice died whatever the group during surgery and during follow-up.

Doppler Imaging of Cerebral Vasoreactivity to Inhaled CO_2

Cerebral vasoreactivity was assessed 8 weeks after the induction of chronic hyperglycemia or chronic hypertension, before cerebral ischemic induction. Mean blood flow velocities at the basilar trunk were not significantly modified after CO_2 inhalation in diabetic mice (air: 12.0 ± 1.7 versus CO_2: 11.0 ± 1.4 cm/s) (n = 7) and in hypertensive mice (air: 15.7 ± 2.2 versus CO_2: 15.8 ± 2.6 cm/s) (n = 14), whereas they were significantly increased when compared to the same control mice (non-diabetic and non-hypertensive mice) (air: 15.4 ± 2.4 versus CO_2: 17.7 ± 2.2 cm/s, p = 0.0001) (n = 9), indicating that in this last group only, CO_2 induced arteriolar vasodilation.

Sensorimotor Deficit

At D2, compared to D-1, we observed a significant reduction in the neurological score in diabetic and hypertensive mice compared to control non-diabetic and non-hypertensive mice, indicating that both diabetes and hypertension induced a more severe sensorimotor deficit compared to mice that were subjected to the same pMCAo stroke model but without vascular risk factor. From D2 to D9, this deficit significantly persisted over time until complete recovery by D14, except in D-PBS that had nevertheless completely recovered by D28. However, whatever the time of evaluation, there was no significant difference in the neurological score between untreated and treated mice whatever the risk factor, indicating that hADMSC had no effect on sensorimotor recovery (**Figures 2A,B** and **Tables 1**, **2**).

Open Field

The ability of mice to spontaneously walk the equivalent distance with similar velocity was verified in the open field,

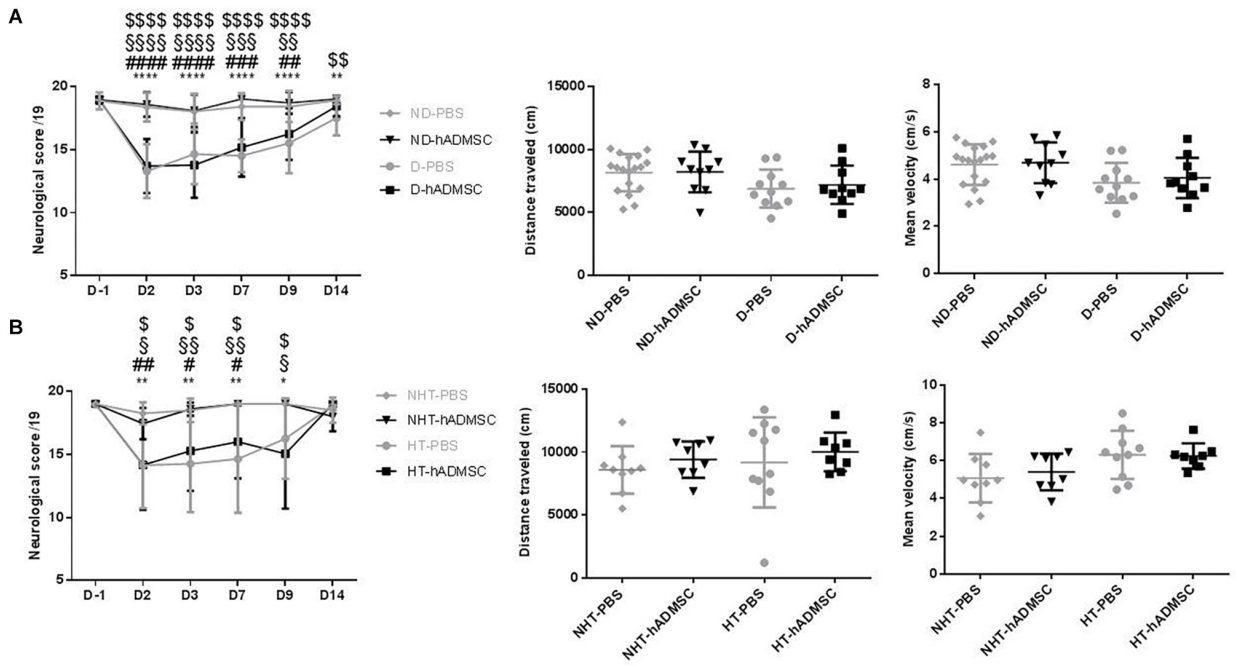

FIGURE 2 | Assessment of sensorimotor deficit between D-1 and D14 and of spontaneous locomotor activity measured at D28 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice and D-hADMSC, treated diabetic mice (n = 13–20) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (n = 8–20) **(B)**. Diabetic and hypertensive mice showed a more severe sensorimotor deficit than control mice during the whole evaluation until they fully recovered at D14 except D-PBS mice ($p < 0.01$ versus ND-PBS and $p < 0.01$ versus ND-hADMSC). No differences were evidenced between untreated and treated mice. At D28, no differences were evidenced between mice in the total distance traveled or mean velocity at open field; $^{*}p < 0.05$, $^{**}p < 0.01$, $^{****}p < 0.0001$ between ND-PBS versus D-PBS mice and NHT-PBS versus HT-PBS mice; $^{\#}p < 0.05$, $^{\#\#}p < 0.01$, $^{\#\#\#}p < 0.001$, $^{\#\#\#\#}p < 0.0001$ between ND-PBS versus D-hADMSC and between NHT-PBS versus HT-hADMSC; $^{\S}p < 0.05$, $^{\S\S}p < 0.01$, $^{\S\S\S}p < 0.001$, $^{\S\S\S\S}p < 0.0001$ between ND-hADMSC versus D-PBS and between NHT-hADMSC versus HT-PBS; $^{\$}p < 0.05$, $^{\$\$}p < 0.01$, $^{\$\$\$\$}p < 0.0001$ between ND-hADMSC versus D-hADMSC and NHT-hADMSC versus HT-hADMSC.

before the Barnes Maze evaluation. Indeed, any residual motor impairment could skew the interpretation of spatial long-term memory. No differences were observed between mice in the distance traveled or mean velocity in the diabetic groups or in the hypertensive groups, whether the mice were treated or untreated (**Figures 2A,B**).

Barnes Maze

In the training phase, D-hADMSC had an impaired learning ability at the 2nd and 3rd day compared to ND-PBS ($p < 0.01$ and $p < 0.001$, respectively). At the 3rd day, D-PBS also presented an impairment compared to ND-PBS ($p < 0.05$) and D-hADMSC compared to ND-hADMSC ($p < 0.01$). However, all mice learned the same on the 4th day. In the retention phase, only diabetic mice without treatment showed a delayed latency to escape reflecting an impaired long-term memory ability (ND-PBS versus D-PBS, $p < 0.001$). D-hADMSC did not show differences compared to non-diabetic mice, nor with D-PBS mice. On the reversal phase, all diabetic mice had an impaired cerebral plasticity compared to non-diabetic mice (ND-PBS versus D-PBS, $p < 0.01$; ND-PBS

Control hypertensive (HT-PBS) and non-hypertensive mice (NHT-PBS) and treated hypertensive (HT-hADMSC) and non-hypertensive mice (NHT-hADMSC).

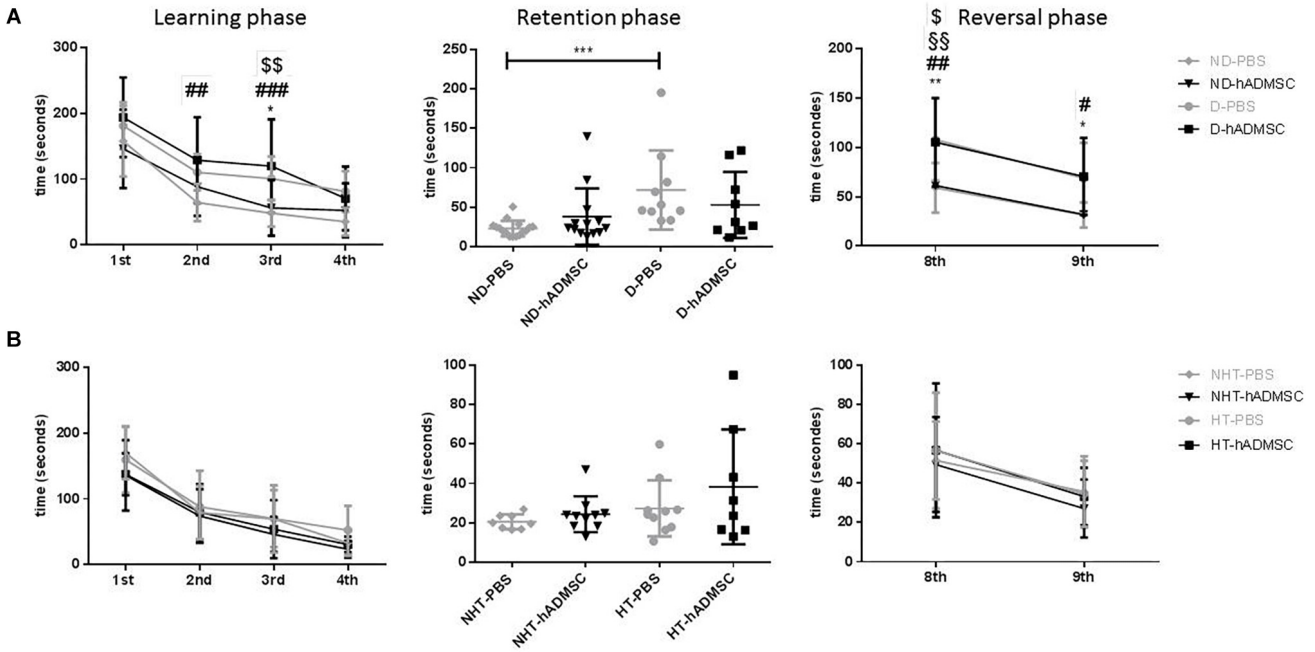

FIGURE 3 | Assessment of long-term spatial memory between D30 and D38 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice and D-hADMSC, treated diabetic mice (n = 9–16) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (n = 8–10) **(B)**. hADMSC did not significantly modify the latency to escape of pMCAo mice whatever the risk factor; $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, ND-PBS versus D-PBS; $^{\#}p < 0.05$, $^{\#\#}p < 0.01$, $^{\#\#\#}p < 0.001$, $^{\#\#\#\#}p < 0.0001$ ND-PBS versus D-hADMSC; $^{\S}p < 0.05$, $^{\S\S}p < 0.01$, $^{\S\S\S}p < 0.001$, $^{\S\S\S\S}p < 0.0001$ ND-hADMSC versus D-PBS; $^{\$}p < 0.05$, $^{\$\$}p < 0.01$, $^{\$\$\$}p < 0.001$, $^{\$\$\$\$}p < 0.0001$ ND-hADMSC versus D-hADMSC.

versus D-hADMSC, $p < 0.01$; ND-hADMSC versus D-PBS, $p < 0.01$; ND-hADMSC versus D-hADMSC, $p < 0.05$). This impairment was also present on the 9th day for D-PBS mice and D-hADMSC compared to ND-PBS mice ($p < 0.05$) (**Figure 3A** and **Table 3**).

To summarize, hADMSC injected intravenously 2 days after a focal cerebral ischemia failed to protect from post-stroke cognitive impairment in diabetic mice.

In hypertensive mice, we evidenced no differences in the training phase, the retention phase or the reversal phase between the four groups, indicating that 16 weeks of hypertension did not induce a worse post-stroke cognitive impairment compared to non-hypertensive mice subjected to a focal cerebral ischemia. As we have previously shown (Mangin et al., 2019) that pMCAo mice, without vascular risk factor, does not have significantly modified scores at Barnes Maze, our results would indicate that our model did not produce cognitive impairment in hypertensive mice. The effect of hADSMC could therefore not be evaluated (**Figure 3B** and **Table 4**).

Infarct Volume

Infarct volume was not significantly modified at day 9 in the diabetic groups or in the hypertensive groups, whether the mice were treated or untreated (**Figure 4**).

Neurogenesis, Microglial/Macrophages, T Lymphocytes, Astrocytes, and Vessel Density and Were Not Significantly Modified by hADMSC in Diabetic and Hypertensive Mice

Neurogenesis

Comparison of the DCX-positive area was performed in order to assess neurogenesis between groups. At D9, no differences were evidenced between untreated and treated non-diabetic and diabetic mice and between untreated and treated non-hypertensive and hypertensive mice.

At D40, there was an overall ANOVA significance between untreated and treated non-diabetic and diabetic mice ($p < 0.01$). The DCX-positive area was significantly increased in D-hADMSC mice (1.6 ± 0.28 mm^3) compared to ND-PBS mice (0.42 ± 0.40 mm^3) ($p < 0.001$), whereas there was no significant difference with the other groups (1.01 ± 0.51 mm^3, ND-hADMSC mice; 1.14 ± 0.57 mm^3, D-PBS mice). No differences were evidenced between untreated and treated non-hypertensive and hypertensive mice.

Between D9 and D40, there was a significant reduction in neuroblasts density in ND-PBS ($p < 0.001$), ND-hADMSC ($p < 0.05$), D-PBS ($p < 0.05$) and D-hADMSC mice ($p < 0.05$), and in NHT-PBS ($p < 0.05$) and NHT-hADMSC mice ($p < 0.01$); no differences were observed in HT-PBS and HT-hADMSC mice over time (**Figure 5**).

Microglial/Macrophages Density

Comparison of the Iba1-positive area was performed in order to assess microglial/macrophages density between groups. Microglia/macrophage cells (Iba1+) adopted a round amoeboid shape in the peri-infarct area, indicating a change in the state of activation. At D9, no differences were evidenced between untreated and treated non-diabetic and diabetic mice or between untreated and treated non-hypertensive and hypertensive mice (**Figure 6**).

At D40, rare microglial/macrophages were evidenced on sections, and therefore no quantification was performed.

T Lymphocytes Density

Comparison of CD3+ cells density was performed in order to assess T lymphocytes density between groups. At D9, no differences were evidenced between untreated and treated non-diabetic and diabetic mice or between untreated or treated non-hypertensive or hypertensive mice.

At D40, no differences were evidenced between untreated and treated non-diabetic and diabetic mice or between untreated or treated non-hypertensive or hypertensive mice.

Between D40 and D9, there was a significant increase in CD3+ cells density in D-PBS mice (84.3 ± 58/section versus 40.6 ± 15.0/section) ($p < 0.05$) only, whereas there were no significant differences in the CD3+ cells density between treated diabetic mice and untreated or treated non-diabetic mice. No differences were observed between untreated or treated non-hypertensive or hypertensive mice overtime (**Figure 7**).

Astrocytes Density

Comparison of the GFAP-positive area was performed in order to assess astrocytes density between groups. Activated astrocytes only were considered, when they adopted a narrow cell body and thickened their branches. At D9, no differences were

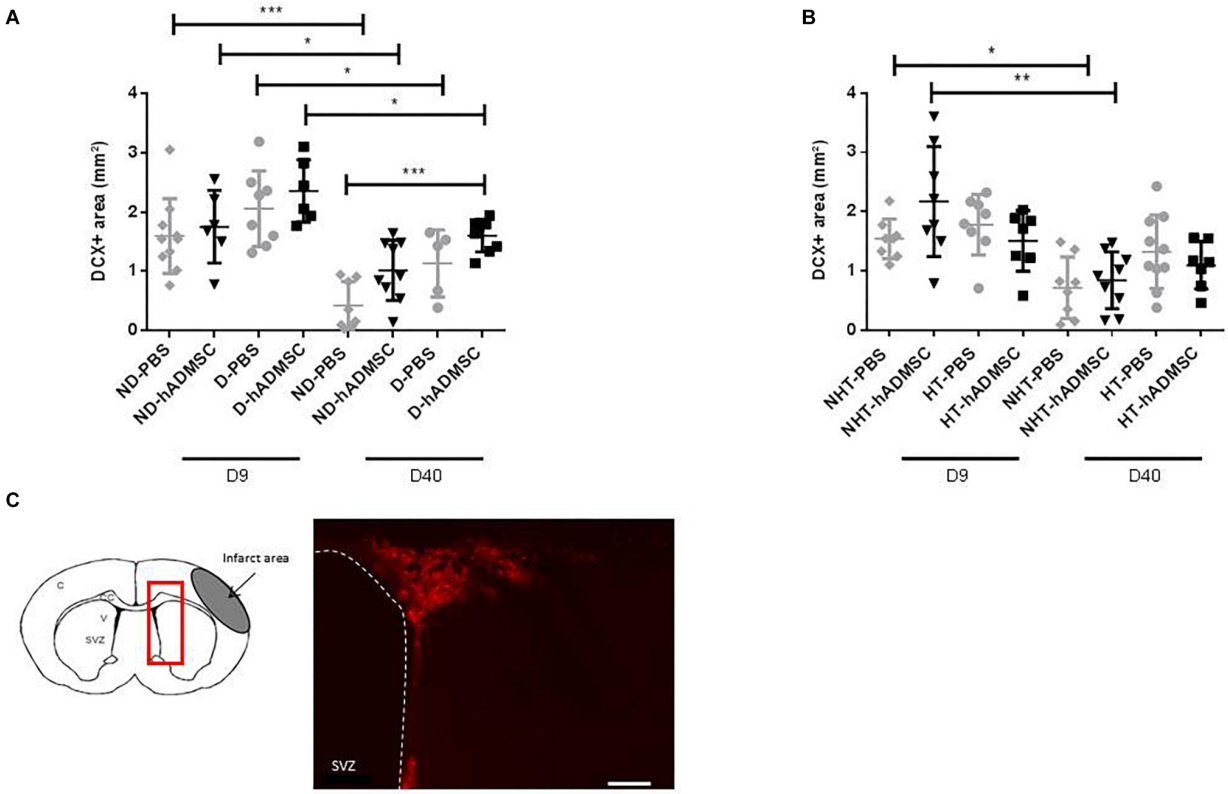

FIGURE 5 | Assessment of neuroblasts density at D9 and D40 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice and D-hADMSC, treated diabetic mice (D9: n = 6–10, D40: n = 5–9) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (D9: n = 7–8, D40: n = 7–10) **(B)**. hADMSC did not significantly increase neuroblasts density except at D40 in D-hADMSC mice compared to ND-PBS mice. Between D9 and D40, a significant decrease in neuroblasts density was evidenced in ND-PBS, $p < 0.001$; ND-hADMSC, $p < 0.05$; D-PBS, $p < 0.05$; D-hADMSC, $p < 0.05$) and in NHT-PBS ($p < 0.05$) and NHT-hADMSC ($p < 0.01$). *$p < 0.05$, **$p < 0.01$, ***$p < 0.001$. DCX immunostaining in the SVZ of untreated diabetic mice, at D9 and at D40, scale bar: 50 μm; C, cortex; V, ventricle; SVZ, subventricular zone; red square, region of interest **(C)**.

evidenced between untreated and treated non-diabetic and diabetic mice. There was an overall significant difference between untreated or treated non-hypertensive or hypertensive mice ($p = 0.02$) and the GFAP-positive area was significantly decreased in HT-PBS (2.59 ± 0.35 A.U.) compared to NHT-PBS mice (8.06 ± 4.58 A.U.) ($p < 0.05$). No differences were evidenced with the other groups.

At D40, no differences were evidenced between untreated and treated non-diabetic and diabetic mice. There was an overall significant difference between untreated or treated non-hypertensive or hypertensive mice ($p = 0.015$) and the GFAP-positive area was significantly increased in HT-hADMSC mice (12.07 ± 2.43 A.U.) versus NHT-PBS mice (5.22 ± 4.52 A.U.) ($p < 0.05$), whereas no differences were evidenced with the other groups.

Between D40 and D9, the GFAP-positive area was significantly reduced in ND-PBS (2.04 ± 0.94 A.U. versus 10.90 ± 4.01 A.U.) ($p < 0.0001$), ND-hADMSC (2.79 ± 1.85 A.U. versus 9.72 ± 5.95 A.U.) ($p < 0.05$), D-PBS (2.34 ± 1.56 A.U. versus 10.49 ± 2.87 A.U.) ($p < 0.01$), and D-hADMSC (4.26 ± 1.74 A.U. versus 8.15 ± 0.80 A.U.) ($p < 0.01$) mice. By contrast, the GFAP-positive area was significantly increased in HT-PBS mice (13.47 ± 4.34 A.U. versus 2.59 ± 0.35 A.U.) ($p < 0.01$) and HT-hADMSC mice (12.07 ± 2.43 A.U. versus 5.49 ± 2.31 A.U.) ($p < 0.001$) (**Figure 8**).

Vessel Density

Comparison of the GLUT-1-positive area was performed in order to assess vessel density between groups. At D9 or at D40, no differences were evidenced between untreated and treated non-diabetic and diabetic mice or between untreated or treated non-hypertensive or hypertensive mice.

Between D9 and D40, no differences in the GLUT-1-positive area were evidenced between untreated and treated non-diabetic and diabetic mice or between untreated or treated non-hypertensive or hypertensive mice (**Figure 9**).

DISCUSSION

We showed that IV administration of hADMSC 2 days after focal cerebral ischemia induction did not significantly modify infarct

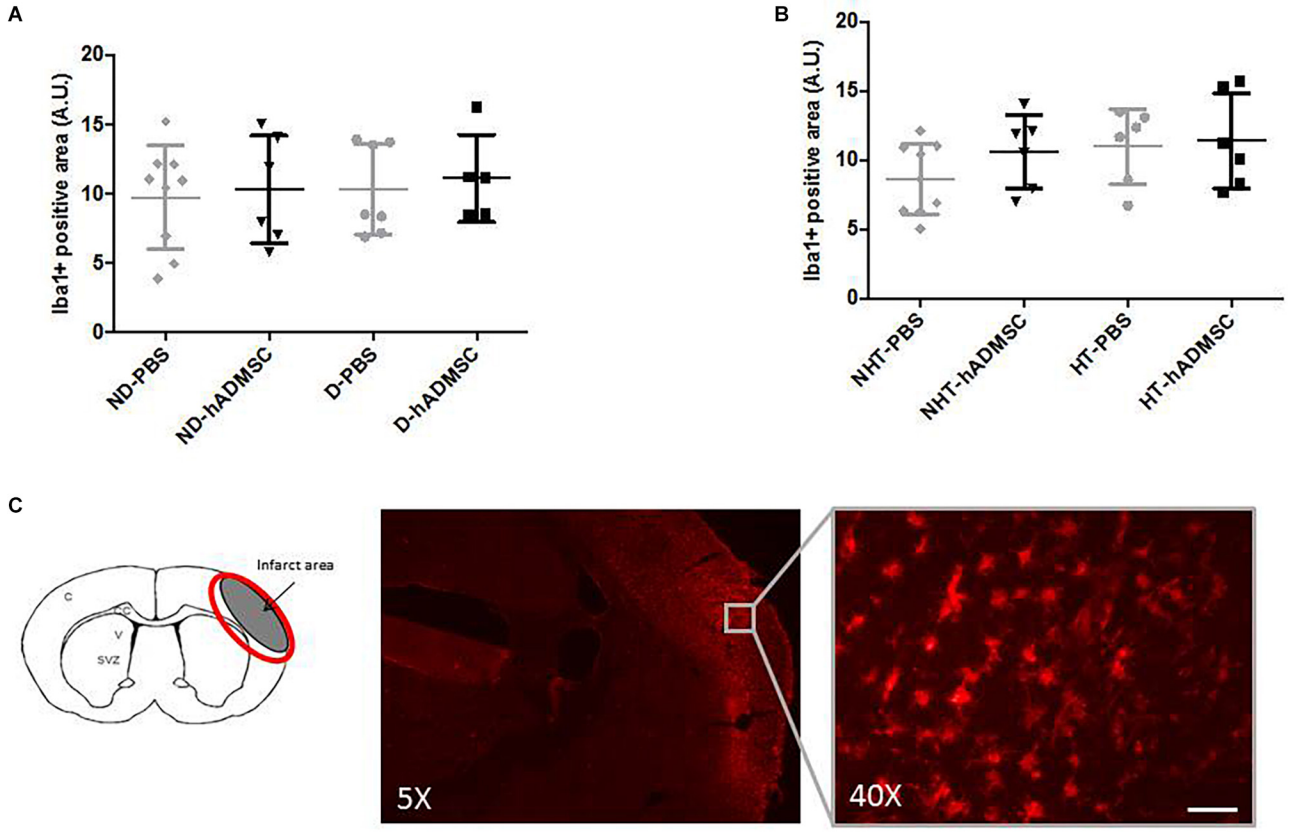

FIGURE 6 | Assessment of Iba1+ cell density at D9 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice and D-hADMSC, treated diabetic mice (n = 5–9) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (n = 6–9) **(B)**. No significant reduction in microglia/macrophages density by hADMSC was evidenced whatever the risk factor. Iba1 immunostaining in D-PBS mice with magnification showing amoeboid cells, scale bar: 50 μm; C, cortex; V, ventricle; SVZ, subventricular zone; red circle: region of interest **(C)**.

volume, short and long-term functional outcome in diabetic or hypertensive mice neither was associated with significant modification of neurogenesis, inflammatory cells density or angiogenesis, whatever the analysis time frame.

Most of preclinical studies investigating the beneficial effect of cell therapy have been performed in healthy young male rodents, even when vascular risk factors are known to worsen the infarct lesion, functional outcome and mortality, and therefore question the efficiency of cell therapy. We have used a diabetic stroke model that we previously characterized (Poittevin et al., 2015). Streptozotocin induced chronic hyperglycemia was associated after 8 weeks to impaired vasoreactivity and decreased brain eNOS and nNOS expression. After stroke induction, diabetic mice had an increased sensori-motor disability (Poittevin et al., 2015) and presented cognitive impairment at D30 compared to non-diabetic mice (Mangin et al., 2019). For the hypertensive model, we used L-NAME in daily drinking water that induced chronic mild hypertension, rather than chronic infusion of angiotensin 2 that is responsible for a more severe hypertension and requires additional surgery for angiotensin 2 pump implantation (Cifuentes et al., 2015, 2017). This model was also associated with impaired vasoreactivity after 8 weeks, but to achieve a sensori-motor impairment in our experimental conditions, we had to administer L-NAME during 16 weeks.

Cell therapy in post-stroke diabetic rodents has already been investigated using various cell types, sources and administration pathways. Allogenic bone-marrow derived MSC (BM-MSC) from healthy rats have been intravenously injected 1 day after stroke in type 1 diabetic rats, and 3 days after stroke in type 2 diabetic rats subjected to tMCAo. In the first case, blood-brain-barrier permeability and mortality were increased with an opposite outcome in the second case (Chen et al., 2011; Ding et al., 2016). In type 2 diabetic rats, xenogenic human BM-MSC that were IV delivered 3 days after a tMCAo, significantly improved neurological function without affecting infarct volume. Endothelial progenitor cells (EPCs) isolated from human umbilical cord blood and IV delivered immediately after reperfusion in type 1 diabetic mice subjected to a tMCAo, reduced blood-brain barrier leakage, reduced infarct volume and attenuated neurological impairment (Geng et al., 2017). By contrast, intraarterial delivery of allogenic BM-EPC in type 2 diabetic mice, 24 h after induction of a photothrombotic stroke, failed to significantly improve behavioral scores and infarct volume (Bai et al., 2015). Diabetes models, stroke models, species,

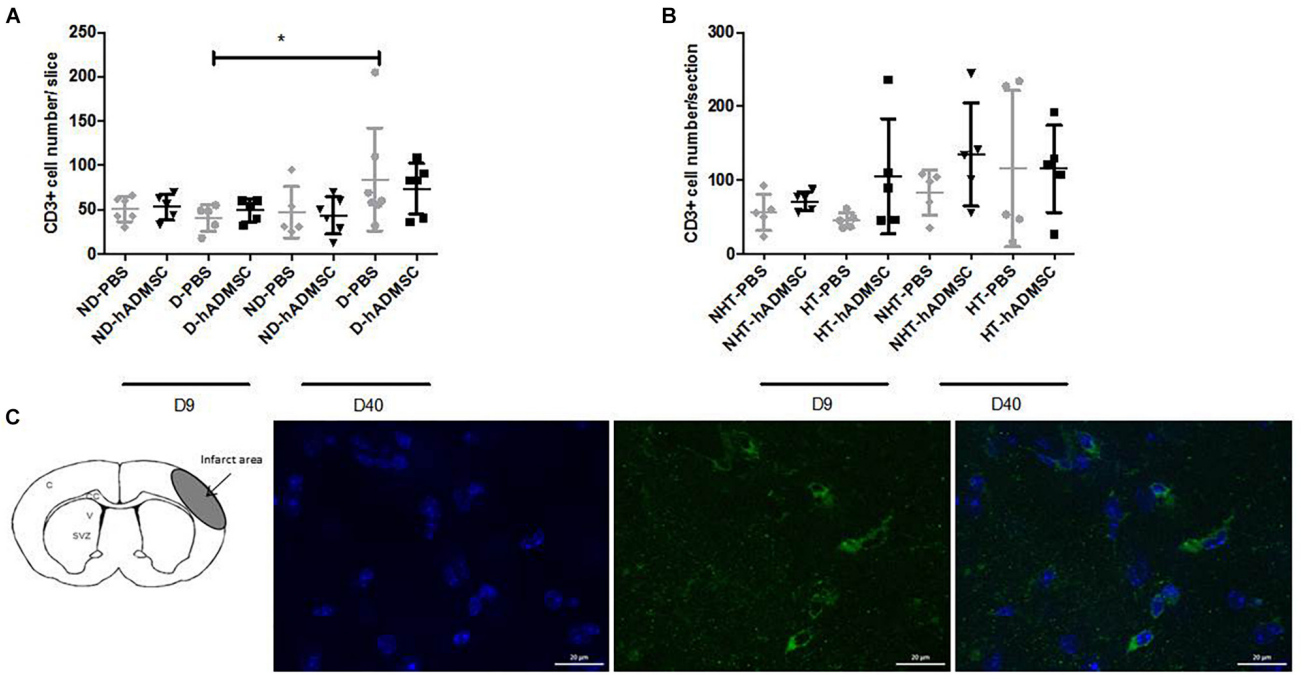

FIGURE 7 | Assessment of CD3+ cells density at D9 and D40 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice and D-hADMSC, treated diabetic mice (D9: $n = 5–6$, D40: $n = 5–7$) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (D9: $n = 5–7$, D40: $n = 5$) **(B)**. hADMSC did not significantly modify the T-lymphocytes density whatever the risk factor. Between D9 and D40, there was a significant increase in T-lymphocytes density in D-PBS mice ($^*p < 0.05$). From left to right, DAPI, CD3 and merge immunostaining, scale bar: 20 μm; C, cortex; V, ventricle; SVZ, subventricular zone **(C).**

delay of injection after stroke and allograft versus xenograft differed between studies and with ours, precluding direct comparison. Interestingly, xenograft or delayed injection of BM-MSC, up to 3 days, in diabetic animals, was not an impediment to improved outcome. Cell therapy in hypertensive rodents have only been investigated in spontaneously hypertensive rats. BM-derived mononuclear cells did not succeed in demonstrating sensori-motor improvement when IV transplanted 1 h after induction of a photothrombotic stroke (Diederich et al., 2014) or IV transplanted 3 h after reperfusion in a tMCAo stroke model (Minnerup et al., 2014), nor did umbilical cord blood mononuclear cells (Weise et al., 2014). Only maternal placenta derived MSC that were intravenously administered, led to an improvement of functional outcome (Kranz et al., 2010). These mitigate results underline the necessity to integrate co-morbidity factors into stroke models.

The source of MSC may matter. Adipose tissue is an interesting alternative donor tissue to bone marrow. Lipoaspiration allows easy collection of great quantities of cells (Mangin and Kubis, 2018). In addition, and in a translational point of view, ADMSC have a low immunogenicity profile enabling allogeneic administration with good tolerance. When transplanted in a tMCAo model, allogenic ADMSC IV delivered soon after reperfusion, showed a remarkable attenuation of ischemic damage compared to BM-MSC treated mice (Ikegame et al., 2011). In rats, a beneficial effect of ADMSC was observed whatever the IV (Gutierrez-Fernandez et al., 2015) or IA (Huang et al., 2017) administration, in a pMCAo and tMCAo model, respectively. Interestingly, xenogeneic ADMSC or allogeneic ADMSC showed equal efficacy in terms of functional recovery and decreased ischemic brain damage when IV delivered 30 min after pMCAo (Gutierrez-Fernandez et al., 2015). To summarize, ADMSC seem to be more promising than BM-MSC, the xenograft and allograft are of equal efficacy, they have been constantly reported to improve functional outcome in rats and mice, the tMCAo stroke model being the most widely used. However, none of these animals had associated vascular risk factors and cells were constantly administered, within 24 h after cerebral ischemia induction, both conditions that might explain our negative results.

Our model is not questioned since, using the same pMCAo model in diabetic mice, we previously showed a dramatic functional improvement and a reduced infarct volume following treatment with the immunomodulatory drug glatiramer acetate (Mangin et al., 2019), with peripheral blood mononuclear cells pretreated with ephrin-B2 in diabetic (personal unpublished data) but also in non-diabetic mice (Hilal et al., 2018). In literature, cell therapy is mainly reported in tMCAo stroke models. However, the pMCAo model offers many advantages. The tMCAO stroke model in diabetic mice is associated with a high mortality after 7 days which prevents any further follow-up (Poittevin et al., 2015). We had previously shown that diabetic mice developed post-stroke dementia after pMCAo (Mangin et al., 2019), which was one of the functional outcomes we

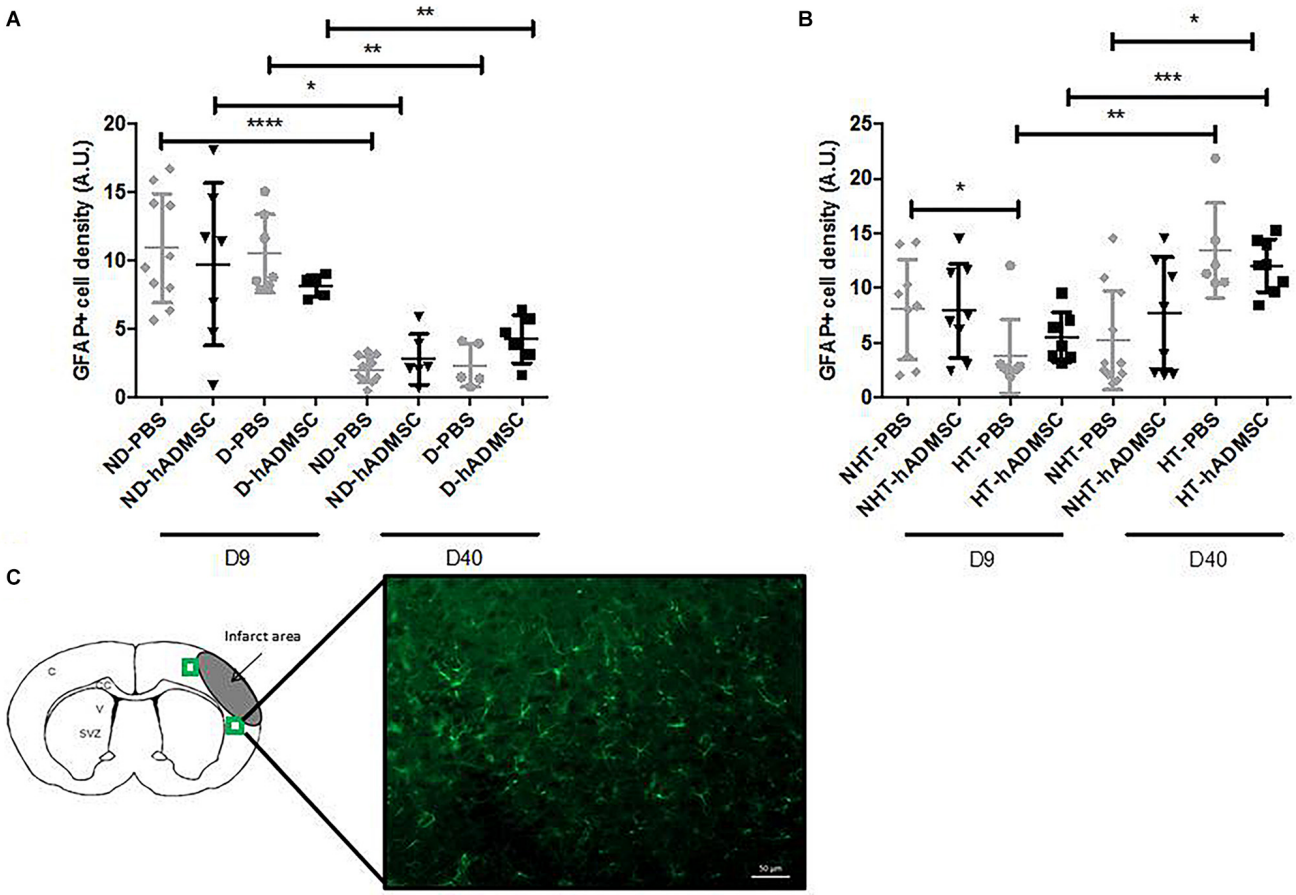

FIGURE 8 | Assessment of GFAP+ cells density at D9 and D40 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice and D-hADMSC, treated diabetic mice (D9: n = 5–10, D40: n = 5–11) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (D9: n = 7–9, D40: n = 6–11) **(B)**. hADMSC did not significantly modify the astrocytes density whatever the risk factor. Between D9 and D40, there was a significant reduction in activated astrocytes in ND-PBS, ND-hADMSC, D-PBS, and D-hADMSC mice and a significant increase in activated astrocytes in HT-PBS and HT-hADMSC mice; $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, $^{****}p < 0.0001$. GFAP immunostaining, scale bar: 50 µm; C, cortex; V, ventricle; SVZ, subventricular zone; green squares: regions of interest **(C).**

wanted to explore. The smaller infarct, restricted to the cortex was crucial in our model, because we did want to spare the hippocampus from the neuronal damage. Moreover, it was recently reported that even a minor stroke increases the incidence of post-stroke dementia and that diabetes is the only vascular risk factor identified (Pendlebury et al., 2019). Although the infarct is smaller in this pMCAo stroke model compared to the tMCAo model in mice, brain inflammation is exacerbated (Zhou et al., 2013) and even more in diabetic mice (Mangin et al., 2019) and in hypertensive rats (Moller et al., 2015). This is important to consider since the efficiency of hADMSC is related to their "immunomodulatory properties" (Leu et al., 2010; Melief et al., 2013). At last, "healthy" non-diabetic and non-hypertensive mice subjected to a pMCAo presented little sensorimotor deficit that recovered completely very quickly and prevented us to evaluate any effect of cells in those mice, but this was not the primary endpoint of our study.

We cannot rule out that a different culture procedure might have led to different results. The fact that hADMSC were collected from only one donor might question the efficiency of these cells. However, using the cells of the same donor, Mu et al. (2019) succeeded in demonstrating functional improvement in treated non-diabetic adult male Sprague Dawley rats, subjected to focal cerebral ischemia, and using the sticky label test. However, this does not exclude that there might be variability in the response that should be tested by comparing the efficiency of these cells between various donors. Also, the delay of injection might have been too late. In our previous cell therapy studies in pMCAO mice, we constantly IV transplanted the cells within the first 24 h after stroke induction (Nih et al., 2012; Hilal et al., 2018) and a beneficial effect was observed when ADMSC were IV (Gutierrez-Fernandez et al., 2015) or IA administered (Huang et al., 2017), 30 min and 24 h respectively after the cerebral ischemia induction. The 48 h delay was chosen in that particular study to get along with the parallel clinical trial that aimed to widen the therapeutic window and because mice were randomized according to the infarct volume determined at cerebral MRI the day before.

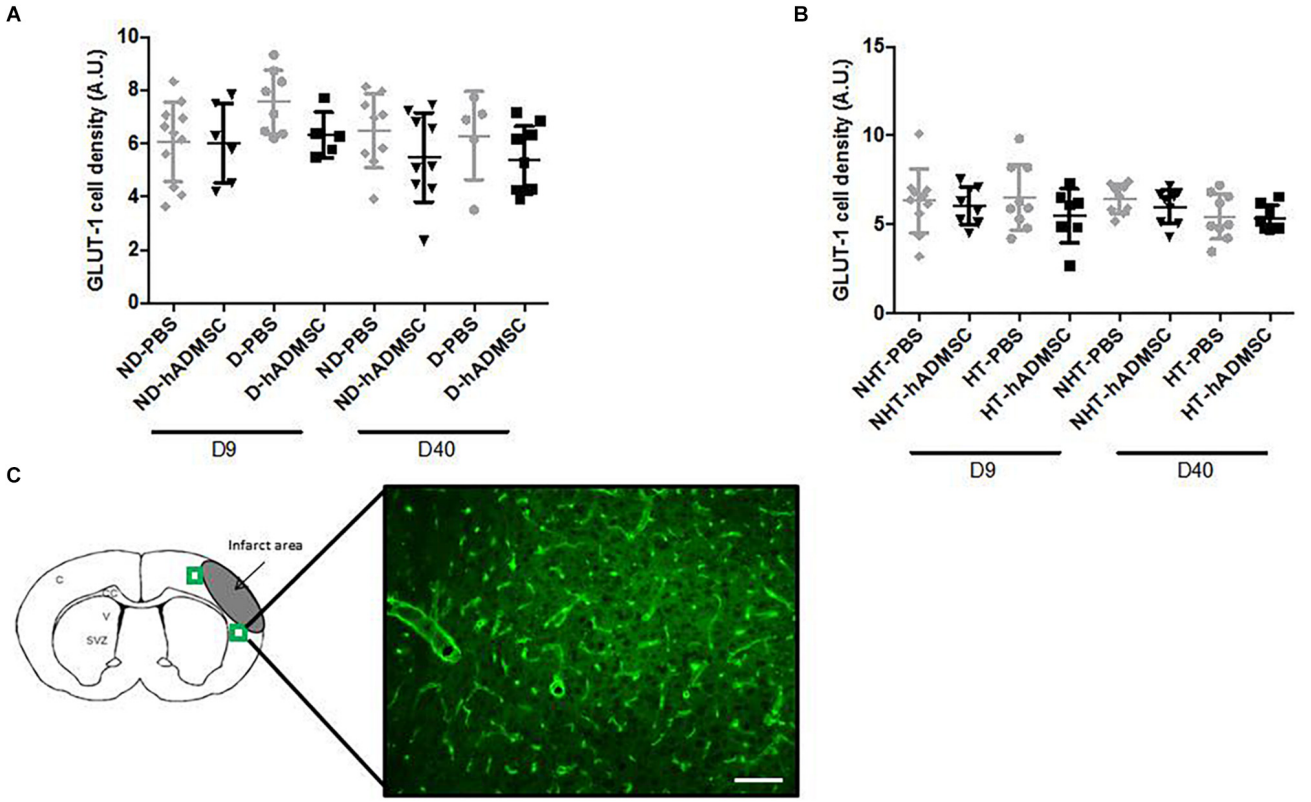

FIGURE 9 | Assessment of GLUT-1+ cells area at D9 and D40 in ND-PBS, untreated non-diabetic mice; ND-hADMSC, treated non-diabetic mice; D-PBS, untreated diabetic mice; and D-hADMSC, treated diabetic mice (D9: n = 5–11, D40: n = 5–9) **(A)** and NHT-PBS, untreated non-hypertensive mice; NHT-hADMSC, treated non-hypertensive mice; HT-PBS, untreated hypertensive mice and HT-hADMSC, treated hypertensive mice (D9: n = 7–10, D40: n = 8–9) **(B)**. Vessel density was not significantly modified over time and hADMSC did not significantly modify the vessels density whatever the risk factor. GLUT-1 immunostaining, scale bar: 100 μm; C, cortex; V, ventricle; SVZ, subventricular zone; green squares: regions of interest **(C)**.

The discrepancies of our results between mice and those obtained in rats by the other teams of the RESSTORE project (Mu et al., 2019), could be related to species differences in the immune system. In an *in vitro* model of oxygen-glucose deprivation on primary cultures of neurons, astrocytes, microglia in rats, mice or humans, the cytokines levels were differently expressed between all three species (Du et al., 2017), or even may be present in one species and not in the other (Mestas and Hughes, 2004). MSC have been shown to secrete cytokines and growth factors that inhibit T cells proliferation, decrease TNFα secreted by dendritic cells (Uccelli et al., 2008) and at the same time polarize lymphocytes and microglial cells to an "anti-inflammatory" and beneficial phenotype (Ankrum et al., 2014). Although hADMSC have been reported to have a higher immunomodulatory capacity than BM-derived counterparts, including increase of IL-6 and TGF-β1 (Melief et al., 2013) and decrease of IL-18 (Leu et al., 2010), we did not evidence any modification of microglial/macrophages, T lymphocytes, or astrocytes densities between treated and untreated mice, when adding co-morbidity, but we did not measure brain cytokines levels. We cannot exclude either a participation of peripheral immune organs and modification of blood immune cells and cytokines release to stroke response and to comorbid factors. Indeed, spleen and systemic immune response have shown contribution to the pathophysiology of stroke (Offner et al., 2006; Vendrame et al., 2006), diabetes (Tong et al., 2017), and hypertension (McMaster et al., 2015) that could impede neurorepair.

Untreated hypertensive mice presented a reduced astrocytes density in the peri-infarct area compared to non-hypertensive mice at D9 and, on the contrary, increased astrocytes density in treated hypertensive mice compared to untreated mice at D40. Moreover, untreated and treated hypertensive mice had increased astrocytes density between D9 and D40. Given the complex role of astrocytes following stroke, this increased glial scar at D40 is difficult to interpret as being a simple epiphenomenon or as a key event resulting in the absence of neurorepair (Morrison and Filosa, 2019).

Post-stroke dementia will eventually affect 25% of patients (Iadecola, 2013). This is a particular important heath issue since it is the second cause of cognitive decline after Alzheimer's disease and that there is no current treatment to prevent or cure the disease. Still too few studies evaluate this aspect because of the need for models that must be maintained over time, complying with the increased early mortality when adding comorbidity (Poittevin et al., 2015). We found that diabetic mice with

pMCAo presented altered spatial memory at Barnes maze but not non-diabetic pMCAO mice (Mangin et al., 2019). Structural alterations in the hippocampus, which is involved in information processing related to spatial memory, have already been observed after focal brain ischemia, with neurodegeneration in the CA1 zone in particular (Wang et al., 2004). Diabetes by itself can also decrease neuronal density (Artola et al., 2005; Amin et al., 2013) and impair long-term potentiation in rats (Artola et al., 2005). In our model, both conditions (pMCAo + diabetes) were necessary to alter the Barnes Maze, that also evaluates brain plasticity (Martin et al., 2000), but again hADMSC did not prevent spatial memory impairment in those mice. MSC beneficial effects rely partly on the promulgation of neurogenesis (Leu et al., 2010; Bao et al., 2011), limitation of neuronal death (Gutiérrez-Fernández et al., 2013), and angiogenesis promotion (Wang et al., 2008) none of which having been observed in treated mice. We failed to show spatial memory impairment in our hypertensive mice after 16 weeks of mild elevated blood pressure, although impaired vasoreactivity after 8 weeks was evidenced just as for diabetic mice. If the duration of the hypertension was appropriate to induce a sensorimotor deficit, we cannot exclude that both the duration of hypertension and/or the time points chosen to assess the Barnes maze test were inadequate and that a later evaluation would have been more contributive.

CONCLUSION

These negative results are of utmost importance, given the importance of vascular risk factors in stroke patients. Comorbid animals should be part of all preclinical stroke studies and could avoid considerable unnecessary costs in clinical studies. The next preclinical study will focus on time administration and other models of vascular risk factors. If hADMSC prove then to be efficient, we will have the opportunity, by comparing the molecular pathways, to explore the in depths-mechanisms involved by these human ADMSC.

DATA AVAILABILITY

The raw data supporting the conclusions of this manuscript will be made available by the authors, without undue reservation, to any qualified researcher.

ETHICS STATEMENT

All experiments and surgical procedures were performed according to the European Community Directive (2010/63/EU), the ARRIVE (Animal Research Reporting In Vivo Experiments) guidelines, and the French national guidelines for the care and use of laboratory animals. The study was approved by the French ministry of Higher Education for Research and Innovation (APAFIS#5431-2016031912549126 v2).

AUTHOR CONTRIBUTIONS

GM performed the mice experiments including the acquisition and interpretation of data and drafted the manuscript. AC performed the analysis and interpretation of the data. AM provided the hADMSC. PB performed the Doppler experiments and analyses. BM performed experiments including the acquisition and interpretation of data. NK conceived and designed the study, and drafted and edited the manuscript. All authors read and approved the final manuscript.

FUNDING

The RESSTORE project received funding from the European Union's Horizon 2020 Research and Innovation Programme under the Grant Agreement No. 681044 RESSTORE project (www.resstore.eu) and GM was directly funded by the RESSTORE project.

ACKNOWLEDGMENTS

The authors thank the FRIM platform (UMS34), University of Paris Diderot, member of France Life Imaging (grant ANR-11-INBS-0006) and IDEX Imagerie Du Vivant networks, and in collaboration with the IAME group (UMR1137), the Institut des Vaisseaux et du Sang (Hospital Lariboisière, Paris).

Front. Neurosci. 13:767. doi: 10.3389/fnins.2019.00767

Tissue perfusion is a necessary condition for vessel survival that can be compromised under ischemic conditions. Following stroke, delayed effects of early brain reperfusion on the vascular substrate necessary for remodeling, perfusion and maintenance of proper peri-lesional hemodynamics are unknown. Such aspects of ischemic injury progression may be critical for neurological recovery in stroke patients. This study aims to describe the impact of early, non-thrombolytic reperfusion on the vascular brain component and its potential contribution to tissue remodeling and long-term functional recovery beyond the acute phase after stroke in 3-month-old male C57bl/6 mice. Permanent (pMCAO) and transient (60 min, tMCAO) brain ischemia mouse models were used for characterizing the effect of early, non-thrombolytic reperfusion on the brain vasculature. Analysis of different vascular parameters (vessel density, proliferation, degeneration and perfusion) revealed that, while early middle cerebral artery recanalization was not sufficient to prevent sub-acute vascular degeneration within the ischemic brain regions, brain reperfusion promoted a secondary wave of vascular remodeling in the peri-lesional regions, which led to improved perfusion of the ischemic boundaries and late-phase neurological recovery. This study concluded that acute, non-thrombolytic artery recanalization following stroke favors late-phase vascular remodeling and improves peri-lesional perfusion, contributing to secondary functional recovery.

Keywords: brain, recanalization, perfusion, blood-brain barrier, angiogenesis, stroke

INTRODUCTION

Long-term, stroke-induced vascular remodeling is a key process governing neural tissue reorganization in response to injury (Navarro-Sobrino et al., 2011; Chen et al., 2014). Local tissue perfusion, hemodynamics and proper neurovascular coupling in the peri-lesional regions contribute to support the metabolic demands necessary for neuronal plasticity and for the survival and differentiation of migrating neural progenitors (Thored et al., 2007; Snapyan et al., 2009), two processes that may underlie long-term functional recovery. Indeed, a functional correlation exists

between delayed blood flow restoration and neurological recovery in stroke patients (Krupinski et al., 1993; Chopp et al., 2007; Arkuszewski et al., 2009; Navarro-Sobrino et al., 2011). Additionally, in the context of vascular remodeling upon damage, vascular perfusion is necessary for vessel survival, stimulates vessel outgrowth and precludes endothelial degeneration (Dimmeler et al., 1996; Haga et al., 2003; Yamamoto et al., 2003). Thus, acute artery recanalization may condition the long-term survival of a vascular substrate for remodeling and vascularization of the ischemic and peri-ischemic brain regions during the chronic neural repair phase after stroke. Several studies have explored vascular remodeling after stroke (Marti et al., 2000; Wei et al., 2001; Zhang et al., 2002; Hayashi et al., 2003; Schaffer et al., 2006; Mostany et al., 2010; Hayakawa et al., 2012; Mao et al., 2014; Marks et al., 2014). In the present report, we intend to go further and elucidate the implication of vessel reperfusion after brain ischemia and also to compare it with a non-reperfusion scenario.

Early restoration of brain tissue perfusion is the main strategy currently pursued in the acute management of stroke patients. However, between 17 and 24% of ischemic stroke patients experience spontaneous arterial recanalization within the first 24 h after stroke onset in the absence of induced thrombolysis (Kassem-Moussa and Graffagnino, 2002; Rha and Saver, 2007). Adding to this, the number of patients undergoing recanalization induced by mechanical thrombectomy or thrombus removal in the absence of thrombolysis is increasing (Smith et al., 2017). In spite of its relative frequency, clinical studies describing the impact of non-thrombolytic reperfusion on the long-term progression of the brain vascular component are scarce. In this study, we have characterized for the first time the effect of arterial recanalization on key components of sub-acute (24h-5d) vascular responses and long-term (7d-14d) vascular remodeling both in the ischemic and the peri-lesional brain regions, focusing on critical aspects for late-phase recovery such as local tissue perfusion, blood-brain barrier functionality and permissiveness of the glial scar for remodeling of the brain vascular network in C57bl/6 mice.

RESULTS

Early Reperfusion Is Not Sufficient to Prevent Sub-Acute Vessel Degeneration After Stroke

The presence of perfused vessels in the sub-acute phase was measured within the infarction at 72 h and 5 days after stroke by quantification of intravascular FITC-lectin intensity. Symmetric fields of view in the contralateral cortex were used as internal controls. The tMCAO procedure led to increased sub-acute perfused vessels irrigating the infarction at 72 h ($p < 0.05$, **Figures 1B,D**) and 5 days ($p = 0.07$, **Figures 1C,D**) as compared to pMCAO. The impact of early reperfusion on the vascular niche was characterized within the infarction by two different approaches: 1) quantification of vascular cell proliferation as a measure of stroke-induced angiogenesis and 2) quantification of vessel density as end-point parameter for vascular remodeling. Vascular cell proliferation was analyzed cumulatively by combining several protocols of BrdU administration (**Supplementary Figure 2A**). Following permanent artery occlusion (pMCAO group), vascular proliferation labeled from 24h after stroke was evident from 48h up to the latest time studied, 5 days after stroke (**Figures 2A,A′** arrowheads, **B**). When measured at 72 h, early reperfusion led to increased cumulative vascular cell proliferation (**Figures 2B,B′** arrowheads, **B**), suggesting an enhancement of the proliferative vascular response to stroke in presence of reperfusion. However, cumulative proliferating cell numbers were similar between pMCAO and tMCAO groups at 5 days ($p > 0.05$, **Figures 2A,B**). Additionally, vessel density decreased after both pMCAO and tMCAO at 48 h up to 5 days after stroke and was not affected by differences in vascular cell proliferation (**Figures 2A,C**), suggesting that proliferation could be counteracted by vascular degeneration, regardless of the presence of reperfusion. This was supported by the occasional presence of vessels with recognizable tip cells showing a crown of extended filopodia, a characteristic feature of angiogenesis (**Figure 2D**, arrowheads) next to interrupted vessels with narrowed lumen, a typical feature of vascular degeneration (**Figure 2D**, arrows). Vessel degeneration was further revealed by identification of endothelial cells undergoing active apoptosis after both pMCAO and tMCAO (**Figure 2A**, Isolectin-B4$^+$/caspase-3$^+$). Together, these observations indicate that improved local measurement of perfused vessels and increased vascular cell proliferation achieved by early reperfusion are not sufficient to prevent sub-acute vessel degeneration within the infarction.

Acute Reperfusion Favors Peri-Lesional Vascular Remodeling Two Weeks After Stroke

The effect of acute reperfusion on long-term vascular remodeling was studied within the infarcted and peri-lesional regions 2 weeks after stroke (regions of interest and BrdU administration protocol are shown in **Supplementary Figures 2B,C**, respectively). Reperfusion achieved by tMCAO led to increased vascular cell proliferation within the infarction between post-stroke days 7 and 10 ($p < 0.05$, **Figures 3A,B**), corresponding with the days of BrdU administration (**Supplementary Figure 2B**). Increased proliferation was reflected in higher vessel density quantified at post-stroke day 14, as compared to pMCAO ($p < 0.05$, **Figures 3A,B**). Additionally, protein expression of the pro-angiogenic factor VEGF-A was better preserved within the infarction after tMCAO ($p < 0.05$, **Figure 3C**). In peri-lesional regions, active vascular cell proliferation was observed to a similar extent after pMCAO and tMCAO ($p > 0.05$, **Figure 3B**). Also, no differences on vessel density were detected within this region ($p > 0.05$, **Figure 3B**).

In order to further characterize the functionality of the remodeling vessels at 14 days after injury, structural and functional blood-brain barrier parameters were analyzed. No permeability of the BBB was detected on the Evans Blue *in vivo* permeability assay (representative brain in **Figure 3D**) regardless

of the presence of early reperfusion. Tight junction protein expression (Claudin-5 and ZO-1) was generally preserved within infarcted and peri-lesional regions, also regardless of the presence of early reperfusion (western blots in **Figure 3D**).

While fluorescent background precluded the quantification of lectin perfusion within the infarction, analysis of vascular lectin intensity within the peri-lesional regions showed that acute recanalization led to a sustained presence of perfused vessels, indicative of local perfusion, in the regions surrounding the injured tissue ($p < 0.05$, **Figures 4A,B**). Improved peri-lesional perfusion was also reflected in the protein levels of hypoxia-inducible factor-1α (HIF-1α) at 14 days after injury within

the infarction, that were significantly lower in animals with acute reperfusion compared to those that underwent permanent ischemia ($p < 0.05$, **Figure 4C**).

Together, our data indicate that early reperfusion favors long-term peri-lesional perfusion and vascular remodeling within the infarction, while preserving BBB integrity.

Glial Scar Shows Features of Higher Permissiveness for Brain Tissue Remodeling After Acute Reperfusion

The glial scar formed in response to CNS injury may preclude tissue repair. Expression of protein markers of two cell populations typically present in the glial scar (GFAP for reactive astrocytes and PDGFR-β for stromal cells of pericytic origin) was quantified at post-stroke day 14 in the infarcted and peri-lesional regions. GFAP expression was expressed to similar extent in both regions after pMCAO and tMCAO ($p > 0.05$, **Figures 5A,B**). PDGFR-β was also expressed to a similar extent in both stroke models ($p > 0.05$, **Figures 5A,B**). In contrast, expression of collagen type-IV, a matrix protein abundantly expressed in the scar, as well as of one of its main degrading proteases, MMP-9, were substantially reduced in animals that underwent acute reperfusion as compared to animals with pMCAO ($p < 0.01$, **Figures 5A–C**). Both intact collagen type-IV (∼230 kDa) and the two main degradation fragments (∼82 kDa and ∼42 kDa) were decreased (**Figure 5C**), suggesting that decreased levels of intact proteins are not a result of increased degradation and that alteration of matrix composition in the glial scar is a long-term effect of acute reperfusion.

Acute Reperfusion Favors Late-Phase Functional Recovery

A final question that remained open in the study was if delayed affectation of peri-lesional remodeling mediated by acute reperfusion is associated to on an improvement on long-term injury progression and functional recovery. To address this question, late-phase functional recovery (beyond 48 h after stroke) was characterized in mice after pMCAO and tMCAO.

Lesion size at 24 h was similar in mice subjected to pMCAO and 60-min tMCAO (**Figures 6A,B**). Neurological deficits at 48 h were also comparable between both groups (not shown). In contrast, late-phase recovery from acute deficits (expressed as percentage of recovery versus the deficits observed at 48 h) was significantly higher in mice that underwent early artery recanalization at 7 and 14 days ($p < 0.05$, **Figure 6C**). However, injury progression (up to 14 days) was similar after pMCAO and tMCAO ($p > 0.05$, **Figure 6D**), indicating that recovery is not related to a reduction of injury size and could be related to the observed enhancement of vascular function in the peri-lesional regions.

DISCUSSION

An adequate restoration of tissue perfusion during the first hours after stroke is the main strategic pursued to reduce brain injury. This approach is especially effective when salvageable tissue

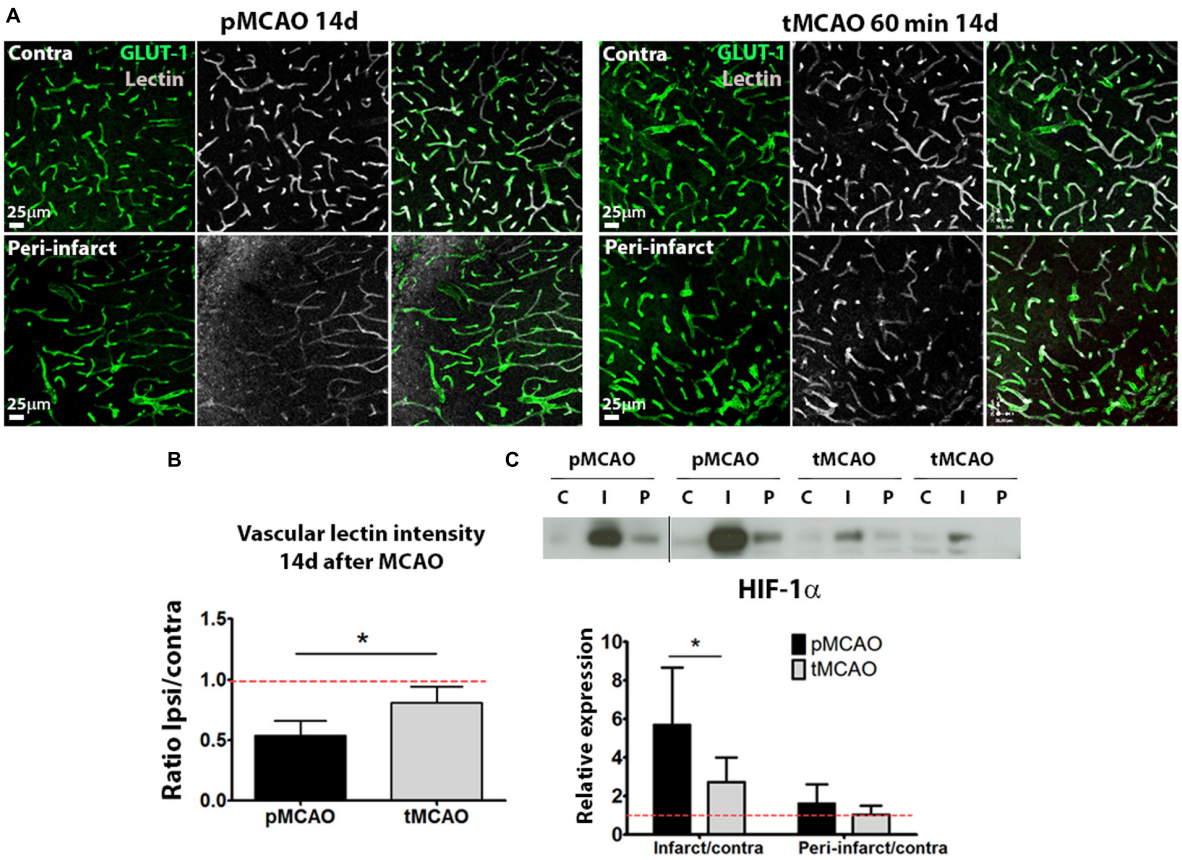

FIGURE 4 | (A) Representative confocal fluorescence micrographs (20x) showing perfusion intensity in ischemic and contralateral regions at post-stroke day 14. **(B)** Quantification of average lectin intensity in vessels expressed as ratio of ischemic/contralateral (internal control) sub-acutely. **(C)** Cropped blots from a representative HIF-1α western blot and quantification at post-stroke day 14, expressed as ratio ischemic/contralateral. remains within the ischemic territory. However, it is assumed that stroke-induced injury is permanently established within the first 48 h after stroke regardless of the initial presence of salvageable penumbral tissue (Heiss et al., 1992; Darby et al., 1999; Markus et al., 2004). One of the most interesting findings in this study is that, beyond the known acute effects on brain injury, reperfusion also impacts vascular remodeling and peri-lesional hemodynamics in the long-term. More importantly, delayed effects of acute reperfusion may underlie late-phase functional recovery occurring after injury consolidation. This conclusion extends the clinical importance of achieving early reperfusion for the chronic recovery phase after stroke.

Importantly, as soon as 24 h after stroke there was a significant decrease in vascular coverage within the injured tissue regardless of the presence of tissue reperfusion, despite the fact that vascular degeneration occurred faster after pMCAO than after tMCAO. However, even though reperfusion prolonged vessel survival in the core, eventually restoration of brain perfusion was insufficient to rescue endothelial cells from death caused by ischemia-reperfusion injury. Notably, our data provide new knowledge on the vascular dynamics at the infarct core, an area that remains so far quite understudied.

Relating to this, recent studies have shown that reperfusion is not always complete at the capillary level, since no-reflow phenomenon has been observed in approximately 32% of capillaries within the injured tissue due to sustained constriction of contractile vascular cells, which can in turn trigger capillary degeneration (Yemisci et al., 2009; Hill et al., 2015). Adding to this, reperfusion itself exacerbates endogenous damaging mechanisms that can affect the survival of brain vessels such as oxidative stress and neuroinflammation (Eltzschig and Eckle, 2011; Iadecola and Anrather, 2011), thus increasing blood-brain barrier leakage and vasogenic oedema (Barber et al., 2005; Krueger et al., 2015) and ultimately compromising vessel survival.

The loss of capillary coverage within the infarcted tissue could potentially be compensated by vascular cell proliferation. Consistent with previous reports (Seevinck et al., 2010; Hossmann, 2012), we have observed a peak in vascular cell proliferation between 48 and 72 h after stroke. Interestingly, this peak of proliferation was increased by reperfusion, but was not reflected in higher vascular coverage later on. The simultaneous presence of apoptotic (activated caspase-3^{+}) vascular cells observed is in agreement with a prior study (Hayashi et al., 2003), and confirms the co-existence of vascular proliferation

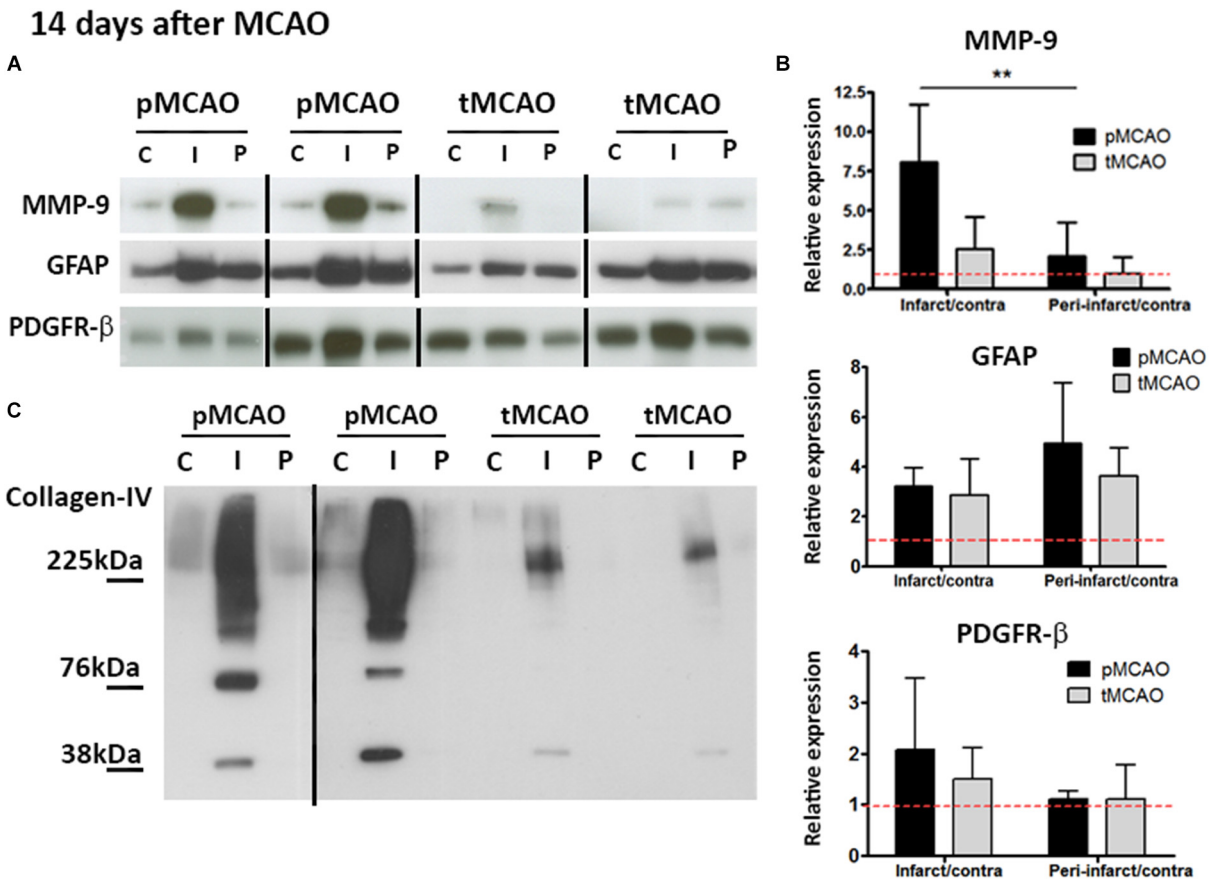

FIGURE 5 | (A,B) Cropped blots from representative MMP-9 (n = 5–6), GFAP (n = 4–5), and PDGFR-β (n = 5–6) western blots **(A)** and quantifications **(B)** in contralateral **(C)**, infarcted (I) and peri-lesional (P) regions at post-stroke day 14. **Student's t-test $p < 0.01$ vs. infarct/contra. and degeneration. Of note, absence of increased vessel density in response to proliferation conflicts with previous reports (Marti et al., 2000; Hayashi et al., 2003), but is a clear observation in our study. Interestingly, our observations at later time points reveal a secondary wave (between post-stroke days 7 and 10) of vascular proliferation within the ischemic and peri-lesional tissue, also described in previous studies (Wei et al., 2001; Zhang et al., 2002). Once more, in spite of the active proliferation and vascular remodeling observed in the peri-lesional regions, vascular coverage remained unchanged regardless of the presence of acute recanalization, in agreement with a previous long-term longitudinal study using intravital microscopy (Mostany et al., 2010). The same study concludes that absence of local angiogenesis does not preclude restoration of cerebral blood flow in the peri-lesional regions. Similarly, improved peri-lesional perfusion that we observed after acute tissue reperfusion can occur in the absence of angiogenesis.

We acknowledge that our study has certain limitations. For instance, transient mechanical vascular occlusion has been suggested not to be a fully adequate model of naturally occurring stroke (Hossmann, 2012) although, in our study, it was deemed appropriate in order to investigate the effect of reperfusion versus the permanent occlusion. In our work, comparisons are established between ipsi- and contralesional sides, thus assuming that the contralesional one does not show any major changes as previously described (Seevinck et al., 2010). However, we cannot discard that minor variations in the contralesional vasculature might take place. In addition, the differential contribution of local (angiogenesis) and/or peripheral (vasculogenesis) endothelial cells/progenitors to vascular outgrowth and remodeling as well as the contribution of recruited collaterals to the improvement of peri-lesional perfusion observed after acute recanalization have not been specifically addressed. It is known that vasculogenesis plays a role in post-stroke vascular remodeling (Hayakawa et al., 2012; Mao et al., 2014), but no correlation with restoration of local cerebral blood flow has been found so far. Regarding collateral circulation, the fact that injury size at 72 h after stroke was similar after pMCAO and tMCAO suggests that compensatory collateral perfusion may occur in the absence of reperfusion, as previously reported (Wei et al., 2001; Schaffer et al., 2006). A clinical study has shown that reperfusion following artery recanalization is a better prognostic marker of good outcome than of good collateral

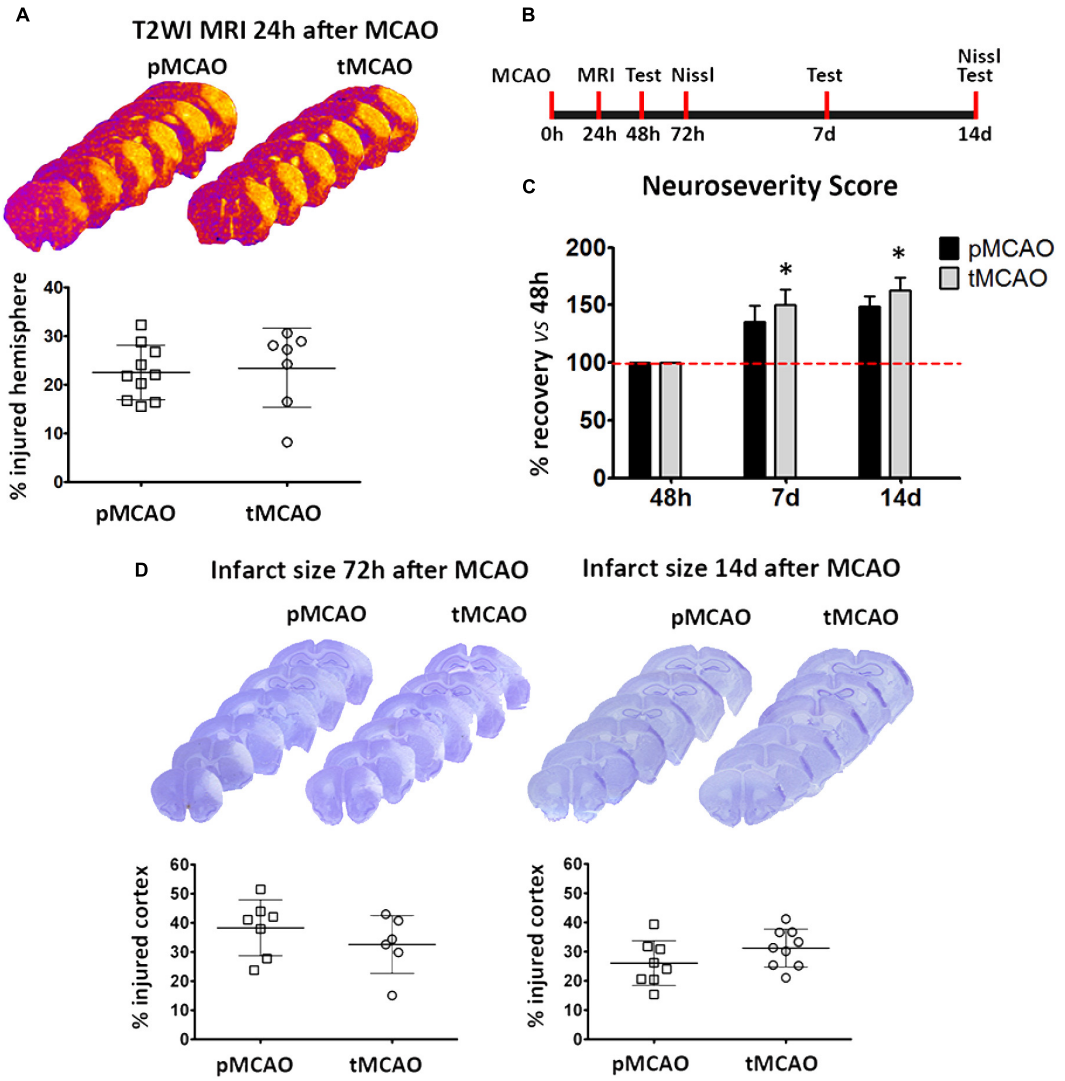

FIGURE 6 | (A) Representative series of T2WI-MRI planes and volumetric quantification showing infarct volumes at 24 h after pMCAO or tMCAO. **(B)** Schematic representation of the experimental design for the measurement of infarct volume and functional deficits after MCAO. **(C)** Data from functional assessment performed at 48 h (basal), 7 and 14 days after pMCAO or tMCAO (n = 7). **(D)** Representative series of Nissl-stained brain sections and corresponding graphs showing the extent of ischemic injury at 72 h and 14 days after permanent (pMCAO) or transient (60 min) middle cerebral artery occlusion (tMCAO). *Two-way ANOVA $p < 0.05$ vs. pMCAO.

circulation (Marks et al., 2014). Collaterals contribute to improve reperfusion following recanalization (Heiss et al., 1992; Darby et al., 1999; Kassem-Moussa and Graffagnino, 2002; Markus et al., 2004; Barber et al., 2005; Rha and Saver, 2007; Yemisci et al., 2009; Seevinck et al., 2010; Bang et al., 2011; Eltzschig and Eckle, 2011; Iadecola and Anrather, 2011; Hossmann, 2012; Liebeskind et al., 2014; Marks et al., 2014; Hill et al., 2015; Krueger et al., 2015; Smith et al., 2017), but to our knowledge a reverse effect of recanalization on collateral circulation has not been yet described. However, we acknowledge the possibility that leptomeningeal collateral remodeling induced by reperfusion may have contributed to the outcomes described here. As far as functional recovery is concerned, our study explores up to 14 days after MCAO; further studies are required to ascertain whether this effect remains at later time points. Finally, reperfusion in the tMCAO was assessed visually. Although this is a quite straightforward procedure when a craniectomy has been performed, as in our case, we acknowledge that this method lacks the resolution of laser Doppler flowmetry.

Our exploration of the injury scar has revealed interesting effects of acute recanalization, especially in what refers to the extracellular matrix composition and turnover. We focused on characterizing expression of the reactive astrocytes marker GFAP and the pericyte marker PDGFR-β, since recent studies have described that a specific subpopulation of pericytes characterized by the expression of this marker are the main source of stromal

cells forming the scar as a result of spinal cord injury (Göritz et al., 2011; Soderblom et al., 2013). While recanalization affected neither GFAP nor PDGR-β protein expression, collagen type-IV was much more abundant in the absence of acute reperfusion, as it was the expression of its degrading protease MMP-9 and its degradation fragments. Increased MMP-9 expression could be a response to higher accumulation of collagen-IV within the injury scar, which ultimately would interfere with tissue remodeling processes in spite of a higher local MMP-9 activity. While collagen type-IV is not a growth inhibitory molecule *per se* (Tonge et al., 1997; Joosten et al., 2000), collagen meshworks in the scar can allocate other inhibitory factors that preclude vascular and neural growth signaling (Hermanns et al., 2006; Klapka and Müller, 2006), effects that may have important consequences on the endogenous mechanisms of repair. In agreement with this hypothesis, an important observation of our study is that functional outcome in the long term (7–14 days) was improved in animals that underwent early recanalization. Since the size of the lesion was though not affected, our findings strongly support that recanalization-induced enhanced vascular function in the peri-lesional regions of these animals accounts for the long-term recovery observed. These observations open the path to a more complete characterization of the effect of acute reperfusion on injury scar formation and composition, with the functional relevance that these processes may have for tissue repair and functional recovery during the chronic phase after stroke.

MATERIALS AND METHODS

All data generated or analyzed during this study are included in this published article (and its **Supplementary Information Files**).

Animals

All experiments were performed in 3-month-old male C57bl/6 mice obtained from Jackson Laboratories. Mice were kept in a ventilated room with controlled temperature and with a 12-h dark/light cycle and were fed *ad libitum* with standard food and water. All experimental protocols had been approved by the Animal Welfare Committee of the Complutense University of Madrid and were in accordance to the guidelines of the Madrid Autonomous Community Government (RD 53/2013) following the European directives 86/609/CEE and 2003/65/CE. Results are reported according to ARRIVE guidelines. Details on the experimental design and number of animals used in each study are provided in **Supplementary Figure 1**.

Induction of Focal Brain Ischemia

Mice were anesthetized and maintained during surgery at 1–2% isoflurane in a 30%/70% mixture of O_2/N_2O and body temperature was maintained at physiological levels with a heating blanket during the surgery and anesthesia recovery. Mice were exposed to focal brain ischemia by distal occlusion of the middle cerebral artery (MCAO). To study the effect of acute reperfusion, two modes of occlusion were used after randomization: permanent middle cerebral artery occlusion (pMCAO, with no reperfusion) and transient MCAO (60 min occlusion followed by reperfusion, tMCAO). MCAO was achieved through ligation of the artery with a 9-0 suture just before its bifurcation into the frontal and parietal branches (Hernández-Jiménez et al., 2013). For tMCAO, the ligation was removed after 60 min and recanalization of the artery was visually assessed. The ipsilateral common carotid artery was also occluded permanently (pMCAO) or transiently (tMCAO) prior to ligation of the MCA. Researchers were blind to the experimental groups thereafter. After surgery mice were returned to their cages with *ad libitum* access to food and water. Mice were observed until anesthesia recovery and once a day until euthanasia. When appropriate, mice were euthanized with a lethal dose of pentobarbital or an overdose of isoflurane.

Experimental Groups

Mice were allocated in experimental groups by randomization by coin toss. A complete chart describing experimental groups, number of animals per group, dead animals (2 mice, 2%) and procedures can be found in **Supplementary Figures 1**, **2**.

Determination of Brain Infarct Size

Infarct size was determined at 24h by T2WI Magnetic Resonance. From 72h to 14d the injured tissue was measured by histological quantification on Nissl-stained serial sections.

T2WI Magnetic Resonance

MRI was performed on a 1 T benchtop MRI scanner [Icon (1T-MRI); Bruker BioSpin GmbH, Ettlingen, Germany]. The system consists of a 1 T permanent magnet (without extra cooling required for the magnet). Its gradient coil provides 450 mT/m. MRI experiments consisted of a series three dimensional T2 weighted images (T2WI) used to evaluate the vascular oedema. Three-dimensional T2WI were acquired using a rapid acquisition with relaxation enhancement (RARE) technique, with a repetition time (TR) = 2350 s, RARE factor = 16, and interecho interval = 15.83 ms, resulting in an effective echo time (TE) = 95 ms, number of average = 1, the field of view (FOV) = 16 × 16 × 8 mm. The acquired matrix size was 96 × 96 × 16 and the resolution 0.167 × 0.167 × 0.500 mm. Infarcts were visualized with the Image J software. The areas of infarcted tissue, the whole ipsilateral hemisphere, and the whole contralateral hemisphere were delineated in all consecutive sections. Data were corrected for edema and expressed as % of injured hemisphere by applying the formula $[(Vol_{Contra}\text{-}Vol_{UninjuredIpsi})/Vol_{Contra}] \times 100$.

Histology

Cryoprotected brains were sliced using a freezing microtome (Leica) and 30 μm serial sections covering the brain were obtained. Serial sections were stained with cresyl violet and infarct volume was measured stereologically (using the software StereoInvestigator, MicroBrightField) or by ImageJ analysis at 72 h and 14 days after MCAO. The contralateral cortex and the uninjured ipsilateral cortex were traced on 10 serial

sections (spaced 300 μm, covering approximately from bregma 1.3 to −2.3 mm) and volumes were calculated using the Cavalieri estimation obtaining a coefficient of error Gundersen ($m = 1$) < 0.05 in all cases. Infarct size was obtained by applying the formula for oedema correction [(Vol_{Contra}-$Vol_{UninjuredIpsi}$)/Vol_{Contra}] × 100 and was expressed as percentage of injured ipsilateral cortex.

Assessment of Neurological Deficits

Neuroseverity Score (James et al., 2009; Hernández-Jiménez et al., 2017) was used to measure functional deficits induced by MCAO in the mice. Motor activity score (Krupinski et al., 1993; Dimmeler et al., 1996; Kassem-Moussa and Graffagnino, 2002; Haga et al., 2003; Yamamoto et al., 2003; Chopp et al., 2007; Arkuszewski et al., 2009; Snapyan et al., 2009; Smith et al., 2017) is based on spontaneous activity, symmetry in the use of the limbs, equilibrium and coordination and sensory score (Krupinski et al., 1993; Dimmeler et al., 1996; Haga et al., 2003; Chopp et al., 2007; Thored et al., 2007; Arkuszewski et al., 2009; Snapyan et al., 2009) is based on tactile, vibrissae, visual and proprioceptive responses, that were measured in the contralateral side of the animalś; body. A minimum score of 7 reflects most severe neurological deficit and a maximum score of 21 reflects absence of deficits. The 48h measurement was taken as the basal value as we consider this time as the starting point of the angiogenesis process.

In vivo Blood-Brain Barrier Permeability Assay

Mice were injected intravenously with 2% Evans Blue (2 mg/kg, Sigma) 30 min before termination at 14 days after MCAO and perfused transcardiacally with saline solution until blood was removed from the system. Contralateral and ipsilateral cortices were collected, weighted and immediately flash-frozen. Cortices were then homogenized in 250 μl 1:2 saline/50% TCA solution and homogenates were centrifuged at 10000 g for 15 min. Supernatants were collected and loaded 1:4 in 95% ethanol on a 96-well plated. Fluorescence (620 nm excitation/680 nm emission) was measured using a fluorimeter. Lowest detection level limited by the current state of the technique was 0.1 μg/ml.

Immunofluorescence

Thirty micrometer-thickness brain serial sections were stained by free-floating immunofluorescence. Sections were incubated with primary antibodies (see **Table 1** for a list of antibodies, dilutions and conditions) in blocking solution (5% Normal Serum) overnight at 4°C and then incubated with secondary antibodies conjugated to the corresponding fluorophores. For proliferation analysis, BrdU (50 mg/kg) was injected intraperitoneally once daily following the experimental designs shown in **Supplementary Figure 2**. For BrdU staining sections were incubated with 2N HCl at 37°C for 30 min prior to incubation with the primary antibodies. For vessel perfusion analysis, *Lycopersicon esculentum* lectin was injected intravenously 20 min prior to animal sacrifice and observed by direct FITC fluorescence under the microscope.

Image Acquisition and Quantification

Regions of interest were defined as follows: infarcted cortex -where infarct rim was clearly visible in MRI images, and in Nissl (as shown in **Figure 1A**, by an abundant nuclei area) and immunofluorescence stainings (increased fluorescence background)- and mirroring region in the contralateral cortex (48 h, 72 h and 5 days), peri-lesional cortex (1 field immediately adjacent to the infarct rim, clearly visible by the presence of the glial scar) and the mirroring contralateral cortex (14 days). Representative images of the area comprising the infarct, the peri-infarct and the healthy tissue were taken with a 5× lens. Z-stacks used for perfusion quantification were captured using a 20x lens and analyzed volumetrically using Volocity software (Improvision). Close-up images were captured with a 40× oil-immersion lens. Vascular coverage was expressed as the sum of length of vessels (Glut-1^+ objects) per unit of volume. Vascular tortuosity was calculated separately for each object by the ratio length/longest axis, and average vascular diameter was obtained for each vessel and expressed as a diameter size distribution for the vessel population. Cell proliferation associated to vessels was calculated by the quantification of $BrdU^+$ cells with whole nuclear staining in contact with Glut-1^+ vessels. Quantification of variations in local perfusion was performed by the analysis of the fluorescence intensity of FITC-lectin in Glut-1^+ vessels following subtraction of background intensity. Images were captured under same exact conditions in the infarcted and contralateral cortex at sub-acute time points (72 h and 5 days)

and in the ischemic boundaries and the contralateral cortex at 14 days. Data are expressed as sum of values obtained from 6 different fields of view per region of interest in each animal.

Western Blot

Whole brain lysates were prepared from flash frozen samples by homogenization in 1x Lysis Buffer (Cell Signaling) containing protease inhibitors (Roche). Western blot membranes were obtained after PAGE-SDS and protein transfer to PVDF membranes. Membranes were incubated with primary antibodies (see **Table 1** for list of antibodies, dilutions and conditions) in 5% non-fat milk in 0.2% Tween-20 TBS and HRP-conjugated secondary antibodies. Band intensity was measured by ImageJ, and data are expressed by normalization to values in the uninjured contralateral tissue due to the high variability between individuals. For that reason, the contralateral tissue was used as internal control in **Figures 3C**, **4C**, **5A**. In **Figure 3D** data are expressed by normalization with actin.

Statistical Analysis

Data were expressed as mean ± SD. Data sets were tested for normality (Kolmogorov-Smirnoff test). Student's *t*-test was used for comparison of two datasets and one- or two-way ANOVA was used for comparison of multiple datasets and variables. For comparisons against a defined value (eg.- ratio/ipsi contra = 1) a one-sample *t*-test was used. A p-value < 0.05 was considered statistically significant.

DATA AVAILABILITY

No datasets were generated or analyzed for this study.

ETHICS STATEMENT

All experimental protocols had been approved by the Animal Welfare Committee of the Complutense University of Madrid, and were in accordance to the guidelines of the Madrid Autonomous Community Government (RD 53/2013) following the European directives 86/609/CEE and 2003/65/CE. Results are reported according to ARRIVE guidelines.

AUTHOR CONTRIBUTIONS

DF-L, VD-L, MÁM, and IL designed the research. VD-L, DF-L, JG-H, AM, AG-C, SP-T, IG-Y, and AV-P performed the research. VD-L, DF-L, IG-Y, and AV-P analyzed the data. DF-L, MÁM, and IL wrote the manuscript. All authors reviewed the manuscript.

FUNDING

This work was supported by grants from the Spanish Ministry of Economy and Competitiveness SAF2015-68632-R (MÁM) and CSD2010-00045 (MÁM), from the Instituto de Salud Carlos III (ISCIII) and co-financed by the Fondo Europeo de Desarrollo Regional (FEDER) "A way to achieve Europe" FIS PI17/01601 (IL) and RETICS RD16/0019/0009 (IL), and from Regional Madrid Government B2017/BMD-3688 (IL).

Front. Neurosci. 13:728. doi: 10.3389/fnins.2019.00728

Neurodegenerative diseases are among the leading causes of disability and death worldwide. The disease-related socioeconomic burden is expected to increase with the steadily increasing life expectancy. In spite of decades of clinical and basic research, most strategies designed to manage degenerative brain diseases are palliative. This is not surprising as neurodegeneration progresses "silently" for decades before symptoms are noticed. Importantly, conceptual models with heuristic value used to study neurodegeneration have been constructed retrospectively, based on signs and symptoms already present in affected patients; a circumstance that may confound causes and consequences. Hence, innovative, paradigm-shifting views of the etiology of these diseases are necessary to enable their timely prevention and treatment. Here, we outline four alternative views, not mutually exclusive, on different etiological paths toward neurodegeneration. First, we propose neurodegeneration as being a secondary outcome of a primary cardiovascular cause with vascular pathology disrupting the vital homeostatic interactions between the vasculature and the brain, resulting in

cognitive impairment, dementia, and cerebrovascular events such as stroke. Second, we suggest that the persistence of senescent cells in neuronal circuits may favor, together with systemic metabolic diseases, neurodegeneration to occur. Third, we argue that neurodegeneration may start in response to altered body and brain trophic interactions established via the hardwire that connects peripheral targets with central neuronal structures or by means of extracellular vesicle (EV)-mediated communication. Lastly, we elaborate on how lifespan body dysbiosis may be linked to the origin of neurodegeneration. We highlight the existence of bacterial products that modulate the gut-brain axis causing neuroinflammation and neuronal dysfunction. As a concluding section, we end by recommending research avenues to investigate these etiological paths in the future. We think that this requires an integrated, interdisciplinary conceptual research approach based on the investigation of the multimodal aspects of physiology and pathophysiology. It involves utilizing proper conceptual models, experimental animal units, and identifying currently unused opportunities derived from human data. Overall, the proposed etiological paths and experimental recommendations will be important guidelines for future cross-discipline research to overcome the translational roadblock and to develop causative treatments for neurodegenerative diseases.

Keywords: lifespan, vascular pathology, senescence, body–brain trophism, dysbiosis

INTRODUCTION

Neurological disorders are the leading cause of disability-adjusted life-years and the second-leading cause of deaths worldwide. This burden has increased substantially over the past 25 years because of expanding population numbers and aging (GBD 2015 Neurological Disorders Collaborator Group, 2017) and will continue to grow in the coming decades due to the further increase in life expectancy.

At intermediate and advanced stages, frequently by the time a diagnosis is made, neurodegeneration has affected higher brain areas that control cognitive, sensory, and motor functions. Because the majority of cases are seen by the age of 50 or older in both men and women, many scientists think of neurodegenerative diseases as processes that reflect abnormal aging. Likewise, since neurodegeneration involves the loss of neuronal populations brain-wide, many researchers believe that neuronal death results from altered processes intrinsic to the nervous system, such as neuroinflammation, abnormal accumulation or deteriorated clearance of toxic proteins, and reduced anti-oxidative defenses.

Hence, current explicative models of neurodegenerative diseases account for signs and symptoms already seen in affected patients. In fact, the majority of these causative models have been formulated in retrospect, based on what is already present in the patient's brain. Given the nature of these models, it is difficult to identify real causes from mere consequences and epiphenomena. This is even more puzzling given that neurodegenerative diseases are life-spanning processes that start silently at least 20 to 30 years before the pathological signs and symptoms are recognized by patients and diagnosed by physicians. In addition, accumulating information suggests an extraneural origin of neurodegeneration.

Clearly, the essential premises guiding research on neurodegenerative diseases seem at least partly incorrect and somewhat misleading. This may explain why, despite researchers' best efforts, neurodegeneration is still a growing health concern and the reason why therapeutic measures are currently palliative, while preventive approaches are often ineffective (Crous-Bou et al., 2017; Hsu and Marshall, 2017; Klein and Tyrlikova, 2017).

Here, we outline four different paths as the basis for a paradigm shift toward an etiologic view on neurodegeneration: (1) the vascular origin of neurodegeneration, (2) cellular senescence as the origin of neurodegeneration, (3) body–brain trophic interactions as the origin of neurodegeneration, and (4) lifespan gut dysbiosis as the origin of neurodegeneration. We did not cover here genetic components as risk factors for neurodegeneration, a comprehensive analysis of which can be found elsewhere (Brainstorm et al., 2018). We provide concrete recommendations on how to investigate the discussed etiological paths experimentally in future studies. This work is the result of the discussions that took place during the German-Mexican Roundtable Exploring New Etiological Paths Towards Neurodegeneration in October 2018.

THE VASCULAR ORIGIN OF NEURODEGENERATION

Neurons depend on blood vessels to deliver oxygen and nutrients, for the removal of carbon dioxide and other by-products of metabolism from the brain's interstitial space, which helps to maintain the homeostasis of the cerebral microenvironment. Therefore, to function properly, it is thought that the cerebral circulation has developed adaptive mechanisms to provide the

trophic molecules and energy substrates needed for neuronal cells at different times and regions, depending on neural activity (Girouard and Iadecola, 2006).

The recognition of these mechanisms led to the concept of neurovascular coupling (Roy and Sherrington, 1890), which refers to the dynamic functional change in cerebral blood flow that occurs in response to local neuronal activity (Dirnagl, 1997; Kisler et al., 2017; Villringer, 1997). This response increases cerebral blood flow within the activated brain regions to fulfill energy demands in a process known as functional hyperemia.

The main players of these dynamic adjustments in the cerebral blood flow are neurons, glia, and vascular cells. All of them come together in a functional morphological entity termed the "neurovascular unit". This view explains why cerebrovascular diseases linked to neurodegeneration are considered as stand-alone etiopathological states (Przedborski et al., 2003; Brown et al., 2005). Vascular diseases, however, may be the forerunners of neurodegeneration. In support of this, it has been shown that shifts in blood pressure lead neurons to adjust the excitability thresholds according to brain perfusion levels, safeguarding their homeostasis. Hence, vascular diseases may occur first and then later neurodegeneration may follow, if the process of neurovascular coupling proceeds ineffectively (Moore and Cao, 2008; Kim et al., 2016).

Cerebral blood vessels originate from large cerebral arteries arising from the circle of Willis. As they find the way through the brain, large cerebral arteries divide into pial arteries and arterioles, which grow gradually deeper and form the penetrating arteries and arterioles that become progressively smaller until they turn into cerebral capillaries (Wittko-Schneider et al., 2014). The development of nerves and astrocytes originating from central and peripheral sources is closely associated with cerebral arteries, arterioles, and capillaries as demonstrated by the observation that the inhibition of angiogenesis during development is accompanied by severe developmental defects in specific regions of the central nervous system (CNS) (Hallene et al., 2006). This highlights the importance of blood vessels during brain formation.

There are different steps and mediators underlying neurovascular coupling. Briefly, neurons and interneurons are responsible for the initiation and modulation of the vascular response by the activation of NMDA and AMPA receptors, which leads to an increase of intracellular Ca^{2+} and calcium-dependent enzymes that exert effects on the endothelium, astrocytes, and pericytes. Because of their close association with synapses and microvessels, astrocytes are in charge of the neurovascular transmission of signals to the capillaries and arterioles while endothelial cells exert a retrograde propagation of vasomotor responses to regulate cerebral blood flow (Iadecola, 2017). The endothelium also regulates the vascular tone by releasing potent relaxing and contracting factors that readjust the vascular musculature and maintain a healthy homeostasis of the vascular wall.

Nitric oxide (NO), prostacyclins, endothelial-derived hyperpolarizing factor (EDHF), and endothelin have been proposed as the main vasoactive factors related to the endothelial response to neural activity. NO promotes the vasodilation of cerebral blood vessels by stimulating soluble guanylate cyclase in the vascular muscle, leading to an intracellular increase of cGMP and relaxation (Schmidt and Walter, 1994). NO is generated by three different isoforms of the enzyme NO synthase (NOS): neuronal (nNOS), inducible (iNOS), and endothelial NOS (eNOS).

In the CNS, nNOS is mainly located in neurons, astrocytes, and neuronal stem cells and has been implicated in synaptic plasticity and in the central control of blood pressure. Abnormal NO signaling is likely to contribute to a variety of neurodegenerative pathologies such as excitotoxicity following stroke, multiple sclerosis (MS), Alzheimer's disease (AD), and Parkinson's disease (PD) (Calabrese et al., 2007).

iNOS expression had initially been shown for macrophages, but it is now clear that it can be induced by cytokines in a variety of cell types in the context of inflammation (Li et al., 1991). During episodes of acute inflammation, the role of NO appears to be protective, while chronic iNOS expression is detrimental. The high levels of NO produced by activated macrophages and other cells may not only be toxic to microbes, parasites, or tumor cells, but may also harm healthy cells (Wong and Billiar, 1995).

Endothelial NOS is mostly expressed in endothelial cells, although the isozyme has been detected in certain neurons of the brain (Caviedes et al., 2017). eNOS-derived NO is a well-known physiological vasodilator and an inhibitor of platelet aggregation and adhesion, but it also inhibits leukocyte adhesion and vascular inflammation, controls vascular smooth muscle proliferation, stimulates angiogenesis, and activates endothelial progenitor cells (Forstermann and Sessa, 2012).

In addition to the production and release of NO, cyclooxygenase produces prostacyclin, which induces the relaxation of cerebral vessels by the activation of adenylate cyclase with the accumulation of cAMP and the activation of potassium channels. Similarly, in large cerebral arteries, the production of EDHF by the cytochrome P-450 monooxygenase metabolism of arachidonic acid causes relaxation by hyperpolarizing the underlying vascular muscle through the activation of potassium channels. The contribution of EDHF increases as the vessel size decreases, with a predominance of EDHF activity in resistance vessels and a compensatory upregulation of hyperpolarization in states characterized by reduced NO availability (Ozkor and Quyyumi, 2011).

Besides vasodilatory factors, under certain conditions, the cerebral endothelium produces vasoconstrictive substances such as endothelins leading to a potent and long-lasting contraction of cerebral vessels dependent on extracellular calcium and the activation of protein kinase C (Faraci and Heistad, 1998).

The alterations of any of the cellular players involved in the neurovascular unit may impair its coupling and functional hyperemia, resulting in an alteration of homeostasis leading to brain dysfunction (Iadecola, 2004).

Heart and Vascular Diseases and the Origin of Neurodegeneration

According to the World Health Organization, cardiovascular diseases (CVDs) lead to one-third of all annual deaths globally,

which is about 17.9 million total deaths (Lim et al., 2012). CVDs are disorders of the heart and blood vessels and include among others coronary heart disease, cerebrovascular disease, and rheumatic heart disease. A large number of studies have reported a strong relationship between indices of vascular pathology (such as carotid intima-media thickness, arterial stiffness, and small-artery remodeling) and cognitive impairment and neurodegeneration (Gorelick et al., 2011).

Because the factors contributing to vascular pathology are often preventable or treatable, targeting them may prove useful for preventing or delaying the onset of neurodegenerative diseases. Epidemiological studies show that treating hypertension and hyperlipidemia reduces the incidence of neurodegenerative diseases (Larsson and Markus, 2018) and slows down the rate of cognitive impairment (Deschaintre et al., 2009). Here, we will focus on the main CVDs known to promote changes in the cerebral microvasculature that lead to neurodegeneration in the long run.

Hypertension

Hypertension – or blood pressure at or beyond 130 mmHg/80 mmHg (systolic/diastolic blood pressure) according to the 2017 American College of Cardiology/American Heart Association guidelines (Whelton et al., 2018) – affects one billion people worldwide and leads to nine million deaths every year (Lim et al., 2012). In normotensive individuals, cerebrovascular autoregulation counteracts the cerebrovascular effects of the fluctuations in arterial pressure that occur during normal activities. Cerebral arteries relax when arterial pressure decreases and constrict when arterial pressure rises. The role of this vascular adjustment is the maintenance of a stable cerebral perfusion despite changes in systemic arterial pressure.

Hypertension alters cerebrovascular autoregulation (Sadoshima et al., 1983) by impairing endothelium-dependent relaxation (Faraci and Heistad, 1998). Hypertension promotes vascular hypertrophy, remodeling, and atherosclerosis in large cerebral arteries and lipohyalinosis in penetrating arterioles. These changes are damaging because they reduce the lumen of the vessel and increase vascular resistance (Dickinson, 2001). In humans, longstanding hypertension induces the deposition of collagen and fibronectin as well as elastin fragmentation, leading to an increased stiffness of the wall of large arteries (Henskens et al., 2008). Hypertension also affects neurovascular coupling as shown by a reduction in the normal increase in cerebral blood flow elicited in the posterior parietal and thalamic areas during cognitive tasks in patients with chronic untreated hypertension relative to normotensive individuals (Jennings et al., 2005).

The disruption of the adjustment mechanisms by a sustained increase in the blood pressure has been linked to different neurodegenerative diseases such as stroke (MacMahon et al., 1990). Hypertension is also considered an important modifiable risk factor for late-life cognitive decline and non-amnestic mild cognitive impairment in the mid-aged population (Knopman et al., 2001; Reitz et al., 2007). The Honolulu Asia aging study demonstrated an association between elevated levels of blood pressure in middle age and vascular dementia (Launer et al., 2000).

Atherosclerosis

Atherosclerosis, a progressive disease, characterized by the accumulation of lipids and fibrous elements in the large arteries, is a major cause of heart disease and stroke (Banerjee and Chimowitz, 2017).

The damage leading to atherosclerosis is elicited over years and is highly influenced by lifestyle. The pathogenic sequence starts with the recruitment of circulating monocytes into the intima, where they differentiate into macrophages and internalize modified lipoproteins to become foam cells (fat-laden M2 macrophages). Then, chemokines and growth factors induce the proliferation of neighboring smooth muscle cells and the synthesis of extracellular matrix components within the intimal compartment, generating a fibromuscular plaque that undergoes progressive structural remodeling resulting in the formation of a fibrous cap, overlying a lipid-rich, necrotic core accompanied by varying degrees of matrix remodeling and calcification (Lusis, 2000). If a rupture of the plaque occurs, the highly thrombogenic contents of the necrotic core are released to the lumen of the vessel, promoting atherothrombotic occlusion.

Epidemiological and post-mortem studies have shown that the atherosclerosis of the arteries that supply the brain is associated with a two- to threefold increased odds of dementia (Hofman et al., 1997; van Oijen et al., 2007; Wendell et al., 2012; Dearborn et al., 2017). Interestingly, this association is independent of the effects of cerebral infarction (Dolan et al., 2010), which can result from the atherosclerosis-induced occlusion of vessels.

Cerebral Small-Vessel Disease

Cerebral small-vessel disease comprises white matter lesions (WMLs), lacunar infarcts, and cerebral microbleeds and is a frequent neuroimaging finding (best seen on magnetic resonance images) in elderly people (de Leeuw et al., 2001).

Factors such as arterial stiffness, also related to aging and hypertension, are considered to expose the small vessels in the brain to highly pulsatile pressure and flow (Poels et al., 2012). This causes thickening of the arterial media of these vessels, which gradually narrows the lumen. In addition, atherosclerotic plaques in large arteries can encroach on the origins of smaller arteries, blocking the blood flow to areas supplied by these arteries. Subcortical white matter is particularly susceptible to such changes, as its blood supply depends on small arteries that get progressively smaller as they descend from the cortex to the deeper parts of the brain. Hypoxia ensues, causing edema, demyelination, and infarction of the white matter.

Cerebral small-vessel disease is associated with an increased risk of cognitive decline, dementia, stroke, balance disturbances, and parkinsonism (Bohnen and Albin, 2011). Individuals with an identical WML pattern present clinically heterogeneous complaints in cognitive and motor performance, ranging from no complaints to dementia and parkinsonism, which means other factors determine the cognitive or motor outcome (de Leeuw et al., 2001). Possible explanations for this heterogeneity are the lack of sensitivity of conventional magnetic resonance imaging to the early loss of microstructural integrity in the normal-appearing white matter (Scheltens et al., 1995), the disagreement on how lesions underlying small-vessel disease

are classified (Wardlaw et al., 2013), and the efficiency of compensation mechanisms that prevent further cognitive and motor deterioration (Mondadori et al., 2006).

Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia affecting 1 to 2% of the general population (Andrade et al., 2014). AF is characterized by disturbances that promote ectopic firing and reentrant mechanisms that lead to impaired atrial function [for a review on the pathophysiology of AF, refer to (Andrade et al., 2014)].

AF can lead to reduced cardiac output, intermittent cerebral hypoperfusion, and transient hypertension in the cerebral capillaries (Anselmino et al., 2016). Such changes have been suggested as possible mediators of AF-related brain damage. On the other hand, AF may be a manifestation of a broader systemic illness that involves widespread inflammation and platelet activation, which can also lead to impaired cerebrovascular function (Dietzel et al., 2018).

AF is associated with increased morbidity and mortality and has long been known as one of the main risk factors for embolic stroke (Kamel et al., 2016). It is now also considered a risk factor for dementia. de Bruijn et al. (2015) analyzed the association of prevalent and incident AF with incident dementia in 6514 dementia-free patients, revealing not only a positive association between AF and the development of dementia but also that the association was strongest for younger participants with the longest duration of AF. These findings have been replicated by several studies (Nishtala et al., 2018), some of which have shown that the association between AF and dementia is independent of the occurrence of embolic stroke (Ryden et al., 2019) and the use of anticoagulants (Graves et al., 2017). Future investigation will determine if optimal treatment of AF can prevent or postpone cognitive decline and dementia.

Vascular Pathology in Neurodegenerative Diseases

The link between vascular risk factors and neurodegenerative disease is strengthened by the evidence showing that vascular and neurodegenerative pathophysiological changes often co-exist in patients with a diverse spectrum of neurodegenerative diseases. Several lines of evidence even suggest that vascular mechanisms are *directly* involved in the pathophysiology of neurodegenerative diseases.

The event that triggers the onset of a stroke, such as the rupture of an atherosclerotic plaque, the embolization of a blood clot, or the damage to a vessel and subsequent bleeding, is often preceded by vascular pathophysiological changes that accumulate over time. One of the earliest changes is endothelial dysfunction induced by oxidative stress (Roquer et al., 2009), which occurs as a result of the aforementioned cerebrovascular risk factors. Immediately after the onset of stroke, a series of overlapping pathophysiological changes occur leading to neuronal death within and beyond the initial area of damage. These include critically low blood flow, the accumulation of free oxygen radicals, the sustained or spreading depolarization of neurons, acidosis, tissue inflammation, damage to the blood–brain barrier (BBB), and regulated cell death (Mergenthaler et al., 2004).

The same vascular mechanisms that lead to acute stroke can also lead to cognitive impairment (Popa-Wagner et al., 2010). In the condition known as vascular dementia (or vascular cognitive impairment), the consequences of these pathophysiological changes are the primary cause of neurodegeneration. They include the development of multiple or strategically located infarcts, damage to the myelin sheath and axons, small cerebral hemorrhages, chronic cerebral hypoperfusion, and brain atrophy (Iadecola, 2013). Each of these represents damaged tissue, and the accumulation of damage eventually manifests as cognitive impairment (Gorelick et al., 2011).

Vascular pathology leading to white matter damage, manifesting as WML, seems to play a particularly important role in the pathogenesis of vascular dementia (Iadecola, 2013). Very often, however, both vascular and neurodegenerative changes contribute to the development of dementia, resulting in a condition known as "mixed" dementia.

The link between vascular pathology and neurodegeneration has also been thoroughly studied in AD. Vascular damage, initiated by vascular and genetic predisposing factors, precedes the accumulation of beta-amyloid (Aβ), which eventually leads to neurodegeneration in AD (Nelson et al., 2016). Neuroimaging studies support this theory, showing that reduced CBF and abnormal neurovascular coupling occurs in elderly people at the risk of AD before they show the hallmarks of the disease such as brain atrophy, cognitive impairment, or accumulation of Aβ (Smith et al., 1999; Bookheimer et al., 2000; Ruitenberg et al., 2005).

Vascular damage may facilitate neurodegeneration by altering a major route through which substances are cleared from the interstitial space of the brain parenchyma. This route is known as the glymphatic system, which facilitates the movement of fluid from perivascular (Virchow-Robin) spaces surrounding pial arterioles to the interstitium into spaces surrounding the brain's deep veins and then to the cervical lymph nodes (Jessen et al., 2015).

Vascular risk factors cause blockages in and around small arteries, which can manifest as an enlargement of the perivascular spaces (Gouw et al., 2011) that are visible on structural magnetic resonance images (Wardlaw et al., 2013). These enlarged spaces are a sign of impeded interstitial fluid flow and hence impaired clearance of substances from the brain parenchyma, and have been linked to an increased risk of dementia (Buerge et al., 2011; Ramirez et al., 2015) and stroke (Mills et al., 2007; Selvarajah et al., 2009).

Interestingly, the spatial distribution of these enlarged perivascular spaces has been linked to different underlying pathologies. A predominant distribution in the basal ganglia indicates vascular disease caused by hypertension (Selvarajah et al., 2009; Charidimou et al., 2013), while a white matter distribution is related to cerebral amyloid angiopathy (Martinez-Ramirez et al., 2013; Charidimou et al., 2014), caused by the accumulation of Aβ protein in the walls of the cerebral and meningeal vessels.

Cerebral amyloid angiopathy, which leads to intracerebral hemorrhage that aggravates the cognitive impairment (Cordonnier, 2011), is found in more than 80% of AD patients (Jellinger, 2010). Aβ itself is a potent vasoconstrictor (Thomas et al., 1996), worsening the hypoperfusion, which, if severe enough, directly injures neurons. However, even milder hypoperfusion alters protein synthesis and plays a role in neurodegeneration (Iadecola, 2004). The critical role of hypoperfusion is supported by the evidence that the induction of chronic global hypoperfusion in animal models causes memory impairment, the accumulation of Aβ, and synaptic dysfunction (Walsh et al., 2002; Koike et al., 2010; Wang et al., 2010).

Blood–brain barrier dysfunction, which involves damage to pericytes and endothelial tight junction molecules, has been observed in several neurodegenerative diseases, including AD, PD, amyotrophic lateral sclerosis (ALS), and Huntington's disease (Zlokovic, 2008; Chao et al., 2009; Duran-Vilaregut et al., 2009; Henkel et al., 2009; Kalaria, 2010; Alvarez et al., 2011). Vascular damage worsens the situation, both by leading to further BBB dysfunction and because low blood flow traps potentially neurotoxic proteins such as Aβ that pass through the leaky barrier. These proteins, which include immunoglobulins, plasmin, thrombin, and albumin, further reduce blood flow and cause vasogenic brain edema, oxidative stress, and axonal demyelination (Chen and Strickland, 1997; Mhatre et al., 2004; Farrall and Wardlaw, 2009; Chen et al., 2010). In patients, this BBB dysfunction is detectable using neuroimaging and the analysis of the biomarkers of neurodegenerative diseases in the cerebrospinal fluid (Olsson et al., 2016; Sweeney et al., 2018).

The presence and severity of vascular damage occurring at the cellular and molecular level, affect the clinical course of neurodegenerative diseases. Large neuropathological studies show the post-mortem presence of infarcts, lacunes, leukoencephalopathy, atherosclerosis, or hemorrhages in 80% of AD patients compared to 67% of similarly aged people without cognitive impairment (Toledo et al., 2013).

Interestingly, the effects of vascular pathology and neurodegeneration on cognitive decline seem to be synergistic, particularly in patients with moderate AD pathology (Zekry et al., 2002; Choi et al., 2011; Lee et al., 2014). Studies show that the worse the vascular pathology in patients with AD, the worse the cognitive impairment (Snowdon et al., 1997; Song et al., 2007; White, 2009). AD patients with infarcts or microangiopathic white matter disease also experience faster cognitive decline (Silvestrini et al., 2006; Helzner et al., 2009).

CELLULAR SENESCENCE AS THE ORIGIN OF NEURODEGENERATION

Since a main feature of aging is the accumulation of senescent cells in various tissues (van Deursen, 2014; Calcinotto et al., 2019), cellular senescence has emerged as a key potential contributor to neurodegenerative and cerebrovascular diseases (Baker and Petersen, 2018; Kritsilis et al., 2018).

Cellular senescence is a phenotype characterized by a durable cell cycle withdrawal (i.e., cells do not respond to mitogens), associated with the expression of tumor suppressors $p21^{CIP1/WAF1}$ (encoded by *Cdkn1a*) and/or $p16^{INK4A}$ (encoded by *Cdkn2a*), as well as by apoptosis resistance (**Figure 1**). Senescent cells display a flattened and vacuolated morphology with abundant stress granules and accumulate lipofuscin. There is a persistent DNA damage response commonly detected by the presence of γH2AX foci, while the most common feature is an increase in the lysosomal activity of the enzyme senescence-associated beta galactosidase isoform (SA-B-Gal), which has been widely used for their detection. Some senescent cells exhibit a formation of senescence-associated heterochromatin

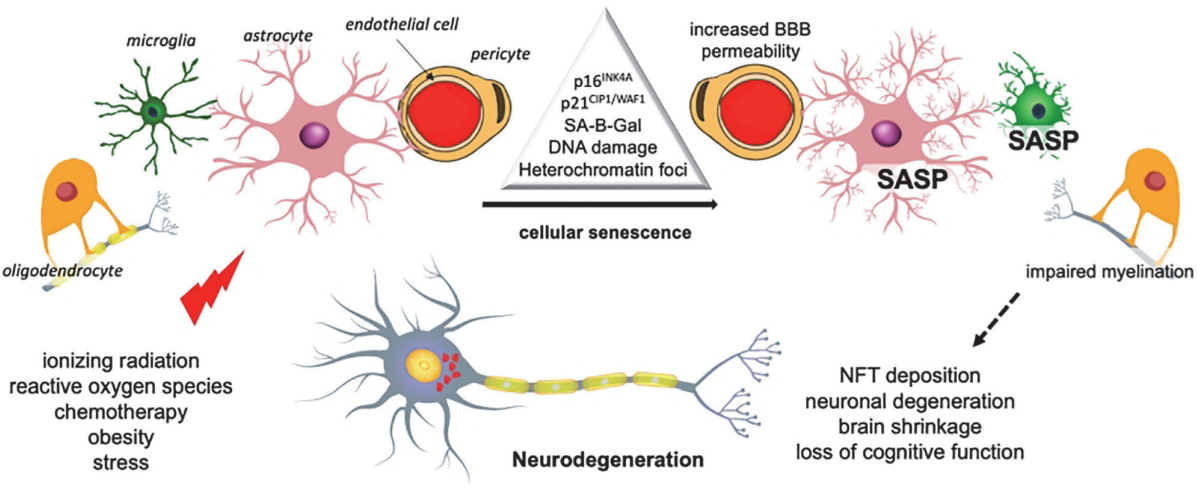

FIGURE 1 | Senescence-mediated neurodegeneration. Cellular senescence can be induced by several stimuli in the different brain cells. Senescence of microglia and astrocytes results in inflammation and the loss of trophic support. Oligodendrocyte senescence reduces myelin, which affects transmission and the BBB may be compromised by endothelial cells senescence. These changes have an impact on the integrity and viability of neurons and ultimately brain function [based on Chinta et al. (2015)]. SASP, senescence-associated secretory phenotype.

foci (SAHF), which are domains enriched in the transcription-silencing histone H2A variant, macroH2A.

However, the most important feature of senescent cells is the secretion of pro-inflammatory cytokines, growth factors, extracellular enzymes, and metalloproteases, collectively known as senescence-associated secretory phenotype (SASP) (Chow and Herrup, 2015; Ask et al., 2018). In early stages, the secretion of cytokines by senescent cells promotes the migration and infiltration of effector immune cells and the secretion of growth factors and proteases, which facilitate tissue repair and remodeling (Munoz-Espin and Serrano, 2014; Davaapil et al., 2017).

Yet, persisting cytokine signaling, as occurs in aging, contributes among other processes to chronic inflammation (*inflammaging*), a major contributor to age-related dysfunctions. SASP molecules also have an autocrine role, fostering the senescent phenotype, and a paracrine role inducing senescence in surrounding cells (Coppe et al., 2010). Notably, during aging, senescent cells accumulate and persist in different organs, including the brain, and are associated with the onset of several diseases (Munoz-Espin and Serrano, 2014).

To avoid confusion, it is however important to differentiate between aging, often termed "senescence" and cellular senescence. Aging is featured by an accumulation of senescent cells, but not all aged cells have the unique cellular senescence phenotype. Further investigations are needed to understand why senescent cells accumulate with aging, perhaps involving a combination of immune system malfunction failing to eliminate them, with changes in senescent cells themselves so that they become less efficiently recognized.

Senescence in Neurodegenerative Diseases

More recent *in vitro* and *in vivo* evidence strengthens the hypothesis of cellular senescence as causative of neurodegeneration. Dysfunctional astrocytes with senescent hallmarks have been detected in post-mortem human brain tissue from patients with ALS, PD, and AD (Bhat et al., 2012; Chinta et al., 2015, 2018; Turnquist et al., 2016). Mouse models and *in vitro* studies provide further evidence of senescence in microglia (Bussian et al., 2018), endothelial cells (Broadwell, 1989), neural stem cells and possibly oligodendrocytes (Kritsilis et al., 2018), which may contribute to neurodegenerative disorders.

Moreover, several senescent features have recently been described in studies of both physiological aging and neurodegenerative diseases using different models, including AD, PD, MS, and stroke (Kritsilis et al., 2018; Walton and Andersen, 2019), supporting the idea that cellular senescence may contribute to neurodegeneration and cerebrovascular disease in a far-reaching way (reviewed by Baker and Petersen, 2018; Walton and Andersen, 2019).

In a recent publication, using weighted gene co-expression analysis, Mukherjee et al. (2019) found a microglial signature of 17 genes that are strongly related with both aging and neurodegenerative diseases, not only in human brains but also in neurodegenerative murine models. An early study from Bhat et al. (2012) suggested that $p16^{INK4A}$-positive astrocytes may increase the risk for sporadic AD, since the prefrontal cortex of AD patients harbors a significant increase of senescent astrocytes expressing $p16^{INK4a}$ and matrix metalloproteinase-1 (MMP-1).

Also, the *in vitro* exposure of astrocytes to $A\beta_{1-42}$ triggers senescence, leading to the secretion of pro-inflammatory cytokines, including interleukin 6 (Bhat et al., 2012). Chinta and colleagues also demonstrated an increase of senescent astrocytes in brain tissue from PD patients, and found that cultured murine and human astrocytes exposed to paraquat (an herbicide associated with sporadic PD) become senescent. Interestingly, the depletion of senescent cells diminished neurodegeneration (Chinta et al., 2018), suggesting that senescence may be the cause, not the consequence of neurodegeneration.

Cellular senescence has also been considered as a therapeutic target in MS (Oost et al., 2018). Although MS is regarded as a classical autoimmune disease, it has been hypothesized that the driver of the autoreactive immune response in MS is actually a primary neurodegenerative process (Trapp and Nave, 2008). The senescence of microglia, T-cells, astrocytes, endothelial cells, and oligodendrocytes, among other cell types, is implicated in MS pathophysiology (Oost et al., 2018). Even though no study has been conducted for senescent cell detection on post-mortem tissue of MS patients, there is initial evidence in animal models about the role of cellular senescence on MS progression (Oost et al., 2018).

Senescence and Synaptic Plasticity

Another common hallmark of neurodegenerative pathologies is the alteration in synaptic structure and function during the early stages of the disease, which is related to subcellular reorganization preceding cell loss. The mechanisms underlying these pathologies are not fully understood. In fact, a decline in synaptic plasticity may be linked to the phenomenon of senescence. Unfortunately, there are only a few studies that have investigated the effect of senescence on the synaptic machinery. However, there is growing evidence of the changes in neuroplasticity caused by inflammation, oxidative stress, and protein misfolding, that may be linked to SASP action as well as the influence of senescence in glial cells, which are associated with an impairment in the neuroplasticity machinery (Gan et al., 2018).

The hippocampus has been pointed out as a brain structure with high plasticity and prone to neurodegeneration with age (Kreutzmann et al., 2015). The neurogenic capacity of the hippocampal dentate gyrus is reduced during aging. This reduction correlates with an impairment in memory formation and is accompanied by other changes, such as an increase of pro-inflammatory cytokines as well as a reduction of neurotrophic and vascular factors (Seib and Martin-Villalba, 2015; Fan et al., 2017).

Aging is also associated with changes in the hippocampal perforant pathway and its synapses, with the dentate gyrus being particularly affected (Wenk and Barnes, 2000). A decrease of synapses and changes in the morphology of dendrites and their spines have been linked to atrophy and a dysfunction of the aged hippocampus (Rogers et al., 1984). A synapto-proteome

study in old animals revealed a general decrease in the expression of neurotransmission regulation proteins, such as post-synaptic density 95, synaptosomal nerve-associated protein 25, shiga toxin 1, synapsin 1 and 2, synaptophysin, and vesicle-associated membrane protein (Wang et al., 2007; VanGuilder et al., 2010; Orock et al., 2019).

Moreover, a recent breakthrough paper, using a classical model of neurodegeneration, shows the accumulation of senescent astrocytes and microglia, but not neurons, in the brains of mice overexpressing human TauP301S. The genetic clearance of senescent glial cells prevented neurofibrillary tangle (NFT) deposition, the degeneration of hippocampal neurons, brain shrinkage, and the thinning of the dentate gyrus, thus preserving cognitive function. The transgenic mice that did not undergo a senescent transformation of microglia cells maintained their cognitive functions (Bussian et al., 2018).

Interestingly, neurogenesis and learning and memory can be impaired when blood and plasma from aged animals are transfused to young animals, showing that systemic factors can affect brain integrity. This phenomenon may be related to chemokine levels, especially the C–C Motif Chemokine Ligand 2 (CCL2), an important SASP component (Villeda et al., 2011). It is possible that when senescent astrocytes accumulate, they release SASP factors that lead to NFT deposition and other neurodegenerative hallmarks in surrounding neurons, oligodendrocytes, microglia, and endothelial cells (**Figure 1**). Investigating senescent cell accumulation in the periphery and in the nervous system should help to understand the process of aging of the brain and, more importantly, neurodegeneration in an integrative way.

Cellular Senescence in Stroke

Cellular senescence accompanying neurological conditions involves many cell types of the CNS (Walton and Andersen, 2019), which may also be of great importance in the case of brain injury following stroke (Buga et al., 2013). Most studies in this field, however, focused on the effects of aging rather than on cellular senescence. The timing of the cellular and genetic response to brain tissue injury is dysregulated in aged animal models due to a premature accumulation of BrdU-positive microglia and astrocytes, activated oligodendrocytes, and degenerated neurons (Popa-Wagner et al., 2007).

There is no consensus whether and to what extent age influences infarct size: several studies reported larger (Popa-Wagner et al., 2011) or smaller ischemic lesions in aged animals when compared to young rodents (Manwani et al., 2013; Ritzel et al., 2018). However, irrespective of the infarct size, aged animals have worse functional when compared to young ones (Popa-Wagner et al., 2011; Ritzel et al., 2018). The slow tissue recovery and rapid development of damage after injuries like stroke in aged animals may be linked to several factors such as a reduced expression of genes linked to neuroprotective pathways, high and accelerated cell death, high oxidative stress by mitochondrial dysfunction, increased permeability of the BBB, high phagocytic activity of brain macrophages, autophagic dysfunction, as well as an imbalanced inflammatory state (Popa-Wagner et al., 2007, 2011; Petcu et al., 2008).

Furthermore, the immune response to ischemic brain injury differs between aged and young mice. In a recent report, older mice displayed an increased number of brain-infiltrating and peripheral neutrophils with decreased phagocytic potential, increased levels of reactive oxygen species and extracellular matrix-degrading enzymes (Ritzel et al., 2018). Rawji and colleagues reported that aging also affects brain-resident immune cells. Aged microglia express excessive amounts of pro-inflammatory cytokines and proliferate at increased rates, but simultaneously display defective phagocytosis and decreased motility. Interestingly, aged peripheral monocytes seem to share the features of impaired phagocytosis and reduced motility, but are less prone to activation and proliferation (Rawji et al., 2016).

Since aging has been linked to the accumulation of senescent cells (van Deursen, 2014; Calcinotto et al., 2019), we speculate that cellular senescence may contribute to the outcome after stroke. However, there is a need for more studies, exploring specifically the impact of cellular senescence rather than the global effects of aging. *In vitro* and *in vivo* experiments show that aging influences the state of endothelial cells, pericytes, and tight junctions, in turn resulting in a compromised function of the BBB (Yamazaki et al., 2016). Acute stroke leads to increased permeability and BBB breakdown, associated with worse outcome in stroke patients (Brouns et al., 2011).

Astrocytes in aged brains display the features of cellular senescence and SASP (Salminen et al., 2011), possibly impacting surrounding cells also in the case of acute brain damage. In the context of senescence hallmarks, human astrocytes are highly sensitive to oxidative stress and trigger a senescence program when faced with multiple types of stressors (Crowe et al., 2016; Liddell, 2017).

Chronic low-grade inflammation contributes to the increased risk of cerebrovascular disease (Lucas et al., 2006) and was shown to be a feature of the aging (Buga et al., 2013). The SASP in many cell types, including peripheral immune cells, astrocytes and microglia may influence a chronic inflammatory state observed in aging (Buga et al., 2013).

Taking into consideration the pathogenesis of cerebrovascular diseases, it is important to mention that cellular senescence may play a role in comorbidities and conditions known as risk factors for stroke (Buga et al., 2013). Cellular senescence impacts the formation and state of atherosclerotic plaques (Ritzel et al., 2018) and endothelial cells showing the hallmarks of senescence triggered by stressors like changes in glucose levels, homocysteine or elevated blood pressure (Tian and Li, 2014) may play a role in age-related vascular diseases. Since cellular stress induces senescence, it remains to be experimentally tested whether stroke itself triggers senescence in brain cells, which may influence the CNS microenvironment, have long-term consequences and an impact on the outcome after cerebral insults.

Systemic Metabolic Disease, Cellular Senescence, and Neurodegeneration

Risk factors in many neurodegenerative disorders include systemic metabolic diseases (see section "Impact of Peripheral Metabolic Disorders on Neurodegeneration"), which, in fact, favor the accumulation of senescent cells by facilitating the

functional changes of cellular distribution and regulation of adipose tissue. As mentioned before, cellular senescence in aging may contribute to a chronic inflammatory state in the brain and peripheral tissues (Buga et al., 2013).

Interestingly, obesity generates an accelerated state of aging, pro-oxidant factors as well as glucotoxicity (Hardie et al., 2006; Eberle and Ament, 2012). It is also associated with an increased senescent cell burden and a wide range of neurodegenerative and neuropsychiatric diseases (Gariepy et al., 2011; Hryhorczuk et al., 2013; Morsi et al., 2018). Ogrodnik and colleagues demonstrated that, in obese mice, glial cells show increased markers of cellular senescence in the periventricular region of the lateral ventricle, a region in close proximity to the neurogenic niche (Ogrodnik et al., 2019).

Furthermore, the affected glial cells in obese mice display excessive fat accumulation, which is in agreement with the role of glial cells on the senescence-mediated induction of neurodegeneration. Since SASP contributes to inflammation, metabolic dysregulation, progeria, pulmonary fibrosis, geriatric syndromes, and the loss of resilience, the clearance of senescent cells may delay or even alleviate multiple age-related diseases (Kirkland and Tchkonia, 2017).

Taking into consideration the increasing body of evidence on the role of cellular senescence in neurodegenerative, cerebrovascular, and metabolic disorders, we propose to investigate senescent cell accumulation in the periphery and in the nervous system as well as the influence of SASP on processes in the CNS, such as neuroplasticity, specific cellular populations, and on the brain–body signaling. This will help to understand the normal process of aging and senescence in an integrative way.

BODY–BRAIN TROPHIC INTERACTIONS AS THE ORIGIN OF NEURODEGENERATION

The disruption of the bidirectional interaction between neurons and the cells they innervate has not been considered as a putative etiologic mechanism of neurodegeneration. According to the trophic theory of neural connections, the body is represented several times within the nervous system along the sensory and motor pathways (Purves, 1988). Thus, changes in size and function of the body must be accompanied by changes in their neural representation at a central level, which may include neurite remodeling and functional adaptations.

Furthermore, novel requirements of the body affect the peripheral and central connections of peripheral neurons. In early phases of metabolic disorders, adipocytes and immune cells are related to peripheral nerve remodeling of both sympathetic and sensory fibers (Pellegrinelli et al., 2018; Yamazaki et al., 2018). In addition, the alteration of the enteric nervous system (ENS) may be a conduit to induce changes in the CNS. Future studies oriented to understand the interactions between neurons and the cells they innervate would help to discover biomarkers for early diagnosis and to monitor disease progression. Here, we present a brief summary of the experimental evidence related to the early events of neurodegeneration in the body and discuss possible mechanisms of intercellular communication that may be operating (**Figure 2**).

Pathological Events in the Peripheral Nervous System

Various neurodegenerative diseases share common molecular and cellular mechanisms including the misfolding of proteins that undergo conformational changes leading to tissue deposition and the formation of inclusion bodies. Increasing evidence suggests that these neurodegenerative proteinopathies may originate in the peripheral nervous system (Wakabayashi et al., 2010) or even across the body.

In PD and dementia with Lewy bodies (DLBs), the histopathological hallmark is the occurrence of neuronal α-synuclein aggregates, also known as Lewy bodies. Lewy bodies are typically found in the substantia nigra in PD. However, LBs can also be present in peripheral organs, neural or not, including the sympathetic ganglia, ENS, cardiac and pelvic plexuses, submandibular gland, adrenal medulla, and the skin (Beach et al., 2010; Wakabayashi et al., 2010). Moreover, in the early pathological stages of PD, α-synuclein pathology is present first in the dorsal motor nucleus of the glossopharyngeal and vagal nerves as well as the anterior olfactory nucleus (Braak et al., 2003a).

In AD, NFTs are observed in the spinal and sympathetic ganglia. However, it seems that they develop independently of the cerebral AD pathology (Shankle et al., 1993). In ALS, TDP-43 is a major component of the ubiquitinated inclusions and also occurs in the neurons of the spinal ganglia (Nishihira et al., 2008).

Sensory abnormalities have been described in neurodegenerative diseases including PD and AD. In this regard, the loss of olfaction represents an important early clinical symptom frequently preceding motor and cognitive impairments typically observed in these neurodegenerative diseases (Driver-Dunckley et al., 2014; Doty, 2017; Marin et al., 2018; Rey et al., 2018). The olfactory system may be particularly affected in neurodegenerative diseases as seen by the accumulation of pathological protein aggregates in olfactory structures including the anterior olfactory nucleus, the olfactory bulb, and the olfactory epithelium (OE) (Doty, 2017; Marin et al., 2018; Rey et al., 2018).

Given that the OE is directly accessible to external factors, it is vulnerable to environmental insults. Thus, external agents (toxins, bacteria, viruses, air pollutants) may trigger neurodegeneration through the OE (Rey et al., 2018). Once these agents enter the brain via the OE, they may cause protein misfolding and the spreading of protein aggregates in a prion-like manner throughout the olfactory pathway to other anatomically connected brain regions (Doty, 2017).

Moreover, xenobiotics and particles in contact with the OE can also induce the production of reactive oxygen species triggering a local inflammatory reaction in a similar way to that induced by misfolded proteins (Lema Tome et al., 2013). Alternatively, the enhanced expression of misfolding-prone proteins in olfactory structures may make those regions prone to develop certain diseases (Duda et al., 1999; Taguchi et al., 2016; Kim et al., 2018).

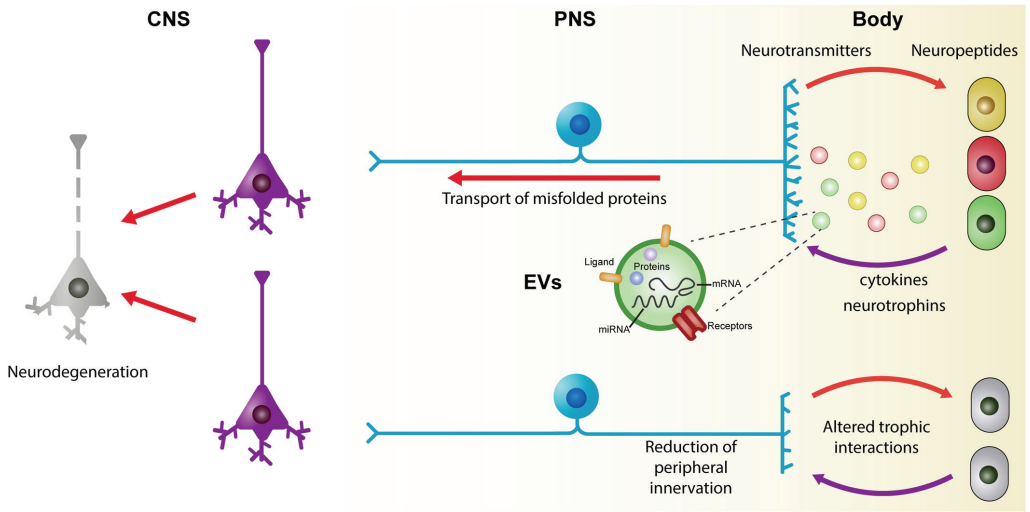

FIGURE 2 | The role of trophic interactions between the brain and the body in the development of neurodegenerative diseases. Under physiologic conditions, there is a continuous exchange of information between neurons and their targets. Neurons control several aspects of the cells they innervate by the release of neuropeptides and neurotransmitters. Reciprocally, peripheral cells modulate neuronal physiology by the release of several molecules including neurotrophins and cytokines. Recently, extracellular vesicles (EVs) have been considered as key players in the development and progression of chronic and degenerative diseases. An alteration of the homeostatic state of peripheral cells is reflected on the molecular cargo of EVs which, in turn, can affect the functioning of the neurons. Common to several chronic and neurodegenerative diseases, there is a reduction of peripheral innervation which leads to a disturbance of the trophic relation between the body and the central nervous system. A continuous alteration of these interactions during maturity of individuals may underlie some of the early events that reflect on neuronal death during aging. CNS, central nervous system; EVs, extracellular vesicles; PNS, peripheral nervous system.

Pain abnormalities are part of the clinical features in patients with PD and the impaired nociceptive processing depends on nociceptor degeneration (Nolano et al., 2008; Reichling and Levine, 2011; Conte et al., 2013). Skin biopsies of PD patients reveal a decrease in cutaneous autonomic innervation, free epidermal nerve endings, and encapsulated sensory endings (Dabby et al., 2006; Nolano et al., 2008). The severity of PD correlates with the loss of Meissner corpuscles and epidermal nerve fibers, accompanied by a reduction in cold and pain perception (Nolano et al., 2008).

The accumulation of misfolded proteins such as α-synuclein and parkin due to a dysfunction of the ubiquitin-proteasome system may partially explain the painful nociceptor dysfunction (Saha et al., 2000). In AD, pain perception seems not to be reduced. However, more studies are necessary to document whether sensory innervation is modified in AD and other neurodegenerative diseases (Cole et al., 2006). Of note, it is important to mention that different mechanisms involving both peripheral and central pain pathways may play a role in sensory dysfunction.

Autonomic dysfunction is present in several neurodegenerative diseases including PD, multiple system atrophy, AD, and other types of dementia such as DLB, PD with dementia, and frontotemporal lobar degeneration (Idiaquez and Roman, 2011; Coon et al., 2018). Orthostatic hypotension has been widely reported in patients with PD and DLBs as seen by the decreased cardiac uptake of the noradrenaline analog meta-iodobenzylguanidine (Orimo et al., 2005).

The presence of orthostatic hypertension may be due to the depletion of cardiac vagal sympathetic nerves as well as the α-synuclein pathology in sympathetic ganglia and adrenal gland that have been reported in Lewy body diseases, which includes PD, PD with dementia, and DLB (Wakabayashi et al., 2010). Interestingly, sympathetic denervation precedes neuronal loss in the sympathetic ganglia (Orimo et al., 2005). Autonomic dysfunction in AD may also be affected by neuropathological changes in central autonomic networks (Collins et al., 2012). Future studies should focus on the temporality of autonomic alterations in neurodegenerative diseases.

Gastrointestinal dysfunction is closely linked to the dysfunction of the ENS. Enteric dysfunction has been reported in PD, AD, ALS, and frontotemporal dementia (Rao and Gershon, 2016). Biopsies of PD patients have demonstrated the presence of Lewy-type pathology in enteric neurons suggesting a role of the ENS in the onset of the disease (Kupsky et al., 1987; Wakabayashi et al., 1988, 1990). The unmyelinated axons of enteric neurons may increase their susceptibility to PD and due to their multiple synaptic terminals may promote the propagation of α-synuclein aggregates via connected ganglia (Chalazonitis and Rao, 2018).

Likewise, in AD patients, Aβ immunoreactivity is found in the submucosa of the intestine (Joachim et al., 1989). In addition, amyloid precursor protein expression is present in the enteric neurons of AD patients (Arai et al., 1991). However, in contrast to PD, data from human samples in AD are still sparse. Other autonomic dysfunctions reported include urinary symptoms, sexual and thermoregulatory, dysfunction, and sleep disturbances (Postuma et al., 2015; Racosta et al., 2015; Pfeiffer, 2016). A better characterization of peripheral damage is required

in those cases where there is evidence of alteration in the peripheral innervation.

Impact of Peripheral Metabolic Disorders on Neurodegeneration

An increasing body of evidence suggests that metabolic disturbances may contribute to neurodegenerative processes in the CNS. We discuss here briefly the impact of diabetes mellitus (DM) and obesity on neurodegeneration.

Diabetes mellitus is one of the most common metabolic diseases and a major disorder of insulin regulation with increasing incidence (Duarte et al., 2012). Especially type 2 diabetes (T2D) is a highly complex, multifactorial metabolic disease, characterized by a progressive pancreatic β-cell failure (relative insulin deficiency), decreased insulin action and peripheral insulin resistance (Campbell, 2011; Carvalho et al., 2012).

T2D develops under a cluster of risk factors that includes high blood glucose, obesity, increased blood triacylglycerols and insulin resistance, which individually or collectively, also increase the risk for neurodegeneration/neuronal death, functional and structural brain changes, culminating in cognitive dysfunction that underlies dementia-type disorders (e.g., AD), which may arise from a complex interplay between T2D and brain aging. Additionally, decreased brain insulin levels/signaling and glucose metabolism in both pathologies further suggests that an effective treatment strategy for one disorder maybe also beneficial in the other (Duarte et al., 2013).

Obesity is clinically identified based on measurements of body mass index, but can be generally defined as the condition in which excess body fat has accumulated to an extent that can negatively affect health. This definition is based on the dramatically enhanced risk for a myriad of disorders, including T2D, CVD, gastrointestinal and respiratory disorders, and several types of cancer (for review, see Haslam and James, 2005). Furthermore, abdominal obesity is a component of the metabolic syndrome, which additionally combines insulin resistance or glucose intolerance, atherogenic dyslipidemia, elevated blood pressure, and increased expression of prothrombotic and proinflammatory markers (for review, see Olufadi and Byrne, 2008) and is an important risk factor for T2D, CVD, and stroke.

While the consequences of obesity on metabolic and cardiovascular pathophysiology are well-studied, epidemiological and experimental data are beginning to reveal that the CNS may also be detrimentally affected by obesity and obesity-induced metabolic dysfunction. In particular, data show that obesity is associated with cognitive decline and enhanced vulnerability to brain injury, while experimental studies in animal models confirm a profile of increased susceptibility to brain damage and decreased cognitive function (Bruce-Keller et al., 2009).

Recent data suggest that both AD and PD can manifest systemic alterations in energy metabolism (e.g., increased insulin resistance and dysregulation of glucose metabolism). Moreover emerging evidence that dietary restriction can forestall the development of AD and PD is consistent with a major "metabolic" component to these diseases, and provides optimism that these devastating brain disorders of aging may be largely preventable (Blum-Degen et al., 1995; Mattson et al., 1999).

Advanced glycation end products generated by chronic hyperglycemia and their receptor RAGE provide critical links between diabetes and AD (Vicente Miranda et al., 2016; Fleitas et al., 2018). Obesity, diabetes, and metabolic syndrome increase the risk of cognitive decline and dementia, including not only vascular dementia, but also AD and PD (Roriz-Filho et al., 2009).

However, due to increased incidence, especially in the aging population, the impact of metabolic disease on neurodegenerative processes will increase tremendously in the upcoming decades. We believe therefore that potential therapeutic approaches aiming at preventing/treating neurodegenerative diseases should include metabolic disorders.

Altered Body–Brain Trophic Communication

Accumulating evidence suggests that patients with neurodegenerative diseases commonly develop sensory and autonomic dysfunctions during maturity. This raises the possibility that the peripheral nervous system may be the gateway to alter brain physiology. The trophic theory of neural connections states that there is a mutual dependence between neurons and their targets (Purves, 1988; Qureshi and Mehler, 2013; Holm et al., 2018). Olfactory or gastrointestinal alterations may reflect a distortion of the communication between a variety of cell types and peripheral neurons. The repercussion of these altered interactions on the development of neurodegenerative diseases are still underexplored. Moreover, the mechanisms of cellular communication between peripheral cells and the nervous system are not fully characterized.

Recently, a novel system of intercellular communication has been proposed to modulate changes in neuronal physiology and to participate in the propagation of misfolded proteins (Fevrier et al., 2004; Asai et al., 2015; Grey et al., 2015; Polanco et al., 2016). This system is mediated by membranous organelles denominated as EVs, which can travel from the periphery to the brain and vice versa (Li et al., 2018).

Apparently, all the cell types of the body can release EVs to transmit information in the form of proteins, RNAs, and lipids. EVs are classified according to their subcellular origin in exosomes when originating from multivesicular bodies and in ectosomes (or microvesicles) when formed from the plasma membrane (Thery et al., 2018). Despite the technical challenges to study the functional role of different EVs subpopulations, their participation in both the maintenance of tissue homeostasis and the progression of chronic degenerative diseases is becoming clearer.

Extracellular vesicles are involved in several processes of brain development and normal functioning, including synapse formation, synaptic plasticity, and communication between glia and neurons. The signaling proteins of hydrophobic nature, such as the Wnt family members and other regulatory proteins, are loaded into EVs (Korkut et al., 2009; Coulter et al., 2018; Lee et al., 2018). During mammalian brain development, the vesicular secretion of the

growth factor sonic hedgehog promotes the proliferation of neural progenitors.

Interestingly, the loss of function of the complex charged multivesicular body proteins 1A reduces the number of intraluminal vesicles and the secretion of a specific subtype of EVs whose functions can be directly related to sonic hedgehog signaling (Coulter et al., 2018). At the *Drosophila* neuromuscular junction, EVs containing the Wnt-binding protein Evennes Interrupt and the Wnt 1 homolog Wingless promote synaptic growth when released from the presynaptic terminal (Korkut et al., 2009; Koles et al., 2012).

There is a constant reciprocal exchange of information through EVs between the pre- and post-synapse to modulate fine aspects of synaptic maturation and remodeling. In rat hippocampal neurons, excitatory synapses can be eliminated by a mechanism dependent on the delivery of Proline-Rich 7 by exosomes to induce the degradation of the post-synaptic density protein-95 (Lee et al., 2018).

Extracellular vesicles contents also influence long-term memory and synaptic plasticity. In neuronal cultures from mouse hippocampus and in neuromuscular junction preparations from *Drosophila*, oligomers of the activity-regulated cytoskeleton-associated protein and its own mRNA are transported through exosomes to the post-synapse (Ashley et al., 2018; Pastuzyn et al., 2018). The translation of the exosomal activity-regulated cytoskeleton-associated protein mRNA increases by the activation of the group 1 metabotropic glutamate receptors (Pastuzyn et al., 2018). The notion that neurons constantly use EV-mediated communication is reinforced by the fact that the release of EVs is activity-dependent and that the delivery of the cargo from presynaptic cells enables retrograde signaling from the post-synaptic cells (Lachenal et al., 2011; Korkut et al., 2013; Lee et al., 2018).

The general hypothesis on the role of EVs related to the development of neurodegenerative diseases relies on their potential to transport protein aggregates, which has been reviewed elsewhere (Howitt and Hill, 2016). Here, we would like to center the discussion on the possibility that a bidirectional exchange of information through EVs between peripheral cells and neurons may have a long-term impact on the brain physiology.

Emerging evidence suggests that both central and peripheral neurons can uptake EVs from a variety of cell types. Thus, under certain circumstances, EVs derived from peripheral cells contain proteins or RNAs that can be deleterious for neuronal functioning. In agreement with this notion, exosomes derived from hyperglycemic Schwann cells contain microRNAs that suppress axonal growth *in vitro* (Jia et al., 2018). Moreover, hyperglycemic Schwann cell-derived exosomes contribute to the development of diabetic peripheral neuropathy when injected into a diabetic mouse (Jia et al., 2018).

Similarly, the CNS can also be affected by the information transported by systemic exosomes. An increase of inflammatory cytokines in the brain and microglial and astrocytic activation is observed after the intravenous injection of serum-derived exosomes from lipopolysaccharide (LPS)-challenged mice (Balusu et al., 2016; Li et al., 2018). Dorsal root ganglion neurons modulate immune cells in the periphery by the release of neuropeptides.

Recent findings also indicate that EV-mediated communication can be an additional mechanism operating during trauma. After nerve injury, dorsal root ganglia neuron-derived exosomes loaded with microRNA-21 increase the infiltration of inflammatory macrophages, which contributes to neuronal sensitization (Simeoli et al., 2017). Further work is required to obtain insights whether EVs from peripheral cells modulate cellular processes in the brain under physiological conditions and which factors can alter the messages coming from the periphery (Ridder et al., 2014).

Despite the few studies focusing on the influence of peripherally derived EVs on peripheral neurons, it is likely that peripheral terminals establish a bidirectional interaction with the cellular elements surrounding them. Both sensory and autonomic axon terminals usually end as free nerve endings in the extracellular matrix intercalated between different cell types. Peripheral neurons are responsive to EVs derived from mesenchymal stem cells and Schwann cells (Lopez-Verrilli et al., 2013, 2016; Ching et al., 2018; Sun et al., 2018; Shiue et al., 2019). The general observation of these studies, performed in conditions of neuronal damage, is that EVs reduce the inflammatory state and have a beneficial role in axonal growth both *in vivo* and *in vitro*.

Taken together, these findings indicate that neurons are susceptible to modify their functioning or gene expression profile as a result of incorporating EVs from neighboring cells. A challenge for future studies is to determine if EVs from any cell source can modify neuronal functioning and how these events are associated with physiological alterations that precede neurodegeneration in the brain.

GUT DYSBIOSIS AS THE ORIGIN OF NEURODEGENERATION

Microbiota is defined as a community of all microorganisms living in our body. Microbiota therefore includes all taxonomic domains such as fungi, protozoa, viruses, and bacteria. Bacterial microbiota living in the gut (further referred as GM) represent about 90% of all microbiota in the body (Thursby and Juge, 2017), with an estimated ratio of human:bacterial cells close to 1:1 (Sender et al., 2016). This large number of bacteria offers different benefits to the host, confers protection against pathogens (Baumler and Sperandio, 2016), regulates host immunity (Gensollen et al., 2016), and products originating from bacterial fermentation can be used as a source of energy for colonocytes (den Besten et al., 2013).

A delicate balance exists between the GM composition and its interaction with the host, while an imbalance in this composition is commonly known as dysbiosis. Gut dysbiosis has been implicated in the development of chronic diseases, such as irritable bowel syndrome (Raskov et al., 2016), coeliac disease (Verdu et al., 2015) as well as metabolic disorders, including obesity, metabolic syndrome, and T2D (Holmes et al., 2011;

Carding et al., 2015; Zhang et al., 2015; Baothman et al., 2016; Org et al., 2017).

Notably, those metabolic diseases, when developed during adulthood, are considered important risk factors for AD (Alzheimer's Association, 2016; Livingston et al., 2017). Furthermore, metabolic alterations are known to induce peripheral low-grade chronic inflammation, associated with higher incidence of neurodegenerative diseases. In AD, systemic inflammation during prodromal stages shortens disease onset (Tao et al., 2018), whereas dysregulation of the gastrointestinal function and colonic inflammation diminished immune competence and preceded motor symptoms in PD patients (Dobbs et al., 1999; Braak et al., 2003b; Lebouvier et al., 2009; Villaran et al., 2010; Forsyth et al., 2011).

During aging, there is an increased permeability of the gut epithelium (Tran and Greenwood-Van Meerveld, 2013). This condition allows bacteria and bacterial products to translocate through the disrupted gut barrier reaching peripheral organs (Zevin et al., 2016). Newest reports suggest that translocated bacteria may even reach the brain (Roberts et al., 2018), where an exacerbated immune reaction can lead to neurodegeneration. These observations remain however to be investigated in detail.

Gut Microbiota Alterations in Neurodegenerative Diseases

Recent reports concomitantly demonstrate a gut dysbiosis in PD (Minato et al., 2017; Wu et al., 2017), ALS, and AD patients (Cattaneo et al., 2017; Vogt et al., 2017).

Understanding how GM may be implicated in brain pathologies requires a clear comparison among the data reported from different research groups. The GM is mainly dominated by four phyla: Firmicutes, Bacteroidetes, Actinobacteria, and Proteobacteria (Szablewski, 2018). The first studies described GM alterations only at the phylum level. However, recent advances in sequencing techniques allow distinction at the species level, which is advantageous since the different species of bacteria belonging to the same genus affect host physiology in a different manner. We compared previously published GM data obtained from AD patients and AD mice models. We noted a strong variation between studies: at phylum level, most transgenic models coincide with an increased abundance of Firmicutes but a decreased abundance of Bacteriodetes (**Table 1**). Whereas at the family and upper taxonomical levels (i.e., genus/species), there is no more consistency (**Table 2**).

Importantly, variations in the experimental design or the type of samples can be observed. Moreover, differences in the animal model, chronological stage of the pathology (age), handling and diet significantly impact GM (Mueller et al., 2006; Hufeldt et al., 2010; Sanchez-Tapia et al., 2017). Thus, experimental variations among published studies may explain discrepancies in the GM composition in AD.

Despite this strong variation, we can observe a general increased abundance of pro-inflammatory bacteria in AD mice and AD patients (Kountouras et al., 2009; Zhan et al., 2016; Cattaneo et al., 2017; Shen et al., 2017; Vogt et al., 2017; Zhang et al., 2017; Syeda et al., 2018) compared to controls. Furthermore, in AD transgenic mice, longitudinal studies clearly indicate an age-associated gut dysbiosis, culminating in a strong pro-inflammatory environment along the development of brain pathological hallmarks (Shen et al., 2017; Zhang et al., 2017; Syeda et al., 2018).

How Can the GM Affect Brain Function or Even Cause Neurodegeneration?

A bidirectional communication between the gastrointestinal system and the brain has been described and has led to the concept of gut-brain axis (Collins and Bercik, 2013). Recent studies illustrated the role of GM in brain Aβ aggregation, as GM absence in germ-free condition (Harach et al., 2017) or GM partial depletion by antibiotic treatment (Minter et al., 2016) reduced the amyloid burden and microglia activation in AD transgenic mice. However, it is still unclear which factors may be associated with the above described gut-brain axis in brain pathologies.

Several groups have implicated the neurotoxin LPS present in the outer membrane of gram-negative bacteria. LPS plays key roles in the host-pathogen interactions of the innate immune system (Hill and Lukiw, 2015; Maldonado et al., 2016). Alterations in the GM composition/abundance are associated with enhanced plasma levels of LPS (Avila-Nava et al., 2017;

TABLE 2 | Alterations in gut microbiota in AD patients and AD mice at FAMILY, GENUS, and SPECIES levels.

Sanchez-Tapia et al., 2017), which may result in an exacerbated metabolic endotoxemia (Cani et al., 2012), a condition characterized by inflammation and the increased release of pro-inflammatory cytokines.

Systemic infections have been related to a higher possibility to develop AD (Holmes et al., 2009) as well as early motor dysfunction in PD patients (Dobbs et al., 1999). Therefore, long-term gut microbiota alterations and gut dysbiosis resulting in a pro-inflammatory environment and inflammation may be linked to brain dysfunction in aging.

As a proof of concept, LPS is detected in the parenchyma and blood vessels of both, non-demented aged and AD brain samples, but at a higher level in diseased tissues (Zhao et al., 2015, 2017; Zhan et al., 2016). LPS also increases in the plasma of AD transgenic mice compared to wild type controls (Syeda et al., 2018). In PD patients, higher plasma LPS correlates with α-synuclein aggregation (Forsyth et al., 2011). Furthermore, LPS is a well-known neuroinflammatory agent driving the generation of $A\beta_{1-42}$ (Lee et al., 2008; Asti and Gioglio, 2014; Hill and Lukiw, 2015; Zhao et al., 2015). LPS administration to mice results in memory impairment, Aβ aggregation, and astrocyte activation (Lee et al., 2008). Therefore, gut dysbiosis may enhance LPS to the blood circulation and even to the brain, producing glia activation and protein aggregation, both important features of neurodegenerative diseases.

Another bacterial product related to the development of neurodegenerative diseases are short-chain fatty acids (SCFAs). SCFAs are produced by the GM after the degradation of non-digestible polysaccharides, with butyrate, acetate, and propionate being the more abundant fermentation products (Wong et al., 2006). About 95% of the SCFAs produced in the gut are absorbed within the colon (Hoyles et al., 2018), while butyrate is used by the colonocytes as an energy source. In order to maintain an optimal equilibrium between intestinal SCFAs and the concentration in the body, the gut intestinal barrier increases its mucus production

(Rios-Covian et al., 2016), while the liver clears the majority of propionate and butyrate from the portal circulation (Bloemen et al., 2010). However, SCFAs can be transported through the bloodstream to reach the brain.

Some alterations in fecal SCFAs concentration have been described in AD transgenic mice compared to controls (Bonfili et al., 2017; Zhang et al., 2017). Butyrate, a well-known neuroprotective agent (Minamiyama et al., 2004; Govindarajan et al., 2011; Liu et al., 2015), is reduced in the fecal samples of AD mice (Zhang et al., 2017). Other reports show increased propionate levels in brain tissue of AD transgenic mice compared to wild type controls, an event associated with GM dysbiosis (Syeda et al., 2018). Although, propionate has some beneficial effects [e.g., on the BBB (Hoyles et al., 2018)], excessive propionate alters dopamine, serotonin, and glutamate systems in a manner similar to that observed in autism spectrum disorders (El-Ansary et al., 2012; Li et al., 2017).

Fecal samples of children with autism spectrum disorder present an increased level of propionate (Wang et al., 2012). In addition, genetic diseases that affect the function of the enzyme propionyl-CoA carboxylase (such as propionic acidemia) are characterized by high levels of propionate and high incidence of dementia (Grunert et al., 2013), while in AD patients, increased levels of acetate and propionate have been found in saliva samples compared to healthy controls (Figueira et al., 2016; Yilmaz et al., 2017). Although, the effects of butyrate and propionate are still controversially discussed, several data support a role of the imbalance between butyrate and propionate in the pathogenesis of AD (Syeda et al., 2018).

Another important pathway connecting the brain and the GM is the involvement of the immune system (Fung et al., 2017) studied, e.g., in stroke. According to recent reports, in the experimental rodent models, stroke leads to dysbiosis (Benakis et al., 2016; Houlden et al., 2016; Singh et al., 2016; Stanley et al., 2018) and dysbiosis may have an effect on the course of the disease (Benakis et al., 2016; Singh et al., 2016; Stanley et al., 2016). This may be linked to GM-related fine-tuning of the balance between pro-inflammatory/anti-inflammatory immune responses primarily in the gut, followed by an infiltration of immune cells to the CNS after injury. Interestingly, pro-inflammatory T-helper cell 17 and γδ T cells found in the ischemic CNS originate from the intestine and the infiltration of these subpopulations has been linked with unfavorable outcome (Benakis et al., 2016; Singh et al., 2016).

However, the optimal (in terms of prognosis after stroke) composition of the GM has not been identified yet and is possibly difficult to pinpoint. Some findings indicate that the complete absence (in germ-free mice) or deep antibiotic depletion of GM can be detrimental, leading to increased infarct volumes (Singh et al., 2018) or increased mortality not related to lesion size (Winek et al., 2016). Alterations in GM have also been identified in stroke patients (Yin et al., 2015; Stanley et al., 2016). Due to its metabolic capacities, GM can also contribute to the pathogenesis of the diseases considered as the risk factors of stroke, like obesity (for review Torres-Fuentes et al., 2017) and atherosclerosis (Karlsson et al., 2012; Tang et al., 2013) (for review, see Li and Tang, 2017).

We can conclude that a predominantly pro-inflammatory GM and the release of neurotoxic substances may negatively affect brain functions, causing systemic and central inflammation over decades. This is in support of the recent hypothesis of an infectious etiology for neurodegenerative diseases, such as AD (Bhattacharjee and Lukiw, 2013; Little et al., 2014; Maheshwari and Eslick, 2015; Itzhaki et al., 2016). The substances released from the GM (i.e., LPS and SCFAs) may be implicated in the pathogenesis of several neurodegenerative diseases; however, more data are still needed to clearly understand this gut-brain-immune interaction.

FROM CONSEQUENCES TO CAUSES: ACADEMIC AND PRECLINICAL CONSIDERATIONS

As we have described above, the neurocentric view entertained as the predominant focus of our effort in treating neurodegeneration is likely insufficient to ensure successful therapeutic intervention.

The Lack of Adequate Experimental Models to Study the Etiology

Investigating the pathophysiological processes behind neurodegeneration in detail requires the use of animal models. A plethora of animal models of neurodegeneration exists, and the nuances of these models are beyond the scope of this manuscript (for recent reviews, see Gitler et al., 2017; Dawson et al., 2018; Ransohoff, 2018).

However, two general problems with current models seem to be particularly widespread and contribute to our limited success in extrapolating findings from preclinical research to patients. Firstly, they often fail to fully integrate our understanding of the etiology of the diseases they are meant to represent, often being restricted to inducing the disease in a single way, despite multiple inducing factors being responsible for the human disease. Secondly, animals used as the model organism of specific diseases often do not exhibit similar comorbidities and demographic characteristics (such as age or gender) seen in human patients. Examples of such problems are the rodent models of stroke, particularly ones that involve surgical ligation or occlusion of blood vessels in otherwise healthy, young animals (van der Worp et al., 2010; Mergenthaler and Meisel, 2012).

Another important issue is the way these models are characterized. For animal models to be used to study neurodegeneration, two essential steps must be taken. First, the validity of the model for the question at hand should be thoroughly and systematically investigated. This is preferably done in a multi-centric and multi-disciplinary way to ensure the generalizability and robustness of the results. Second, the external (face, construct, and predictive) validity of the model (Willner, 1984) should be empirically and thoroughly tested, as well as the inter-rater agreement on, and replicability of, the model's characteristics (McKinney and Bunney, 1969). Such studies aimed at characterizing the model should be very clearly

and unequivocally separated from experiments using the model to test hypotheses, such as the effect of an intervention on the course of the model's progression.

For these strategies to be successful, research into and using these models must be conducted in the setting of appropriate, rigorous, and transparent experimental design and reporting (Kilkenny et al., 2010; Holman et al., 2016; Percie du Sert et al., 2017). Beyond that, we should make an active effort to think of the drawbacks of the models and methods we have used and how this may restrict or bias the knowledge we gain from such studies (Garner et al., 2017). Finally, we need a framework for integrating the knowledge gained from individual studies using different models and methods to address similar research questions. Systematic reviews and quantitative meta-analyses, widely used for knowledge synthesis in clinical research, may be helpful tools to help us achieve this.

Studying Human Disease in Human Systems

Although animal models are a powerful tool toward understanding the etiology of neurodegenerative diseases, they still present considerable limitations (Jucker, 2010). As a consequence, there has been little success translating the knowledge obtained from model organisms to therapeutically valuable outcomes. This constraint can only be addressed by studying neurodegenerative diseases directly on humans.

The recent increase in the generation of digital data including imaging, genotypic, and phenotypic information coupled with a fast development of computational methods allows us to obtain new insights from this massive amount of data. Major efforts from consortiums such as the Alzheimer's Disease Initiative (ADNI), the Australian Imaging, Biomarkers & Lifestyle Study of Ageing (AIBL), the Parkinson's Progression Markers Initiative (PPMI) or more recently the United Kingdom Biobank have made available an unprecedented amount of data, which can be exploited through the use of big data algorithms.

Having large amounts of information coming from heterogeneous populations and acquisition systems increases the power of statistic approaches and reduces the risk of bias. Big data approaches are inherently limited since in general they cannot be used to perform causal inference, but rather to find correlations or associations between variables. However, these correlations have proven to be an invaluable tool for hypothesis generation, drug and safety surveillance, disease and treatment heterogeneity among many other applications (Lee and Yoon, 2017).

Such computational models have been used for example to build a model of senescence signaling via DNA damage, insulin-TOR, FoxO3a transcription factors, oxidative stress response, mitochondrial regulation, and mitophagy using a systems biology approach (Dalle Pezze et al., 2014). A recent review of mathematical models in neurodegenerative diseases reports several mathematical models involving some of the processes we addressed above, such as energy metabolism and synaptic plasticity (Lloret-Villas et al., 2017). A multivariate Bayesian model of biomarker measurements was used to estimate AD dementia onset age (Bilgel and Jedynak, 2019). Similarly, multivariate models have been used to relate image based morphological features to the risk of dementia (Gutierrez Becker et al., 2018; Cole et al., 2019).

Recent trends in stem cell methods have also opened new possibilities for human brain cell cultures, which can in turn be used to model neurodegeneration. Induced pluripotent stem cells and neural stem cell cultures can now be used to generate human neurons from human and sometimes patient cells (Abud et al., 2017; Korhonen et al., 2018). This has been reviewed extensively elsewhere (Xie and Tang, 2016; Robbins and Price, 2017).

CONCLUSION

Disease is typically defined in juxtaposition to the state of health, which has been even more generally defined as "a state of complete physical, mental, and social well-being" (International Health Conference, 2002). However, in order to characterize a bodily or mental state as diseased, we need a more practical, operational definition of the healthy state, characterized in terms of physiological parameters and defined by the description of the steady state functioning of the body and its subsystems.

Typically, pathophysiological events of neurodegeneration are detected through behavioral observations and self-reporting and subsequently confirmed and classified using neurological examination and diagnostic imaging. The result of this diagnostic approach usually reveals typical defining features for each neurological disease (such as hemorrhage, tumor, or deformations), that allows the classification of the disorder. However, these defining characteristics are not necessarily the root causes of the disease but rather elements of the disease manifestation or even merely epiphenomena. In addition to the complex and usually obscure causal relationships giving rise to brain disorders, a parameter that further complicates the identification of causation is the widespread and intricate comorbidities between presumably distinct and unrelated disorders.

Together, these facts limit the therapeutic potential to treat the symptoms rather than the causes. The complex causality chain hinders the early detection and treatment of the root causes of brain disorders overall and neurodegeneration more specifically. These limitations highlight the critical need for a drastic shift of perspective and the improvement of the models used to investigate and understand neurodegenerative diseases.

Given the complexity of the brain and its disorders, researchers and clinicians have retreated to a highly segregated approach, focusing on describing subsets of the symptoms of each disease and trying to identify mechanistic explanations and treatments for those symptoms. However, the lack of a holistic perspective, taking into account the deviations from the default homeostatic state at an organismal level, renders this endeavor nearly impossible and doomed to fail.

Importantly, characterizing the expected, default healthy brain, is a necessary precondition to being able to identify and meaningfully interpret the deviations from it. Thus, characterizing and understanding the brain function in health is of paramount importance in the attempt to understand and treat the diseased brain.

In summary, there is an identifiable need for an interdisciplinary approach to explore the brain function at multiple levels, from molecular to systems, while maintaining a holistic perspective that treats the brain as an element of a complex system, rather than a separate entity. Using this approach, fundamental research can proceed hand-in-hand and maintain a constant dialogue with clinical research, to propose, improve, and revise current models of health and disease.

We hope that our work inspires the opening of new research avenues among those interested in understanding and pursuing the complexities of the "neuro-degenerating" brain focusing on lifespan processes. Therefore, the proposed etiological paths and suggestions will be important guidelines for future cross-discipline research to overcome the translational roadblock and to develop causative treatments for neurological disorders.

AUTHOR CONTRIBUTIONS

AP, GG-O, and MZ applied for funding and organized the workshop. AK, AP, AV, BG-B, MZ, NK, and XC were participants of the subgroup "The Vascular Origin of Neurodegeneration." AV-C, JP-V, KR, KW, LR, and SC-O of the subgroup "Cellular Senescence as the Origin of Neurodegeneration." CP-C, EM-M, GG-O, HG, and JL-N of the subgroup "Body–Brain Trophic Interactions as the Origin of Neurodegeneration." Accordingly, the authors wrote the respective sections of this manuscript, except CP-C who together with TS wrote the section "Gut Dysbiosis as the Origin of Neurodegeneration" with contributions from KW. AP contributed to the section "Body–Brain Trophic Interactions as the Origin of Neurodegeneration." BG-B wrote the section on "Studying Human Disease in Human Systems." AK on "The Lack of Adequate Experimental Models to Study the Etiology." NK wrote the conclusion. MZ wrote the remaining sections of the manuscript. AV commented on the manuscript. All authors discussed and commented on the final version of the manuscript.

FUNDING

This work was supported by a grant from the German Federal Ministry of Education and Research (BMBF grant number 01DN18054) to MZ, AP, and GG-O.

ACKNOWLEDGMENTS

This is a spin-off article from the workshop "German-Mexican Roundtable Exploring New Etiological Paths Towards Neurodegeneration," which took place at the Instituto de Investigaciones Biomédicas at the National Autonomous University of México, Mexico City, on October 15–17th, 2018. Miguel Morales Pacheco helped in the design of **Figure 1**.

Ischemic stroke is a major cause of disability and mortality worldwide, but effective restorative treatments are very limited at present. Regenerative medicine research revealed that stem cells are promising therapeutic options. Dental pulp stem cells (DPSCs) are autologously applicable cells that origin from the neural crest and exhibit neuro-ectodermal features next to multilineage differentiation potentials. DPSCs are of increasing interest since they are relatively easy to obtain, exhibit a strong proliferation ability, and can be cryopreserved for a long time without losing their multi-directional differentiation capacity. Besides, use of DPSCs can avoid fundamental problems such as immune rejection, ethical controversy, and teratogenicity. Therefore, DPSCs provide a tempting prospect for stroke treatment.

Lan X, Sun Z, Chu C, Boltze J and Li S (2019) Dental Pulp Stem Cells: An Attractive Alternative for Cell Therapy in Ischemic Stroke. Front. Neurol. 10:824. doi: 10.3389/fneur.2019.00824

The past decade has witnessed intense advancement and tremendous therapeutic achievements in the ability to diagnose and treat stroke, a cerebrovascular disease of which 87% is ischemic in nature. Nevertheless, stroke remains a major cause of disability, morbidity, and mortality worldwide, and constitutes a major socioeconomic problem (1, 2). Ischemic stroke, due to partially or completely blocked blood flow in a cerebral artery, causes ischemic necrosis of brain tissue seriously impairing the health of affected individuals. The main therapeutic strategy for ischemic stroke is timely recanalization. This can either be achieved by tissue-type plasminogen activator application or mechanical thrombectomy. Particularly the latter can be applied up to 24 h after stroke in patients exhibiting a penumbra, and has revolutionized acute stroke treatment. However, the absolute number of patients qualifying for recanalization remains very low (3, 4). Hence, additional treatment approaches being effective beyond the first hours after stroke onset are urgently required.

Stem cell transplantation is a promising strategy to restore neurological function after stroke (5). Experimental stem cell transplantation in animals showed that numerous cell populations can improve functional recovery by a broad spectrum of mechanisms (6–8). Several kinds of stem cells are currently considered for therapy. These include embryonic stem cells (ESCs), fetal stem/progenitor cells, induced pluripotent stem cells (iPSCs), and adult stem cells. While embryonic or induced pluripotent stem cells exhibit a tremendous differentiation potential, they may also inherit a risk for tumor formation (9). The use of embryonic stem cells or fetal stem/progenitor cells raises ethical concerns. Adult stem cells show a limited proliferation and differentiation potential, but can still be beneficial after stroke due numerous mechanisms beyond tissue restoration. They are further believed to be safer in clinical application and their use is ethically less challenging (9–13).

Recent systematic reviews and meta-analyses on the most prominent adult stem cell therapy candidates, mesenchymal stem cells (MSCs), presented evidence that MSCs improve the outcome

after stroke in animals (14) and patients, and confirmed the safety and feasibility of the approach (15). Nevertheless, there is still a lack of adult (stem) cells that can be derived from an autologous source, and may exhibit therapeutic abilities beyond those of MSCs.

DENTAL PULP STEM CELLS (DPSCs): A NEW SOURCE OF ADULT STEM CELLS

The dental pulp is a soft tissue located in the center of teeth. It comprises blood vessels, neural fibers, and connective tissue. The dental pulp contains both mesenchymal and ectodermal tissue as well as neural crest cells (16). Limited dentinal repair in the postnatal organism relies on specialized precursor cell populations residing in the dental pulp tissue. Gronthos et al. first reported the isolation and characterization of stem cells from dental pulp tissue of the third molar in 2000 (17). DPSCs are ectoderm-derived stem cells, originating from migrating neural crest cells (**Figure 1**). They are a subpopulation among dental pulp cells (DPCs) which possess MSC properties, such as a fibroblast-like morphology, adherence to a plastic surface, as well as surface marker expression, proliferation and colony forming behavior similar to that of MSCs (18, 19). It is not clear whether or not DPSCs are a kind of MSC population. Given their differentiation abilities as reviewed below, it might be assumed that DPSCs are a more naïve stem cell population that also, but not exclusively, exhibits MSC properties. A major benefit of DPSCs is that they can be isolated during routine dental procedures such as the eruption of deciduous teeth or extraction of impacted wisdom teeth (20) in simple and autologous fashion without ethical concerns. Another primary advantage of DPSCs is their potential for cell banking. Several studies have demonstrated that DPSCs retain their stem cell properties after long cryopreservation (21, 22). This is essential as cryopreservation can impact therapeutic capacities of other adult stem cell-containing populations in stroke (23). In addition, DPSC cultures can be established from extracted human molars with high efficiency, even after the whole tooth has been cryopreserved for up to 1 month (24). DPSCs also exhibit a multilineage differentiation potential into chondrocytes, adipocytes, odontoblasts, and potentially even neural-like cells (25–28).

Currently, there are no specific markers that uniquely define DPSCs. In general, DPSCs, as a heterogeneous population, express a variety of markers similar to MSCs (**Table 1**) (**Figure 1**), and do not express hematopoietic markers such as CD14, CD19, CD34, and CD45 (18, 26, 29–32). DPSCs isolated by their high proliferative potential tend to include a large population of cells expressing $CD44^+$, $CD90^+$, and $CD166^+$. However, DPSCs also express stemness-related markers similar to ESCs such as Oct-3/4, Nanog, and Sox-2, as well as the cytoskeleton-related markers nestin and vimentin (**Figure 1**) (33–35). They further express insulin-like growth factor 1 receptor (IGF1R) which is regarded as a pluripotency marker in ESCs. DPSC-secreted IGF1 interacts with IGF1R through an autocrine signaling pathway to maintain self-renewal and proliferation potential (36).

In addition, DPSCs (as neural crest-derived stem cells) not only express a number of neural stem cell (NSC) associated markers including nestin (26, 37) and Sox2 (38) (**Figure 1**), but also express low basal levels of markers associated with mature central nervous system cell types, including the neuronal markers βIII-tubulin, microtubule-associated protein 2 (MAP2), neurofilaments (NF) (33, 39), NeuN (40), the astrocytic marker glial fibrillary acidic protein (GFAP) (26, 33), and oligodendrocyte-associated CNPase (33). Taken together, this suggests that DPSCs can indeed differentiate into neuron-like cells under appropriate conditions, and differentiated cells even exhibit typical electrophysiological properties after neuronal differentiation (41, 42).

DPSCs AS A POTENTIAL CANDIDATE FOR THERAPY OF NEUROLOGICAL DISEASES

Brain-derived NSCs are considered a promising population for stroke treatment due to their ability to self-renew and to differentiate into neural cells types (neurons, astrocytes, oligodendrocytes) (43). However, autologous harvest of adult human NSCs requires neurosurgical procedures due to their brain parenchymal residence (44), while allogeneic or even xenogenic NSCs grafting imposes the risk of graft rejection and additional immunological damage. Only a limited number of clinical trials currently explore the potential of NSCs for stroke treatment because of these limitations.

Adult stem cells or stem cell-containing populations are more frequently applied in translational research. As stated above, DPSCs share many biological characteristics with MSCs including bone marrow MSCs (BM-MSCs), adipose tissue-derived stem cells (ADSCs) and umbilical cord MSCs (UC-MSCs) but there are some variations in their proliferation potential (17, 27, 45), differentiation potential (17, 27, 46), immunomodulatory activity (27), secretome characteristics, and secretory capacity (47–49). Specifically, DPSCs have a higher proliferation rate and a greater clonogenic potential than MSCs (17, 45). Next to DPSCs, the DPC population also contains a higher number of stem/progenitor cells as compared to bone marrow (50). This may be attributed to the developmental state of the respective tissues. All teeth, even the permanent molars, are generated early in individual development and rest in the jar until they erupt. Abilities and capacities of stem cells may be much better preserved in tissue with a slow turnover such as the dental pulp when compared to BM, which exhibits a tremendous turnover throughout life apart from some niches. DPSCs maintain their high rate of proliferation even after extensive subculturing.

Like MSCs, DPSCs can differentiate into cells of mesenchymal and non-mesenchymal tissues *in vitro* and *in vivo*. However, DPSCs exhibit stronger odontogenesis and neurogenesis capabilities, in turn being not as potent to produce adipogeneic, osteogeneic and chondrogeneic tissue than BM-MSCs (51) and ADSCs (46). Besides, DPSCs also have immunomodulatory capacities exceeding those of BM-MSCs, for example a higher suppression rate of T lymphocyte growth (17, 27).

DPSCs exhibit superior neuroprotective and neuro-supportive properties in neurological injuries and pathologies as

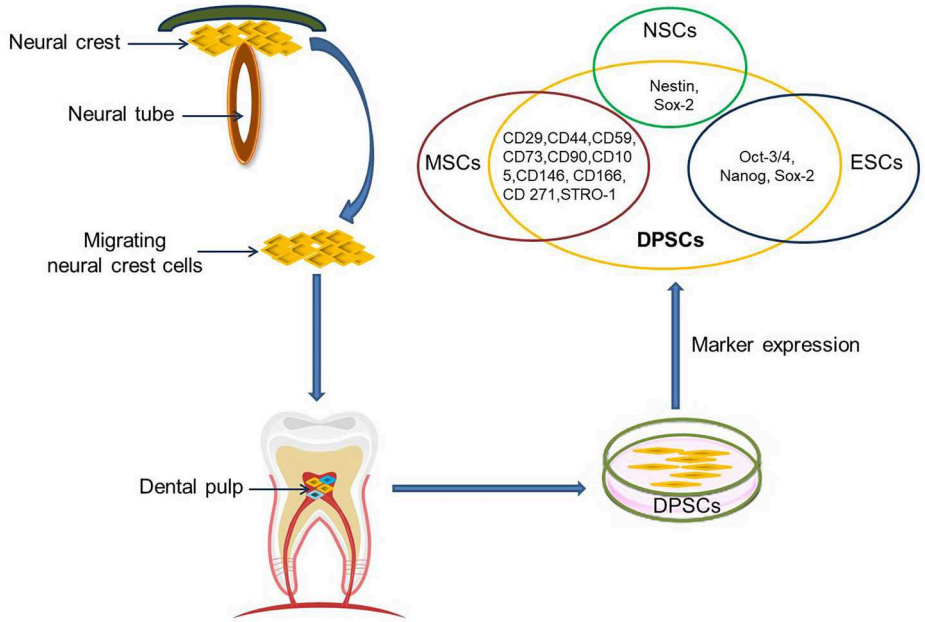

FIGURE 1 | DPSCs origin, isolation, and marker expression. DPSCs originate from migrating neural crest cells, coming to rest in dental pulp, and express markers overlapping with MSCs, ESCs, and NCSs.

TABLE 1 | Characteristics of DPSCs.

	Marker expression overlapping with			*In vitro* multipotency	Secretomes

CD29, CD44, CD59, CD73, CD90, CD105, CD146, CD166, CD 271, STRO-1	Oct-3/4, Nanog, Sox-2	Nestin,Sox-2	MAP2, NF, βIII-tubulin, NeuN (neurons), GFAP, S100 (astrocytes), CNPase (oligodendrocytes)	Adipo, chondro, myo, osteo, neuro, odonto	Neuroprotective effect: BDNF, GDNF, VEGF, NGF, IGF-1, PDGF, CNTF, RANTES, GM-CSF; Anti-apoptotic effect: MCP-1, FRACTALKINE; Immunomodulation effect: FLT-3, TGF-β, IL-6

MAP2, microtubule associated protein 2; NF, Neurofilament; GFAP, glial fibrillary acidic protein; adipo, adipocyte; chondro, chondrocyte; myo, myoblast; neuro, neuronal cell; odonto, odontoblast; osteo, osteoblast. BDNF, brain-derived neurotrophic factor; GDNF, glial cell-derived neurotrophic factor; VEGF, vascular endothelial growth factor; NGF, nerve growth factor; PDGF, platelet derived growth factor; CNTF, ciliary neurotrophic factor, FLT-3, fms-related tyrosine kinase 3; GM-CSF, granulocyte-macrophage colony-stimulating factor; MCP-1, monocyte chemotactic protein 1; TGF-β, transforming growth factor-β; IL-6, interleukin-6.

compared with BM-MSCs and ADSCs (52). This might be related to a higher expression of trophic factors including brain derived neurotrophic factor (BDNF), glial cell-derived neurotrophic factor (GDNF), nerve growth factor (NGF), vascular endothelial growth factor (VEGF), and platelet derived growth factor (PDGF) in DPSCs as compared to BM-MSCs (47, 48), although the spectrum of growth and trophic factors secretion is similar (53). DPSCs also express higher quantities of CXCL14 and monocyte chemoattractant protein 1 (MCP-1) than ADSCs (49). Besides, the DPSC secretome contains higher concentrations of RANTES, FRACTALKINE, fms-related tyrosine kinase 3 (FLT-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), and MCP-1 than the BM-MSCs secretome (54). DPSCs show higher angiogenic and neurogenic potentials in ectopic transplantation models compared to BM-MSCs and ADSCs, and exhibit the highest migration capacity. Transplantation of DPSCs in a mouse hindlimb ischemia model produced higher blood flow and capillary density than transplantation of BM-MSCs and ADSCs, which being associated with superior recovery of limb movement abilities and reduction of ischemic hindlimb damage (55). DPSCs also mediate stronger anti-apoptotic effects in a microenvironment challenged by oxidative and serum deprivation than BM-MSCs, ADSCs and UC-MSCs (45).

Cell size and diameter are important for safety after intravascular delivery as they are the major, but not the only, determinants of vascular obstruction and complications (56) (**Table 2**). Previously reported studies showed that the cell diameter of human DPSCs is around 15–16 μm (59), which is comparable to NSCs (57, 58) but slightly smaller than for most MSC populations (57, 60) including human BM-MSCs (61). Still this means that one has to expect a considerable pulmonary passage filtering effect after intravenous delivery, as well as a risk for microembolism after intraarterial administration (62).

TABLE 2 | Overview of cell size of cell populations.

Cell population	Cell diameter	Cell source
NSCs (57, 58)	16 μm	Human fetal brain
DPSCs (59)	15–16 μm	Human dental pulp
MSCs (57, 60)	17–18 μm	Bone marrow; adipose tissue; human umbilical cord blood
Hematopoietic stem/progenitor cells (57)	6–10 μm	Bone marrow; peripheral blood; cord blood
Mononuclear cells (57, 60)	7 μm	Bone marrow; peripheral blood; cord blood

Hence, thorough investigations identifying the optimal route of DPSC administration by considering safety and efficacy aspects are recommended in DPSC translational research.

DPSCs FOR ISCHEMIC NEURONAL DAMAGE: *IN VITRO* EFFECTS

Treatment with immunosorted IGF1R$^+$ DPSCs significantly modulates neurite regeneration and anti-inflammation in primary cortical cultures subject to oxygen/glucose deprivation (OGD) (36). DPSCs cultivated on adult mouse hippocampal slices were able to stimulate neurogenesis in both the CA1 zone and at the edges of the hippocampal slices through neurotrophic support *in vitro* (41). Besides, DPSCs can protect primary hippocampal, mesencephalic (63) and dopaminergic neurons (64) from β-amyloid peptide and 6-OHDA induced toxicity, respectively. Furthermore, DPSCs and conditioned medium from DPSCs show superior protective, migratory, and angiogenic effects in OGD-injured astrocytes as compared to BM-MSCs (52, 65). Reducing reactive gliosis, reactive oxygen species production and inflammatory mediators might contribute to this protective effect (52).

DPSCs EFFECTS AFTER ISCHEMIC STROKE *IN VIVO*

Human DPSCs can differentiate toward functionally active neurons under appropriate culture conditions (66–68). This comes on top of their bystander effects, indicating that DPSCs might provide enhanced therapeutic capacities in neurological diseases including stroke, Parkinson's disease, Alzheimer's disease, and spinal cord injury (52, 63, 69). To date, there are several preclinical studies demonstrating that DPSCs exert neuroprotective effect resulting in improved functional outcome and reduced infract volumes in rodent stroke models (**Table 3**) (52, 66, 68, 70–76). No obvious deleterious effects were observed in these studies (66, 68, 71–73, 75), but have not been always explicitly looked for.

A number of remarkable improvements were seen in behavioral tests (**Table 3**), underpinning the considerable effect DPSCs may exert after ischemic stroke. However, many of the behavioral tests used are known for a tendency to overestimate true functional recovery in standard rodent models so future research may also include the use of highly specific behavioral readout systems (77).

During ischemia, neurons are unable to maintain normal transmembrane ion gradient and balance, resulting in cell death by apoptosis, excitatory toxicity, and oxidative stress. Inflammatory reactions contribute to cell death in subacute and even chronic stages what can be exacerbated in the presence of important stroke risk factors (78, 79). These pathophysiological processes are interrelated and can trigger each other, forming a vicious cycle (80, 81). Indeed, neuroinflammation and immune response after stroke have been recognized as key factors contributing to overall brain damage and the extent of neurological deficit (82). The administration of DPSCs during the acute phase of stroke dampens inflammation *in vivo*, and can promote recovery from in post-ischemia/reperfusion brain injury (70). Moreover, intracerebral transplantation of DPSCs or immunosorted IGF1R$^+$ DPSCs into the ischemically injured neonatal murine brain significantly increases immunomodulation, enhances poststroke recovery, and promotes neuroplasticity (36, 67). Further, intravenous transplantation of DPSCs or DPSC-derived neurosphere cells significantly ameliorates the impact of global cerebral ischemia, decreases neuronal cell death in the hippocampal CA1 region, improves neuromotor and cognitive function as well as overall survival rates in stroke animals (73). Moreover, intracerebral transplantation of DPSCs also enhanced poststroke functional recovery after brain injury through increasing expression of the anti-apoptotic protein Bcl-2 (67).

Transplanted DPSCs can migrate into the boundary of ischemic areas, and express neural cell and NSC markers such as βIII tubulin, doublecortin (DCX), nestin, and NF (72). The cells' beneficial effects may even be exerted after xenogeneic transplantation as evidenced by a study showing that porcine DPSCs (CD31$^-$/CD146$^-$ side population cells) injection promotes recovery form motor impairment and reduced infarct volume, promoted migration and differentiation of endogenous NSCs, and finally induced vasculogenesis after stroke in rats (66).

DPSC EXOSOMES—GREAT OPPORTUNITIES FOR CELL THERAPY WITHOUT CELLS

The limited survival, differentiation and integration of DPSC-derived cells into the ischemically lesioned brain implies that the functional improvement is more likely mediated through bystander effects rather than cell replacement and differentiation (33). It has been well-documented that the MSC secretome contains a variety of cytokines, chemokines, and growth factors, along with extracellular vesicles (EVs). The most important EVs in MSC-conditioned medium are exosomes, which are of "nano" size (30–100 nm in diameter) (83, 84). EVs play an important role in intercellular communication because they can transfer RNA, micro-RNA, proteins, membrane receptors and even organelles (mitochondria) between cells (85, 86). MSC-derived EVs are of increasing interest since they may have

TABLE 3 | Overview of DPSCs therapy for ischemic stroke animal models.

Cell type and dose	Delivery method	Delivery time	Animal model	Transplantation paradigm	Function and mechanisms	Primary endpoint and effect sizes
Human DPSCs; 6 × 10^5 in 4 μl (68)	Intracerebral (striatum and cortex)	24 h after MCAO	Rat MCAO (2 h)	Xenogeneic	Improved functional recovery; Differentiation into astrocytes; Paracrine effects.	Neuroscore: 35% improve ($p < 0.05$)*
Human DPSCs; 4 × 10^6 in 500 μl (52)	Intravenous (tail vein)	24 h after MCAO	Rat MCAO (2 h)	Xenogeneic	Improved functional recovery and reduced infarct volume; Differentiated into astrocytes and neuron-like cells; Promoted angiogenesis and inhibited astrogliosis.	Infract volume: 44% decrease, ($p < 0.05$); mNSS: 38% improve ($p < 0.05$)*
Human DPSCs; 1 × 10^6 in 1 ml (70)	Intravenous (tail vein)	immediately after MCAO	Rat MCAO (90 min)	Xenogeneic	Reduced the infarct volume and improved the neurological recovery; Inflammation modulation; BBB permeability modulation; Promoted angiogenesis.	Infract volume: 23% decrease ($p < 0.01$); Rotarod test: 108% improve ($p < 0.01$) *; Forelimb grip strength: 54% improve ($p < 0.05$)*
Rat DPSCs; 3 × 10^6 in 300 μl (71)	Intravenous (tail vein)	24 h after MCAO	Rat MCAO (2 h)	Allogeneic Homologous	Enhanced sensorimotor functional recovery; Differentiation into neuronal progenitor cells and neuron-like cells, and triggered neurogenesis.	mNSS: 52% improve ($p < 0.05$)*; Adhesive-removal test: 38% improve ($p < 0.05$)*
Rat DPSCs; 1 × 10^6 in 500 μl (72)	Intravenous (tail vein)	24 h after MCAO	Rat MCAO (2 h)	Allogeneic Homologous	Reduced infarct volume and cerebral edema; Differentiated into neuron-like cells	Infract volume: 31% decrease ($p < 0.05$)
Rat DPSCs and dental pulp-derived neurospheres; 1×10^6 in 1 ml (73)	Intravenous (tail vein)	3 h after brain ischemia	Rat severe forebrain ischemia model (11 min)	Allogeneic Homologous	Improved survival rate and cognitive function; Reduced the dead neurons of hippocampus CA1.	Survival rate: 36% improve ($p < 0.05$); Water-maze test: 62% improve ($p < 0.05$)*
Human DPSCs; 1 × 10^6 in 1 ml (74)	Intravenous (tail vein)	immediately and 3 h after MCAO	Rat MCAO (90 min)	Xenogeneic	Reduced ischemic damage and improved functional recovery; Inflammation modulation	Infract volume: 30% decrease ($p < 0.05$); Rotarod test: 97% improve ($p < 0.01$)*; Forelimb grip strength: 40% improve ($p < 0.01$)*

**Compare with vehicle-treated stroke animals.*

a comparable therapeutic potential to MSCs themselves, but are relatively safer in application, and can pass through the BBB far more easily than cells (87). Studies demonstrated that administration of BM-MSC or ESC-derived exosomes could significantly increases neurogenesis and vasculogenesis, and promotes functional recovery in stroke animal (88, 89).

Likewise, accumulating evidence demonstrated the potent neuroprotective properties of DPSC-derived EVs. An *in vitro* study showed that DPSC-EVs which were grown on laminin-coated microcarriers display neuroprotective properties in 6-OHDA-exposed human dopaminergic neurons (90). DPSC-EVs also reduce cytotoxicity through anti-apoptotic mechanism by upregulating endogenous Bcl-2, and decrease the expression of the pro-apoptotic regulator Bax in Aβ peptide-exposed human neuroblastoma (SH-SY5Y) cells (54). An *in vivo* study showed that exosomes derived from DPSCs have beneficial effects after focal cerebral ischemia in the rat by stimulating angiogenesis and neurogenesis (91). In addition, the therapeutic potential of DPSC-derived conditioned medium (CM) was found to be similar to that of the injection of living cells in animal model of stroke, leading to motor function improvement and infarct volume reduction (76). Moreover, CM from human DPSCs also induced significant neuroprotection, enhanced neuronal sprouting, and reduced neuroinflammation in a mouse model of Alzheimer disease (92). DPSC-derived exosomes were further shown to exert strong anti-inflammatory effects at levels comparable to those of glucocorticoids. They also suppress cathepsin B and matrix metalloproteinase (MMP) activities at the site of inflammation in mice, likely mediated by the transport of annexin A1, phospholipases, and lipid mediators to the site of inflammation (93). Taken as a whole, these studies showed the potential of DPSC-derived exosomes for the treatment of central nervous system disorders.

Investigation of molecules within EVs provides new insight to EV-mediated beneficial mechanism, although determining the exact composition and content of the exosomal content (cargo) produced by different cell types is hard to establish due to inevitable differences regarding the conditions in which the cells are prepared and processed (83). High-throughput mass spectrometry-based analysis of proteins revealed some surface receptors (CD105, CD73, CD29, CD81, and CD44), signaling molecules (many of which are involved in controlling of TGF-β, BMP, MAPK, and PPAR recipient cell signaling pathways), adhesion molecules and MSC-associated markers which may account for the therapeutic potential of MSC-derived EVs (94, 95). Baglio et al. (96) reported a substantial similarity between the most represented miRNAs in ADSC and BM-MSC exosomes, but their relative proportions are different. The top 5 most abundant miRNAs (accounted for 50 % of the total miRNA reads) in ADSC exosomes were miR-486-5p, miR-10a-5p, miR-10b-5p, miR-191-5p, and miR-222-3p, while miR-143-3p, miR-10b-5p, miR-486-5p, miR-22-3p, and miR-21-5p were among the most abundant for BM-MSC exosomes. Besides, exosome libraries were highly enriched in the class of tRNAs, which represented >50 % of total small RNAs in ADSC exosomes and 23–35% in BM-MSC exosomes. However, since the studies of DPSC exosomes are just at the initial stage, there is no exactly content of these exosomes reported.

POSSIBLE MECHANISMS OF DPSC THERAPY FOR ISCHEMIC STROKE

Previous studies suggested that human DPSCs potentially differentiate into functional neural progenitors or neurons which may integrate into the brain (64, 97, 98). Similarly, studies showed that grafted DPSCs survive, migrated to infarct boundary zones, and differentiate into neurons and astrocytes in the rat. The cells also express neuron-specific markers including βIII tubulin and NF (52, 72). However, only a very small part of transplanted DPSCs (2.3 ± 0.7%) survived in the post-stroke brain, migrated to the peri-infarction areas, and differentiated into astrocytes (51.0 ± 8.6% $GFAP^+$) in preference to neurons (8.7 ± 6.1% $NeuN^+$) (68). Hence, the therapeutic potential of DPSCs is believed to be mainly exerted by their bystander effects (**Figure 2**) (76).

DPSCs have the potential to improve the microenvironment and enhancing neurogenesis (47, 64, 99, 100). DPSCs also have been shown to exert potent immune-modulatory properties *via* inhibition of activated T cell responses (27) and peripheral blood mononuclear cell proliferation (101), regulating the expression of inflammatory factors such as TGF-β and interleukin (IL)-6 (102), and the induction of Fas ligand-mediated T cell apoptosis (103). Although the suppression of T cell proliferation seen in *in vitro* studies is now established, this property of DPSCs may not be the sole mechanism of action *in vivo*, particularly since blood circulation increases the number of T cells perpetually. More studies are therefore warranted to further understand the interaction between DPSCs and the immune system because this cross talk has important therapeutic implications.

LIMITATIONS OF DPSCs AND CHALLENGES RELATED TO THEIR USE

Though DPSCs have a higher proliferation rate than MSCs, it still needs at least 1 to 2 months to acquire enough cells for therapy from primary isolation (104) (**Table 4**), which may limit their use at the acute stage of acute onset diseases. The long-term side effects associated with the use of DPSCs also have not been sufficiently studied so far. Further studies are warranted to clarify possible long-term risks associated with the use of these cells, as well as optimal cell preparation, storage and application procedures including routes and time points of application. Tailored potency assays for clinical trials are also lacking, and the optimal route of delivery awaits detailed investigation. Moreover, clinical investigation of the cells has just started (105) so appropriate double-blinded, randomized clinical trials have not yet been reported, currently preventing any conclusion on a potential clinical efficacy of these cells. In addition, further studies thoroughly assessing efficacy, safety and also the content of DPSC-derived EVs are required since EVs are highly promising therapeutic tools for regenerative medicine, but a thorough proof of concept is still missing. Additional research is also needed to capitalize on the DPSC differentiation potential. This might require specialized stroke models, for instance mimicking lacunar stroke, that may be more permissible

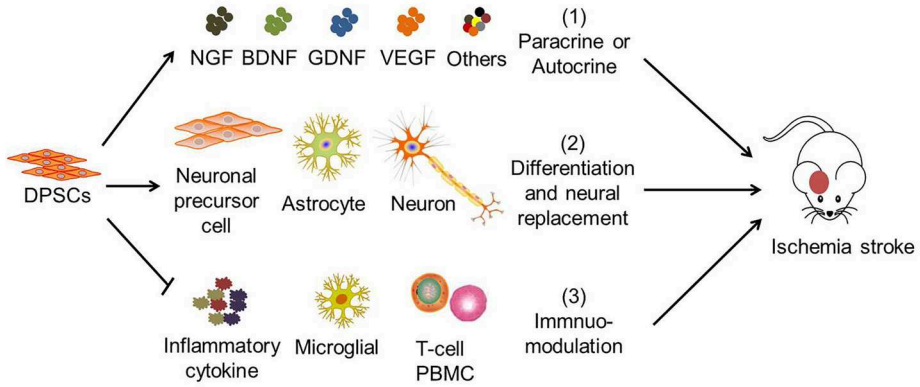

FIGURE 2 | The mechanisms of DPSC therapy for ischemic stroke. The therapeutic effects of DPSCs in stroke are attributed to (1) paracrine or autocrine production of cytokines and growth factors, (2) neural replacement through differentiation into neuronal progenitor cells, astrocytes and neuron-like cells, (3) immuno-modulation with mitigation of pro-inflammatory cytokine expression, of microglial activation, inhibition of activated T-cell response, and peripheral blood mononuclear cell (PBMC) proliferation. (1) and (3) are believed to be the main therapeutic effects of DPSCs.

TABLE 4 | The comparison of DPSCs with other stem cells.

	DPSCs	ESCs	NSCs	MSCs		
				BM-MSCs	ADSCs	UC-MSCs
Basic abilities						
Proliferation potential	++	++	+/–	+	+	++
Neurogenic differentiation	+	++	++	+/–	+/–	+/–

Required cultivation time to achieve sufficient cell numbers	1–2 months	1–2 months	>2 months	1–2 months	1–2 months	1–2 months
Cryopreservation abilities	+	+	+/–	+	+	+
Cell banking opportunities for adults	+	+/–	–	+/–	+/–	+/–
General amount of information available about cell properties	–	+	+	++	+	+

(++) very high, (+) high, (+/–) average, (–) low, (––) very low.

for tissue restoration, and/or the use of biomaterials to support cell engraftment and survival (106).

CONCLUSIONS

This review summarizes the main DPSC characteristics including surface marker expression, proliferation and differentiation potential, cytokine and trophic factor secretion ability, as well as therapeutic effects in *in vitro* and *in vivo* stroke models. It also elucidates important underlying therapeutic mechanisms. DPSCs express a variety of markers that are found on MSCs, ESCs, and NSCs. Although they can differentiate into different types of neuronal cells, bystander effects are believed to be their predominant therapeutic mechanism. DPSCs are widely available, easily accessible, and can support well-established stroke therapies, thereby potentially extending the therapeutic time window and/or augmenting the therapeutic impact. DPSCs differ from the other adult stem cell populations due to their embryonic origin from the neural crest and are of special interest because of their neurotropic character, which makes DPSCs and their exosomes particularly attractive as a new therapeutic tool for the alleviation of symptoms of stroke and, potentially, other neurodegenerative diseases. Besides, DPSCs exhibit a higher proliferation rate, higher expression of trophic factors, stronger neuroprotective effects and neuro-supportive properties *in vitro* and *in vivo* than MSC populations (**Table 4**), which provide a tempting prospect for stroke treatment.

AUTHOR CONTRIBUTIONS

XL, ZS, and CC wrote the manuscript. JB and SL designed the literature assessment strategy and edited the manuscript.

FUNDING

The work was fund by the National Natural Science Foundation of China (81300985), Natural Science Foundation of Liaoning Province (2015020549), LiaoNing Revitalization Talents Program (XLYC1807124) and Dalian Municipal Health and Family Planning Project (1711014, 1811014).

Stroke remains the leading cause of long-term disability with limited options available to aid in recovery. Significant effort has been made to try and minimize neuronal damage following stroke with use of neuroprotective agents, however, these treatments have yet to show clinical efficacy. Regenerative interventions have since become of huge interest as they provide the potential to restore damaged neural tissue without being limited by a narrow therapeutic window. Neurotrophins, such as brain-derived neurotrophic factor (BDNF), and their high affinity receptors are actively produced throughout the brain and are involved in regulating neuronal activity and normal day-to-day function. Furthermore, neurotrophins are known to play a significant role in both protection and recovery of function following neurodegenerative diseases such as stroke and traumatic brain injury (TBI). Unfortunately, exogenous administration of these neurotrophins is limited by a lack of blood-brain-barrier (BBB) permeability, poor half-life, and rapid degradation. Therefore, we have focused this review on approaches that provide a direct and sustained neurotrophic support using pharmacological therapies and mimetics, physical activity, and potential drug delivery systems, including discussion around advantages and limitations for use of each of these systems. Finally, we discuss future directions of biomaterial drug-delivery systems, including the incorporation of heparan sulfate (HS) in conjunction with neurotrophin-based interventions.

INTRODUCTION

Stroke consistently remains a leading cause of death and disability worldwide (Mozaffarian et al., 2015). While stroke preferentially affects older people, stroke can affect anyone of any age, race, or gender (Feigin et al., 2014). In addition, ethnic disparities are known to exist, for instance, New Zealand Māori, and Pacific Island populations experience a stroke at a much younger age than Europeans (Feigin et al., 2006). With the global population continuing to age, the number of people suffering from a stroke and subsequently living with a lasting disability is also expected to rise. As a result, there is an urgent and unmet need to find treatment options to aid in improving recovery of lost functions.

The central nervous system CNS has a limited capacity to regenerate, which is one of the main causes for why stroke patients recover poorly. In addition, there is a lack of spontaneous recovery seen after stroke, leading to a large personal, and societal burden (Mozaffarian et al., 2015). This burden has led research into investigating neural mechanisms of regeneration and repair, in the hope to restore and improve lost functions following stroke. Depending on the neuronal area affected by the stroke (i.e., motor, speech, or language centers), rehabilitation, mental practice, and music therapies have all been shown to increase the capacity to recover after a stroke (Johansson, 2011). However, in patients who have had a large stroke, rehabilitation is less effective in facilitating an improvement in functional recovery (Johansson, 2011).

Significant work has shown that exogenous administration of GFs can help facilitate the repair of injured CNS tissue via their ability to regulate neuronal growth and survival (Connor and Dragunow, 1998; Sofroniew et al., 2001; Berretta et al., 2014). In particular, BDNF has been highlighted as being a key regulator of rehabilitation-induced recovery after stroke (Ploughman et al., 2007, 2009). Moreover, activity-driven increases in BDNF have also been shown to promote motor recovery after stroke (Fritsch et al., 2010; Clarkson et al., 2011).

The regenerative capabilities of neurotrophin-mediated interventions have already been observed in preclinical models of neurodegenerative diseases. Specifically, systemic administration of BDNF, NGF, and NT-3 have been reported to enhance neurite outgrowth, neurogenesis, and functional recovery in rodent models of stroke (Grill et al., 1997; Jakeman et al., 1998; Ramer et al., 2000; Winkler et al., 2000; Schäbitz et al., 2004, 2007). However, the translation of such treatments into a clinical setting has been challenged by poor BBB permeability, off-target effects on the PNS, and short half-life (Chan et al., 2017). Approximately 98 percent of all compounds targeting the CNS have failed to cross the BBB (Pardridge, 2005), creating a need for alternative approaches. As a novel solution to this issue, various biomaterials have been engineered to provide an effective, and sustained drug-delivery system to the injured brain. These systems allow stem cells and/or small drug molecules including neurotrophins to bypass the BBB (Aizawa et al., 2008) and be delivered directly to the site of injury.

Heparan sulfate, as the GAG cleaved from its protein backbone, is thought to provide a novel approach for the delivery of neurotrophins to the injured CNS. HS plays a critical role in coordinating GFs and mediating their biological potential (Xu and Esko, 2014). This highly sulfated biopolymer is ideally suited as a component of a biomaterial therapeutic for brain injury. It is chemically stable, physiologically tolerated, has a demonstrated long-term benefit to wound repair by tunable protein-interactions and has been demonstrated to tolerate the level of γ-irradiation treatment required to sterilize sufficiently medical-device-like materials (Smith et al., 2018). In addition, HS has demonstrated a remarkable propensity to stabilize short-lived GF's in what appears to be a selective fashion (Wang et al., 2014; Wijesinghe et al., 2017).

The effects of BDNF and other GFs have previously been investigated in various stroke models and have shown strong regenerative potential (Berretta et al., 2014). In general, BDNF is believed to have a beneficial effect on stroke recovery via several mechanisms: protection against acute ischemic injury (Schäbitz et al., 2007), increased angiogenesis (Kermani and Hempstead, 2007), neurogenesis (Schäbitz et al., 2007), and neural repair (Mamounas et al., 2000) as well as enhanced synaptic plasticity (Waterhouse and Xu, 2009; Clarkson et al., 2011). Whilst the use of BDNF and other GFs to promote neuroprotection and minimize the spread of damage during the acute phase of injury has been extensively studied (Pardridge, 2005; Wu, 2005; Cai et al., 2014), this work will not be reviewed here. This review instead summarizes past experimental evidence that highlights how neurotrophins have shown potential as a delayed treatment option for aiding in repair and regeneration of neural tissue for stroke and other neurodegenerative diseases. In addition, we discuss novel biomaterial delivery systems that have been utilized to enhance the delivery of neurotrophins to the CNS, as utilizing such delivery systems have resulted in a further improvement in

functional recovery when treatment is delayed by days to weeks post injury.

Stroke Pathophysiology and Mechanisms of Endogenous Repair

Stroke occurs when blood flow to the brain is either obstructed by an occlusion (ischemic) or following rupturing (hemorrhagic) of a cerebral blood vessel. Lack of oxygen and glucose, and a build-up of toxic by-products, cause the areas of the brain deprived of blood flow to undergo a chain of pathological events (ischemic cascade), ultimately leading to cell death, and loss of function associated with that region of the brain (Dirnagl et al., 1999). As time passes, a lack of reperfusion to the penumbra (regions surrounding the core infarct) results in further expansion until the stroke is fully formed. Whilst neuroprotective agents have shown preclinical success at restoring reperfusion and minimizing cellular damage, they are only effective when administered within the first few hours following stroke onset and have failed to translate into clinical use, with the exception of thrombolytic compounds (Moretti et al., 2015). As a result, much needed stroke research unraveling the mechanisms associated with neuroregeneration and repair in the days to weeks following a stroke have highlighted a number of targetable treatment options, some of which have already resulted in the establishment of clinical trials.

Whilst the CNS shows limited capacity for regeneration and repair, under pathological conditions such as stroke, axonal sprouting, endogenous neurogenesis, and spontaneous functional recovery appear to be enhanced (Carmichael et al., 2001; Benowitz and Carmichael, 2010). In addition, Stroemer et al. (1995) reported that both GAP-43 and synaptophysin, two proteins involved with neurite growth and synaptogenesis; are upregulated throughout the neocortex 2 weeks following a focal infarct in rats. Further, these researchers show a positive correlation between improved locomotor function and stroke-induced elevations in GAP-43 and synaptophysin. It has since been established that enhancing neuronal connections throughout the ischemic brain via pharmacological interventions correlates with an improvement in functional motor recovery after stroke (Lee et al., 2004; Overman et al., 2012; Clarkson et al., 2013; Cook et al., 2017).

Neurogenesis occurs continuously in two areas of the healthy adult CNS: the SVZ of the lateral ventricle, and the subgranular zone (SGZ) of the hippocampal dentate gyrus. In these areas, self-renewing multipotent cells known as NSPCs differentiate into both neuronal, and glial cells (Taupin, 2006). Under physiological conditions these NSPCs migrate to the dentate gyrus or olfactory bulb to replenish the continuously dying granule cells or olfactory neurons, respectively. Following acute injury to the CNS, these resident neural progenitors may also be induced in an attempt to replace damaged neurons (Zhang et al., 2005; Greenberg, 2007). Supporting this notion, many animal models of stroke have reported the upregulation of SVZ and SGZ neurogenesis, peaking around 7–10 days post-stroke (Iwai et al., 2002, 2003; Parent et al., 2002; Carmichael et al., 2005). Furthermore, stroke-induced local changes to the microvasculature has been found to attract neuroblasts generated within the SVZ and facilitate their migration to the ischemic boundary zone (peri-infarct), an area lying lateral to the stroke (Carmichael et al., 2005; Yamashita et al., 2006; Thored et al., 2007).

Interestingly, preclinical research indicates NSPCs offer the majority of their regenerative potential through bystander effects, specifically by providing a rich source of GFs to the injured tissue rather than contributing to structural reconstruction (Chen et al., 2000). Supporting this, preclinical work has shown that MSCs facilitate an improvement in functional recovery, even though they fail to differentiate into mature neurons or glia when grafted into the ischemic boundary zone of rats exposed to a MCAo (Chen et al., 2000). Moreover, at least a portion of the therapeutic potential of MSCs has been ascribed to their ability to enhance endogenous neurogenesis and protect newborn cells from deleterious environments (Yoo et al., 2008), both of which are mechanisms mediated by neurotrophin signaling pathways. Although explicit evidence directly linking enhanced neurogenesis and functional recovery is sparse, a direct causal relationship seems probable with almost all neuroregenerative agents that improve neurological function following stroke also potentiating neurogenesis (Zhang et al., 2001; Wang et al., 2004; Schäbitz et al., 2007; Cook et al., 2017). Of note, HS has also been demonstrated to support the proliferation (without differentiation) of stem cells *ex vivo* (Dombrowski et al., 2009; Wijesinghe et al., 2017).

In addition to changes in neurogenesis, angiogenesis and axonal sprouting, work over the past few years has highlighted a chronic imbalance in brain excitability following stroke (Clarkson, 2012). Specifically, stroke has been reported to weaken transcallosal inhibition from the ipsilesional hemisphere onto the intact, contralesional hemisphere (Murase et al., 2004; Duque et al., 2005). This further exacerbates an increase in tonic GABAergic inhibition onto the stroked hemisphere, limiting its potential for cortical plasticity, and spontaneous recovery after stroke (Clarkson et al., 2010). Indeed, restoring neuronal excitability in the ipsilesional stroke hemisphere via increasing AMPA activity, and/or dampening tonic GABAergic inhibition has shown great promise to enhance recovery of lost function (Clarkson et al., 2010, 2015; Orfila et al., 2017). Whilst the above evidence collectively supports an intrinsic capability of the ischemic brain to regenerate and repair itself, it must be reiterated that these mechanisms alone are most often insufficient to cause a complete reversal of the functional impairment (Yamashita and Abe, 2012). Furthermore, age-related decreases in neurogenesis (Cooper-Kuhn et al., 2004; Kernie and Parent, 2010) and angiogenesis (Sonntag et al., 1997) have been reported, making it even harder for endogenous repair mechanisms to overcome damage and promote recovery. Accordingly, regenerative interventions have begun to target the potentiation of these endogenous mechanisms to try and maximize functional recovery in animal models of stroke and other neurodegenerative conditions such as SCI and Alzheimer's disease (Wang et al., 2004; Piantino et al., 2006; Schäbitz et al., 2007; Weishaupt et al., 2014; Choi et al., 2018). This has been demonstrated in the case of the endogenous stimulation of key

GF's by addition of HS on a biomaterial support to the wound site (Murali et al., 2013).

Neurotrophins for Repair and Regeneration

Neurotrophins are the predominant mediators of neuronal survival and regeneration throughout the CNS, making them of particular interest in neuroregenerative research. The neurotrophin family consists of several main GFs, including NGF, BDNF, and NT-3. All neurotrophins are initially synthesized as precursor proteins, known as pro-neurotrophins. These pro-neurotrophins can then be cleaved intracellularly by furin or proconvertases, or extracellularly by metalloproteases and plasmin, to form stable mature neurotrophins. Whilst mature neurotrophins selectively bind to their respective Trk to exert neurotrophic effects, pro-neurotrophins have been found to conduct somewhat opposing, pro-apoptotic effects through the $p75^{NTR}$/sortilin receptor (see **Figure 1**: further information on neurotrophin signaling pathways can be found below; (Nykjaer et al., 2004; Teng et al., 2005). This finding has left the scientific world moving away from the passive function of these pro-domains, and has brought a new level of complexity to the role and function of neurotrophin signaling in the CNS (Zanin et al., 2017).

The expression of both neurotrophins and their respective receptors typically decrease with age, indicating neurons and glia yield a limited trophic ability to combat natural, and pathological neurodegeneration (Webster et al., 2002; Lommatzsch et al., 2005). In support of this, reduced BDNF expression in the hippocampus has been shown to correlate with impairments in both spatial and working memory in gerbils and rats (Schaaf et al., 2001; Hwang et al., 2006). Furthermore, excitotoxic lesions to the nigrostriatal pathway increases BDNF expression in the striatum of young, but not aged rats (Yurek and Fletcher-Turner, 2000, 2001). Similarly, lesions to the medial septum significantly elevates hippocampal levels of NGF in young rats only (Scott et al., 1994). Interestingly, further assessment of these young rats revealed an enhancement in neurite outgrowth compared to their aged counterparts (Scott et al., 1994; Kaseloo et al., 1996).

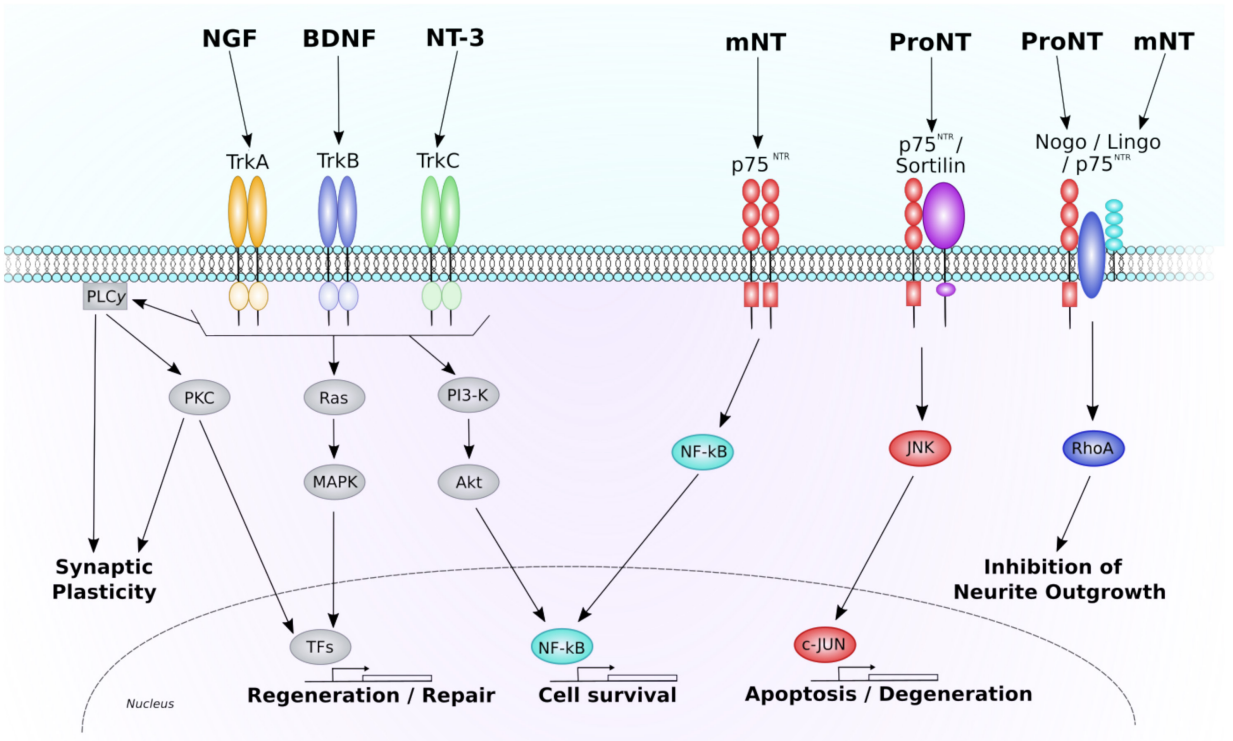

FIGURE 1 | Neurotrophin signaling through the $p75^{NTR}$ and Trk receptors. This diagram depicts the major intracellular signaling pathways associated through each neurotrophin receptor. Each Trk receptor isoform binds mature neurotrophins and acts through three predominant pathways. Activation of PLC-γ1 results in PKC-mediated promotion of synaptic plasticity. Activation of Ras initiates MAPK-mediated promotion of neuronal regeneration and growth. Activation of PI3-K results in activation of Akt and promotion of NF-κB-mediated cell survival. Each of these pathways are also known to regulate genetic transcription, further promoting pro-survival, and regenerative gene expression. The $p75^{NTR}$ receptor also regulates three main pathways. When a mature neurotrophin binds to an isolated $p75^{NTR}$ NF-κB-mediated cell survival is promoted. If the $p75^{NTR}$ is co-expressed with the sortilin receptor, pro-neurotrophins can bind, and cause activation of JNK-c-Jun mediated cell death and degeneration. A receptor complex consisting of Nogo, $p75^{NTR}$, and Lingo1 can bind both pro- and mature-neurotrophins to alter neurite outgrowth in a RhoA-dependent manner. NGF, nerve growth factor; BDNF, brain-derived neurotrophic factor; NT-3, neurotrophin-3; Trk, tropomyosin receptor kinase; mNT, mature neurotrophin; ProNT, proneurotrophin; $p75^{NTR}$, pan neurotrophin receptor 75; PLC*γ1*, phospholipase C gamma one; PKC, protein kinase C; MAPK, mitogen-activated protein kinase; TFs, transcription factors; PI3-K, phosphoinositide 3-kinase; NF-kB, nuclear factor kappa-light-chain-enhancer of activated B cells; JNK, c-Jun N-terminal kinase.

Evidence from preclinical animal models also supports an age-related difference in expression of BDNF, with stroke inducing a lessened elevation of BDNF in aged mice compared to young stroke controls (Clarkson et al., 2015). In summary, aging exacerbates the degree of functional impairment as a consequence of damage to the brain, relative to young animals. This is thought to be in part, due to the differing recovery trajectories observed in aged and young animals, including differences in spontaneous recovery, neurogenic activity, and the neuronal sprouting transcriptome (Li S. et al., 2010; Hermann and Chopp, 2012). Therefore, it has been postulated that age-specific interventions may be required to maximize the effectiveness of regenerative interventions. Specifically, aged animals may require a combinatorial intervention to gain functional recovery to the same extent as young mice. Supporting this, systemic administration of the high impact AMPAKine (positive allosteric modulator of AMPA receptors), CX1837, has been reported to stimulate an increase in BDNF expression and promote functional recovery in aged mice following photothrombotic strokes (Clarkson et al., 2015). Interestingly, the use of low impact AMPAkines (positive allosteric modulator of AMPA receptors) have failed to elicit functional recovery in the same animal model (Clarkson et al., 2011). Although neurotrophins mediate intrinsic repair mechanisms, the above collectively supports that their intrinsic regeneration abilities decline during aging.

Neurotrophin Signaling Pathways

The neurotrophin family shares two common classes of transmembrane receptors; the Trk receptors that bind the mature neurotrophins, and the $p75^{NTR}$, a receptor from the tumor necrosis factor (TNF) receptor superfamily that preferentially binds the pro-neurotrophins. Whilst the low-affinity $p75^{NTR}$ binds to all members of the neurotrophin family with similar nanomolar affinities (Bothwell, 1995), each neurotrophin shows preference for different Trk receptor isoforms; specifically, NGF binds to the TrkA, BDNF to TrkB, and NT-3 to TrkC. Once a mature neurotrophin has bound to its respective Trk receptor, the Trk receptor dimerizes and undergoes transphosphorylation to specific intracellular tyrosine kinase residues. These phosphorylated tyrosine-kinase residues act as docking sites for adaptor proteins that allow additional kinases to be recruited for activation of intracellular signaling pathways (see **Figure 1**).

Activation of the Trk receptor is known to phosphorylate and activate PLC-γ1 and its associated second messenger signaling pathway. PLCγ activity generally generates two distinct second messenger systems: IP3 and DAG, both of which increase intracellular release of calcium (Ca^{2+}) and stimulate PKC-mediated signaling, resulting in enhanced neuronal and synaptic plasticity (Chao, 2003; Yoshii and Constantine-Paton, 2010). Trk receptors have also been found to activate Ras, a small GTP-binding protein that further activates the MAPK signaling pathway to generate ERK. ERK then phosphorylates and activates a range of TFs including CREB, causing downstream transcriptional changes to genes that control neuronal differentiation and neurite outgrowth (Kaplan and Miller, 2000). Another major pathway activated by Trk receptors is the PI3-K pathway, which leads to downstream activation of the serine/theronine kinase, AKT to promote NF-kB-mediated neuronal survival (Reichardt, 2006). The PI3K/AKT signaling pathway plays a central role in regulating cell growth, proliferation, and survival under physiological and pathological conditions (Cantley, 2002). In addition, PI3K/AKT signaling has been revealed to contribute to axonal sprouting in cultured hippocampal neurons (Atwal et al., 2000; Sanchez et al., 2001; Jaworski et al., 2005), which is an important mechanism underlying post-stroke functional recovery (Li S. et al., 2010; Overman et al., 2012; Clarkson et al., 2013). For instance, in a recent paper by Clarkson et al. (2015), experimenters combined systemic administration of a high impact AMPAKine, CX1837, and local hydrogel delivery of BDNF, resulting in a synergistic increase in phosphorylation of AKT, MEK, and CREB in aged (22–24 months old) mice. This upregulation was observed in parallel to increased functional recovery of motor function. In addition, recent work has also shown that modulation of GSK-3 after stroke can enhance axonal outgrowth (Ueno et al., 2012). Activation of the AKT/GSK-3/CREB pathway has also been observed in other age-related neurological disorders such as Alzheimer's disease, with activation of this pathway leading to an improvement in cognitive function (Tang et al., 2014). To this end the full complement of Trk-mediated signaling pathways that play a role in post-stroke recovery, or their involvement in mechanisms associated with recovery, still remain to be full elucidated.

Whilst neurotrophins signal via two different receptor pathways, most of the attention has been focused on the activation of Trk receptors and their subsequent biological effects (see **Figure 1**). However, over the past couple of decades research has also begun to investigate the surprisingly diverse functions of $p75^{NTR}$, including a somewhat paradoxical involvement in pro-apoptotic signaling (Reichardt, 2006). Most neuronal populations that respond to neurotrophins co-express both $p75^{NTR}$ and Trk receptors. Whilst the exact mechanism remains elusive, the interaction between these two receptors is known to positively modulate Trk function following binding of a mature neurotrophin (Reichardt, 2006). Contrastingly, in the absence of Trk, $p75^{NTR}$ can also promote apoptotic signaling when a complex is formed with sortilin, a Vps10-domain containing protein that acts as a co-receptor for pro-neurotrophin binding (Nykjaer et al., 2004; Teng et al., 2005). In this scenario the activated pro-neurotrophin-receptor complex activates Rac, a GTP-binding protein that promotes the JNK cascade (Harrington et al., 2002), leading to activation of pro-apoptotic genes and apoptotic cell death (Reichardt, 2006).

The $p75^{NTR}$ itself lacks any catalytic intracellular domains, however, it is able to signal via several adaptor proteins. Specifically, $p75^{NTR}$-mediated recruitment of NRIF1/NRIF2, NADE and SC-1 can activate several apoptotic signals including Rac, JNK and NF-kB (Mukai et al., 2000; Dechant and Barde, 2002; Yeiser et al., 2004). The $p75^{NTR}$ is also known to form a signaling complex with the transmembrane proteins Lingo-1 and Nogo-66 (NgR1) receptor, a receptor previously reported to inhibit axonal sprouting and neural plasticity (Schwab, 2010).

Although it is not fully understood how, this receptor complex is known to activate the small GTPase protein, RhoA, leading to inhibition of oligodendrocyte differentiation and myelination, and inhibition of axonal growth in the CNS (Tan et al., 2011). Both pro-neurotrophins and mature neurotrophins have been reported to bind to the $p75^{NTR}$/NgR1/Lingo1 receptor complex, with opposing effects on neurite growth being observed (Lehmann et al., 1999; Deinhardt et al., 2011; Sun et al., 2012). Specifically, introduction of proBDNF or proNGF to neuronal cultures induces growth cone collapse (i.e., the developing or regenerating tip of a neurite) and inhibition of further neurite extension (Lehmann et al., 1999; Deinhardt et al., 2011; Sun et al., 2012). Contrastingly, binding of mature forms of BDNF and NGF to this receptor complex appears to inhibit RhoA activity leading to subsequent disinhibition of neurite outgrowth (Yamashita et al., 1999). Collectively, these findings indicate bidirectional effects of $p75^{NTR}$ depending on both the ligands and receptors present in a particular neuronal microenvironment. It must be reiterated, however, that the mature neurotrophins' enhanced affinity for the Trk receptor counteracts the proapoptotic action of $p75^{NTR}$ activity, resulting in the predominant function of neurotrophin being trophic.

Nerve Growth Factor (NGF)

In the early 1950's Levi-Montalcini (1987) first discovered NGF, demonstrating its' ability to regulate the survival and maturation of developing PNS neurons. NGF has since become one of the best characterized members of the neurotrophin family, acting on many neuronal and glial cell populations throughout the nervous system to promote axonal sprouting, dendritic arborization, and cell body growth (Cuello, 1996; Debeir et al., 1999; Sofroniew et al., 2001). Moreover, recent work has highlighted an interaction between NGF and cells from the immune-hematopoietic linage, including mast cells (Skaper, 2017). Specifically, mast cells have been found to synthesize and release NGF, with NGF also acting back on mast cells to promote survival (Skaper, 2017). Further, NGF concentrations are elevated in various inflammatory and autoimmune states in humans, such as multiple sclerosis and chronic arthritis (Aloe et al., 1992; Laudiero et al., 1992). Whilst this area of research is in its infancy, these findings suggest that under certain conditions, NGF may be able to promote inflammatory cascades, and have deleterious effects on surrounding tissues, arguing a more complicated role of this neurotrophin than previously thought.

Various CNS injuries such as ischemia, seizure-activity and trauma induce a rapid upregulation in the expression of NGF and the TrkA receptor (Lindvall et al., 1994; Goss et al., 1998; Gottlieb and Matute, 1999; Dmitrieva et al., 2016). Although the exact function of this injury-induced upregulation is not fully understood, several lines of evidence suggest enhanced NGF signaling may facilitate the repair of damaged nervous tissue. For example, implantation of fibroblasts, genetically modified to secrete NGF reduce cholinergic cell death and promote axonal sprouting in the aged rats and non-human primates undergoing lesion-induced degeneration (Kawaja and Gage, 1991; Kordower et al., 1994). Moreover, exogenous NGF has also been reported to have a similar effect on transected SC axons, promoting regeneration of damaged axons and restoration of stimulus-driven electrophysiological activity (Ramer et al., 2000). However, it must be noted that the ability of NGF to promote functional recovery in animal models of neurodegenerative diseases remains largely understudied with somewhat opposing findings. For example, enhanced NGF-induced sprouting following SCI is known to be a primary cause of autonomic dysreflexia, a condition in which potentially life threatening episodic hypertension is triggered by stimulation of sensory nerves in the body below the site of injury (Krenz et al., 1999; Weaver et al., 2006). In these situations, enhanced NGF signaling stimulates sprouting of small-diameter primary afferent fibers, thereby amplifying SC reflexes, and promoting dysreflexia. For a more detailed discussion of NGF treatment's mixed success for treating SCI see a recent review by Keefe et al. (2017).

The systemic administration of NGF in clinical trials has also revealed a variety of adverse side effects including marked reductions in body weight, and myalgia to the muscles of the trunk and back (Petty et al., 1994; Eriksdotter Jönhagen et al., 1998). Despite this, the topical administration of recombinant human NGF to the eyes of patients with ophthalmological diseases such as neurotrophic keratitis and dry eye disease has shown promise in relieving symptoms and promoting healing of the damage eye (Bonini et al., 2018; Rocco et al., 2018; Sacchetti et al., 2019).

Brain-Derived Neurotrophic Factor (BDNF)

Brain-derived neurotrophic factor is the most abundant neurotrophin in the CNS (Andero et al., 2014). BDNF-TrkB signaling is well documented to regulate a wide range of neuronal functions including cell survival, neuronal differentiation and migration, neurite outgrowth, and facilitation of LTP and plasticity (Encinas et al., 1999; Boyd and Gordon, 2003b; Pang and Lu, 2004). Both BDNF and its high affinity receptor, TrkB, are widely produced throughout the CNS with high expression being observed in areas such as the neocortex, hypothalamus, and amygdala (Connor and Dragunow, 1998; Binder and Scharfman, 2004).

Studies using *in situ* hybridization have revealed a stroke-induced upregulation of BDNF mRNA expression in both the ipsilateral cortex and hippocampus in rat models of forebrain ischemia (Comelli et al., 1993; Kokaia et al., 1995; Dmitrieva et al., 2016). This upregulation appears to peak within the first 12 h after stroke and remains elevated as late as 1 week later (Béjot et al., 2011; Clarkson et al., 2011). Indeed, stroke-induced changes in BDNF protein have also been observed, with microsphere embolism-induced MCAo causing elevated BDNF expression over a similar time course (Miyake et al., 2002). However, these changes appear to vary across brain regions, with a suppression in BDNF protein expression being observed in the parietal cortex 24-h after MCAo in rats (Kokaia et al., 1995). The expression of BDNF and TrkB levels are also modulated in animal models of SCI (Ikeda et al., 2001) and traumatic brain injury (TBI), which occurs following blunt or penetrating forces

to the skull causing damage to white matter tracts, intracranial hemorrhaging, and ischemia (Rostami et al., 2014).

It must be noted, however, that stroke-induced increases in endogenous BDNF are insufficient to reverse functional impairments (Li B. et al., 2010). Supplementing the ischemic brain with exogenous BDNF has thus been investigated over the past few decades, with research supporting BDNF-enhanced axonal sprouting (Mansour-Robaey et al., 1994; Batchelor et al., 2000, 2002; Mamounas et al., 2000), angiogenesis (Kermani and Hempstead, 2007), neurogenesis (Schäbitz et al., 2007), neuronal plasticity (Yacoubian and Lo, 2000; Zakharenko et al., 2003), and behavioral recovery (Schäbitz et al., 2004; Guan et al., 2012). Importantly, several studies have also reported that a critical threshold in BDNF activity is required in order to achieve an improvement in functional recovery in the weeks following stroke (Ploughman et al., 2009; Clarkson et al., 2011; MacLellan et al., 2011). This was first shown following enriched rehabilitation has been found to only improve motor recovery in rats with elevated BDNF levels post-MCAo (MacLellan et al., 2011). Furthermore, suppressing endogenous BDNF translation with antisense oligonucleotides prevents such improvements (Ploughman et al., 2009). Clarkson et al. (2011) further demonstrated functional motor recovery in mice following administration of a BDNF-inducing AMPAkine following photothrombotic stroke. This effect was not observed when a non-BDNF inducing AMPAkine was applied, or when BDNF function was inhibited with the BDNF ligand decoy, TrkB-Fc (Clarkson et al., 2011). Interestingly, BDNF and the TrkB receptor is abundantly expressed throughout the sensory neurons in the inner ear, leading many researchers to investigate the potential of BDNF in treating deafness (Ramekers et al., 2012). For example, Shibata et al. (2010) treated neomycin-deafened rats with transgenic vectors overexpressing the gene for BDNF within the BMA of the inner ear. Results showed that treatment with the BDNF vectors could promote regrowth of damaged nerve fibers into the cochlear epithelium and enhance survival of spinal ganglion neurons.

Given neurotrophic effects of BDNF it is reasonable to presume that the injury-induced upregulation of BDNF and is receptor acts to restrict pro-apoptotic signaling following injury. Further support for this notion lies in clinical studies investigating a common SNP of the BDNF gene, where valine is substituted for methionine at codon 66 (BDNF val*66*met, otherwise known as rs6265). A resulting 19–30% reduction in activity-dependent secretion of BDNF protein has been reported in humans carrying this SNP (Shimizu et al., 2004), with worse functional outcomes being reported in these individuals following a stroke (Siironen et al., 2007; Mirowska-Guzel et al., 2012). Be that as it may, the val*66*met allele has also been reported to promote recovery of executive function in individuals with TBI (Krueger et al., 2011). Moreover, knock-in-mice homozygous for the Met allele have been reported to display enhanced functional recovery following chronic stroke (Qin et al., 2014). These findings argue a more complicated role of this SNP that requires future investigation to clarify its role following CNS injury.

To date, only a few studies have conducted clinical trials investigating BDNF as a therapeutic intervention. Both intrathecal and subcutaneous administrations of BDNF have been found to be well tolerated in ALS patients (Beck et al., 1994; Bradley, 1999; Ochs et al., 2000). The neurorehabilitative potential of BDNF, however, was not observed due small cohort size and limited half-life. Other proposed factors limiting BDNF's success in human trials includes the difficulty of producing sufficient amounts of BDNF for use in human interventions, and the lack of studies investigating higher doses of BDNF in animal models (Nagahara and Tuszynski, 2011). However, the use of biomaterial drug-delivery systems holds promise in circumventing these issues, as lower concentrations of BDNF can be administered directly to the brain without worrying about BBB passage as discussed below.

Neurotrophin-3 (NT-3)

Neurotrophin-3 is another member of the neurotrophic family, sharing 55 percent amino acid homology with BDNF, and NGF (Maness et al., 1994). Contrasting to other members of the neurotrophin family, NT-3 expression within the CNS appears to peak at the time of fetal development, during which time NT-3 plays a strong role in neuronal survival, and differentiation (Ernfors et al., 1990; Maisonpierre et al., 1990; Ghosh and Greenberg, 1995). NT-3 conducts most of its trophic effects through a high affinity interaction with the TrkC receptor (Lamballe et al., 1991). However, at high concentrations NT-3 is also known to interact with other Trk isoforms at a much lower affinity compared to that of NGF and BDNF (Clary and Reichardt, 1994; Strohmaier et al., 1996).

Maisonpierre et al. (1990) first reported in 1990 that induction of the NT-3 gene facilitated neurite outgrowth in DRG explants. NT-3 has since been reported to mediate aspects of neurogenesis, with NT-3 neutralizing antibodies, and conditional NT-3 knockouts both causing significant reductions in NSPC differentiation and survival (Ghosh and Greenberg, 1995; Barnabé-Heider and Miller, 2003; Shimazu et al., 2006).

Contrasting with the other members of the neurotrophin family, NT-3 mRNA expression is significantly reduced in the first 12–24 h following injury to the CNS (Kokaia et al., 1995; Boris-Möller et al., 1998; Boyd and Gordon, 2003a). This is likely an intrinsic mechanism to help minimize damage, as conditional NT-3 knockout animals and animals administered NT-3 neutralizing antibodies have smaller infarct volumes following MCAo stroke and enhanced survival of axotomized corticospinal neurons, respectively, indicating a detrimental role of NT-3 in the acute phase of injury (Giehl and Tetzlaff, 1996; Bates et al., 2002). However, contrasting reports show intrathecal and intraventricular administration of NT-3 promote neurite extension, axonal sprouting, and neuronal survival when administered immediately after trauma to the SC (Schnell et al., 1994; Bradbury et al., 1999). Based on these findings, it is possible that NT-3 has differing rolls in both the CNS and PNS after injury, however, further work is required to confirm this hypothesis.

Contrary to findings showing early administration of NT-3 to the CNS being damaging, delayed administration of NT-3 (>3 days) after stroke appear to promote protection and repair (Zhang et al., 1999). NSCs engineered to overexpress NT-3 have been found to enhance neuronal differentiation in the

penumbra and infarct cavity when administered to mice 3 days after hypoxic-ischemic injury (Park et al., 2006). Furthermore, Duricki et al. (2015, 2018) showed that intramuscular injections or prolonged subcutaneous infusion of human recombinant NT-3, given 24 h after endothelin-1 and MCAO-induced stroke, can enhance sensorimotor recovery in elderly rats. Interestingly, anterograde tracing revealed NT-3-enhanced neuroplasticity in the CST, with increased numbers of fibers extending from the intact to affected side. This change in plasticity has also been reported by Weishaupt et al. (2014) in a rat model of SCI, with enhanced axonal sprouting being observed from injured CST axons following intrathecal injections of a NT-3 expressing AAV.

To the best of our knowledge, the therapeutic potential of NT-3 has not been investigated in clinical trials for neurodegenerative CNS diseases (Bezdjian et al., 2016). However, phase I and II clinical trials in neurologically healthy adults have confirmed that NT-3 administration is safe and well tolerated (Chaudhry et al., 2000; Parkman et al., 2003). Furthermore, a pilot clinical study showed potential for the subcutaneous administration of NT-3 in patients with CMT1A, a PNS neuropathy resulting from a mutation to a gene for peripheral myelin protein in Schwann cells (Sahenk et al., 2005). Results revealed that patients treated with NT-3 showed significant improvement in the Mayo Clinic NIS and sensory modality function, compared to those treated with a placebo. It is hypothesized that these behavioral changes occur as a result of NT-3-mediated regeneration of sensory nerves. Whilst these findings do support the potential of NT-3 use clinically, larger cohort studies are required.

Biomaterial-Based Delivery of Neurotrophins

It is already well established that neurotrophins play a major role in regulating neuroregenerative processes and facilitating an improvement in functional recovery in various animal models of neurodegenerative diseases. However, the translation of growth factor-based treatments into the clinic has been challenged by extremely poor BBB permeability, short therapeutic half-life and undesirable PNS side-effects, such as bone pains and increased hematocrit (Zhang et al., 2001; Ren and Finklestein, 2005; Lanfranconi et al., 2011; Chan et al., 2017). In 2006, an international panel of 44 experts conducted a forefront study identifying the top ten most promising applications of regenerative medicine for improving health in developing countries (Greenwood et al., 2006). Applications were evaluated for disease burden, therapeutic impact, feasibility, affordability, acceptability, and indirect benefits. The use of growth factor-seeded scaffolds for directing and enhancing SC and PNI was named in the top ten. Since then, it has become evident that this technology can be effectively applied into rehabilitative and regenerative approaches in other CNS injuries and diseases, in the hope to overcome the barriers faced by systemic administration.

The term biomaterial refers to a material that has been engineered to interact with a biological system, being tuned to hold various biodegradable, biocompatible, cytocompatible, physical, and topographical properties. The effect of altering these properties will not be included within the scope of this review, but the authors direct readers to the following review for their own reading (Führmann et al., 2017). Biomaterial scaffolds used in medical and scientific research are generally synthesized from biodegradable, aliphatic poly(esters) such as PLGA, PGA, PCL, PLA, PLLA, and poly(phosphoesters) (PPEs). These poly(esters) are preferentially used due to their excellent biocompatibility and biodegradability and their current FDA approval for use as a drug delivery system (Lewis, 1990). Proteinaceous scaffolds utilizing materials such as foamed-collagen (e.g., freeze-dried) also fulfill the requirements for biomedical implants that can exhibit controlled biodegradation.

When engineered specifically for stroke, biomaterials are typically designed to degrade in synchrony with the hosts healing process whilst supporting the efficacy of NSPCs grafts, and/or to amplify endogenous repair mechanisms with a sustained release of therapeutic agents (Bhatia, 2010; Wang L. et al., 2012). Although hundreds of biomaterials have been generated and investigated in the past decade, they can be generally categorized into the following categories, which will be discussed in relation to neurotrophin-based interventions below: microspheres, electrospun nanofibers and hydrogels (see **Figure 2**). The following studies are summarized in **Tables 1**, **2** to highlight past use of neurotrophins for regenerative interventions without (see **Table 1**) or with (see **Table 2**) biomaterial drug-delivery systems, respectively.

Microsphere-Based Delivery Systems

Microspheres, also known as microparticles, are polymeric spheres with a diameter between one and 1000 μm. Historically, microsphere technology has been utilized for a diverse range of applications including cosmetics, electronics, and material engineering. In medical and scientific fields, microspheres are used to encapsulate drugs, and mediate their release to an injury site.

There are many techniques employed for microencapsulation of drugs including phase separation/precipitation, emulsion-solvent evaporation/extraction, spray drying and *in situ* polymerization (Jain, 2000). Each method has its own advantages and disadvantages, leaving the synthesis process to be chosen based on the application involved (i.e., polymer attributes, site of drug action, and therapy duration). The most common method of encapsulation is the emulsion-solvent extraction/evaporation method, which results in lyophilized ready to inject drug-loaded microspheres. In contrast to systemic methods of neurotrophin administration, microsphere-based drug delivery systems can be surgically injected straight into the injury site, avoiding issues with BBB passage. Microspheres also offer the advantage of being highly tunable with choice of polymer, particle size, and method of erosion all altering the rate of drug delivery from microspheres (Xu et al., 2002). Drug-loaded microspheres can also be injected into the peripheral circulation as they can cross the BBB. Furthermore, as loaded neurotrophins are encapsulated they are not enzymatically degraded until the microsphere degrades, thereby increasing the therapeutic half-life.

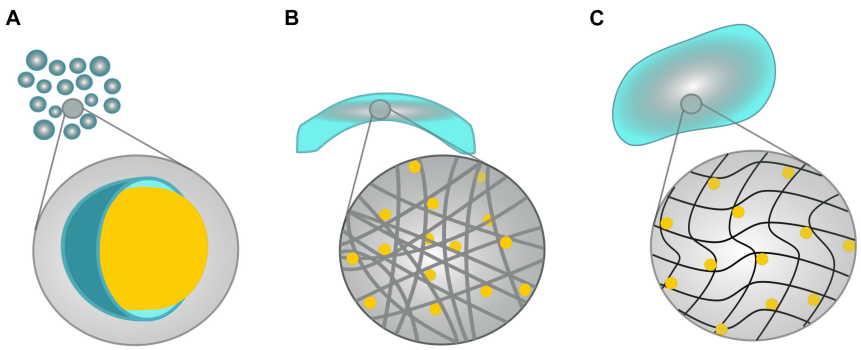

FIGURE 2 | Schematic of possible biomaterial scaffolds. Although hundreds of biomaterials have been generated, they fall neatly into four main categories: **(A)** Microspheres are small, polymeric spheres (shown in blue) that encapsulate a target drug or molecule (as depicted by the yellow sphere). **(B)** Electrospun fibers consist of long, usually cylindrical, and fibers that are commonly crafted into tubes or conduits. Target drugs can either be bound to the fibers themselves, or left to freely diffuse from the fiber network. **(C)** Hydrogels consist of hydrophilic, polymeric networks that swell to conform to cavities formed by neurodegenerative diseases/injuries, and facilitate the passive release of target molecules.

Santos et al. (2016) have illustrated the neurotrophic potential of PLGA microspheres loaded with NGF or BDNF. When applied to organotypic cultures derived from the SC and DRG, both of the loaded-microspheres enhanced neurite outgrowth when assessed 1 week after application. In contrast, free BDNF or NGF alone failed to show neurotrophic effects at this time, supporting the augmentation of neurotrophic effects as a direct result of microsphere encapsulation (Santos et al., 2016). In this same study, Santos et al. (2016) further confirmed a neurotrophic effect in a rat model of PNI. Briefly, neurotrophin encapsulated microspheres were loaded into a silicon tube filled with collagen gel before being injected into transected sciatic nerves. The use of retrograde tracers confirmed silicon tubes loaded with either NGF- or BDNF-loaded microspheres significantly increased the number of regenerated motor neuron axons in the SC, compared to control tubes loaded with free-floating neurotrophins. Furthermore, tubes loaded with encapsulated-NT-3 significantly increased the number of sensory axons in the DRG compared to free-floating controls (Santos et al., 2016). Similarly, sustained release of NGF from PLGA microspheres has also been reported by De Boer et al. (2010, 2011) with increased neurite outgrowth being observed as late as 35 days following subcutaneous implantation of the PLGA microspheres in rats. However, it should be noted that the long-term functional recovery observed in rats receiving the NGF-loaded microspheres was no greater than that of rats receiving autologous grafts (De Boer et al., 2011). The authors suggested that this may due to a "catch-up" or "blow through" effect, where intrinsic regeneration of the rat sciatic nerve is thought to be so effective that minor or early intervention-induced differences go unnoticed when long term regeneration is accessed (Young et al., 2001; De Boer et al., 2011). It is also possible that NGF exposure from the microspheres had stopped before a lasting NGF-mediated trophic effect could have been induced, resulting in a rebound effect.

The application of microsphere technology to stroke remains sparse due to several reasons. Whilst microspheres do support the sustained release of neurotrophins, the use of microspheres alone lack the mechanical support that benefits injuries with large lesion sites (i.e., stroke, SCI) (Sharp et al., 2012). Another major issue lies in the difficulty of sustaining the release of GFs in order to maintain levels within a given concentration range, an issue hampered by the challenge to create microspheres of a consistent diameter (Mohtaram et al., 2013). Further, it is known that there is a higher, initial burst of compound release from microspheres that restricts the overall duration and concentration of release (Binan et al., 2014). In attempts to overcome this, Bertram et al. (2010) have produced a PLGA-PLLA-PEG based microsphere delivery system that yields a consistent release of NGF without an initial burst, and with delivery lasting as long as 65 days. Nevertheless, the application of polymeric microspheres for therapeutic interventions has been found to be safe and well tolerated in human trials of brain tumors (Brem and Gabikian, 2001). Additionally, treatments utilizing neurotrophin-loaded microspheres in conjunction with other biomaterial scaffolds are emerging and showing promise (Xu et al., 2003; Lampe et al., 2011; Ju et al., 2014). For instance, Ju et al. (2014) investigated the therapeutic potential of loading PLGA microspheres with VEGF and Ang1, two factors that stimulate angiogenesis. The loaded microspheres were then embedded within a hyaluronic acid-derived hydrogel (containing anti-Nogo receptors) and injected into the stroke cavity of mice. Animals treated with the composite system showed enhanced angiogenesis around ischemic regions and facilitated recovery of locomotor function 6 weeks post-stroke. It is worth highlighting that to the best of our knowledge, no one has compared these hybrid delivery systems to systems containing the single biomaterial type, leaving the exact benefit of these hybrid models requiring future investigation.

Electrospun Nanofibers and Conduits

Another fabrication technique that has proven useful in generating tunable, three-dimensional scaffolds consisting of micro-, and nano-sized fibers is electrospinning. Electrospinning was initially designed to generate textiles and filters before being proposed to produce wound dressing material (Doshi and Reneker, 1995). Nowadays, electrospun nanofibers are commonly used as neural scaffolds due to their ability to mimic

TABLE 1 | Evidence supporting the neuroregenerative properties of classical neuroptrophin use in the context of treatments for CNS disease/injury.

	Mice	Striatal lesion	Intrastriatal infusion of BDNF antisense oligonucleotides via minipumps	Suppressed peri-wound dopaminergic sprouting	Batchelor et al., 2000
	Rat	PCA-induced lesions (forebrain or hippocampus)	BDNF infusions to lesion site via osmotic minipumps	Enhanced sprouting of 5-HT axons at the lesion site (both the forebrain and hippocampus)	Mamounas et al., 2000
	Rat	Complete transection of the thoracic spinal cord	Intrathecal BDNF via osmotic minipumps	Enhanced functional recovery of the hindlimb, modest sprouting of cholinergic fibers within injury cavity	Jakeman et al., 1998
	Rat	Photothrombotic stroke to the parietal cortex	Intravenous BDNF injections	Enhanced functional recovery of motor function, promoted widespread neuronal remodeling	Schäbitz et al., 2004
	Rat	Photothrombotic stroke to the parietal cortex	Intravenous BDNF injections	Enhanced functional recovery of sensorimotor function, neurogenesis (DG) and SVZ progenitor cell migration	Schäbitz et al., 2007
	Rat	MCAO via permanent intraluminal vascular occlusion	Intraventricular injections of CBD-bound BDNF	Enhanced SVZ progenitor cell proliferation, enhanced angiogenesis and improved neurological performance	Guan et al., 2012
	Rat	Endothelin-1-induced MCAO	Intraventricular infusion of BDNF antisense oligonucleotides via minipumps	Attenuated rehabilitation-mediated functional recovery of motor skills	Ploughman et al., 2009
	Mice	Photothrombotic stroke to the motor cortex	TrkB-Fc-embedded hydrogel into stroke cavity	Occluded AMPAkine-mediated and spontaneous functional recovery	Clarkson et al., 2011
NT-3	Mice	N/A	Conditional NT-3 knockout	Impaired NPC differentiation and LTP, deficits in spatial memory	Shimazu et al., 2006
	Rat	Partial bilateral transection of the thoracic spinal cord	Intrathecal NT-3 injection	Enhanced axonal sprouting of transected corticospinal tract	Schnell et al., 1994
	Rat	Partial bilateral crushing of the thoracic spinal cord	Intrathecal NT-3 via osmotic minipumps	Enhanced axonal growth within and outside the lesion site	Bradbury et al., 1999
		Focal hypoxic-ischemic brain injury	Implantation of NT-3-overexpressing NSCs	Promoted NSC differentiation into neurons, dampened glial scarring	Park et al., 2006
	Rat	Partial bilateral transection of the thoracic spinal cord	Implantation of NT-3-secreting fibroblasts	Enhanced axonal growth around and distal to lesion site, partial recovery of motor function	Grill et al., 1997

DRG, dorsal root ganglion; CBF, cholinergic basal forebrain; RGC, retinal ganglion cells; PCA, p-chloroamphetamine; DG, dentate gyrus; SVZ, subventricular zone; MCAO, middle cerebral artery occlusion; CBD, collagen binding domain; TrkB-Fc, tropomyosin receptor kinase B-Fc; NPC, neural progenitor cell; LTP, long term potentiation; NSC, neural stem cells.

TABLE 2 | Examples of biomaterial-based neurotrophin treatments for regeneration and repair following CNS disease/injury *in vivo*.

Neurotrophin	Species	Disease model/Injury	Biomaterial/Treatment	Effect of treatment	References
NGF	Rat	Sciatic nerve transection	Nerve conduits loaded with NGF-embedded PLGA microspheres	Enhanced regeneration of motor and sensory axons	Santos et al., 2016
	Rat	Sciatic nerve transection	NGF-loaded PCL nerve conduit	Significantly enhanced mean axon diameter and myelin thickness, increased total number of regenerated fibers, enhanced recovery of electromyographic function	Liu et al., 2011
	Rat	Sciatic nerve transection	NGF-loaded chitosan conduit	Facilitated axonal regeneration, enhanced target muscle innervation and motor recovery	Wang H. et al., 2012
BDNF	Rat	Sciatic nerve transection	Nerve conduits loaded with NGF-embedded PLGA microspheres	Enhanced regeneration of sensory axons	Santos et al., 2016
	Mouse	Photothrombotic stroke to the motor cortex	Hyaluronan-based hydrogels loaded with BDNF	Improved recovery of motor function	Clarkson et al., 2015
	Mouse	Photothrombotic stroke to the motor cortex/L-NIO induced stroke	Hyaluronan-based hydrogels loaded with BDNF	Enhanced axonal sprouting, enhanced migration of neuroblasts to the peri-infarct cortex, enhanced recovery of forelimb function	Cook et al., 2017
	Rat	Acute brain injury via needle insertion	Electrospun PCL sacffolds embedded with a BDNF-mimetic	Redirected endogenous neuroblasts toward the scaffold, enhanced neuroblasts integration and promoted local neurite sprouting	Fon et al., 2014
NT-3	Rat	Complete transection of the thoracic spinal cord	Multichannel PLGA conduits loaded with rhNT-3	Enhanced axonal regrowth between spinal cord stumps, partial recovery of hindlimb locomotor function	Fan et al., 2011
	Rat	Partial bilateral transection of the dorsal spinal cord	Collagen-derived hydrogel loaded with NT-3	Enhanced regrowth of CST axons, mild improvements in motor function	Houweling et al., 1998
	Rat	Partial bilateral transection of the dorsal spinal cord	Acrylate-based hydrogel loaded with NT-3	Enhanced axonal outgrowth in the CST and raphespinal tract, recovery of locomotor function	Piantino et al., 2006

rhNT-3, recombinant human neurotrophin-3; L-NIO, N5-(1-iminoethyl)-L-ornithine; CST, corticospinal tract.

the structure and surface-to-volume ratio of the ECM (Chew et al., 2005; Alhosseini et al., 2012; Jiang et al., 2012). Compared to other biomaterials, electrospun nanofibers offer the advantage of an easily adaptable shape and structure, reduced initial drug release and enhanced cell or drug attachment (Han et al., 2011). Conversely, electrospinning has proven difficult to maintain consistency in fiber sizes, with concerns also being placed on the use of toxic solvents involved in the synthesis of polymer-drug emulsions (Li et al., 2002).

Many groups have encapsulated neurotrophic factors within electrospun nanofibers and shown retention of neurotrophic factor bioactivity. For instance, Chew et al. (2005) showed the sustained release of NGF from *E*-caprolactone and ethyl ethylene phosphate (PCLEEP) electrospun copolymers. Three months after loading, NGF was still being released and capable of causing mild differentiative effects upon PC12 cells. PCL nanofibers have also been reported to release a NGF-BSA mixture for as long as 28 days, with significantly enhanced neurite outgrowth still being observed in PC12 cells (Valmikinathan et al., 2009). Similarly, electrospun PLC nanofibers that have been tethered to BDNF have been found to promote neurite extension and NSPC proliferation and differentiation into neurons and oligodendrocytes (Horne et al., 2009).

Electrospun scaffolds and conduits have been extensively studied as an intervention for SCI and peripheral nerve regeneration. In these injuries, axonal repair requires fine, ordered control to ensure functional recovery. Electrospun nanofiber scaffolds alone have already demonstrated the ability to promote stem cell proliferation and differentiation, and more importantly, enhance the outgrowth of new connections from neurons in the direction of aligned nanofibers (Yang et al., 2005; Corey et al., 2007; Xie et al., 2009). Fan et al. (2011) further illustrated the regenerative potential of a multichannel PLGA conduit loaded with recombinant human NT-3. Following complete transection of the thoracic SC in rats, use of retrograde tracing confirmed axonal regrowth between caudal and rostral SC stumps, with partial locomotor recovery also being observed 150 days post-injury. The use of NGF-loaded electrospun conduits has also been investigated in order to aid the regeneration of the PNS (Liu et al., 2011). Supporting this, chitosan-based conduits preloaded with NGF have been shown to facilitate the re-establishment of nerve function following injury to the sciatic nerves, with improved muscle innervation and functional recovery of motor function being observed 24 weeks after treatment (Wang H. et al., 2012). Furthermore, Liu et al. (2011) showed that PCL electrospun fibers containing NGF could promote nerve regeneration and improve electromyographic function in a rodent model of PNI. Amazingly, this electrospun treatment was found to provide the same degree of recovery as autografts, which is the current "gold standard" of nerve regeneration (Liu et al., 2011).

The use of neurotrophin-embedded electrospun fibers in the injured brain has been questioned due to the haphazard arrangement of the cerebrum and the invasive nature of electrospun conduit application. However, Fon et al. (2014) conducted a study to investigate the use of electrospun PCL scaffolds embedded with a small molecule BDNF-mimetic following acute injury to the brain. The PCL scaffolds were implanted toward the SVZ, with the needle tract resulting from implantation acting as the acute injury. Eight days after injury, authors found scaffold implantation with and without the BDNF mimetic, facilitated a significant increase in neuroblast migration from the rostral migratory stream (RMS) to the injury site. In contrast, at 21 days post-injury, a significant increase in neuroblast migration was only observed in animals treated with scaffolds containing the BDNF-mimetic (Fon et al., 2014). These findings suggest that electrospun fibers may be able to direct neurogenic processes to the injured brain, including influencing neuroblast infiltration into 3D biomaterial scaffolds. In further support of this notion, Rivet et al. (2015) investigated the use of a hybrid biomaterial system that utilized hydrogels loaded with PLLA-fibronectin electrospun fiber fragments. Sixty days after implantation into the striatum of rats, immunohistology revealed enhanced astrocyte and macrophage/microglia infiltration into the scaffolds. Whilst these findings support that resident cells of the brain were able to locate and utilize cues from the electrospun fibers, further works is needed to confirm the regenerative potential of these systems.

Hydrogel-Based Neurotrophin Delivery Systems

First introduced as a novel material to construct soft contact lenses, Wichterle and Lim (1960) displayed the plausibility of using a porous material with low immunoreactivity in a living organism. Hydrogels have since become of immense interest as a vehicle for drug administration throughout the biomedical and pharmaceutical worlds. Hydrogels refer to three-dimensional, hydrophilic, polymeric networks that are capable of absorbing large amounts of water, or biological fluids (Peppas et al., 2000). Opposed to the fixed encapsulation of GFs, hydrogels allow neurotrophins to be blended into a polymer scaffold, resulting in a steady release of the neurotrophins from within the implantation site as the gel slowly biodegrades.

Compared to the other biomaterials, hydrogels offer many advantages for application in stroke treatments. Hydrogels typically express low toxicity, have a minimally invasive administration procedure, and have a relatively soft consistency that resembles neural tissue (Ratner and Hoffman, 1976). Additionally, *in situ* hydrogels show the unique ability to swell and fill the irregular conformations of stroke-induced lesions. This is hugely advantageous as it provides maximal mechanical and sustained pharmaceutical support directly to the damaged tissue. Specifically, drugs embedded into hydrogels have a sustained, consistent release into surrounding tissue lasting around 2–3 weeks (Tae et al., 2006; Overman et al., 2012; Clarkson et al., 2015; Cook et al., 2017). This overcomes various difficulties encountered by other delivery systems including increased adverse side effects resulting from higher doses and injuries acquired during repetitive drug administrations.

Hydrogels are known to yield anti-inflammatory and regenerative properties when used as a vehicle for NSPCs *in vivo*. For instance, a hyaluronan-heparin-collagen based hydrogel was able to promote survival of NSPCs and reduce infiltration of

inflammatory cells following photothrombotic stroke in mice (Zhong et al., 2010). Similarly, Park et al. (2002) demonstrated the ability of a PGA-derived hydrogel to enhance neuronal differentiation and neurite elongation, reduce monocyte infiltration, and minimize glial scarring when used as a scaffold for NSPC application in a mouse model of hypoxic-induced ischemia. Further, the anti-inflammatory properties of hydrogels themselves have also been observed in rat models of SC injury (Woerly et al., 1998). These intrinsic properties of hydrogels make them ideal candidates as a drug-delivery system for neurotrophin-based treatments, in the hope to further maximize repair, and functional recovery.

The use of BDNF-embedded hydrogels has shown huge promise in repairing the ischemic brain and promoting functional recovery (Clarkson et al., 2015; Cook et al., 2017). A promising study from the Carmichael lab investigated the use of a BDNF-loaded hyaluronan-based hydrogel that was cross-linked with PEG, in two mouse models of stroke (Cook et al., 2017). In both models, treatment beginning at 1-week post-stroke was sufficient to induce significant axonal sprouting throughout cortical and cortico-striatal regions. These animals further displayed enhanced migration of neuroblasts to the peri-infarct cortex and improved functional recovery of forelimb activity. Worth noting, the regenerative potential of BDNF-loaded hydrogels has also been confirmed in aged mice receiving photothrombotic strokes, however, the magnitude of recovery was less than that of young mice (Clarkson et al., 2015). Hydrogels embedded with NT-3 have also displayed neuroregenerative properties when applied as a therapeutic intervention for SCI (Houweling et al., 1998; Piantino et al., 2006). Early work with a NT-3 embedded collagen-derived hydrogel revealed significant regrowth of CST axons following bilateral transection of the dorsal SC in rats (Houweling et al., 1998). In the same animal model, an acrylate-based hydrogel loaded with NT-3 was found to facilitate motor performance on the horizontal ladder walking task and the Basso-Beattie-Bresnahan locomotor score (Piantino et al., 2006). Collectively, the above highlights the benefits of hydrogel-derived delivery systems, providing sustained support to the injured brain and facilitating repair of nervous tissue.

Heparan Sulfate Proteoglycans (HSPGs): A Promising Future Delivery System

The neuronal ECM is a complex and dynamic environment composed of a wide variety of glycoproteins and PGs. PGs are a group of proteins that consist of long, unbranched GAGs side chains covalently linked to a core protein. Interestingly, many GFs are known to require the presence of these extracellular GAGs in order to exert their biological function (Taipale and Keski-Oja, 1997; Whitelock and Iozzo, 2005).

Heparan sulfates are a subset of the class of linear GAG polysaccharide sugars. HS, as extracted from tissue sources and cleaved from its protein component, presents as a ∼15 kDa polymeric mixture. Constructed from a repeating disaccharide comprised of a glucosamine α – linked (1–4) to an uronic acid [glucuronic (*D*-GlcA) or the C-5 epimer iduronic (*L*-IdoA)]. Varying degrees and combinations of acetylation, sulfation or no-substitution at the amine moiety, as well as O-sulfation at the 2-position of the uronic acid and/or 6-position of the glucosamine gives rise to a considerable number of disaccharide permutations (Carnachan et al., 2016). These in turn can be combined into a vastly complex linear array. Enzymatic depolymerization generally reveals eight main disaccharide components (Carnachan et al., 2016), with the most abundant constituent being non-sulfated and comprising ∼30% of the population (as described in **Figure 3**).

Heparan sulfates are particularly evident during times of tissue growth and repair (Gallagher, 1989; Bernfield et al., 1999). Over the past decade the involvement of HS and/or HSPGs in cellular signaling mechanisms has become more and more evident. Many HSPGs are known to be involved in both synaptic and structural neuroplasticity, regulating synaptogenesis, LTP, and dendritic spine maturation (Ksiazek et al., 2007; Allen et al., 2012; Senkov, 2014). Several studies have also discovered HSPG-mediated potentiation of neurite outgrowth and cell migration *in vitro* (Walz et al., 1997; Hu, 2001; Jung Kim et al., 2003).

Many of the regenerative and reparative properties of HS are thought to be mediated through GAGs ability to act as a medium-affinity co-receptor for binding GF's to their receptors (Bespalov et al., 2011; Chen et al., 2012). This GF-GAG interaction further enhances protein stability and bioavailability of GFs and their receptors (Chen et al., 2012; Chan et al., 2017). HSPGs are also highly sulfated giving the sugar a unique ability to create large binding pockets that can be utilized to house an abundance of GFs. Supporting this notion, early work from Kanato et al. (2009) used horizontal native- PAGE and gel chromatography analysis to confirm a direct molecular interaction between HS and the neurotrophins NT-3 and BDNF. The resulting complex was found to bind to both $p75^{NTR}$ and TrkB, respectively, in a manner similar to polysialic acid, a protein that has been proposed to house and mediate BDNF concentrations and function (Kanato et al., 2008). Whilst this interaction remains to be identified both *in vitro* and *in vivo*, the above findings do support the idea that GAGs may regulate local GF concentrations, which could further serve to provide a reservoir of neurotrophins on cell surfaces or around the ECM. However, is should also be acknowledged that the exact role of HS with respect to its interaction with GFs, still requires future investigation (Lander, 2007).

The therapeutic use of HS remains sparsely investigated due to the low yield experienced when fractionating heparanoid raw materials (sourced as byproduct from Heparin manufacture). This is further complicated by limited supply and quality control of HS (Mulloy et al., 2016). The preparation of individual oligosaccharides remains highly costly, time consuming and difficult (DeAngelis et al., 2013), but recent advancements in technology have led to innovative synthetic or chemoenzymatic approaches allowing access to significantly longer purified HS structures (Kuberan et al., 2003; Liu et al., 2010; Tyler et al., 2015). However, the heterogeneity of native HS means synthesis of even a small portion of the structural diversity that is found in nature, even if limited in size to as small as an octasaccharide, is a daunting challenge.

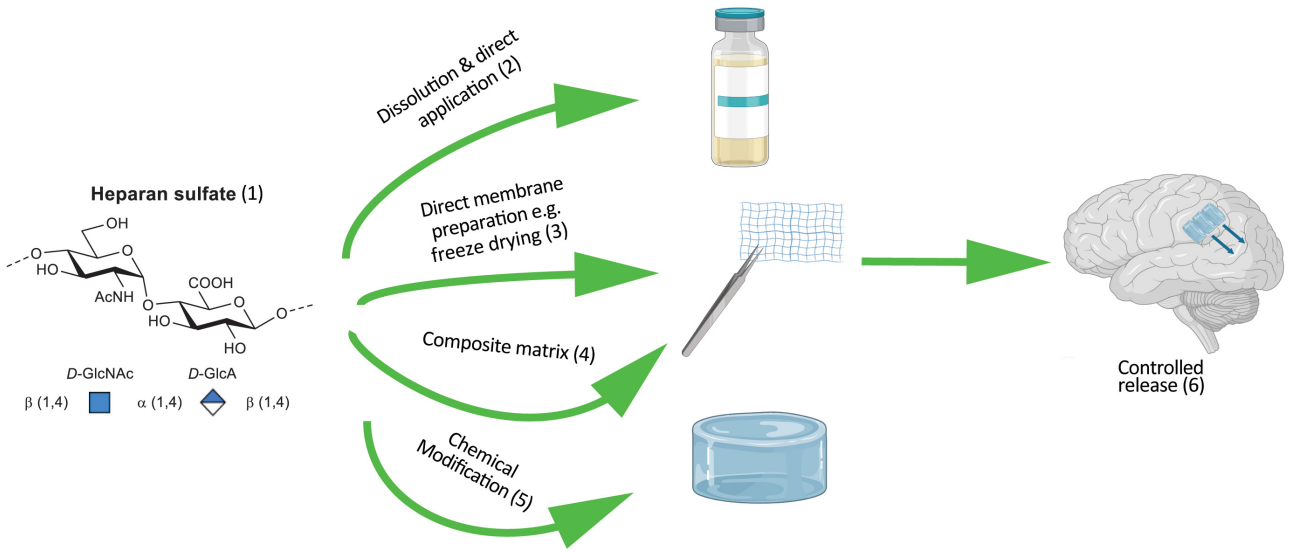

FIGURE 3 | Schematic of incorporating HS into therapeutic devices. (1) Synthetic HS that approximates the degree of sulfation and acetylation of naturally occurring HS can be derived from heparin through chemical modifications. Example modifications of HS and composition of device. (2) HS adsorbed onto a collagen membrane. (3) Solid form of HS as a carbohydrate foam. (4) Electrostatically bound HS (net –ve charge) protein substrate (net +ve charge). (5) Pegylated, alkylated or alternative chemical modification of HS to control hydrophobicity and release for direct coating onto a device. (6) Device characteristics tuned to release HS into the extracellular matrix facilitating tissue regeneration.

Whilst literature investigating the ability of HS and heparin to cross the BBB is sparse, several studies suggest that these molecules may in fact cross the BBB. Early *in vitro* work has indicated Heparin of 3000 Da and smaller fragments (i.e., di, tetra, and hexasaccharides) can all cross a BBB barrier in a model system, without any obvious correlation with size to transport efficiency (Leveugle et al., 1998). Ma et al. (2002) have since reported BBB passage of small fragments of C3, a low molecular weight (2000 ± 200 Da) heparin-derived oligosaccharide designed for treatment of vascular dementia and Alzheimer's disease. Specifically, C3 was able to penetrate the BBB and retain its' inhibitory effect on factor Xa after systemic administration to non-human primates (Ma et al., 2002). Further supporting evidence has come from a recent study by Hippensteel et al. (2019) who found fluorescein-labeled HS fragments penetrated the BBB during sepsis and inhibited BDNF-mediated hippocampal memory. In addition, they further show that the binding affinity of HS fragments to BDNF increased with sulfation at the 2-O-position of iduronic acid and N-position of glucosamine (Hippensteel et al., 2019). These findings support that sulfation at these sites is critical for memory impairments, although it has not been shown if this is the case for all cognitive domains. Whilst, the involvement of these sulfation sites in post-stroke motor and sensory impairments is yet to be investigated. Given that poor BBB passage is thought to be an underlying cause for a lack of clinical translation of compounds targeting the CNS (Pardridge, 2005), HS may prove extremely useful as a backbone for therapeutic interventions targeting the injured brain.

Although HS application into CNS disease is extremely limited so far, a recent study by Hill et al. (2012) illustrated the neuroregenerative potential of the HSPG glypican, in the MCAo model of stroke. Intracerebral glypican was administered through micro-osmotic pumps for a week following stroke, which resulted in a significant decrease in GFAP and increased MAP2 expression in the peri-infarct region. These findings support a glypican-mediated reduction in astrocyte activation and enhanced neuronal survival, respectively. Furthermore, when put through various sensorimotor tasks glypican-treated animals performed significantly better when assessed 10- and 14-days after stroke, compared to control animals (Hill et al., 2012). Another HSPG, Perlecan domain V, has also been shown to afford neuroprotection in both young and aged mice (Bix et al., 2013). Perlecan domain V has also been shown to regulate both VEGF and BDNF levels (Lee et al., 2011; Bix et al., 2013). Whilst the regenerative potential of Perlecan domain V when administrated via a hydrogel or other biomaterial has yet to be studied, it is likely that similar if not better effects would be observed compared to when Perlecan domain V is given systemically.

A key component of biomaterial design lies in the topography and three-dimensional structure of its' scaffold (Führmann et al., 2017). Given the physiological role of HS chains in supporting the ECM of the CNS, the incorporation of HS chains into biomaterial scaffolds has been of interest in the field of regeneration and repair. Fibrin glue loaded with a HS scaffold has been shown to increase mineralized bone deposition and osteogenic marker expression, reflecting enhanced bone repair (Woodruff et al., 2007). Microcomputed tomography further revealed almost complete closure of chronic cranial defects sites in rats 3 months after treatment with the fibrin-HS glue, compared

to minimal healing seen in fibrin glue without HS chains (Woodruff et al., 2007).

Heparan sulfates, as the sodium salt, demonstrates very good water solubility and only when solutions get above 10% w/w does any increase in viscosity become apparent. In an anhydrous form it will reach an equilibrium water-content of 13% at room temperature, which must be accommodated for (or freshly freeze-dried material must be used) or else dose control in constructs becomes erroneous (Murali et al., 2013). Other salt-forms are generally more problematic in terms of physical handling; the pyridinium salt, for example, being very hygroscopic. This solubility means a preformed porous substrate can be dosed with a solution (**Figure 3**, direct application) prior to wound inclusion (Murali et al., 2013). Alternatively, solid support foams can readily be prepared through freeze drying a solution of neat HS, or by combining HS with other materials in solution to form a stable solid matrix (**Figure 3**, composite matrix and or membrane preparation). Pre-formed microspheres or membranes generated through electrospinning as depicted in **Figure 2** may have the HS included during preparation and/or adsorbed into the construct or coated onto the material surface.

Collagenous matrices with covalently attached HS chains have also been found to promote matrix integrity, facilitate angiogenesis and reduce foreign body reactions when implanted subcutaneously into rats (Pieper et al., 2000). Early *in vitro* work has also confirmed a trophic effect of HS-incorporation on cells of the CNS. Guan et al. (2013) discovered that a chitosan-gelatin scaffold containing GAGs, HA, and HS, promoted NSC/NPC adhesion, survival and long-term growth. A similar finding was observed by Uygun et al. (2009) who recorded increased MSC density, migration, and proliferation of MSCs cultured on chitosan membranes modified with HS chains. The trophic potential of HS-embedded biomaterial scaffolds has also been acknowledged by Mammadov et al. (2012), who illustrated that combining a heparan-sulfate-mimicking peptide nanofibers with a laminin-derived nanofiber scaffold significantly enhances neurite outgrowth of PC-12 neurons. The above literature supports the use of HS-seeded biomaterials for neurotrophin-mediated regeneration, leaving the translational potential of such treatments to future research. It is also worth noting that in the body, HS chains are manufactured as a PG, which are present in the ECM at relatively high concentrations compared to free HS fragments (i.e., mg/mL. PPM) (Lander and Selleck, 2000). Certainly, it is recognized that the shedding of HS chains from HSPGs can release sequestered GFs to stimulate GF activity (Yu et al., 2017). However, it remains a matter of debate as to whether or not all GF-GAG interactions are mediated by HS chains or the full HSPG (i.e., HS chains and protein core). For example, the HSPG, glypican, requires the presence of its HS chains in order to facilitate FGF-2 (Song et al., 1997; Lander and Selleck, 2000) but not BMP signaling (Kirkpatrick et al., 2006). Furthermore, the protein core of glypican has been found to bind and promote Hedgehog (Hh) signaling without the involvement of HS chains (Capurro et al., 2008). Future work elucidating the exact molecular mechanism associated with this GF-HS interaction will help guide the development of HS-embedded biomaterials for therapeutic application.

CONCLUDING REMARKS

Neurodegenerative diseases, such as stroke, remain the leading cause of adult death and disability worldwide. With the aging population on the rise, and these diseases preferentially affecting the elderly, there is a growing interest in the development of interventions that can fight against neurological decline and enhance functional recovery. Protective therapies for stroke are massively limited due to the narrow window of opportunity that is required for success. Consequently, the generation of regenerative interventions have become of utmost importance to help treat stroke at a clinically relevant time point, and to successfully translate findings from bench to bedside.

After decades of preclinical studies and still no successful treatments for stroke recovery in humans, researchers have agreed that future work investigating the neurobiology, and progression of post-stroke recovery (both spontaneous and treatment-induced) will be crucial on the journey toward the identification of key molecular targets and an optimal time of intervention (Bernhardt et al., 2017; Corbett et al., 2017). Armed with this knowledge, the scientific and medical worlds will have the greatest chance of providing maximal recovery from stroke in multidisciplinary phase II clinical trials.

Neurotrophins have shown great promise in modulating the injured brain and promoting functional recovery in preclinical models of neurodegenerative disease. However, the clinical success of these treatments is yet to be observed due to poor BBB passage, short half-life and lack of sufficient quantities for clinical use. The use of biomaterials creates a unique delivery system that alters the pharmacokinetic profile of neurotrophins and offers a mechanism to penetrate the BBB and treat the injured brain with concentrations that are only a fraction of those used during systemic administration. Recent animal-based experimental research has shown great promise using biomaterial-delivery systems to deliver neurotrophins to enhance functional recovery, with each biomaterial type yielding distinct properties that suit different biomedical applications. For example, the linear nature of electrospun conduits has shown the most success in promoting controlled nerve regeneration in animal models of SCI (Fan et al., 2011; Wang H. et al., 2012). Alternatively, the ability of hydrogels to expand and fill irregular injury sites in conditions such as stroke has proven extremely useful for providing additional mechanical stability that other biomaterial systems lack.

Heparan sulfates offers a new therapeutic potential in promoting rapid tissue regeneration. It has shown significant benefit in repair of large defects in controlled wound sites (Murali et al., 2013; Wang et al., 2014) yet its full therapeutic benefit is unexplored, in no small way due to availability and reliability of supply (Mulloy et al., 2016). The versatility of this biopolymer, intrinsic to cellular regulation, is well suited to biomaterial applications *in vivo*: it is extremely well tolerated, readily decomposed by native enzymatic processes, is compatible with accepted medical device materials (e.g., collagen sponge or

hydrogels) and can be included into device technologies through a variety of mechanisms.

Of note, an exciting biomaterial approach that is emerging involves not just one, but many biomaterial types combined into a hybrid delivery system. Early work with this technology has shown the fine-tuned release of multiple GFs over different release profiles (Burdick et al., 2006). Specifically, the sequential release of glial cell-derived neurotrophic factor (GDNF)- and BDNF-loaded PLGA microspheres was achieved by loading neurotrophins to opposite ends of a PEG-based hydrogel implant (Lampe et al., 2011). Healthy rats given the combinational treatment, with the implant being applied to target the striatum (BDNF) and sustantia nigra (GDNF) with the hope of assisting transplant survival and long-term axon extension, respectively, in future work with animal models of Parkinson's disease. Results showed that GDNF was released within 28 days of implantation, whereas BDNF release was observed as late as 56 days. Due to the recency of the development of these sequential drug-delivery systems, they have sparsely been investigated in animal models of CNS injury or disease. Nonetheless, given the complex spatiotemporal, pathological events that occur in the days to weeks to months following neurodegenerative diseases, these delivery systems will yield great promise with delivery of multiple GFs to appropriate regions of the brain at relevant therapeutic time points to maximize recovery.

To ensure such treatment options translate into the clinic, much needed follow-up studies are required and clinical validation studies to be undertaken. Given the knowledge we have already gained around neurotrophic signaling especially with respect to BDNF-mediated improvements in functional recovery and the advances made in the biomaterial-delivery field, there is an exciting prospect of being able to deliver a potential treatment to contribute toward recovery from stroke and other neurological disorders.

AUTHOR CONTRIBUTIONS

JH, NA, SH, and AC wrote and edited the final version of the manuscript. JH prepared the figures. AC conceived the idea for the review of the manuscript.

Brain injuries causing chronic sensory or motor deficit, such as stroke, are among the leading causes of disability worldwide, according to the World Health Organization; furthermore, they carry heavy social and economic burdens due to decreased quality of life and need of assistance. Given the limited effectiveness of rehabilitation, novel therapeutic strategies are required to enhance functional recovery. Since cell-based approaches have emerged as an intriguing and promising strategy to promote brain repair, many efforts have been made to study the functional integration of neurons derived from pluripotent stem cells (PSCs), or fetal neurons, after grafting into the damaged host tissue. PSCs hold great promises for their clinical applications, such as cellular replacement of damaged neural tissues with autologous neurons. They also offer the possibility to create *in vitro* models to assess the efficacy of drugs and therapies. Notwithstanding these potential applications, PSC-derived transplanted neurons have to match the precise sub-type, positional and functional identity of the lesioned neural tissue. Thus, the requirement of highly specific and efficient differentiation protocols of PSCs in neurons with appropriate neural identity constitutes the main challenge limiting the clinical use of stem cells in the near future. In this Review, we discuss the recent advances in the derivation of telencephalic (cortical and hippocampal) neurons from PSCs, assessing specificity and efficiency of the differentiation protocols, with particular emphasis on the genetic and molecular characterization of PSC-derived neurons. Second, we address the remaining challenges for cellular replacement therapies in cortical brain injuries, focusing on electrophysiological properties, functional integration and therapeutic effects of the transplanted neurons.

Keywords: pluripotent stem cells, stroke, cortex, hippocampus, brain injuries, brain repair, cell-based therapy, differentiation protocols

INTRODUCTION

Brain injuries represent a large variety of disabling pathologies. They may originate from different causes and affect distinct brain locations, leading to an enormous multiplicity of various symptoms ranging from cognitive deficits to sensorimotor disabilities. They can also result in secondary disturbances, such as epileptic foci, which occur within the lesioned and perilesional tissues

(Herman, 2002). Indeed, frequently a secondary functional damage can take place in a region distant from the first insult (e.g., the hippocampus after traumatic brain injury), providing an explanation for cognitive and memory deficits arising after a brain lesion (Girgis et al., 2016). Brain injuries can have traumatic or non-traumatic etiologies, including focal brain lesions, anoxia, tumors, aneurysms, vascular malformations, encephalitis, meningitis and stroke (Teasell et al., 2007). In particular, stroke covers a vast majority of acquired brain lesions. *Stroke* is usually referred to as a sudden cerebrovascular dysfunction leading to focal deficits and/or impairment of global brain functions and lasting more than 24 h (Mackay and Mensah, 2004). Since brain function is strictly dependent on a constant supply of oxygen and glucose, normally assured by blood circulation, a sudden block of blood supply determines suppression of neural function in less than 1 min, primarily due to interference with synaptic functions (Hofmeijer and Van Putten, 2012). Brief blood deprivations may cause only a reversible damage, which becomes permanent only if the circulation is not promptly restored (Krnjević, 2008; Vrselja et al., 2019). The neocortex represents the highest level of cognitive and sensorimotor integration, and it is therefore not surprising that, independently of different etiologies, lesions occurring in the cerebral cortex are particularly impacting on the clinical phenotype (Delavaran et al., 2013). For example, an insult occurring in the motor cortex results in functional impairment of one or more body parts contralateral to the infarct. The degree of the motor impairment depends on many factors, such as the extent of the lesion, the identity of the damaged region and the effectiveness of the initial neuroprotective interventions.

Following stroke, there is a window of neuroplasticity during which the greatest gains in recovery occur (Zeiler and Krakauer, 2013). Indeed, in the first weeks after stroke a limited spontaneous restoration of function may be observed, and about 30% of stroke survivors are able to carry on everyday activities (Activity of Daily Living or ADLs, i.e., eating, drinking, walking, etc.) without any help (Mozaffarian et al., 2014). However, other patients do not recover at all (Winters et al., 2018). In particular, impairments of upper and lower limbs make very hard to retain a sufficient degree of independence in ADLs. These impairments can be ameliorated with a variable degree of success, through rehabilitation of the affected body parts, including several physical activities improving strength and coordination of the affected muscles and promoting recover of motility. Furthermore, combining rehabilitation with treatments that enhance neuroplasticity has been demonstrated to boost recovery (Alia et al., 2017; Spalletti et al., 2017) but further steps forward in the field are necessary for clinical translation.

Besides physical rehabilitation and plasticizing treatments, another therapeutic approach is cell-based therapy, which has been pioneered in the therapy of Parkinson Disease (PD). Indeed, initial studies showed that fetal dopaminergic neurons grafted in the striatum ameliorated PD symptoms, both in animal models (Herman and Abrous, 1994) and in patients (Lindvall et al., 1990; Kordower et al., 1998). Since fetal transplantation poises both ethical issues and technical challenges (Robertson, 2001), other non-neural cells, such as mesenchymal stem cells (MSCs), may represent a more accessible alternative. In fact, MSCs can be readily derived from various sources, show a low immunogenic effect and proved to be beneficial in stroke treatment (Eckert et al., 2013; Zhang and Chopp, 2013). Notably, MSCs-conditioned medium alone is sufficient for a similar therapeutic effect, suggesting that the beneficial effect is likely due to a bystander effect and trophic support, rather than actual cell replacement (Eckert et al., 2013). Recent clinical trials proved the safety of immortalized neural cells when stereotaxically injected in the brain of patients with stable paresis of the arm following an ischemic stroke (Kalladka et al., 2016). Finally, induced pluripotent stem cells (iPSCs) are easily accessible, since they can be reprogrammed starting from somatic cells, can be *in vitro* differentiated in the desired type of neurons and, being autologously derived and carry low risk of immune rejection (Jung et al., 2012; Trounson and DeWitt, 2016).

Due to the high clinical relevance of cerebral lesions, protocols to differentiate neural stem cells in telencephalic neurons are highly valuable. These protocols are frequently inspired by findings in neural development.

DEVELOPMENTALLY INSPIRED STEM CELLS DIFFERENTIATION PARADIGMS

Attempts to generate identity-specific cortical neurons require exploitation of the right embryonic developmental signals in a culture dish. The six layers of the mammalian neocortex originate from inside-out in a timely regulated manner during embryonic development and are characterized by a specific pattern of gene expression and connectivity (reviewed in: Rubenstein, 2011; Bronner and Hatten, 2013; Greig et al., 2013; Lodato and Arlotta, 2015). Both intrinsic and environmental factors control the progressive restriction of competence of cortical progenitors resulting in the sequential generation of the different cortical neurons, with deeper layer cortical neurons generated earlier than upper layer neurons (Gorski et al., 2002; Kriegstein and Noctor, 2004; Molyneaux et al., 2007).

The hippocampus arises from the invagination of the dorsal midline of the telencephalon, adjacent to the cortical hem. The boundaries between choroid plexus, cortical hem and hippocampus are defined early in development by the non-overlapping expression of molecular markers signatures. In particular, BMP4/7 are strongly expressed by the choroid plexus (Grove et al., 1998; Bulchand et al., 2001), while the cortical hem expresses high level of WNT3a, WNT2, and WNT5, whose signaling is essential for the correct development of the hippocampus (Grove et al., 1998) (**Figure 1A**). Consistently, experiments in which the cortical hem is ablated, or hem-dependent WNT expression is abrogated or compromised, showed the crucial role of the cortical hem in the hippocampal development (Grove et al., 1998; Grove and Tole, 1999; Lee et al., 2000). The Dentate Gyrus (DG), the CA1 and CA3 layers are the different fields forming the hippocampal formation; each one has its own cellular composition, morphology, connectivity and expresses specific molecular markers. In particular, KA1, a glutamate receptor subunit, is detectable in the CA3, while SCIP, a POU-domain transcription factor, is expressed in the CA1. The

pyramidal neurons of the CA1-3 originate in the more dorsal ventricular zone of the hippocampus and then migrate toward the pial surface on a glial scaffold (Nadarajah et al., 2001), while the DG cells arise from a smaller and specialized medial region close to the fimbria, the dentate neuroepithelium (Danglot et al., 2006). Furthermore, new neurons are generated in the hippocampus of rodents throughout life, while cortical neurogenesis rapidly subsides after birth (Eriksson et al., 1998; van Praag et al., 2002). This makes hippocampus the region of choice to assay the ability of *in vitro* produced PSC-derived hippocampal-like neural cells to make projections and to send them to appropriate targets.

Pluripotent stem cells cultured in low-density, serum-free and feeder-free conditions, in absence of any exogenous growth factor, readily differentiate into neural progenitor cells (Tropepe et al., 2001; Ying et al., 2003). This process faithfully reproduces *in vivo* neurogenesis (reviewed in: van den Ameele et al., 2014; Brown et al., 2018; Varrault et al., 2019), following the same timely regulated sequential neurogenic waves observed in vivo (Eiraku et al., 2008; Gaspard et al., 2008; Bertacchi et al., 2013; Molyneaux et al., 2015), which is therefore conserved *in vitro* (Shen et al., 2006). In fact, differentiating PSCs give rise to neural rosettes expressing the early neural markers Sox1, Pax6 and Nestin and closely resembling the early embryonic neural tube (Perrier et al., 2004). When dissociated and replated, PSC-derived neural rosettes give rise to neural progenitor cells (NPCs) which subsequently differentiate into a heterogeneous mixture of different subtypes of neurons (GABAergic, dopaminergic, serotonergic, and cholinergic), astrocytes and oligodendrocytes (Zhang et al., 2001; Barberi et al., 2003). Furthermore, PSCs cultured in this conditions spontaneously acquire an anterior dorsal neural identity (Watanabe et al., 2005; Pankratz et al., 2007), while the addition of growth factors to the medium can steer the differentiation of PSCs toward midbrain/hindbrain (Kawasaki et al., 2000; Perrier et al., 2004) or spinal cord (Wichterle et al., 2002; Li et al., 2009) fates. Thus, PSCs are first committed toward an anterior neural fate and successively patterned by caudalizing factors to acquire a more posterior neural identity, supporting a mammalian model of default neural induction (Muñoz-Sanjuán and Brivanlou, 2002; Smukler et al., 2006; Stern, 2006; Levine and Brivanlou, 2007; Gaulden and Reiter, 2008). Finally, recent evidence suggest that the regionalization of the presumptive neural ectoderm precedes neural commitment; indeed these results further support the notion that FGF, WNT and RA signaling are required for the acquisition of posterior neural identity by PSCs differentiating *in vitro* (Metzis et al., 2018).

The positional identity of neural cells obtained by pluripotent cell during *in vitro* differentiation is often established by the simple study of their neurotransmitter phenotype (Eiraku and Sasai, 2011; Shi et al., 2012; Yu et al., 2014; Shiraishi et al., 2017), or by deeper investigation of their molecular nature through methods of global gene expression analysis (Bertacchi et al., 2013, 2014; Espuny-Camacho et al., 2013; Leemput et al., 2014; Edri et al., 2015; Yao et al., 2017; Terrigno et al., 2018a). However, specific neural subtypes present in different areas of the adult brain show, in addition to distinct gene expression profiles, also defined connectivity patterns, electrophysiological proprieties and morphologies (Cadwell et al., 2015; Fuzik et al., 2015; Tiklová et al., 2019). Whereas the molecular signature of neurons can be established prior their transplantation, the evaluation of all the other parameters require *in vivo* analysis. Understanding how to obtain a precise subtype of neuron, patterned with the proper temporal and positional identity, is pivotal and might have considerable repercussion on possible clinical applications.

In this review, we have considered available protocols to differentiate murine and human pluripotent stem cells into cortical- or hippocampal-like stem cells (**Figures 2**, **3**) expressing at least a forebrain marker (FOXG1 or EMX1/2) and an early cortical or hippocampal marker (TBR1/2, BCL11B or PROX1).

Derivation of Cortical-Like Neurons From Pluripotent Stem Cells

The derivation of cortical-like neurons from PSCs was first reported a decade ago by the laboratories of Pierre Vanderhaeghen (Gaspard et al., 2008) and Yoshiki Sasai (Eiraku et al., 2008). Interestingly, Sasai's protocol is also the first report on 3D cortical organoid from both murine and human PSCs obtained by inhibiting both the endogenous WNT and TGFβ signaling. On the contrary, in Vanderhaeghen's protocol PSCs are cultured as low density adherent monolayer in a minimal, chemically defined medium supplied with a SHH inhibitor, Cyclopamine. Indeed, these authors pioneered the generation of cortical-like cells from PSCs, paving the road for the subsequent studies on human PSCs and induced PSCs (**Figures 2**, **3**). Notably, cortical-like cultures, expressing anterior neural markers (FOXG1 and EMX1/2) and enriched in several cortical cell types (BCL11B, TBR1/2, SATB2, BRN2, and CUX1), can be obtained by simply differentiating PSCs, cultured in suspension as embryoid bodies (Ebs), or as attached monolayer, in a chemically defined minimum medium, devoid of any grow factors (Gaspard et al., 2008; Li et al., 2009; Zeng et al., 2010; Lancaster et al., 2013). However, most authors block endogenous posteriorizing or ventralizing factors (**Figure 1**) to promote the commitment toward an anterior dorsal fate and enrich the culture in cortical cell types (Eiraku et al., 2008; Gaspard et al., 2008; Mariani et al., 2012; Shi et al., 2012; Bertacchi et al., 2013, 2014; Espuny-Camacho et al., 2013, 2018; Kadoshima et al., 2013; Renner et al., 2013; Yu et al., 2014; Paşca et al., 2015; Sakaguchi et al., 2015; Motono, 2016; Gunhanlar et al., 2017; Sarkar et al., 2018; Terrigno et al., 2018a), including BMP inhibitors (Noggin, BMPR1A-Fc, LDN193189, or Dorsomorphin), WNT inhibitors (Dkk1, IWR-1-endo, 53AH, or WNTC59) and TGFβ inhibitors (Lefty, SB431542). In addition, the default fate of PSC-derived neural progenitors appears to be dorsal, thus fewer protocols include the inhibition of SHH signaling (Gaspard et al., 2008; Yu et al., 2014; Sarkar et al., 2018).

Interestingly, by default PSC-derived cortical neurons appear to acquire mainly limbic and occipital cortical identities (Gaspard et al., 2008; Bertacchi et al., 2013; Terrigno et al., 2018b). In fact, cortical-like cultures show high levels of posterior cortical markers, namely COUP-TF1 (Gaspard et al., 2008; Bertacchi et al., 2013; Terrigno et al., 2018b), an orphan nuclear receptor that is expressed in a high posterior-lateral to low anterior-medial expression gradient by both progenitors and cortical neurons, and is required to balance the antero-posterior patterning of the

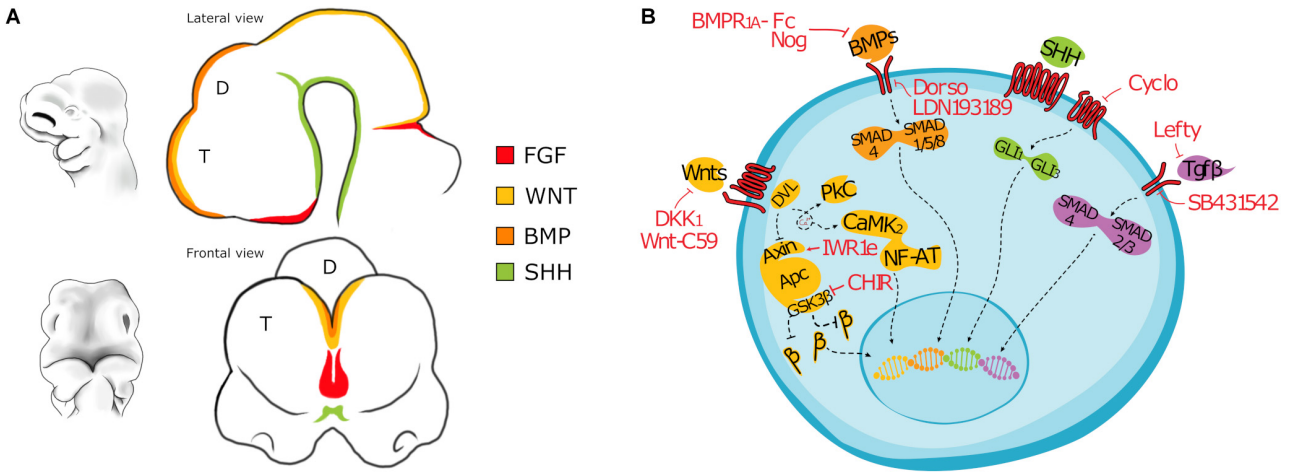

FIGURE 1 | (A) Drawing depicting the main morphogens involved in the patterning of the forebrain of a mouse embryo (E10). T, Telencephalon; D, Diencephalon. **(B)** Cartoon showing main signaling pathways active in differentiating PSC and the inhibitors most commonly used. BMP signaling: Noggin, Bone Morphogenetic Protein Receptor 1A Fc chimera (BMPR1A-Fc), LDN193189, or Dorsomorphin; WNT signaling: CHIR99021, Dickkopf-related protein 1 (Dkk1), IWR-1-endo, 53AH or WNT-C59; TGFβ signaling: Lefty, SB431542; SHH signaling: Cyclopamine. β: β-catenin (CTNNB1).

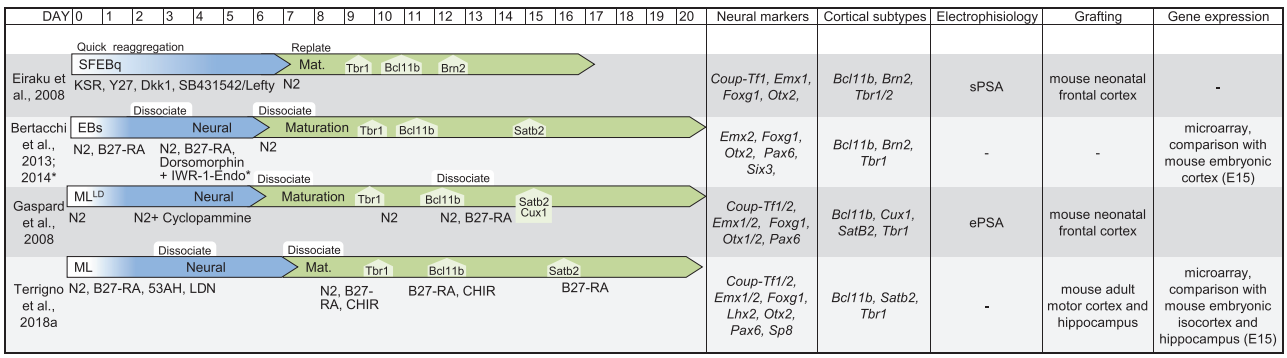

FIGURE 2 | Table showing original reports of differentiation protocols of murine PSCs in cortical and hippocampal neurons. For each entry we indicated (from left to right): reference, schematic layout of the protocol, neural markers, cell-type markers, electrophysiological proprieties, target of transplantation assay to assess integration, global gene expression analysis to identify cell positional identity. If the information was available, we indicated the time of emergence of main cortical cell types (TBR1, BCL11B, BRN2, SATB2, and CUX1). Due to the sheer number of studies on this topic, derivative reports of minor modifications to previously published protocols are not included in this table. SFEBq, serum-free culture of embryoid body-like aggregates; EB, embryoid body; ML, monolayer; LD, low-density; sPSA, spontaneous post-synaptic activity; ePSA, evoked post-synaptic activity.

neocortex (Armentano et al., 2007; Liu et al., 2010). In addition, heterotopic transplantation experiments into the adult murine cortex showed patterns of projection strikingly similar to grafted embryonic visual cortical cells (Michelsen et al., 2015; Espuny-Camacho et al., 2018), supporting the hypothesis of a default occipital fate for PSC-derived neurons. Indeed, treatment with the morphogen FGF8 can induce frontal motor cortical fates in PSC-derived cultures (Eiraku et al., 2008; Kadoshima et al., 2013; Imaizumi et al., 2018; Terrigno et al., 2018b). Intriguingly, Motono et al. reported the generation of PSC-derived anterior cortical neurons (low COUP-TF1 / high SP8 expression) by blocking both the canonical and non-canonical WNT signaling with an inhibitor of Porcupine (PORCN), a membrane-bound O-acyltransferase involved in the palmitoylation, and subsequent secretion, of WNT proteins (Motono et al., 2016). Although these results remain to be confirmed by whole genome expression profiling of the cells and a more extensive analysis of their morphology and connectivity following homotopic and heterotopic transplantation, they are yet another example of how culture conditions profoundly influence the positional identity of PSC-derived cortical neurons. Finally, since different protocol to obtain cells with anterior cortical identity are now available (Eiraku et al., 2008; Kadoshima et al., 2013; Motono, 2016; Imaizumi et al., 2018; Terrigno et al., 2018b), further studies should focus on PSC-derived neurons with motor cortical identity transplanted in the damaged motor cortex.

Besides positional identity, the cellular composition of the cell culture has great clinical implications, since the projection pattern of transplanted PSC-derived neurons varies according to their cellular identity. That is, TBR1- and BCL11B-positive

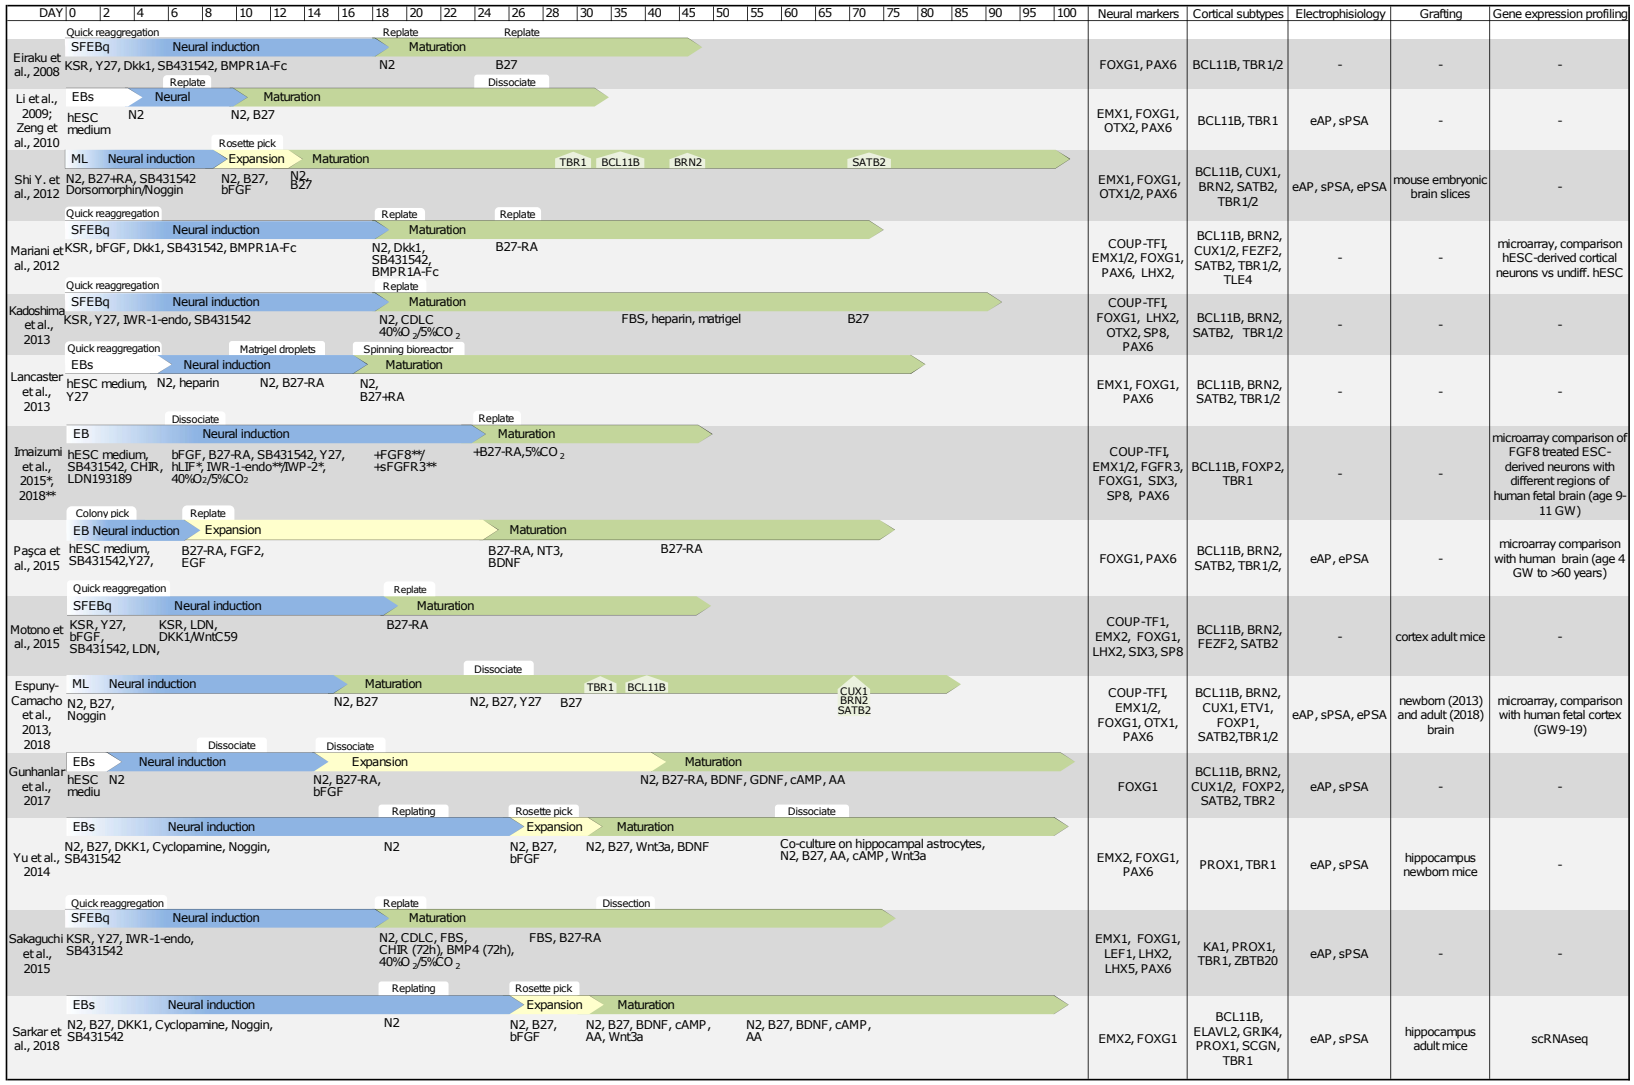

FIGURE 3 | Table showing original reports of differentiation protocols of human PSCs in cortical and hippocampal neurons. With same criteria as those indicated in **Figure 2** SFEBq, serum-free culture of embryoid body-like aggregates; EB, embryoid body; ML, monolayer; scRNAseq, single cell RNA sequencing; eAP, evoked action potential; sPSA, spontaneous post-synaptic activity; ePSA, evoked post-synaptic activity.

PSC-derived neurons transplanted in the adult brain generate, respectively, cortico-thalamic and corticofugal projections (Espuny-Camacho et al., 2013; Michelsen et al., 2015), consistently with the connectivity of normal TBR1- and BCL11B-positive cells. In fact, differentiating PSCs can generate all the cell-types of the six cortical layers (van den Ameele et al., 2014), although culture conditions strongly influence their ratio. Indeed, the production of cortical pyramidal neurons by PSCs cultured in minimal medium as monolayer cultures is strongly skewed toward lower layer identity (Gaspard et al., 2008; Espuny-Camacho et al., 2013). However, the proportion of upper cortical neurons can be increased by supplying retinoids during dual SMAD inhibition (Shi et al., 2012), by transplantation in host brain (Espuny-Camacho et al., 2013) or by culturing PSCs as aggregates (Eiraku et al., 2008; Mariani et al., 2012; Lancaster et al., 2013). Organoid cortical cultures more faithfully reproduce several features of *in vivo* corticogenesis (reviewed in Lancaster and Knoblich, 2014; Di Lullo and Kriegstein, 2017; Giandomenico and Lancaster, 2017), such as migration of newborn neurons on radial glia processes (Bamba et al., 2017), interkinetic nuclear migration (Paşca et al., 2015), and interactions and connections between different regions of the neuroepithelium, such as the interneuron migration and cortical invasion in 3D co-cultures of dorsalized and ventralized PSC-derived neurons (Birey et al., 2017). Finally, although these methods do not allow the identification of the signals responsible for PSC specification, aggregate cultures display higher axonal outgrowth (Chandrasekaran et al., 2017) and cell survival (Daviaud et al., 2018) following cortical transplantation, holding great promises for *in vitro* modeling of neurodegenerative diseases (Quadrato et al., 2016).

During telencephalic development, GABAergic interneurons are generated in the subpallial caudal and medial ganglionic eminence (CGE and MGE) and migrate tangentially to the cortex and hippocampus (Marín and Rubenstein, 2001; Xu et al., 2004; Hansen et al., 2013; Ma et al., 2013). Several neurological disorders are caused by dysfunctions of the GABAergic system and in the last decades GABAergic cell-based therapies have emerged as a promising treatment in restoring the lost balance between inhibitory and excitatory circuits (Danjo et al., 2011; reviewed in Alvarez Dolado and Broccoli, 2011; Hunt et al., 2013; Shetty and Upadhya, 2016). Furthermore, several groups were able to efficiently generate forebrain GABAergic interneurons from PSCs (Gaspard et al., 2008; Li et al., 2009; Zeng et al., 2010; Falk et al., 2012; Germain et al., 2013; Liu et al., 2013; Maroof et al., 2013; Nicholas et al., 2013; Tornero et al., 2013; Yuan et al., 2015; Liao et al., 2016; Sun et al., 2016; Xu et al., 2016). However, due to the ventral origin of the forebrain interneurons, PSCs committed in culture to dorsal telencephalic fates, such as cortex and hippocampus, generate mainly glutamatergic neurons (Zhang et al., 2001; Bibel et al., 2004; Eiraku et al., 2008; Gaspard et al., 2008, 2009; Bertacchi et al., 2013, 2014; Espuny-Camacho et al., 2013; Yu et al., 2014; Michelsen et al., 2015; Livesey et al., 2016; Motono, 2016; Sarkar et al., 2018; Terrigno et al., 2018a). Since GABA-ergic inhibition is essential for maintaining the balanced activity of cortical neural circuits and for the development of neural network activity (Ben-Ari et al., 2007), grafting of PSC-derived cortical or hippocampal cultures enriched with interneurons could have significant clinical repercussions and should be further investigated.

Derivation of Hippocampal-Like Neurons From Pluripotent Stem Cells

The first report of PSC-derived neural progenitors committed to a medial pallial identity was by Sasai and colleagues (Eiraku et al., 2008). Since then, several authors described methods to commit PSC to either choroid plexus or hippocampus (**Figures 1**, **2**; Yu et al., 2014; Sakaguchi et al., 2015; Sarkar et al., 2018; Terrigno et al., 2018a). Most of these protocols share an initial phase of WNT, BMP and TGFβ inhibition, followed by activation of BMP and WNT signaling, by either suppling WNT3a or a small-molecule inhibitor of GSK3 (CHIR). In particular, Sakaguchi et al. showed that a short-term activation of WNT and BMP signaling in anteriorized neural progenitors specifies a hippocampal primordium-like tissue *in vitro*, expressing the hippocampal markers ZBTB20, KA1 and PROX1; while a prolonged treatment results in increased expression of LMX1A and TTR, markers of choroid plexus (Sakaguchi et al., 2015). Consistently, other authors showed that double inhibition of WNT and BMP endogenous signaling in differentiating PSC followed by timely activation of WNT signaling results in hippocampal specification (Yu et al., 2014; Sarkar et al., 2018; Terrigno et al., 2018a). In particular, the laboratory of Fred Gage showed that a prolonged treatment with WNT3a results in the commitment of PSC to DG fate, while a shorter treatment and with a lower concentration of WNT3a specifies CA3 identity (Yu et al., 2014; Sarkar et al., 2018). Notably, PSC-derived hippocampal-like neurons, but not cortical-like cells, transplanted into adult hippocampus were capable of long-term survival, contacted relevant targets of the hippocampal formation and formed functional synaptic contacts with the host network, further confirming the importance of the identity match between transplanted cells and surrounding environment (Terrigno et al., 2018a).

IN VIVO INTEGRATION AND THERAPEUTIC EFFECT OF GRAFTED EXOGENOUS NEURAL CELLS IN THE BRAIN

Once obtained the cell type(s) of interest, the next step is to evaluate if these cells can properly integrate in the host tissue, sending short and long projections to their natural targets and rebuilding damaged circuitry. Neurons suitable for transplantation must be able to integrate into the host context, produce the appropriate type of neurotransmitter and neurotransmitter receptors and develop synapses with functionally relevant targets and electrophysiological properties of mature neurons.

Anatomical Characterization of Grafted Neurons in the Host Circuits

Initial reports showed that the outgrowth from grafts of fetal neurons in adult host brain was limited and dependent on the site of injection (Gonzalez et al., 1988; Isacson et al., 1988; Fricker et al., 1999). The first consistent observation of long-distance axons and extensive innervation of the host brain by fetal transplants following experimental deletion of cortical projection neurons was reported by Hernit-Grant and Macklis (1996) and Fricker-Gates et al. (2002). However, in these studies the specificity of efferent projections from the grafted cells toward appropriate host target sites was not assessed. Subsequently, Gaillard et al., 2007 described the reconstruction of damaged cortical circuitry in adult mice and the formation of long-range projections targeting the appropriate host regions, notably the pyramidal tract and the spinal cord. 2 months after the transplantation of fetal cortical tissue in the damaged motor cortex, they observed outgoing projections toward most of the cortical and subcortical targets of the cortical motor neurons, comparable to those established by neurons of the contralesional motor cortex. Furthermore, they verified that most of the grafted neurons sent projections along motor pathways, by injecting the retrograde tracer cholera toxin in the brain regions where fibers were found (i.e., thalamus and dorsolateral caudate putamen). Interestingly, the fact that in the same study visual grafts were not competent to replace degenerating motor pathways suggests that transplanted cells retain positional identity and functional capability of the donor. Altogether, these initial reports showed that transplanted embryonic neurons are able to extend long-range projections to distant targets with great specificity, suggesting that guidance cues persist in the adult brain or are re-expressed after injury, although no electrophysiological and/or behavioral evidence was provided to corroborate the anatomical observations (Gaillard et al., 2007).

More recently, Falkner et al. (2016) performed *in vivo* 2-photon imaging of embryonic cortical neurons transplanted 7 days after ablation of layer II-III callosal projecting neurons in the monocular visual cortex, evaluating longitudinal structural maturation, morphology, dendrite elongation and spine refinement of grafted neurons. Notably, already at 3–4 days post-transplantation, grafted neurons extended branched neurites, with identifiable growth cone and boutons, followed by the formation of apical dendrites which reached complete development within 4 weeks post-transplantation (wpt). Spine and bouton density greatly increased up to 4 wpt and then reached a plateau, while turnover rates increased at 5 wpt and subsequently stabilized after 8 wpt. Interestingly, as soon as 5 wpt, grafted cells displayed appropriate identity of pyramidal neurons and projected to the natural targets of V1 neurons, including ipsilateral visual areas, retrosplenial and entorhinal cortices and the corpus callosum. Furthermore, grafted cells received topographically correct synaptic inputs from appropriate cortical and subcortical regions, as assessed by performing monosynaptic rabies virus tracing. Overall, the authors showed that fetal neurons integrate adequately into the adult cerebral cortex, mature over time and re-establish a normal pattern of projection according to their original positional identity.

As previously discussed, in the last decade several groups worked to overcome the ethical and technical challenges of using fetal tissue, developing protocols to differentiate both mouse and human embryonic stem cells into neurons with appropriate cellular identity and area specification (**Figures 1**, **2**).

Among the first, Pierre Vanderhaeghen and collaborators showed that murine PSC-derived pyramidal neurons grafted into the frontal cortex of neonatal mice and analyzed after 1 month displayed specific patterns of axonal projections corresponding to visual and limbic occipital cortex, despite the frontal site of transplantation (Gaspard et al., 2008). Furthermore, cultures transplanted at later stages of differentiation were enriched in later-born, superficial layer cell types. A similar pattern of projections was found 2 months after transplantation of human PSC-derived cortical neurons in frontal cortex of mouse pups, although 6 months post-transplantation the selectivity of these cells to contact the appropriate targets seems to decrease, with axonal projections reaching a wider range of regions, including motor and somatosensory areas (Espuny-Camacho et al., 2013). Noteworthy, Ideguchi and colleagues found no intrinsic regional identity in their PSC-derived pyramidal neurons, showing instead projection patterns coherent with the site of transplantation (Ideguchi et al., 2010). Thus, there may be a variability (likely depending on the protocol used for the differentiation) in the ability of the transplanted cells to retain the identity acquired *in vitro*.

In subsequent studies by Vanderhaeghen and collaborators, murine and human PSC-derived neurons were transplanted in a model of visual cortex lesion in adult mice and the re-establishment of the damaged pathways was assessed from 4 to 90 days after grafting (Michelsen et al., 2015). Grafted cells successfully differentiated, mainly in glutamatergic neurons, and showed reciprocal long-range axonal projections with targets of the damaged cortex such as the ipsilateral and contralateral cortex (layers II/III/IV), striatum (V), thalamus (VI) and midbrain/hindbrain nuclei (layer V). This study further confirmed that transplanted neurons display layer-specific patterns of projection in accordance with their molecular identity and consistent with the pattern of projection of native neurons of the visual cortex. Interestingly, these results were only obtained following homotopic transplantation in visual and not in motor cortex, as also confirmed by transplantation of fetal visual and motor cortical neural precursors. Human PSC-derived neurons maintained positional identity after transplantation and displayed the same projection properties of corresponding mouse cells, but required a longer time of maturation (Espuny-Camacho et al., 2018). Taken together, these results suggest that the success of transplantation in adult cortex is highly dependent on a strict match between the areal identity of the lesioned cortex and the positional identity of transplanted cells (Gaspard et al., 2008; Espuny-Camacho et al., 2013, 2018; Michelsen et al., 2015).

Among the first reports of mouse PSC used as cell therapy in animal models of stroke, Bühnemann et al. (2006) found that PSC-derived neural precursors transplanted into an Endothelin-1 (ET-1)-induced corticostriatal ischemic lesion,

or in the perilesional striatum in rats, survived for up to 12 weeks and differentiated into distinct neuronal subtypes without expressing a specific cortical area-specific identity. However, the size of the surviving graft decreased from 4 to 12 weeks, probably due to graft rejection despite cyclosporine treatment, while paucity of fibers and high neuron mortality rate did not allow a proper analysis of the projection pattern.

Tornero et al., 2013 transplanted human IPSCs-derived, cortically committed or non-committed neural precursors, in the perilesional somatosensory cortex of a rat stroke model obtained by middle cerebral artery occlusion (MCAO). After 2 months they found that non-fated neural precursors cells (NPCs) proliferate more than their cortical counterpart. Both cell types migrated toward the ischemic lesion, but cortically fated cells differentiated more efficiently into TBR1- and SATB2-positive cortical neurons with a pyramidal morphology (Tornero et al., 2013). The same authors reported that grafted iPSC-derived cortical NPCs received synaptic inputs from the same areas as endogenous neurons (e.g., perilesional and contralateral cortex, ipsilateral and contralateral claustrum, specific thalamic nuclei, globus pallidus, etc.) as shown by the injection of a modified rabies virus that labeled monosynaptic afferents to grafted neurons. Finally, 6 months post-transplantation, immunoelectron microscopy confirmed that grafted neurons exhibited the ultrastructural features of mature neurons and formed synaptic contacts with host axon terminals, showing all of the ultrastructural criteria for synapses (Tornero et al., 2017).

Our group recently developed a protocol to produce either hippocampal or isocortical neurons that were then co-transplanted in healthy and lesioned brain regions. The analysis of *in vivo* projection pattern revealed that the different molecular identity acquired *in vitro* profoundly affect the different ability of these cells to extend axonal projections. In fact, we found that, accordingly to their molecular identity, isocortical neural precursors were not able to project once transplanted in the dentate gyrus (DG) of the hippocampus, contrary to PSC-derived hippocampal cells that properly elongated fibers to CA3 following endogenous hippocampal pathways. Instead, when grafted in their proper healthy cortical region, isocortical neurons sent projections toward the motor cortex and other cortical and subcortical targets. Interestingly, consistently with previous findings (de la Rosa-Prieto et al., 2017), fiber quantification revealed that the presence of an ischemic cortical lesion had an impressive impact in increasing the number of projections from isocortical cells, possibly through the same cellular mechanisms that spontaneously trigger and enhance post-stroke endogenous neural regeneration (Lindvall and Kokaia, 2015). Following stroke, the cortical cells elongated far reaching process that successfully integrated in motor pathways channeling in corticospinal tract segments, as the internal capsule (Terrigno et al., 2018b). However, PSC-derived isocortical cells transplanted into either intact or photothrombotic motor cortex failed in sending projections to thalamic nuclei and midbrain, in keeping with previous observations (Michelsen et al., 2015). This finding suggests that they might simply have maintained a general isocortical identity and that a further motor specification step may be required to generate also thalamic and midbrain projections.

Due to the clinical relevance and incidence of cortico-striatal lesions in humans, transplantation studies using neural precursors to rebuild lost circuitry focus mostly on sensory and motor cortices and striatum. However, since 1995 Fred Gage's laboratory explored the possibility of transplanting cells in the hippocampus, publishing evidence that hippocampal neural stem cells long expanded *in vitro*, can integrate in the dentate gyrus and differentiate into mature neurons (Gage et al., 1995, 1998). Subsequently, it has been shown that pyramidal neurons obtained *in vitro*, integrate in the hippocampus, spreading throughout the CA3 region and the hilus, and elongate long projections to the contralateral hippocampus (Englund et al., 2002).

Electrophysiological Properties of Grafted Neurons

Studying electrophysiological properties of grafted neurons is an unavoidable step to demonstrate the effective integration in the pre-existing circuitry and the formation of active synapses with the host tissue.

Different strategies can be adopted to study functional properties of grafted neurons, each one with its own limitations. Whole cell patch clamp in an *ex vivo* preparation permits the visualization of fluorescent grafted cells with the certainty to record from a single grafted neuron, allowing the experimenter to precisely study the input/output connectivity of the transplanted cells with surrounding neurons. However, with this *ex vivo* technique it is not possible to test the response of grafted neurons to more physiological environmental events, such as somatic or visual stimuli. On the other hand, during *in vivo* electrophysiological recordings it is challenging to unambiguously identify grafted cells within the cortex, posing uncertainty on the source of the recorded activity. However, appropriate strategies have been developed to overcome these limitations.

Several studies showed that neurons transplanted in the cortex differentiate and mature in functional neurons, which are characterized by appropriate electrophysiological properties of resting membrane potential, spontaneous and induced action potentials (APs) and spontaneous post-synaptic activity in voltage or current clamp configuration (Bühnemann et al., 2006; Daadi et al., 2009; Oki et al., 2012; Espuny-Camacho et al., 2013, 2018; Tornero et al., 2013; Michelsen et al., 2015). In one of the first reports, Bühnemann et al. (2006) studied the electrophysiological proprieties of murine neural progenitors transplanted in a stroke model. The authors showed appropriate voltage-gated sodium and potassium currents with reversal potential similar to control neurons and blocked them using specific drugs (TTX and TEA, respectively). In addition, they recorded APs and spontaneous excitatory post-synaptic currents in graft-derived cells indicating synaptic input. Moreover, spontaneous APs decreased their duration over time (3 to 6 weeks after transplantation) suggesting that maturation processes could take place in this window (Bühnemann et al., 2006).

Action potentials of murine and human grafted neurons, transplanted both in naïve and pathological conditions, have been recorded in spontaneous conditions or in voltage clamp configuration, using a depolarizing current (Daadi et al., 2009; Oki et al., 2012; Espuny-Camacho et al., 2013, 2018; Tornero et al., 2013; Michelsen et al., 2015). Interestingly, many of these studies reported both excitatory and inhibitory spontaneous post-synaptic activity of transplanted cells. This activity was totally blocked using AMPA, NMDA or GABA antagonists (CNQX, AP-V and Gabazine, respectively), indicating that transplanted cells successfully received inputs from resident neurons. Specific inputs from host neurons have been detected by electrically stimulating a cortical site far away from the transplant (e.g., the contralateral cortex) and visualizing post-synaptic activity (PSP or PSC) in some of the grafted cells, although action potentials were not reported, suggesting mature and functional host-to-neurons synapses but with a low density distribution (Oki et al., 2012; Espuny-Camacho et al., 2013, 2018; Tornero et al., 2013). In addition to electrical stimulation, optogenetic tools have been exploited to study afferent connectivity to grafted neurons. In fact, Tornero et al. (2013) reported host thalamic inputs to transplanted iPSC-derived cells that differentiated into pyramidal neurons and fast spiking interneurons. After light stimulation of the host neurons expressing Channelrhodopsin-2 in the ventral thalamic nuclei, EPSP and EPSC were detected in grafted neurons 3 months after transplantation in the ipsilesional somatosensory cortex (Tornero et al., 2017).

In another recent study, Wuttke et al. (2018) tested the callosal host inputs on grafted PSC-derived neurons, using a remarkably clean optogenetic approach. TdTomato-conjugated Channelrhodopsin-2 was *in utero* electroporated in correspondence to the layer II-III neuron production peak during corticogenesis (E14.5). At birth, they transplanted PSC-derived neurons in the contralateral homotopic region to the electroporaton site. Starting from P21, in acute slice, they patched grafted neurons (GFP+) surrounded by TdTomato fibers arising from contralateral callosal projecting neurons. In voltage-clamp configurations, grafted neurons showed spontaneous excitatory and inhibitory post-synaptic activity (EPSC and IPSC). After light stimulation of the contralateral ChR2-electroporeted neurons, authors found post-synaptic currents in grafted neurons, although no action potentials occurred (Wuttke et al., 2018). Notably, based on the latencies between the onsets of the light pulses and the light-evoked postsynaptic currents, the authors were able to distinguish between excitatory, monosynaptic transcallosal connections and polysynaptic, inhibitory inputs mediated by local interneurons. Finally, the authors assessed whether the grafted cells established functional contacts with the host neurons. Thus, after grafting ChR2-TdTomato cells in the neonatal cortex, they patched host neurons and optogenetically stimulated transplanted cells. They found that stimulation of grafted neurons induced EPSC in endogenous cells with a greater efficiency in ipsilateral compared to contralateral host neurons (Wuttke et al., 2018).

The main challenge of cell therapy in adult disease models is to obtain neurons behaving as the endogenous counterparts and properly responsive to environmental stimuli. In this regard, Pierre Vanderhaeghen and colleagues (Michelsen et al., 2015) tested the responsiveness to a visual stimulus of *in vitro* differentiated murine pyramidal visual cortex neurons, after their transplantation in the visual cortex of adult mice that was previously lesioned by ibotenic acid injection. The authors performed extracellular recordings in anesthetized animals 3–9 months after the transplant, placing the electrode in the center of the transplant and performing juxtacellular neurobiotin injection after the recordings. Grafted neurons showed spontaneous action potential firing with frequencies similar to control neurons. Then, they tested whether a physiological stimulus (1-s flash) was able to evoke spike activity in grafted neurons and found that half of recorded neurons increased their firing rate after flash presentation, with latencies and frequencies similar to naïve control neurons (Michelsen et al., 2015).

Falkner et al. (2016) reported functional maturation of murine grafted neurons in visual cortex after a selective degeneration of callosal projecting neurons in adult mice. The authors transplanted E14.5–E15.5 fetal cortical cells previously transduced with a calcium indicator. From 4 to 15 weeks post-transplantation they performed 2-photon imaging sessions, presenting gratings to the contralateral eye and reported a refinement over time of the orientation preference with sharp tuning properties in the later sessions (Falkner et al., 2016). These data are remarkable as the transplanted neurons appear to assume tuning properties indistinguishable from endogenous pyramidal cells.

Tornero et al. (2013) grafted human iPSCs-derived cortical neural precursor cells in the somatosensory cortex, 1 week after MCAO. Animals were subjected to extracellular recordings 3 months after transplantation, during tactile stimulation of different parts of the body. In these experiments the electrode was placed in the core of the transplant at least 70 μm far away from the border. Spike sorting allowed the identification of single unit responses. Authors reported an increased firing rate of some grafted neurons after stimulation of nose, forelimbs or hindlimbs, with latencies ranging from 9 to 32 ms. Moreover, spontaneous activity in some of the recorded neurons was inhibited by tactile stimulation but with a longer latency (46 to 85 ms) indicating a fine integration of these neurons in the cortical network, responding with an opposite directionality to stimuli from different parts of the body. In addition to single unit recordings, Local Field Potentials (LFPs) were also analyzed in this paper. Authors demonstrated that the evoked potential after nose stimulation was affected in untreated MCAO rats, showing a longer latency with respect to healthy animals. Grafting IPSC-derived cortical neurons rescued this deficit, shortening the latencies and making them similar to those of naïve rats (Tornero et al., 2017). Indeed, this is one of the few studies in which functional recovery after stroke was corroborated by electrophysiological evidences, suggesting that the therapeutic effect of the grafted neurons may be, at least in part, mediated by actual cellular replacement.

In animal models of epilepsy, several studies reported reduction of electrographic seizure activity mediated by neural

transplantation (Hattiangady et al., 2008; Baraban et al., 2009; Maisano et al., 2012; Hunt et al., 2013; Southwell et al., 2014). In particular, it has been showed that grafting fetal interneurons, derived from human PSCs, in the hippocampus of a pilocarpine-induced temporal lobe epilepsy murine model, rescued the epileptic phenotype, with a very significant decrease in the number of seizures and amelioration of cognitive deficits and hyperactivity (Cunningham et al., 2014). 4 months post-transplantation, grafted interneurons were integrated in the hippocampus and showed spontaneous post-synaptic currents and regular membrane potential properties. In addition, efferent graft-to-host connections were tested using whole-cell patch clamp of endogenous neurons during optogenetic stimulation of Chr2-expressing cells. Post-synaptic activity induced by blue light stimulation in host neighboring neurons was totally abolished by the GABA antagonist bicuculline, thus demonstrating correct and mutual integration (Cunningham et al., 2014).

Overall, these results suggest that exogenous neurons can successfully integrate in a pre-existing neural network, developing mature synaptic contacts with resident neurons. In selected cases, transplanted neurons appear to contribute to rescue functional deficits. To determine the extent of integration within the host circuitry, it is now of paramount importance to assess how the grafted cells respond in awake animals during physiologically relevant behaviors. So far, only sensory stimuli have been used to drive grafted neurons. Thus, it would be of great interest to evaluate the responsiveness of transplanted cells during motor tasks. Hopefully, further research will shed light on these important questions.

Therapeutic Effectiveness of Cell Replacement Therapies

The final goal of cell-based therapies is to improve recovery from functional deficits. In this context, beneficial effects of grafted cells can be ascribed to two, not mutually exclusive, mechanisms: (i) grafted cells could enhance functional recovery by secreting trophic factors and molecules with a neuroprotective/neuroplastic effect (also known as bystander effect); (ii) transplanted neurons could properly rebuild damaged circuitry, reestablishing lost sensorimotor synaptic connections. Consistently, cell-based therapy efforts are either directed toward grafting cells to produce and release trophic factors on site, or toward obtaining neurons with a specific identity in order to promote actual cell-replacement. Indeed, the fact that in several reports grafted cells were not detected in transplanted animals, despite an apparent functional improvement, indicates that: (i) the beneficial effect of the grafting was not related to long-term cell integration in the host neuronal circuitry and was exerted in the initial phase before the cells degenerated and (ii) the effect might be due to secretion of beneficial molecules released from grafted cells, or from resident cells stimulated by the grafting, in early post-implantation phase (Ramos-Cabrer et al., 2010; Oki et al., 2012; Hermanto, 2017).

Vascular endothelial growth factor (VEGF) has been implicated in mediating cell-induced functional recovery (Lee et al., 2007). In fact, neurons derived from human neural stem cells and overexpressing VEGF improved animal performance in the rotarod and limb placement tests when transplanted in the perilesional tissue after a hemorrhagic lesion, with early effects (8 days post-transplantation). Cells overexpressing VEGF also increased microvessels proliferation and diminished apoptotic cell death (Lee et al., 2007). Subsequently, Horie et al. (2011) confirmed that VEGF was responsible for the therapeutic effect of grafted neurons. They transplanted neurospheres in the peri-ischaemic cortex and observed an amelioration in the vibrissa-evoked forelimb placing test. Intriguingly, the recovery was totally abolished when VEGF was sequestered by a specific monoclonal antibody. In addition, histological investigations also reported a better blood brain barrier integrity, increased neovascularization and reduced inflammation (Horie et al., 2011). Moreover, the same authors showed that VEGF-mediated beneficial effects positively modulate axonal transport of host neurons, and stimulated axonal sprouting and dendritic plasticity (Andres et al., 2011).

It is generally accepted that grafted neurons could improve recovery by modulating neural plasticity. Indeed, transplanted interneurons induce plasticity in the host brain as reported by Southwell and colleagues, who demonstrated that grafting inhibitory interneurons in the adult visual cortex could re-open the critical period for ocular dominance plasticity (Southwell et al., 2010). In line with these results, hippocampal neural stem cells co-transplanted with astrocytes and microvascular endothelial cells in the hippocampus improved memory deficit after experimental stroke (Cai et al., 2015). Moreover, motor improvements have been reported following grafting of human derived neural precursors in rats with stroke (Daadi et al., 2008; Tornero et al., 2013; Tatarishvili et al., 2014), and after combination of grafting and exposure to enriched environment (Hicks et al., 2009). Recent findings confirmed the synergistic effect of coupling transplantation of murine E14.5 cortical NPCs with physical exercise, resulting in an increased and targeted fiber extension and a better motor improvement after aspiration of motor cortex in rats (Shimogawa et al., 2019).

CONCLUSION

The final goal of neuroscientists working in cell therapy for brain diseases is to restore injured neural circuits, thus rescuing physiological impairments. Among the challenges faced by the clinical application of cell-based therapies is the choice of the cell source (fetal cells, embryonic PSCs or iPSCs). Indeed, both embryonic PSCs and fetal transplantations raise ethical issues, since fetuses are hardly a reliable and scalable source of material. Thus, iPSCs represent a good choice from a translational point of view, showing low immunogenicity and posing no ethical concerns. Human Leukocyte Antigen (HLA)-matched banking of iPSCs would reduce both the time and the cost associated with the derivation of clinically compliant induced pluripotent stem cell lines (reviewed in: Solomon et al., 2015) and several

groups are making continuing efforts to improve the immune compatibility of PSCs, reducing the risk of immune rejection caused by HLA mismatching (Rong et al., 2014; Gornalusse et al., 2017; Xu et al., 2019). In addition, of great importance is the development of footprint-free reprogramming tools, to induce pluripotency while preserving the genetic stability of the reprogrammed cells and reducing the risk of tumorigenesis after transplantation, together with optimized protocols, allowing a more efficient cell replacement of the different damaged brain regions (reviewed in Martin, 2017). Finally, further preclinical studies should involve chemogenetic and optogenetic tools for stimulating activity of transplanted neurons and endogenous cells, during specific tasks in which these cells are involved. This would facilitate the strengthening of correct and effective synaptic contacts among grafted and naïve neurons, via mechanisms of Hebbian plasticity. Indeed, the establishment of new neuronal circuitry required for functional recovery after brain injuries likely depends on the same mechanisms of synaptic plasticity that drive experience-dependent refinement of connections during brain development.

Background and Purpose: Remote white matter and cortex reorganization may contribute to functional reorganization and clinical outcome after acute infarcts. To determine the microstructural changes in the remote intact corticospinal tract (CST) and precentral gyrus cortex connected to the acute infarct after subcortical stroke involving the CST over 6 months.

Methods: Twenty-two patients with subcortical stroke involving the CST underwent magnetic resonance imaging (MRI) and clinical assessment in the acute phase (baseline) and 6 months (follow–up) after the stroke. The MRI sequences included T1-weighted imaging, T2–weighted imaging, fluid-attenuated inversion recovery, diffusion tensor imaging (DTI), and diffusion kurtosis imaging. Fractional anisotropy (FA) and track–density imaging (TDI) values were generated using DTI data for the centrum semiovale, corona radiata, posterior limb of internal capsule, and cerebral peduncle. The mean kurtosis (MK) value of the precentral gyrus cortex was calculated. Changes in the FA, TDI, and MK values between the baseline and follow-up and the relationship between these changes were analyzed.

Results: The TDI and FA values of all parts of the ipsilesional (IL) CST, including the noninvolved upper and lower parts, decreased at the 6-month follow-up ($P < 0.001$). The MK values of the stroke lesion ($P < 0.001$) and IL precentral gyrus cortex ($P = 0.002$) were lower at follow-up than at the baseline. The ΔTDI ($r = 0.689$, $P < 0.001$) and Δ FA values ($r = 0.463$, $P = 0.03$) of the noninvolved upper part of the IL CST were positively correlated with the ΔMK value of the IL precentral gyrus cortex.

Conclusion: Secondary degeneration occurred in the remote part of the CST and the remote IL precentral gyrus cortex after subcortical stroke involving the CST. The secondary degeneration in the upper part of the CST was correlated with that in the IL precentral gyrus cortex.

INTRODUCTION

Ischemic stroke is a leading cause of death and long-term disability. Motor disability is one of the most common sequelae of stroke. In stroke survivors who do not receive timely and effective arterial thrombolysis or thrombectomy in the hyperacute phase to salvage the ischemic brain tissue, movement function can still be recovered to a certain extent mainly through the structural reorganization of the central nervous system after brain damage (1, 2). Cortical regions that are distant from the acute ischemic infarct are considered to play an important role in this reorganization (3–5). Secondary damage and degeneration of the remote white-matter tracts connected to the acute ischemic infarct as well as focal cortical thinning in remote cortical regions related to the infarct lesion have been reported after subcortical stroke (6, 7). A magnetic resonance spectroscopy (MRS) study showed that the *N*-acetylacetate (NAA) value of the intact primary motor cortex (M1) decreased after subcortical stroke, indicating neuronal depression, and dysfunction in the M1 area due to ischemia and/or diaschisis of the remote white-matter tracts connected to the acute ischemic infarcts (8). However, other studies have shown that the volume of the remote intact cortex may increase or remain unchanged during the post-stroke rehabilitation period (9, 10). Therefore, there is some controversy about the changes in the volume of the distal intact cortex after subcortical stroke. Possible reasons for this controversy may include differences in follow-up duration, and extent and location of the stroke lesions. Nevertheless, the above studies do suggest that the microstructure of the intact cortex connected to the area of subcortical stroke may change over time.

Diffusion tensor imaging (DTI) and fractional anisotropy (FA), a measurement typically associated with tract integrity, have been used to evaluate cerebral reorganization after ischemic stroke (11, 12). However, DTI cannot precisely evaluate fiber orientation in voxels containing more than one principal fiber direction, for example, in the case of crossing or branching fiber tracks. Another limitation of DTI is partial volume effects due to the coexistence of different types of tissue architecture in the same voxel (13). Recently, track-density imaging (TDI), a new technique with sub-millimeter resolution, was developed using a new algorithm based on whole-brain fiber-tracking. The intensity of TDI maps is proportional to the number of streamlines traversing each voxel. Although whole-brain TDI maps are generated using diffusion-weighted imaging (DWI) data, they provide higher spatial resolution than that of the acquired diffusion MRI data (e.g., FA maps) (14, 15). In addition, diffusion kurtosis imaging (DKI), which is based on non-Gaussian water distribution, can more sensitively detect changes in the tissue microstructure than conventional DWI (16, 17). Therefore, DKI may have certain advantages in evaluating cortical structural remodeling after cerebral infarction.

The aim of this study was to use TDI and DTI combined with DKI to explore the microstructural changes in the corticospinal tract (CST) involved by the stroke lesion as well as the remote intact CST and precentral gyrus cortex connected to the acute infarct during a 6-month follow-up period. In this way, we hoped to provide quantitative information about structural remodeling after subcortical stroke.

MATERIALS AND METHODS

Patients

The study was approved by the institutional review board of our hospital. Written informed consent was obtained from all patients or their legal representatives. We enrolled patients with subcortical ischemic stroke who were treated in our center between September 2016 and June 2018. The inclusion criteria were as follows: (a) subcortical ischemic stroke involving the CST, (b) first-ever stroke occurred within 2 weeks of onset, and (c) ischemic stroke involving only one hemisphere, as confirmed by magnetic resonance imaging (MRI). The exclusion criteria were as follows: (a) any cortical ischemic lesion, (b) previous infarct lesion involving the CST on the initial MRI scan, (c) intracranial hemorrhage, (d) recurrent stroke, or other neurological disorders that may affect limb motor function, and (e) death during the 6-month follow-up period. A total of 22 patients were enrolled in this study. The average age of the patients was 63.0 ± 10.47 years, and the ratio of male-to-female patients was 12:10. No new cerebral ischemic stroke occurred in any of the patients during the 6-month follow-up. The mean time of the first MRI examination was 4.59 ± 1.44 days after onset, and the mean follow-up duration was 187.95 ± 5.52 days. Neurological function recovered to a certain extent during the follow-up. The clinical characteristics and demographics are shown in **Table 1**.

Clinical Assessment

The severity of neurological symptoms was evaluated using the National Institutes of Health Stroke Scale (NIHSS), the Fugl-Meyer Upper Extremity (FM-UE) scale, and the modified Rankin Scale (mRS) in the acute phase and at 6 months after the stroke.

MRI Protocol

MRI was performed in the acute phase (baseline) and at 6 months (follow-up) after the stroke by using a clinical 3.0-T MR scanner (Magnetom Verio, Siemens Healthcare, Erlangen, Germany) with an eight-channel head coil. The MRI sequences were as follows: axial fast spin echo T1-weighted (repetition time [TR]/echo time [TE] = 2,000/9 ms, inversion time [TI] = 860 ms, 24 slices with slice thickness = 5 mm, field of view [FOV] = 220 × 220 mm, matrix = 204 × 320); T2-weighted imaging (TR/TE = 6,000/95 ms, FOV = 220 × 220 mm, matrix = 244 × 384, 24 slices with slice thickness = 5 mm); fluid-attenuated inversion recovery (TR/TE = 8,500/94 ms, TI = 2438.9 ms, 24 slices with slice thickness = 5 mm, FOV = 220 × 220 mm, matrix = 324 × 512); and spin echo echoplanar conventional DWI (FOV = 220 × 220 mm, TR/TE = 5,000 ms/60 ms, resolution = 162 × 162, b = 0 and 1,000 s/mm^2, 28 slices with slice thickness = 4 mm). Both DTI and DKI were carried out using a spin echo echoplanar imaging diffusion sequence (for DTI, FOV = 220 × 220 mm, TR/TE = 8,831 ms/95 ms, resolution = ×, 54 slices with slice

TABLE 1 | Clinical characteristics and demographics.

Demographics and Characteristics ($n = 22$)	
Male, *n* (%)	12 (60)
Age (years, mean ± SD)	63.0 ± 10.47
Location of infarction, *n* (%)	
Left posterior limb of the internal capsule	6 (27.3)
Right posterior limb of the internal capsule	4 (18.2)
Left corona radiata	6 (27.3)
Left centrum semiovale	2 (9.1)
Right centrum semiovale	2 (9.1)
Vascular risk factors, *n* (%)

thickness = 2 mm); for DKI, FOV = 220 × 220 mm, TR/TE = 6,100 ms/109 ms, resolution = ×, 54 slices with slice thickness = 2 mm) with 30 different diffusion encoding directions. For each direction, DTI with two b values (b = 0 and 1,000 s/mm^2) and DKI with six b values (b = 0, 500, 1,000, 1,500, 2,000, and 2,500 s/mm^2) were acquired. The total scan time of all sequences was about 25 min.

Data Processing

Whole-brain fiber-tracking maps and super-resolution TDI maps were generated using the MRtrix package (http://www.mrtrix.org/). First, the high-angular resolution diffusion imaging data were corrected for eddy-current distortion. The T2W images were used as the reference data for motion correction. The Brain Extraction Tool (BET2version2.1) from the FMRIB software library (http://www.fmrib.ox.ac.uk/fsl) was used to calculate the margins of the brain and skull and to remove the skull and scalp tissues. Then, constrained spherical deconvolution (CSD) was used to obtain multiple fiber orientations, and second-order integration was used to generate probabilistic tractography. Track lengths <0.5 mm were discarded, and the tractography termination criteria were as follows: exit the brain (or the numerical phantom) or when the CSD bra orientation distribution amplitude was <0.1. The resulting streamlines were then used to generate maps of track density at 0.25 mm isotropic spatial resolution in the DICOM format for side-by-side comparisons. FA maps were created using FMRIB's Diffusion Toolbox (FSL, Oxford, UK).

DKI post-processing was performed using the Diffusional Kurtosis Estimator (http://www.nitrc.org/projects/dke), where the diffusivity and kurtosis maps were generated using all DKI images. Before the calculation, motion correction through a 6-parameter rigid-body transformation was applied to all DKI images. After the calculation, the mean kurtosis (MK) map was generated.

According to the location of the stroke lesion, the CST was divided into the ipsilesional (IL) CST and contralesional (CL) CST. Regions of interest (ROIs) of FA and TDI were manually drawn along the CST on FA pseudo-color maps at the baseline. First, the whole-brain fiber-tracking map and TDI map were used as a reference, and ROIs were manually drawn at the level of the centrum semiovale, corona radiata, posterior limb of the internal capsule, and cerebral peduncle of the CST. If the above sites of the CST were involved by the stroke lesion, the involved part of the CST was also included in the ROI. The ROIs of the CL CST corresponded to those of the IL CST. We analyzed the impact of the stroke lesion on the remote intact CST based on the level of the CST involved by the stroke lesion. The mean value of the ROIs above the level at which the CST was involved by the stroke lesion was considered to be the value of the remote intact upper part of the CST. Similarly, the mean value of the ROIs below the level of involvement was considered to be the value of the remote intact lower part of the CST. For example, when the posterior limb of the internal capsule was involved by the stroke lesion, the mean value of the area between the corona radiata and the centrum semiovale was considered the value of the remote intact upper part of the CST, and the value of the cerebral peduncle was considered the value of the remote intact lower part of the CST. If the centrum semiovale was involved by the stroke lesion, an extra ROI was manually drawn on the IL CST between the involved centrum semiovale and the precentral gyrus cortex to evaluate the change in the remote intact upper part of the CST. The difference value of TDI and FA (ΔTDI and ΔFA) between follow-up and baseline in the remote intact upper part and lower part of the CST was calculated. The ROI on the CL CST corresponded to this manually drawn ROI (**Figure 1**). To determine the mean kurtosis (MK) value, we manually drew an ROI on the stroke lesion based on the hyperintensity on DWI. Another ROI was manually drawn on the corresponding CL area. According to the location of the stroke lesion, the precentral gyrus was also divided into an IL and CL part. Six ROIs were manually drawn on the precentral gyrus cortex, and the mean value of these six ROIs was considered to be the MK value of the precentral gyrus (**Figure 2**). The difference value of MK (ΔMK) between follow-up and baseline in the precentral gyrus cortex was also calculated.

Statistical Analysis

SPSS v16.0 (IBM, Armonk, NY, USA) was used for statistical analyses. Differences in clinical outcomes (FM-UE scale, NIHSS, and mRS scores) between the baseline and follow-up were analyzed using the Wilcoxon signed-rank tests. Differences in quantitative MRI measurements (TDI, FA, and MK) between the baseline and follow-up were analyzed using the paired *t*-test. The correlations (r) between ΔTDI and ΔFA in the IL

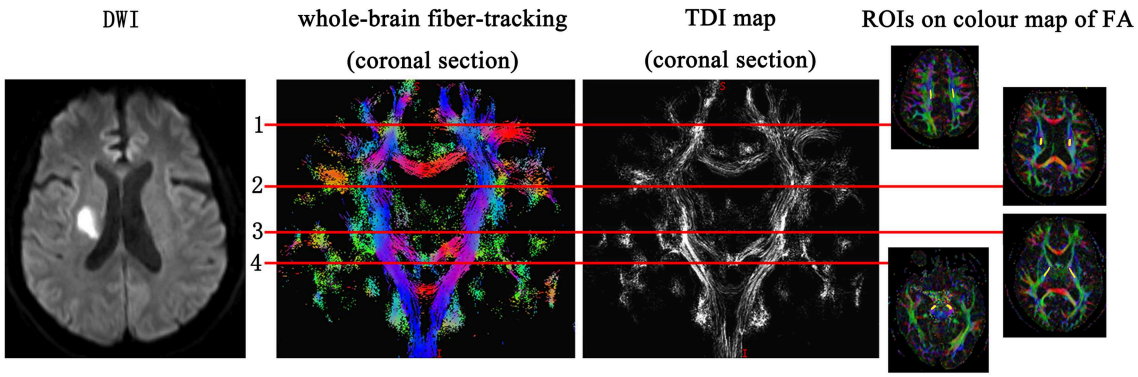

FIGURE 1 | Regions of interest (ROIs) on the corticospinal tract (CST) were manually drawn at the level of the centrum semiovale, corona radiata, posterior limb of the internal capsule, and cerebral peduncle. If any of the above parts of CST were involved by the stroke lesion, the involved part of the CST was also included in the ROI.

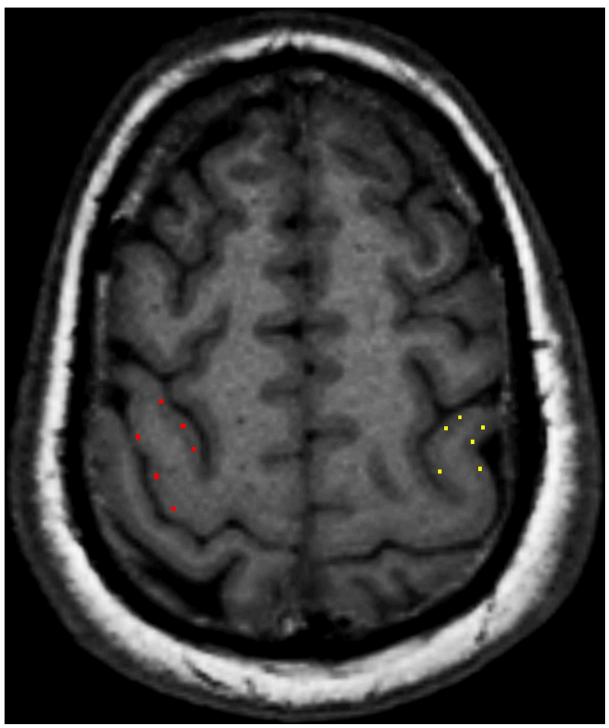

FIGURE 2 | Six regions of interest (ROIs) were manually drawn on the precentral gyrus cortex, and the mean value of these six ROIs was considered to be the mean kurtosis (MK) value of the precentral gyrus cortex.

CST and ΔMK in the IL precentral gyrus cortex were calculated using the Pearson correlation test. $P < 0.05$ was considered statistically significant.

RESULTS

Changes in the TDI and FA Values of the CST

In the case of the IL CST, the TDI and FA values of all levels were lower at the 6-month follow-up than at the baseline (all $P < 0.001$). In the case of the CL CST, however, no differences were found in the TDI and FA values at any level between the baseline and follow-up (**Tables 2**, **3**).

The TDI values of the non-involved upper (ΔTDI, 0.406) and lower parts (ΔTDI, 0.512) of the IL CST were lower at the 6-month follow-up than at the baseline ($P < 0.001$). Similarly, the FA values of the non-involved upper (ΔFA, 0.131) and lower parts (ΔFA, 0.173) of the IL CST were lower at follow-up than at the baseline ($P < 0.001$). In the case of the CL CST, the TDI and FA values of the parts corresponding to the non-involved upper ($P = 0.93$ and $P = 0.935$, respectively) and lower parts ($P = 0.995$ and $P = 0.38$, respectively) of the IL CST showed no significant difference between the follow-up and baseline (**Figures 3**, **4**).

Changes in the MK Values of the Stroke Lesion and Precentral Gyrus Cortex

The MK value of the stroke lesion was significantly lower at follow-up than at the baseline ($P < 0.001$); however, the corresponding CL ROI showed no significant change in MK value ($P = 0.368$). The MK value of the IL precentral gyrus cortex was lower (ΔMK, 0.052) at follow-up than at the baseline ($P = 0.002$), while the value of the CL precentral gyrus cortex showed no significant change ($P = 0.472$; **Table 4**, **Figure 3**).

Relationship Between the ΔTDI and ΔFA Values of the IL CST and the ΔMK Value of the IL Precentral Gyrus

The ΔTDI ($r = 0.689$, $P < 0.001$) and ΔFA values ($r = 0.463$, $P = 0.03$) of the non-involved upper part of the IL CST were positively correlated with the ΔMK value of the IL precentral gyrus (**Figure 5**). In contrast, the ΔTDI ($r = -0.062$, $P = 0.783$) and ΔFA values ($r = 0.31$, $P = 0.16$) of the non-involved lower part of the IL CST did not correlate with the ΔMK value of the IL precentral gyrus cortex.

DISCUSSION

In this study, we used DTI, TDI, and DKI to examine patients with subcortical infarction involving the CST in the acute phase

and 6 months after onset. The results showed that (a) the TDI and FA values were reduced in both the involved part and the remote intact part of the IL CST, (b) the MK value decreased in the infarct lesion as well as in the IL precentral gyrus, and

(c) the ΔTDI and ΔFA values of the non-involved upper part of the IL CST were correlated with the ΔMK value of the IL precentral gyrus.

In this study, the neurological function of ischemic stroke patients recovered to a certain extent during the 6-month follow-up. A previous study has shown that during the post-stroke rehabilitation process, both the white matter and cortex may undergo a certain degree of structural remodeling to compensate for impaired neurological function (18). After ischemic stroke, nerve fibers disintegrate due to ischemia, hypoxia, and necrosis of the local tissue. In addition, axonal injury and demyelination occur in the remote intact tissue due to Wallerian degeneration (19, 20). Therefore, the integrity and number of nerve fibers decrease. We used TDI combined with FA to monitor changes in the CST after subcortical infarction involving the CST. TDI accurately reflects the number of white matter fibers passing through a voxel (14), while FA values reflect the integrity of white-matter fibers (11). Thus, both these parameters could reflect the severity of damage to the local white-matter fibers. Our results showed that during follow-up, the TDI and FA values decreased in the centrum semiovale, corona radiata, posterior limb of the internal capsule, and cerebral peduncle of the IL CST compared to the baseline, indicating that the number and integrity of white-matter fibers in the IL CST reduced during the 6-month follow-up. Among our patients, most ischemic stroke lesions were located in the posterior limb of the internal capsule and corona radiata. Only four stoke lesions were located in the centrum semiovale, while the cerebral peduncle was not involved at all by the stroke. Nevertheless, the TDI and FA values of the cerebral peduncle and the non-involved upper part of the IL CST reduced during the follow-up, confirming that the integrity and number of remote non-involved nerve fibers reduced after stroke.

To understand the changes in the remote non-involved nerve fibers of the IL CST, we divided the CST into a lower and an upper part according to the location of the infarct. Consistent with previous studies (21, 22), our results showed that the TDI and FA values reduced in both the non-involved lower and upper parts of the IL CST during follow-up, indicating that the integrity and number of fibers reduced in both the proximal and distal parts of the remote non-involved IL CST. In addition to the changes in the infarct itself, the infarct lesion will cut off the nutritional supply and synaptic connection between the inferior nerve fibers and the upper cortex, leading to Wallerian degeneration of the inferior nerve fibers, which causes axonal and myelin sheath disintegration and nerve fiber atrophy (19, 20). These changes lead to a reduction in the TDI and FA values. We also found a similar reduction in the non-involved upper part of the IL CST. Although Wallerian degeneration mainly occurred in the descending nerve fibers, one study has shown that Wallerian degeneration can occur in a retrograde fashion and affect the upper nerve fibers (23). However, the mechanism underlying the decrease in the number and integrity of fibers in the non-involved upper part of the IL CST is unknown (24)—some studies have shown that the secondary degeneration of nerve fibers may be bi-directional (25, 26). In addition, the downward transmission of excitatory stimulation of the remote intact cortical neurons may be not smooth due to the involvement of the CST by the infarct, leading to loss of local synaptic inputs and atrophy of the non-involved upper part of the IL CST (6). This may be one of the reasons for the decrease in the TDI and FA values of the non-involved upper part of the IL CST.

Besides the nerve fibers, the cortex also plays an important role in the structural reorganization after cerebral infarction (27). Although the IL cortex was not involved by the subcortical infarction, the activation areas induced by impaired limb movement switched to the corresponding CL motor cortex or other distal cortical areas (3, 5). Other studies have found that the thickness and NAA value of the cortex connected with the nerve fibers involved by the subcortical infarction changed during follow-up (6, 8). In this study, DKI was used to analyze the changes in the infarct lesion and the IL precentral gyrus cortex; the results showed that besides the changes in the infarct, the MK value of the IL precentral gyrus cortex decreased during the follow-up, indicating that the complexity of the internal structure of the precentral gyrus cortex decreased. The connected cortex may be transsynaptic affected by the secondary degeneration of the non-involved upper part of the IL CST. Loss of synaptic input due to the infarct could induce compromised metabolism. The secondary degeneration and compromised metabolism could induce changes such as neuronal apoptosis and atrophy in the cortex connected with the involved nerve fibers after subcortical stroke (28). In addition, loss of synaptic input may lead to the shrinkage of dendrites and cell bodies (6). These pathological changes may reduce the complexity of the focal microenvironment to a certain extent, thereby reducing the MK value.

The above findings raise the question of whether there is any correlation between the structural remodeling in the remote non-involved CST and the connected cortex after subcortical stroke. Our results showed that the ΔTDI and ΔFA values of the non-involved upper part of the IL CST were positively correlated with the ΔMK value of the IL precentral gyrus cortex, while no correlation was found between the ΔTDI and ΔFA values of the lower part of the IL CST and the ΔMK value of the IL precentral gyrus cortex. Both the upper fibers and the remote cortex were located above the level of the infarct and were directly connected. The loss of synaptic input to the cortex could cause degeneration and atrophy of the connected nerve fibers, which in turn may cause atrophy of the neuronal bodies and dendrites (6). Therefore, it is unsurprising that there would be a correlation between the upper fibers and the remote cortex. The connection between the non-involved lower part of the IL CST and the remote IL precentral gyrus cortex was cut off by the infarct lesion, so there was no linear correlation between the ΔTDI and ΔFA values of the non-involved lower part of the IL CST and the ΔMK value of the remote IL precentral gyrus cortex. We also found that the degree of correlation was higher for ΔTDI than for ΔFA. Although DTI can evaluate the integrity of white-matter fibers, it has some limitations in evaluating complex fibers, such as cross fibers (13). TDI, which is an ultra-high resolution technology, may more accurately evaluate changes in cross fibers than FA (14, 15). In this study, lesions were mainly located in the centrum semiovale, corona radiata, and posterior limb of the internal capsule, so the ROIs of the non-involved upper part of the IL CST

were located in the centrum semiovale and corona radiata, which have many bundles of cross fibers. Therefore, TDI might be more sensitive than FA to reflect changes in the CST.

Studies have shown that both the CL CST and cortex may undergo structural remodeling and functional reorganization to a certain extent after cerebral infarction (3, 5). However, the TDI and FA values of the CL CST and the MK values of the CL precentral gyrus cortex did not change during the 6-month follow-up. This may be because the compensatory function switched to the IL hemisphere with the partial recovery of motor function. In addition, differences in infarction site and follow-up duration may be possible reasons.

There are some limitations to this study. First, the small sample size may have introduced some bias. Second, this study focused on the cortex of the IL precentral gyrus connected with the IL CST; other cortical regions were not analyzed. We evaluated the IL precentral gyrus cortex because it is directly connected to the CST, thus it may reflect more intuitively the impact of subcortical stroke involving the CST. Third, only two time points were used in this study, and these could not reflect dynamic changes in the CST and cortex of the precentral gyrus. Finally, we did not analyze the relationship of the changes in the CST and precentral gyrus with neurological function. The main purpose of this study was to determine the microstructural changes in the IL CST and IL precentral gyrus cortex, and other cortical regions were not analyzed. Therefore, simply evaluating the relationship of the changes in the IL CST and IL precentral gyrus cortex with neurological function may have some deficiencies.

In conclusion, our results showed that subcortical infarction involving the CST not only reduced the number and integrity of the remote IL CST but also caused changes in the remote IL precentral gyrus cortex. The changes in the number and integrity of the nerve fibers in the non-involved upper part of the IL CST were correlated with microstructural changes in the IL precentral gyrus cortex. In addition, TDI was more sensitive than FA to detect pathological changes in the CST after subcortical stroke, and may be used as a tool to evaluate pathological changes in white-matter fibers.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript/supplementary files.

AUTHOR CONTRIBUTIONS

X-EW and Y-HL conceived and designed of the study. X-EW and KS organized the database. X-EW, KS, JZ, and Y-JZ performed the follow-up and MRI scan. The processing of MRI was performed by X-EW, KS, and JZ. X-EW wrote the first draft of the manuscript. Y-HL and Y-JZ wrote sections of the manuscript. All authors read and approved the submitted version.
