Front. Neurosci. 13:781. doi: 10.3389/fnins.2019.00781

Background: Tumor necrosis factor, which exists both as a soluble (solTNF) and a transmembrane (tmTNF) protein, plays an important role in post-stroke inflammation. The objective of the present study was to test the effect of topical versus intracerebroventricular administration of XPro1595 (a solTNF inhibitor) and etanercept (a solTNF and tmTNF inhibitor) compared to saline on output measures such as infarct volume and post-stroke inflammation in mice.

Methods: Adult male C57BL/6 mice were treated topically (2.5 mg/ml/1μl/h for 3 consecutive days) or intracerebroventricularly (1.25 mg/kg/0.5 ml, once) with saline, XPro1595, or etanercept immediately after permanent middle cerebral artery occlusion (pMCAO). Mice were allowed to survive 1 or 3 days. Infarct volume, microglial and leukocyte profiles, and inflammatory markers were evaluated.

Results: We found that topical, and not intracerebroventricular, administration of XPro1595 reduced infarct volume at both 1 and 3 days after pMCAO. Etanercept showed no effect. We observed no changes in microglial or leukocyte populations. XPro1595 increased gene expression of *P2ry12* at 1 day and *Trem2* at 1 and 3 days, while decreasing *Cx3cr1* expression at 1 and 3 days after pMCAO, suggesting a change in microglial activation toward a phagocytic phenotype.

Conclusion: Our data demonstrate that topical administration of XPro1595 for 3 consecutive days decreases infarct volumes after ischemic stroke, while modifying microglial activation and the inflammatory response post-stroke. This suggests that inhibitors of solTNF hold great promise for future neuroprotective treatment in ischemic stroke.

Keywords: ischemic stroke, behavior, cytokines, microglial activation, neuroprotection

INTRODUCTION

Inflammatory events after ischemic stroke contribute to secondary injury mechanisms that can expand tissue injury and are thus targets of new treatment options (Lambertsen et al., 2018). Tumor necrosis factor (TNF) is a multifunctional, proinflammatory cytokine that participates in all phases of ischemic stroke, from development to repair and long-term inflammatory effects (reviewed in Hallenbeck, 2002). It exists both as a transmembrane (tmTNF) and a soluble (solTNF) protein, the latter released via proteolytic cleavage by TNFα converting enzyme (TACE, also called ADAM17) (Black et al., 1997). TNF mediates its effects via TNF receptor 1 (TNFR1, p55TNFR) and 2 (TNFR2, p75TNFR); solTNF primarily mediates acute and chronic inflammation, while tmTNF has been shown to support innate immune function and promote neuronal survival and axonal remyelination, synaptic function, and neurotransmission (Ruuls et al., 2001; Alexopoulou et al., 2006; Brambilla et al., 2011; Barnum et al., 2014; Cavanagh et al., 2016). In ischemic stroke, TNF plays an important role in infarct development (Lambertsen et al., 2018). In support of this, conventional (Lambertsen et al., 2009) and conditional myeloid (Clausen et al., 2016a) deletion of TNF resulted in increased infarct volumes in mice subjected to permanent middle cerebral artery occlusion (pMCAO). Interestingly, genetic ablation of solTNF using tmTNF$^{\Delta/\Delta}$ mice resulted in decreased infarct volumes after pMCAO (Madsen et al., 2016), suggesting that inhibition of solTNF, but preservation of tmTNF, is required for neuroprotection in ischemic stroke.

Current FDA- and EMA-approved TNF inhibitors are used for treating chronic autoimmune inflammatory diseases such as rheumatoid arthritis, inflammatory bowel disease, and psoriasis (Lis et al., 2014), where they also relieve potential symptoms of depression (Tyring et al., 2006). The dimeric Fc-fusion protein etanercept targets both tmTNF and solTNF. Being a large (150 kDa) protein, it is not able to cross the blood-brain barrier. When administered perispinally, however, etanercept improved neurological outcome in patients with chronic stroke, traumatic brain injury and Alzheimer's disease (Griffin, 2008; Tobinick, 2011; Tobinick et al., 2012; and reviewed in Lambertsen et al., 2018). The downside of drugs like etanercept is that inhibition of both solTNF and tmTNF can provoke demyelination and induce neuropathies, infections, sepsis, congestive heart failure and lupus, emphasizing the importance of leaving tmTNF available to preserve adequate function of the innate immune system (Scheinfeld, 2004). XPro1595 is a dominant-negative inhibitor of solTNF (Steed et al., 2003). In animal models of multiple sclerosis, XPro1595 promotes axonal preservation and remyelination (Brambilla et al., 2011); in Parkinson's disease XPro1595 reduces neuronal loss (McCoy et al., 2006; Barnum et al., 2014); in Alzheimer's disease it decreases beta-amyloid plaques and promotes synaptic function (Cavanagh et al., 2016; MacPherson et al., 2017); and in spinal cord injury it decreases lesion volume (Novrup et al., 2014). We have previously shown that using etanercept and XPro1595 for systemic inhibition of TNF improved functional outcome and affected the inflammatory response after pMCAO in mice, but with no effect on infarct volume (Clausen et al., 2014). The altered inflammatory response after systemic administration of TNF inhibitors was likely a result of peripheral immunomodulation that decreased the granulocyte infiltration to the ischemic lesion, which was earlier shown to be neuroprotective (Soriano et al., 1999; Clausen et al., 2014). Peripheral treatment likely also changed microglial activation (Clausen et al., 2014). In light of these studies and our earlier studies demonstrating that topical (and not systemic) administration of XPro1595 decreased lesion size following moderate spinal cord injury (Novrup et al., 2014), we hypothesized that topical and/or intracerebroventricular (i.c.v.) delivery of XPro1595 would reduce lesion size, ameliorate brain inflammation, and improve functional outcome after focal cerebral ischemia in mice.

MATERIALS AND METHODS

Animals

Adult male C57BL/6 mice (aged 7–8 weeks) were purchased from Taconic Ltd. (Ry, Denmark) and transferred to the Biomedical Laboratory at the University of Southern Denmark, Odense, Denmark. tmTNF$^{\Delta/\Delta}$ (Ruuls et al., 2001) breeding couples were kindly donated by Dr. Tacchini-Cottier, University of Lausanne, Switzerland and a breeding colony was established at the Biomedical Laboratory at the University of Southern Denmark. Animals were housed under diurnal lighting conditions, and food and water were available *ad libitum*. Mice were allowed to acclimatize for at least 1 week before behavioral testing. All animal experiments were approved by the Danish Animal Inspectorate under the Ministry of Food and Agriculture (J. No. 2013-15-2934-00924).

Permanent Middle Cerebral Artery Occlusion

Permanent occlusion of the distal part of the middle cerebral artery was performed by electrocoagulation under Hypnorm-Dormicum anesthesia (fentanyl citrate (0.315 mg/ml, Jansen-Cilag), fluanisone (10 mg/ml, Jansen-Cilag, Birkerød, Denmark), and midazolam (5 mg/ml, Hoffmann-La Roche, Hvidovre, Denmark) as routinely done in our laboratory (Lambertsen et al.,

2001, 2009; Clausen et al., 2014, 2016b). Post-operatively, mice were injected with 0.9% physiological saline subcutaneously (s.c.) and placed in a 28°C heating cabinet for 24 h. Mice with 3 days survival were returned to the conventional animal facility after 24 h. Buprenorphine hydrochloride (0.001 mg/20 g Temgesic, Schering-Plough, Ballerup, Denmark) was administered three times at 8 h intervals starting immediately prior to surgery. Sham mice were subjected to similar surgery but without electrocoagulation of the middle cerebral artery (MCA).

Pharmacological Treatment

Saline, XPro1595 (Xencor Inc., Monrovia, CA, United States), or etanercept (Enbrel, Amgen-Wyeth, Thousand Oak, CA, United States) was administered topically using mini-osmotic pumps (Alzet, 1003D, Durect Corporation, Cupertino, CA, United States) implanted 30 min after pMCAO. XPro1595 and etanercept were diluted in saline for the final concentration. The pumps were placed in such a way that the delivering end of the catheter was on top of the infarct core. The catheter was sutured to the musculature, and the suture and placement of it were secured using Vetbond (3M Animal Care Products, St. Paul, MN, United States). The pumps were set to deliver either saline (0.9% physiological NaCl) with a flow of 1 μl/h, XPro1595 or etanercept with a flow of 2.5 mg/ml/1μl/h for 3 consecutive days, as previously described (Novrup et al., 2014).

In addition, intracerebroventricular (i.c.v.) injection of saline, XPro1595, or etanercept was performed 30 min after pMCAO. For i.c.v. delivery, animals were fixed in a stereotactic frame (David Kopf Instruments, United States) immediately after pMCAO, and anesthesia was maintained with isoflurane (2% isoflurane in O_2). One single i.c.v. injection (0.5 μl) of either saline, XPro1595 (1.25 mg/kg), or etanercept (1.25 mg/kg) was administered using a 2 μl Hamilton micro-syringe. The injection was made in the left lateral ventricle using the following coordinates with reference to bregma: anterior -0.2 mm; lateral 0.9 mm; ventral 2.5 mm; tooth-bar -1.0 mm. After injection, the syringe was left in place for a further 5 min before being slowly retracted.

Group Size and Study Design

Groups of mice for infarct volumetric, functional, and inflammatory analyses consisted of mice treated topically for 1 day (n = 7–11/group) or for 3 days (n = 20/group) or mice treated i.c.v. for 1 day (n = 6–7/group) or for 3 days (n = 20/group) after pMCAO. Animals were excluded from the study if the infarct volume was less than 3 mm^3 due to lack of successful occlusion of the MCA. Animals with MCA bleedings were excluded due to hematoma formation. A total of 29 mice subjected to pMCAO were excluded due to lack of infarct or bleedings.

To evaluate microglial and leukocyte profiles, a group of sham-treated mice were allowed to survive 3 days (n = 5/group). Mice allowed to survive for 1 day (n = 5–6/group) or 3 days (n = 5/group) after pMCAO were included for flow cytometric studies.

Mortality was 9% and independent of treatment. In total, in the day one groups, 2 mice treated topically with saline, 1 mouse treated topically with XPro1595, 1 mouse treated i.c.v. with XPro1595, and 1 mouse treated i.c.v. with etanercept died. In the day 3 groups, 1 mouse with 3 days survival treated topically with saline, 2 mice treated topically with XPro1595, and 1 mouse treated topically with etanercept, 2 mice treated i.c.v. with saline, 1 mouse treated i.c.v. with XPro1595, and 3 mice treated i.c.v. with etanercept died.

Behavioral Tests

Functional outcome was evaluated using the Hargreaves test (2 days after surgery) and a grip strength test (3 days after surgery). Prior to behavioral testing, mice were allowed to acclimatize in the behavior room. Neuromuscular testing of mice with mini-osmotic pumps was not possible as the pumps were placed in subcutaneous pockets on the lateral back of the mice and affected the animals' balance. Behavioral testing was therefore only performed with i.c.v. treated mice.

Thermal Nociception Assay

Thermal hyperalgesia was evaluated using the Hargreaves nociception assay (Hargreaves et al., 1988). The plantar test (37370, Ugo Basile, Comerio VA, Italy) was used to measure the withdrawal latencies after predisposing the hind paws to heat (Clausen et al., 2016b). Five measurements were registered for each hind paw prior to and 2 days after pMCAO; the lowest and highest values were excluded, and the mean was calculated. Data are presented as symmetry between contra- and ipsilateral hind paws prior to and after surgery. The mice were allowed to recover for 15 min between trials. Mice were excluded if they did not complete all the trials. In total, four animals were excluded.

Grip Strength

Grip strength was measured 1 day prior to and 3 days after surgery using a grip strength meter (BIO-GT-3, BIOSEB, Vitrolles, France). We measured the peak force generated when the mouse loosened its grip when being gently pulled horizontally backwards. We tested both the front right (R) and the front left (L) paw as well as the total grip strength. The peak force (g) of five trials was recorded, and the highest score was registered. Results are presented as delta (Δ) grip strength in grams (g), representing the difference in grip strength prior to and after pMCAO (Lambertsen et al., 2009; Clausen et al., 2014). Mice were excluded if they could not complete the trials with both paws separately and together. A total of four mice were excluded.

Tissue Processing

Fresh Frozen Tissue

Animals were sacrificed by cervical dislocation 1 or 3 days after induction of ischemia. Brains were dissected, frozen in CO_2 snow, and stored at −80°C until further processing. Brains were cut into six parallel series of 30 μm thick sections as previously described (Clausen et al., 2014).

Flow Cytometric Tissue

Mice treated topically with saline, XPro1595, or etanercept were sacrificed 1 or 3 days after pMCAO or 3 days after sham surgery. All mice were given an overdose of pentobarbital

(200 mg/ml) containing lidocaine hydrochloride (20 mg/ml) (Glostrup Apotek, Glostrup, Denmark) and perfused through the left ventricle with phosphate buffered saline (PBS, pH 7.4). Ipsilateral and contralateral cortices were dissected and placed in Hanks' balanced salt solution (HBSS) containing 10% fetal bovine serum (FBS). Lymph nodes were collected for positive detection of T cells. A pool of cells collected from ipsilateral cortices was used for fluorescence minus one (FMO), and isotype controls and a contralateral pool with cells from lymph nodes for compensation. Live/dead cell staining was performed using eBioscience Fixable Viability Dye eFluor 506 (Thermo Fisher Scientific, Roskilde, Denmark).

The tissue was mechanically dissociated using 70 μm cell strainers (BD Biosciences) as previously described (Madsen et al., 2016). Samples were washed with FACS buffer containing HBSS, 2% FBS, and 0.1% sodium azide, fixed with BD Cytofix/Cytoperm (BD Biosciences) and blocked for non-specific binding using 50 μg/ml Syrian Hamster Gamma Globulin (Trichem) and Mouse BD Fc Block (BD Biosciences) diluted in FACS buffer. For detection of microglia and leukocytes, cells were incubated with CD45-PerCP-Cy5.5 (clone 30-F11) and CD11b-PE (clone M7/70).

For separation of macrophages and granulocytes, the following antibodies were used: Ly6C-PE-Cy7 (clone AL21) and Ly6G-BV421 (clone 1A8). T cells were detected with CD3-APC (clone 145-2C11). Respective isotype controls were: IgG2b-PerCP-Cy5.5 (clone A95-1), IgG2b-PE (clone A95-1), IgM-PE-Cy7 (clone R4-22), IgG2a-BV421 (clone R35-95), and IgG1κ-APC (clone A19-3). All antibodies were from BD Biosciences. Flow cytometry was performed as previously described using FACSVerse (BD Biosciences) and analyzed by FACSuite software (Clausen et al., 2014). Positive staining for $CD45^{dim}CD11b^{+}$ microglia, $CD45^{high}CD11b^{+}LY6C^{+}Ly6G^{-}$ macrophages, $CD45^{+}CD3^{+}$ T cells, and $CD45^{high}CD11b^{+}Ly6C^{+}Ly6G^{+}$ granulocytes was determined based on FMO controls and intensity of the respective isotype control as previously described (Clausen et al., 2016a; Madsen et al., 2016). A total of 1,000,000 events were collected using side scatter (SSC). The mean fluorescence intensity (MFI) was calculated as the geometric mean of each population.

Infarct Volumetric and Rostrocaudal Distribution Analysis

Every sixth section was stained with Toluidine blue, and infarct volume was estimated based on Cavalieri's principle for volume estimation as previously described (Gregersen et al., 2000; Lambertsen et al., 2009). The rostrocaudal distribution of the infarct was estimated 3,600 μm anterior of the anterior commissure to 3,600 μm posterior of the anterior commissure as previously described (Clausen et al., 2016a; Madsen et al., 2016).

Real-Time Polymerase Chain Reaction (RT-PCR)

One series of brain tissue was used for RT-PCR. The RNA was extracted using the TRIzol (Invitrogen) method as previously described (Meldgaard et al., 2006). Purity of RNA was controlled spectrophotometrically with 260/280 and 230/260 values using NanoDrop (Thermo Fisher Scientific). Degradation of RNA was measured by RNA integrity factor (RIN) using Agilent 2100 Bioanalyzer (Agilent Genomics). Samples were used for PCR if they had a RIN factor of 7.6 or above. RNA was reverse transcribed into complementary DNA (cDNA) according to the High-Capacity cDNA Reverse Transcription kit protocol (Applied Biosystems). PCR was performed according to the Maxima SYBR Green/ROX qPCR Master Mix (2X) (Thermo Fisher Scientific) protocol. Primer sequences used for RT-PCR (**Table 1**) were designed to target exon-exon junctions whenever possible. Primers were ordered from TAG Copenhagen. Values were normalized to hypoxanthine phosphoribosyltransferase 1 (HPRT1) mRNA, and relative values were calculated relative to a calibrator pool of unmanipulated mice as previously described (Meldgaard et al., 2006).

Cytokine and Receptor Protein Expression and Drug Concentration Analysis

One series of brain tissue was lysed in Complete Mesoscale buffer according to the manufacturer's protocol (Mesoscale Discovery, Rockville, MD, United States). Protein concentrations were determined according to the protocol from Micro BCA protein

assay kit (Thermo Fischer Scientific). Cytokine and chemokine concentrations were estimated using an MSD Mouse Pro-Inflammatory V-Plex Plus Kit (Mesoscale Discovery) and TNF receptor concentrations using the Mouse TNF-RI and TNFR-II Ultra-Sensitive Kits (Mesoscale Discovery). XPro1595 levels were measured in ischemic brain tissue lysates using a human TNF V-Plex immunoassay (Mesoscale Discovery) as previously described (Karamita et al., 2017). The standard in the kit was replaced with XPro1595, which was diluted in the kit diluent number 2. Etanercept levels were measured using a human TNFRII Ultra-Sensitive immunoassay (Mesoscale Discovery) (Karamita et al., 2017). The standard in the kit was replaced with etanercept diluted in the kit diluent number 2. All kits were read on a SECTOR Imager 6000 plate reader (Mesoscale Discovery) according to the manufacturer's instructions. All samples were run in duplex, and coefficient of variation (CV) values below 25% were accepted.

Characterization of Cells From Mice With Genetic Ablation of SolTNF

Cell Purification for Proteomics

Microglia and neurons were purified from cortices from adult (8 weeks) tmTNF$^{\Delta/\Delta}$ and tmTNF$^{wt/wt}$ mice by MACS affinity-based cell sorting (Miltenyi Biotech, Bergisch-Gladbach, Germany) as previously described (Clausen et al., 2016b). Mice were sacrificed by cervical dislocation, cortices dissociated with Neuronal dissociation papain kit (P) (Miltenyi Biotech) and microglia and neurons purified according to the manufacturer's protocol. The cell suspensions were incubated with monoclonal CD11b beads (Miltenyi Biotech) and applied to LS magnetic separation columns (Miltenyi Biotech) attached to a magnetic field for positive selection of microglia. The flow through was further incubated with Neuron Isolation Kit (Miltenyi Biotech) and applied to LD magnetic separation columns (Miltenyi Biotech) for negative selection of neurons. The cell pellets were stored at −80°C until preparation for mass spectrometry.

Sample Preparation/Digestion for Mass Spectrometry

Microglia and neurons were prepared using a filter-aided sample preparation protein digestion protocol essentially according to Kruse Meyer et al. (2015). Briefly, samples were lysed in cold lysis buffer (5% sodium deoxycholate, 50 mM triethylammonium bicarbonate, pH 8.5) and homogenized by bead beating (Bullet Blender Gold (NextAdvance, United States); 0.9–2.0 mm steel bead blend; Setting 10; 2 × 5 min; +4°C) and heat-denaturized at 95°C for 5 min. Protein concentrations were estimated using a NanoDrop 1000 UV-Vis spectrophotometer (Thermo Fisher Scientific) using bovine serum albumin as reference standard. Protein lysate was transferred to a 10 kDa molecular weight cutoff spin-filter (Millipore, Billerica, MA, United States) and protein disulfide bonds were reduced with 10 mM tris(2-carboxyethyl)phosphine (Thermo Fisher Scientific) for 30 min. Afterward, cysteine residues were blocked with 50 mM chloroacetamide (Sigma-Aldrich, St. Louis, MO, United States) for 30 min in the dark. Protein digestion was performed with sequencing grade modified trypsin (Promega, Madison, WI, United States) at an enzyme to substrate ratio of 1:50 (w/w) for 16 h at 37°C. The peptide material was eluted from the spin-filter, acidified with trifluoroacetic acid to a final concentration of 1% and purified by phase inversions with ethyl acetate 1:2 (v/v). The peptide rich aqueous phase was dried down in a vacuum centrifuge.

UPLC-MS/MS Sample Analysis

Ultra-performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS) analysis was performed using an UltiMate 3000 UPLC system (Thermo Fisher Scientific) coupled online to a Q Exactive HF mass spectrometer (Thermo Fisher Scientific). Peptide material was separated on a 75 cm C18 Acclaim PepMap100 analytical column (Thermo Fisher Scientific) with 96% solvent A (0.1% FA) and 4% solvent B (0.1% FA in acetonitrile), which was increased to 30% solvent B on a 60 min ramp gradient at a constant flow rate of 250 nL/min. Eluting peptides were introduced directly into the mass spectrometer by a picotip emitter for electrospray ionization (New Objective, Woburn, MA, United States).

The mass spectrometer was operated in positive mode using a data-dependent TOP12 acquisition method with the following settings: mass range m/z 400–1200; isolation window m/z 1.6; NCE 27; charge state exclusion: unassigned, 1, >6; peptide match preferred; dynamic exclusion 30 s.

Protein Quantification and Filtering

The .RAW files were investigated by Progenesis QI for Proteomics to access the chromatographic quality. The raw data were searched with two complementary label free quantitative approaches: MaxQuant (v1.5.6.0) against the UniProt Mouse reference proteome database with isoforms (UP000000589, November 2016). Standard settings were employed in MaxQuant, including max two tryptic missed cleavages, and a first search with 20 ppm mass tolerance followed by data calibration and a main search with 4.5 ppm mass tolerance. The match between runs feature was enabled to allow the transfer of identified precursors between different runs, based on accurate mass and retention time. The following peptide modifications were found to be abundant with the applied protocol and were included in the search: carbamidomethylated cysteine residues (fixed), acetylation of the N-terminal of proteins (variable), oxidation of methionine (variable). Identified proteins and peptide spectral matches were filtered to <1% false discovery rate (FDR) using a forward/reverse database search strategy in MaxQuant, and proteins tagged as common contaminants were removed. Relative protein quantities were calculated by summing the unique peptide peak areas of each protein in MaxQuant using the LFQ (label-free quantitation) feature. Additional filtering steps were employed in Perseus (v1.5.6.0): (1) The quantitation of any protein was required to be based on at least two unique peptides. (2) Unique peptides were required to be quantifiable in at least three of the tmTNF$^{wt/wt}$ or tmTNF$^{\Delta/\Delta}$ samples. (3) Pearson's correlation coefficients (R) between the technical repeats should be greater than 0.95, based on log2 transformed protein LFQ values.

Data Processing

All abundances were log2-transformed and proteins with less than two unique peptides and (>50% missing values) filtered out. Proteins with a statistically significant mean abundance difference between the $tmTNF^{wt/wt}$ and $tmTNF^{\Delta/\Delta}$ samples were identified by independent two-sample t-tests in Perseus, with permutation-based truncation using standard parameters (s0 = 0.1, 250 randomizations) to correct for multiple hypothesis testing. In this way, the p-value requirement was adjusted to expect <5% false positives among the statistically significant findings.

The MS data has been deposited to the ProteomeXchange Consortium[1] via the PRIDE partner repository with dataset identifiers PXD014440. Protein-protein interaction analysis was performed by STRING[2].

Phagocytosis Assay

In order to test phagocytic activity of primary microglia derived from $tmTNF^{wt/wt}$ and $tmTNF^{\Delta/\Delta}$ mice, the microglia were plated, activated and incubated with fluorescent beads. As a measure of phagocytic activity, the number of engulfed beads was counted and morphological changes estimated as previously described (Al-Ali et al., 2017; Gao et al., 2017). Microglial cultures were prepared using brain tissue from $tmTNF^{\Delta/\Delta}$ (n = 3) and $tmTNF^{wt/wt}$ (n = 6) pups at post-natal age 5–7. The meninges and blood vessels were removed, and brains collected in ice-cold HBSS without Ca^{2+} and Mg^{2+} (Thermo Fisher Scientific) under sterile conditions. Cortices were processed using Neural Tissue Dissociation Kit (P) (Miltenyi Biotech) according to the manufacturer's protocol. Cell suspensions were filtered through 70 μm cell strainers (BD Biosciences, San Jose, CA, United States) and washed with HBSS with Ca^{2+} and Mg^{2+} (Thermo Fisher Scientific). Cell suspensions were centrifuged, and the pellet used for MACS sorting. Microglia were purified by MACS sorting using magnetic $CD11b^{+}$ beads on LS columns (Miltenyi Biotech) and cultured in culture medium A (76 % Dulbecco's modified Eagle's medium (DMEM) (Thermo Fisher Scientific), 20% FBS (Thermo Fisher Scientific), 1% minimum essential media (MEM) (Thermo Fisher Scientific), 1% penicillin streptomycin (Thermo Fisher Scientific), 1% Glutamax™ (Gibco, Thermo Fisher Scientific), 1% pyruvate (Thermo Fisher Scientific)) on poly-L-ornithine-coated plates in a humified CO_2 incubator at 37°C. After 3 days half of the media was changed to culture medium B (86% DMEM, 10% FBS, 1% MEM, 1% penicillin streptomycin, 1% Glutamax™, 1% pyruvate). Four days after the media change microglia were activated by adding 100 ng/mL LPS (Invitrogen, Thermo Fisher Scientific) for 24 h. After activation, FluoSpheres™ Carboxylate-Modified Microspheres (1.0 μm, 505/515, yellow-green fluorescent) (Thermo Fisher Scientific) were added onto the cultured cells. After 2 h phagocytosis was terminated by adding cold culture medium B. Cells were fixed with 4% paraformaldehyde, blocked in 5% normal goat serum in tris-buffered saline and incubated overnight in anti-Iba1 antibody (1:500, Fujifilm Wako Pure Chemical Corporation, Japan). The next day, cells were stained using alexa 594-conjugated anti-rabbit antibody (1:750, Alexa594 Molecular Probes) (Thermo Fisher Scientific) and 4′,6-diamidino-2-phenylindol (DAPI) (Thermo Fisher Scientific). Pictures were taken using a FV1000 (Olympus) confocal microscope from nine randomly chosen positions per coverslip. Analysis of phagocytosis measured as engulfed beads/cell and cell morphology measured as cell area, membrane irregularity and perimeter length was done by automated counting software Puntomorph[3] (Al-Ali et al., 2017).

Statistical Analysis

Data are presented as mean ± SEM. Statistical comparison between the three groups (saline, Xpro1595, and etanercept) was assessed by one-way ANOVA followed by Tukey's *post hoc* test (GraphPad Prism Software Inc., San Diego, CA, United States). Comparison of the rostrocaudal distribution of the infarct and comparison of phagocytosis in $tmTNF^{\Delta/\Delta}$ and $tmTNF^{wt/wt}$ microglia were tested by two-way ANOVA followed by Tukey's *post hoc* test. Statistical significance of the asymmetry of the paws in the grip strength test and the Hargreaves nociception test was tested by Student's paired *t*-test. Normal distribution of variables was tested using both Brown-Forsythe and Bartlett's tests. Significance was set at $p \leq 0.05$.

RESULTS

Topical Delivery of XPro1595 Decreases Infarct Volume 1 and 3 Days After pMCAO

Infarct volumes were estimated in Toluidine blue-stained brain sections from mice treated topically or i.c.v. with saline, XPro1595, or etanercept and allowed to survive 1 or 3 days after pMCAO (**Figure 1** and **Supplementary Figure 1A**). At day 1, infarct volumes were significantly reduced in mice treated topically with XPro1595 compared to mice treated topically with saline (**Figure 1B**). Etanercept treatment showed no effect. The rostrocaudal distribution of the infarcts was comparable between groups (**Figure 1C**). At day 3, infarct volumes were also significantly reduced in mice treated topically with XPro1595 (**Figure 1E**). Again, the rostrocaudal distribution of the infarct was comparable between groups (**Figure 1F**).

Intracerebroventricular administration of XPro1595 or etanercept was not effective in decreasing infarct size (**Supplementary Figure 1A**). In support of this, we observed no difference in functional outcomes as assessed by the Hargreaves thermal hyperalgesia (**Supplementary Figure 1B**) or grip strength tests (**Supplementary Figures 1C,D**), except for a total

weaker grip strength on day 3 compared to baseline in mice treated with etanercept (**Supplementary Figure 1D**).

XPro1595 and Etanercept Can Be Detected in Brain Ischemic Tissue

To validate the presence of XPro1595 and etanercept and estimate their concentrations in the ischemic brain following topical and i.c.v. delivery, we measured the concentration of XPro1595 and etanercept 1 day after pMCAO (**Figures 2A,B**). We found topical administration to be an efficient method to deliver a high concentration of XPro1595 to neural tissue (**Figure 2A**). After topical administration, the concentration of XPro1595 in brain tissue 1 day after pMCAO was 630,300 ± 160,000 pg/mg. The concentration of XPro1595 was lower after i.c.v. administration, with a mean of 69,400 ± 51,300 pg/mg (**Figure 2A**). This concentration in the neural tissue is, however, sufficient to neutralize solTNF and to promote neuroprotection, based on previous publications in an animal model of Alzheimer's disease (MacPherson et al., 2017).

Etanercept was detected in the brain tissue after both delivery routes (**Figure 2B**). The concentration of etanercept in brain tissue 1 day after pMCAO was 1,600 pg/mg after topical administration and 1,500 ± 200 pg/mg after i.c.v.

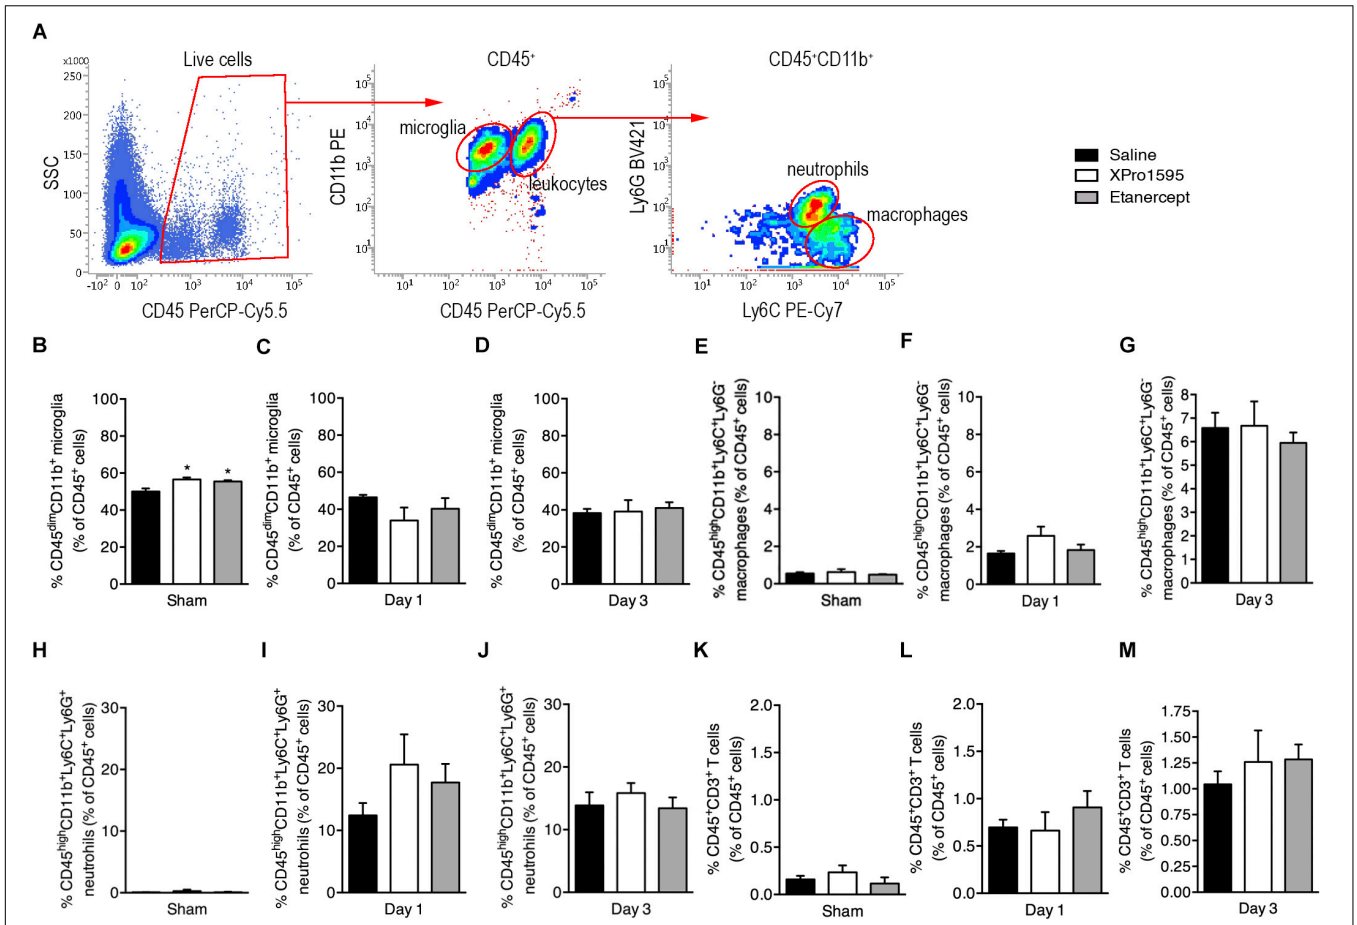

FIGURE 3 | Flow cytometric analysis of ipsilateral hemispheres in sham and pMCAO mice after topical saline, XPro1595, or etanercept treatment**. (A)** Gating strategy for CD45$^+$ cells, CD45^{dim}CD11b$^+$ microglia, CD45^{high}CD11b$^+$ leukocytes, CD45^{high}CD11b$^+$Ly6C$^+$Ly6G$^-$ macrophages, and CD45^{high}CD11b$^+$Ly6C$^+$Ly6G$^+$ granulocytes. **(B–D)** Changes in CD45^{dim}CD11b$^+$ microglia presented as % of CD45$^+$ cells 3 days after sham surgery or 1 or 3 days after pMCAO. **(E–G)** Changes in CD45^{high}CD11b$^+$Ly6C$^+$Ly6G$^-$ macrophages presented as % of CD45$^+$ cells after sham surgery or 1 or 3 days after pMCAO. **(H–J)** Changes in CD45^{high}CD11b$^+$Ly6C$^+$Ly6G$^+$ granulocytes presented as % of CD45$^+$ cells after sham surgery or 1 or 3 days after pMCAO. **(K–M)** Changes in CD3$^+$ T cells presented as % of CD45$^+$ cells after sham surgery or 1 or 3 days after pMCAO. N(sham) = 3–5/group; n(day 1) = 4–5/group; n(day 3) = 5/group; *$p \leq 0.05$; one-way ANOVA followed by Tukey's *post hoc* test.

administration. This demonstrated that both XPro1595 and etanercept successfully accessed the ischemic brain tissue.

Topical Treatment With XPro1595 Does Not Affect Microglial and Leukocyte Cell Populations After pMCAO

To investigate potential changes in microglial and leukocyte populations in mice subjected to pMCAO and treated topically with saline, XPro1595 or etanercept, we performed flow cytometry and gated for CD45^{dim}CD11b$^+$ microglia, CD45^{dim}CD11b$^+$Ly6C$^+$Ly6G$^-$ macrophages, CD45^{dim}CD11b$^+$Ly6C$^+$Ly6G$^+$ granulocytes (**Figure 3A**), and CD45$^+$CD3$^+$ T cells.

We found that compared to saline, both Xpro1595 and etanercept treatment increased the percentage of microglia in the ipsilateral cortex 3 days after sham surgery (**Figure 3B**), whereas no difference was observed between groups at day 1 (**Figure 3C**) or day 3 (**Figure 3D**) after pMCAO. In all groups of mice 3 days after pMCAO, the microglial population constituted ∼80% of all live CD45$^+$ cells in the contralateral cortex, with only ∼60% in sham. By 1 day after pMCAO the microglial population constituted ∼60% of all live CD45$^+$ cells (**Supplementary Figures 2A–C**). The percentage of infiltrating macrophages (**Figures 3E–G**), granulocytes (**Figures 3H–J**), and T cells (**Figures 3K–M**) did not differ between groups at any time point investigated, although the percentages of cells increased over time in the ipsilateral cortex (**Figures 3E–M**) and remained relatively constant in the contralateral cortex (**Supplementary Figures 2D–L**).

Since microglia and macrophages upregulate their expression of CD11b and CD45 after ischemia (Ito et al., 2001; Ponomarev et al., 2005; Clausen et al., 2008; Morrison and Filosa, 2013), their activation status was evaluated based on the MFI of these cell surface markers. MFIs of CD11b and CD45 were comparable between treatment groups 3 days after sham surgery

and 1 and 3 days after pMCAO (**Supplementary Figures 3A–L**). However, both microglia and leukocytes seemed to downregulate their expression of CD11b and upregulate their expression of CD45 3 days after pMCAO, which was not the case in sham mice and 1 day after pMCAO (**Supplementary Figures 3A–L**, please compare C to A and B; I to G and H; F to D and E; and L to J and K).

XPro1595 Affects Microglial Activation

We next investigated changes in mRNA expression of selected microglial/macrophage and inflammatory markers in brain tissue derived from mice subjected to pMCAO and treated topically (**Figure 4**) or i.c.v. (**Supplementary Figure 4**) with saline, XPro1595, or etanercept and allowed to survive 1 or 3 days after pMCAO.

We found *Tnf* mRNA expression to be significantly upregulated 1 and 3 days after pMCAO in mice treated topically with XPro1595 when compared to saline- and etanercept-treated mice (**Figure 4A**). *Tnfrsf1a* (TNFR1, **Figure 4B**) and *Tnfrsf1b* (TNFR2, **Figure 4C**) mRNA expression was comparable between treatment groups at both days 1 and 3 after pMCAO. At 3 days, *Il-1beta* mRNA levels were significantly upregulated in mice treated topically with XPro1595 compared to saline- and etanercept-treated mice (**Figure 4D**), whereas no significant changes in *Nos2* (iNOS) mRNA expression was observed between groups, although XPro1595 tended to downregulate the expression at 3 days ($p = 0.08$; **Figure 4E**).

To study whether TNF inhibition using XPro1595 or etanercept affects chemokine gene expression, we measured the mRNA levels of *Cxcl1*, *Cxcl10,* and *Ccl2* at 1 and 3 days after pMCAO. Topical etanercept treatment significantly increased *Cxcl1* mRNA compared to saline and XPro1595 at day 1 and compared to XPro1595 at day 3 after pMCAO (**Figure 4F**). In contrast, *Cxcl10* mRNA levels decreased at day 3 in mice treated topically with etanercept compared to saline (**Figure 4G**), and *Ccl2* mRNA levels significantly increased at day 3 in XPro1595-treated mice compared to both saline- and etanercept-treated mice (**Figure 4H**).

We further measured mRNA expression levels of microglial/macrophage markers *Cx3cr1*, *P2ry12*, *Trem2*, *Cd11b,* and *Arg1*. We found that at days 1 and 3 after pMCAO, topical XPro1595 treatment decreased *Cx3cr1* mRNA expression compared to saline-treated mice (**Figure 4I**). In contrast, *P2ry12* mRNA expression was significantly increased at 1 day after pMCAO in topically XPro1595-treated mice compared to saline-treated mice (**Figure 4J**), as well as *Trem2* mRNA expression at 1 and 3 days after pMCAO (**Figure 4K**). *Cd11b* and *Arg1* mRNA levels were comparable between groups except for a significant decrease in *Arg1* mRNA levels in XPro1595-treated mice at day 3 (**Figures 4L,M**).

Even though i.c.v. administration of TNF inhibitors had no effect on infarct volume or functional outcome, we also investigated potential changes in mRNA expression after i.c.v. injection of XPro1595 or etanercept (**Supplementary Figure 4**). We observed no change in *Tnf*, *Tnfrsf1a*, *Tnfrsf1b*, *Il-1beta*, *Nos2*, *Cxcl1*, *Cx3cr1*, or *CD11b* mRNA expression between groups. Etanercept significantly increased *Cxcl10* mRNA levels compared to saline at day 1 and compared to both XPro1595 and saline 3 days after pMCAO (**Supplementary Figure 4**). Also, *P2ry12* mRNA levels increased significantly at day 1 in etanercept-treated mice compared to saline- and Xpro1595-treated mice, and *Ccl2* and *Trem2* mRNA levels increased significantly at day 3, while *Arg1* decreased significantly.

Cytokine, Chemokine, and TNF Receptor Expression in Brain Tissue 1 and 3 Days After TNF Inhibitor Treatment

To study whether topical (**Figure 5**) or i.c.v. (**Supplementary Figure 5**) XPro1595 and etanercept treatment after pMCAO affected cytokines, TNF receptor and/or chemokine protein levels, we measured TNF, TNFR1, TNFR2, IL-1β, CXCL1, IL-6, IL-10, IL-4, IL-5, and IL-12p70 levels in brain tissue 1 day after pMCAO, when neuroinflammation is maximal (Lambertsen et al., 2012), in addition to 3 days after pMCAO using multiplex ELISA.

We found that despite increased *Tnf* mRNA expression after topical XPro1595 treatment, the protein expression tended to be downregulated in XPro1595-treated mice ($p = 0.06$, **Figure 5A**), whereas TNF levels in etanercept-treated mice were comparable to saline-treated mice 1 day after pMCAO. At 3 days, TNF levels had increased significantly in etanercept-treated mice compared to saline-treated mice. Compared to topical saline treatment, etanercept treatment downregulated TNFR1 levels at day 1, which also showed tendency to be downregulated after XPro1595 treatment ($p = 0.08$), whereas TNFR1 levels were comparable at 3 days (**Figure 5B**). Topical treatment had no effect on expression of TNFR2, IL-1β, Cxcl1, IL-6, IL-10, IL-4, IL-5, or IL-12p70 (**Figures 5C–J**).

Intracerebroventricular administration of TNF inhibitors showed no effect on the TNF or TNFR1 protein expression (**Supplementary Figures 5A,B**) although TNFR2 was downregulated after etanercept-treatment compared to saline treatment 1 day after pMCAO (**Supplementary Figure 5C**). Treatment with XPro1595 showed a tendency toward reducing TNFR2 levels at day 1 after pMCAO ($p = 0.07$) (**Supplementary Figure 5C**). At 1 day after pMCAO, etanercept treatment significantly increased IL-1β levels compared to saline (**Supplementary Figure 5D**), but no effect was observed on CXCL1, IL-6, IL-10, IL-4, IL-5, or IL-12p70 levels (**Supplementary Figures 5E–J**).

tmTNF Microglia Have an Upregulated Expression of Phagocytosis-Related Proteins

In order to investigate the hypothesis that ablation of solTNF improves microglial phagocytosis, we investigated differentially expressed proteins in microglia derived from $tmTNF^{\Delta/\Delta}$ and $tmTNF^{wt/wt}$ mice using mass spectrometry. In total, 1,564 proteins with two or more unique peptides were quantified by label free quantification in microglia cells (**Supplementary Table 1**). Of these, 87 proteins were differentially regulated between $tmTNF^{wt/wt}$ and $tmTNF^{\Delta/\Delta}$ mice (**Figure 6A**). Several of the upregulated proteins, 3-mercaptopyruvate

sulfurtransferase (3-MPST), hematopoietic prostaglandin D synthase (HPGDS) and apoptosis-associated speck-like protein containing a CARD (PYCARD/ASC) are neuroprotective (Liu et al., 2009; Chen et al., 2015; Kimura et al., 2017; Shan et al., 2017) or related to regulation of phagocytosis (Rajakariar et al., 2007; Ippagunta et al., 2011). 3-MPST has previously been shown to be upregulated in activated microglia treated with a neuroprotective compound (Cobourne-Duval et al., 2018). tmTNF expressing microglia had an increased expression of HPGDS, which is known to be expressed in

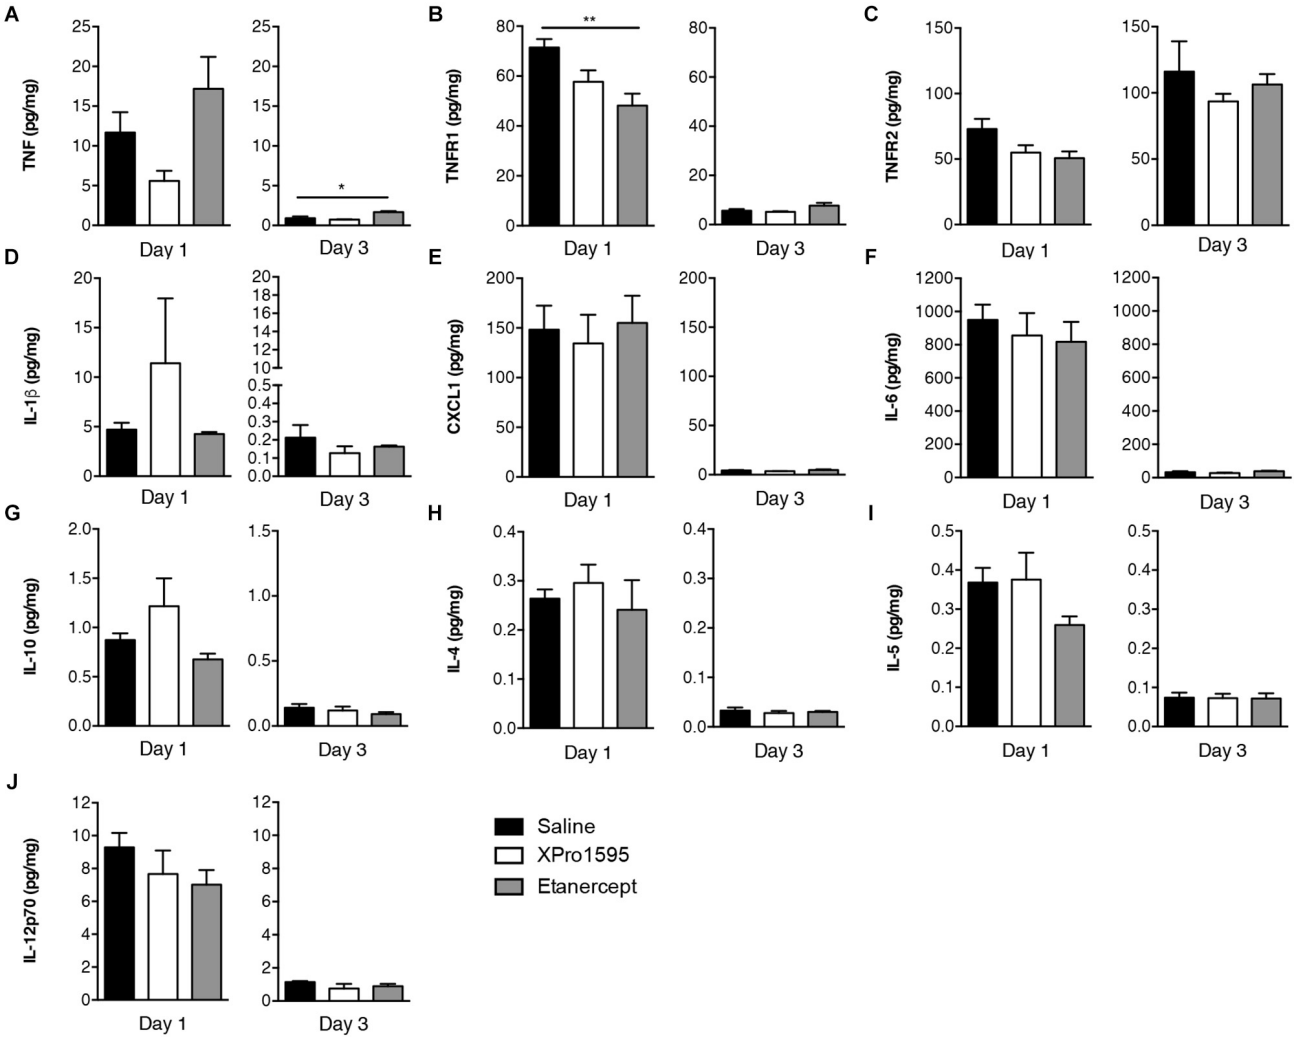

FIGURE 5 | Cytokine and TNF receptor protein expression in brain tissue 1 and 3 days after pMCAO in mice treated topically with saline, XPro1595, or etanercept. **(A)** Expression of TNF (n = 4–11/group). **(B)** Expression of TNFR1 (n = 4–11/group). **(C)** Expression of TNFR2 (n = 4–10/group). **(D)** Expression of IL-1β (n = 3–11/group). **(E)** Expression of CXCL1 (n = 3–11/group). **(F)** Expression of IL-6 (n = 3–9/group). **(G)** Expression of IL-10 (n = 3–10/group). **(H)** Expression of IL-4 (n = 2–11/group). **(I)** Expression of IL-5 (n = 4–10/group). **(J)** Expression of IL-12p70 (n = 4–11/group). $^{**}p \leq 0.01$; one-way ANOVA with Tukey's *post hoc* test.

activated microglia in the core of the infarct after ischemic stroke and to enhance their differentiation into a phagocytic phenotype (Mohri et al., 2003; Liu et al., 2007). PYCARD/ASC supports the function of a normal immune system (Ippagunta et al., 2011). Among the downregulated proteins was MPO. Interestingly, upregulation of myeloperoxidase (MPO) expression is linked to pathological phagocytosis of myelin leading to demyelination in patients with multiple sclerosis (Minohara et al., 2006; Gray et al., 2008). Moreover, the expression of Methyl-CpG-binding protein 2 (MECP2) (Cronk et al., 2015) was downregulated in tmTNF expressing microglia. The absence of microglial MECP2 has shown to increase *Tnf* mRNA expression (Cronk et al., 2015). Interestingly, tmTNF expressing microglia had downregulated expression of Histone H1.5, which promotes microglial proinflammatory functions (Gilthorpe et al., 2013), Heat shock protein 27, which is neuroprotective in ischemic brain (Stetler et al., 2012) and Heat shock 70 kDa protein 1, which functions as a chaperone (Stetler et al., 2010) supporting earlier studies showing solTNF to be needed for optimal control of inflammatory response (Ruuls et al., 2001; Musicki et al., 2006; Dambuza et al., 2011; DeBerge et al., 2014). Downregulation of Human growth and transformation-dependent protein (HGTD-P), a protein which is proapoptotic in ischemia (Qu et al., 2009), and downregulation of Vimentin, which has been shown to mediate microglial activation (Jiang et al., 2012), supports the beneficial function of tmTNF. Two other histones, Histone H4 and Core histone macro-H2A.1 were downregulated in tmTNF expressing microglia. String analysis of the differentially regulated proteins in microglia showed clustering of the aforementioned immune system-related proteins Histone H1.5, Heat shock protein 27,

Microglia Expressing Only tmTNF Display Improved Phagocytic Properties

Due to the upregulated expression of phagocytosis-related proteins in microglia expressing only tmTNF, we next investigated the phagocytic properties and morphological changes 1 day after LPS stimulation in primary microglia derived from 5 to 7 days old tmTNF$^{\Delta/\Delta}$ and tmTNF$^{wt/wt}$ pups (**Figure 7A**). Phagocytosing microglia have a neuroprotective role in clearing apoptotic cells and debris after stroke (Neumann et al., 2009; Sierra et al., 2013). At 1 day after LPS stimulation, the phagocytic activity of microglia derived from tmTNF$^{\Delta/\Delta}$ pups was significantly increased compared to microglia derived from tmTNF$^{wt/wt}$ pups, measured as engulfed beads per cell (**Figure 7B**). Cell area (**Figure 7C**), perimeter length (**Figure 7D**), and membrane irregularity (**Figure 7E**) increased significantly after LPS activation in both tmTNF$^{wt/wt}$ and tmTNF$^{\Delta/\Delta}$ microglia indicating both tmTNF$^{wt/wt}$ and tmTNF$^{\Delta/\Delta}$ microglia to take an amoeboid form after LPS activation. Cell morphology was, however, comparable between tmTNF$^{wt/wt}$ and tmTNF$^{\Delta/\Delta}$ microglia after LPS activation (**Figures 7A,C–E**).

Proteomic Characterization of Neurons Derived From tmTNF$^{\Delta/\Delta}$ and tmTNF$^{wt/wt}$ Mice

In total, 763 proteins with two or more unique peptides were quantified by label free quantification in neurons. Of them, 11 proteins were differentially expressed between tmTNF$^{\Delta/\Delta}$ and tmTNF$^{wt/wt}$ mice (**Supplementary Figure 6**). Calcium-activated potassium channel subunit alpha-1 ($K_{Ca}1.1$) was upregulated in tmTNF$^{\Delta/\Delta}$ mice. HGTD-P that promotes apoptosis in ischemia (Qu et al., 2009) was downregulated in neurons derived from tmTNF$^{\Delta/\Delta}$ mice suggesting improved neuroprotection.

DISCUSSION

In the present study, we found that topical administration of the selective solTNF inhibitor XPro1595 decreased infarct volumes 1 and 3 days after pMCAO. Inhibition of TNF by the non-selective solTNF and tmTNF inhibitor etanercept showed no effect. Furthermore, there was no reduction in infarct volume or improvement in functional outcome when TNF inhibitors were delivered by i.c.v. administration, even though the concentrations of the inhibitors in brain tissue were sufficient to neutralize TNF and potentially promote neuroprotection as demonstrated in previous studies using animal models of Alzheimer's disease (MacPherson et al., 2017).

We have previously shown that topical, but not systemic, administration of XPro1595 decreased lesion volume and improved functional outcome after moderate spinal cord injury (Novrup et al., 2014). Systemic administration of XPro1595 and etanercept had no effect on the infarct volume after pMCAO (Clausen et al., 2014), and systemic etanercept administration had no effect after transient focal cerebral ischemia (Sumbria et al., 2012), indicating that TNF inhibitors have to be administered directly to infarcted brain tissue and not by

intracerebroventricular or peripheral routes. The length of treatment may also play a role in suppressing the infarct formation in the acute phase of ischemic stroke. It is known that the infarct volume correlates with functional outcome (Saver et al., 1999; Yoo et al., 2012), and since TNF inhibitors are known to improve functional outcome even without reduction in infarct volume when administered systemically (Clausen et al., 2014), assessment of the functional outcome would have been ideal to evaluate the neuroprotective effects of topical XPro1595 administration. Evaluation of the functional outcome was impossible, however, due to the placement of the mini-osmotic pumps in topically treated animals.

The expression of *Tnf* mRNA in central nervous system has been shown to peak 12 h after pMCAO in mice (Lambertsen et al., 2005, 2009), and TNF protein expression 24 h after pMCAO (Lambertsen et al., 2005, 2009; Clausen et al., 2008). Expression of *Tnf* mRNA in the contralateral hemisphere has been shown to remain at baseline levels after pMCAO (Lambertsen et al., 2009). In permanent focal cerebral ischemia, TNF is believed to exert its neuroprotective effects through TNFR1 (Taoufik et al., 2007; Lambertsen et al., 2009). *Tnfr1* mRNA expression peaks 1–2 days after pMCAO (Lambertsen et al., 2007, 2009), while the protein expression can be detected from 4 to 6 h until 5 days (Botchkina et al., 1997; Lambertsen et al., 2007). The expression of *Tnfr2* increases 1–10 days after pMCAO and reaches its peak 5 days after occlusion (Lambertsen et al., 2007). The protein expression of TNFR2 can be detected 24 h after pMCAO (Botchkina et al., 1997). In our study, topical administration of XPro1595 tended to suppress the expression of TNF protein 1 day after pMCAO, while gene expression was significantly upregulated due to the feedback mechanism by which TNF induces its own gene expression when the amount of available protein is repressed. In addition, inhibition of both solTNF and tmTNF with etanercept downregulated TNFR1 protein levels at day 1. Together with earlier findings that TNFR1 knock-out mice develop larger infarct volumes (Bruce et al., 1996; Gary et al., 1998) and neuroprotection in ischemic stroke is mediated through the TNFR1-NFκB-FLIP(L)-ERK1/2 pathway (Taoufik et al., 2007; Lambertsen et al., 2009; Marques-Fernandez et al., 2013), downregulation of TNFR1 is likely to contribute to the lack of neuroprotection after TNF inhibition with etanercept (Gary et al., 1998; Lambertsen et al., 2009). Given the neuroprotective effect of TNFR2 signaling in our spinal cord injury model (Novrup et al., 2014) and the protective effect of this receptor in chronic, inflammatory conditions such as multiple sclerosis (Brambilla et al., 2011; Gao et al., 2017), we cannot exclude that TNFR2 signaling on microglia may have contributed to the protective effects observed after topical XPro1595 treatment.

TNF is primarily secreted by activated resident microglia and at later time points by infiltrating macrophages after pMCAO (Clausen et al., 2008; Lambertsen et al., 2009). In contrast to earlier studies showing that systemic inhibition of solTNF increased the number of microglia 6 and 24 h after pMCAO (Clausen et al., 2014), flow cytometric analysis of the percentage of microglia and infiltrating macrophages or their CD11b and CD45 MFI values showed no difference between treatment groups. Interestingly, the number of $CD45^{dim}CD11b^{+}$ microglia was higher in sham mice treated with either TNF inhibitor when compared to saline-treated mice. In contrast to earlier studies where XPro1595 decreased glial activation in an animal model of Parkinson's disease (Barnum et al., 2014), it is possible that topical administration of XPro1595 shifted the microglial phenotype without influencing the activation status of the cells. In support of this, *Cx3cr1* mRNA levels were significantly downregulated after 1 and 3 days of topical administration of XPro1595. Also, CX3CR1 deficiency has been shown to be neuroprotective in the early phase after ischemia by promoting microglial polarization to an M2-like phenotype and to decrease microglial activation and neurotoxicity by decreasing the expression of M1-like microglial phenotype that is associated with proinflammatory molecules; all of which lead to smaller infarct volumes (Fumagalli et al., 2013; Tang et al., 2014). XPro1595 also increased the expression of *P2ry12*, a protein related to resting state microglia (Haynes et al., 2006), 1 day after pMCAO when administered topically, suggesting that XPro1595 decreases microglial activation as earlier reported (Barnum et al., 2014; Hsiao et al., 2014; Novrup et al., 2014; MacPherson et al., 2017). Furthermore, the expression of *Trem2* was upregulated 1 and 3 days after pMCAO in mice treated topically with XPro1595. Trem2-knock out mice have altered microglial phagocytosis and larger infarct volumes after cerebral ischemia (Takahashi et al., 2005; Kawabori et al., 2015), supporting earlier studies where XPro1595 was found to promote neuroprotection by improving phagocytosis of dying neurons and cell debris in demyelinated lesions in an animal model of multiple sclerosis (Karamita et al., 2017). Chemokine expression was also altered after treatment with TNF inhibitors.

In the present study, topical administration of XPro1595 increased the relative expression of *Ccl2* mRNA 3 days after pMCAO. CCL2 is necessary for hypoxia-required ischemic tolerance, and upregulation after XPro1595 treatment supports the neuroprotective properties of the selective solTNF inhibitor (Stowe et al., 2012; Wacker et al., 2012). *Cxcl1* mRNA, a proinflammatory granulocyte attracting chemokine expressed by monocytes and granulocytes, was upregulated in etanercept-treated but not XPro1595-treated mice 1 and 3 days after pMCAO. However, there was no difference in the CXCL1 protein levels or in granulocyte infiltration between the treatment groups, contradicting earlier findings where systemic treatment with TNF inhibitors decreased the number of infiltrating granulocytes (Clausen et al., 2014) and TNF deficiency increased the number of infiltrating leukocytes 24 h after pMCAO (Lambertsen et al., 2009).

Intracerebroventricular administration of XPro1595 or etanercept had no effect on the infarct volume nor any beneficial effect on functional outcome despite both drugs being shown to access neural tissue in therapeutically relevant concentrations. In both experimental conditions (i.c.v. versus topical administration), XPro1595 and etanercept were present in more than 1000-fold excess of TNF in the ischemic brain tissue. However, it is possible that despite the penetration of XPro1595 and etanercept, the drugs did not reach their site of action, the penumbra, within the therapeutic window, which in our pMCAO model has been shown to be 6 h (Clausen et al., 2006).

Proteomic characterization of microglia derived from tmTNF$^{\Delta/\Delta}$ mice revealed that several phagocytosis-related proteins were significantly upregulated compared to proteins from microglia derived from tmTNF$^{wt/wt}$ mice. Microglia derived from tmTNF$^{\Delta/\Delta}$ mice showed an upregulated expression of 3-MPST, an enzyme protecting cells from oxidative stress by producing redox regulators (Kimura et al., 2017). In addition, 3-MPST regulates hydrogen sulfide production, which has been shown to promote phagocytosis (Dufton et al., 2012), functions as a vasodilator supporting blood flow (Zhao et al., 2001), and promotes angiogenesis (Papapetropoulos et al., 2009). Among the upregulated proteins was HPGDS, which is upregulated in microglia and macrophages after ischemic stroke and is likely to promote microglia/macrophage differentiation to the phagocytic phenotype (Mohri et al., 2003, 2006; Liu et al., 2007). In addition, HPGDS inhibits production of reactive oxygen species and downregulates the expression of the pro-inflammatory cytokine IL-1β through the formation of prostaglandins (Gomez-Abellan et al., 2015). Microglia derived from tmTNF$^{\Delta/\Delta}$ mice also had an upregulated expression of PYCARD/ASC. PYCARD/ASC deficient mice have impaired lymphocyte migration and are deficient in the number of lymphocytes and dendritic cells in secondary lymphoid organs compromising the normal immune system function (Ippagunta et al., 2011). Upregulation of the microglial PYCARD/ASC could contribute to the maintenance of the innate immune system and the secondary lymphoid organs where tmTNF has shown to be crucial (Ruuls et al., 2001; Alexopoulou et al., 2006). Among the downregulated proteins in tmTNF expressing microglia was MPO, a reactive oxygen species generating enzyme known to be expressed by leukocytes and to increase in cerebral ischemia (Lau and Baldus, 2006; Breckwoldt et al., 2008). Inhibition of MPO increases the proliferation and survival of neurons in animal models of ischemic stroke (Kim et al., 2016). In addition, HGTD-P, that mediates apoptosis in the ischemic brain when activated by hypoxia-inducible factor-1 (Qu et al., 2009), was downregulated in tmTNF expressing microglia.

In order to study whether the up- and downregulation of the phagocytosis-related proteins would affect microglial phagocytosis *in vitro*, we tested phagocytic capacity after 1 day of LPS stimulation. Primary microglia derived from tmTNF$^{\Delta/\Delta}$ mice showed increased phagocytic activity that most likely can lead to increased clearing of debris thereby promoting neuronal survival in the ischemic area when solTNF is ablated. Earlier studies have demonstrated increased phagocytosis after inhibition of solTNF (Karakantza et al., 2003) and impaired phagocytic ability of TNFR2 deficient microglia (Gao et al., 2017). Since tmTNF preferentially binds to TNFR2, it is likely that phagocytosis is regulated through the tmTNF-TNFR2 pathway. In the present study, we also show that inhibition of solTNF by XPro1595 increased the gene expression of *Trem2*, a receptor that is known to be involved in promoting microglial phagocytosis (Takahashi et al., 2005), an upregulation that was likely to increase microglial phagocytosis in mice treated topically with XPro1595.

This study demonstrates that selective inhibition of solTNF is neuroprotective after pMCAO when administered topically for 1 and 3 consecutive days. Furthermore, topical administration of XPro1595 promotes a phagocytic, microglial phenotype possibly supporting a neurotrophic environment in the ischemic lesion. We suggest that topical administration of XPro1595 has potential to be clinically beneficial in treating patients with ischemic stroke.

Progressive neurological deterioration poses enormous burden on the aging population with ischemic stroke and neurodegenerative disease patients, such as Alzheimers' disease and Parkinson's disease. The past two decades have witnessed remarkable advances in the research of neurovascular unit dysfunction, which is emerging as an important pathological feature that underlies these neurological disorders. Dysfunction of the unit allows penetration of blood-derived toxic proteins or leukocytes into the brain and contributes to white matter injury, disturbed neurovascular coupling and neuroinflammation, which all eventually lead to cognitive dysfunction. Recent evidences suggest that aging-related oxidative stress, accumulated DNA damage and impaired DNA repair capacities compromises the genome integrity not only in neurons, but also in other cell types of the neurovascular unit, such as endothelial cells, astrocytes and pericytes. Combating DNA damage or enhancing DNA repair capacities in the neurovascular unit represents a promising therapeutic strategy for vascular and neurodegenerative disorders. In this review, we focus on aging related mechanisms that underlie DNA damage and repair in the neurovascular unit and introduce several novel strategies that target the genome integrity in the neurovascular unit to combat the vascular and neurodegenerative disorders in the aging brain.

Keywords: aging, neurovascular unit, cerebral ischemia, DNA damage, DNA repair, blood brain barrier

INTRODUCTION

Aging populations are forcing nations and societies to confront the problem of an increasing prevalence of ischemic stroke and neurodegenerative diseases, including Parkinson's disease (PD) and Alzheimer's disease (AD). Specifically, approximately 4.7 million Americans were living with the most common neurodegenerative disease AD in 2010; by 2050 this number reaches 16 million (Hebert et al., 2013). Of note, the epidemiological trends of dementia are expected to cause an immense burden on health-care expenditure (Yang et al., 2013). Meanwhile, our understanding of these neurological disorders is still rudimentary, effective disease-modifying drugs are warranted to treat these disorders.

The neurovascular unit (NVU) is a functional unit with multiple components in the central nervous system (CNS), including vascular cells [pericytes, vascular smooth muscle cells (VSMCs), endothelial cells], glial cells (astrocytes, microglia, oligodendrocytes) and neurons (Banks et al., 2018). These cells together, ultimately determine the function of NVU and their responses in health and disease (Mazeika and Doraiswamy, 2002; Lo and Rosenberg, 2009; Cai et al., 2017). Aging related NVU dysfunction falls into two categories, NVU dysfunction resulting from normal aging or cell senescence and pathological NVU dysfunction under aging-related diseases, such as cerebral ischemic stroke, PD and AD (Cai et al., 2017). The pathological NVU dysfunction has emerged as an important element in the neuronal injury of ischemic stroke and neurodegenerative diseases, in which neuronal cell death, glial cell activation, blood-brain barrier (BBB) disruption, and penetration of peripheral immune cells may ensue with the diseases progress (Mazeika and Doraiswamy, 2002; Lo and Rosenberg, 2009; Cai et al., 2017; Baker and Petersen, 2018). Maintenance of genome integrity is a prerequisite for the maintenance of the normal function of the brain. However, aging not only results in accumulated DNA damages in neurons, the center of the NVU, including DNA breaks, cross-links, and bases mismatch (McKinnon, 2013; Lodato et al., 2018), but also impairs multiple DNA repair mechanisms (Santos et al., 2013; Chow and Herrup, 2015; Zhao et al., 2017). In this review, we provide new insights into DNA damage and repair in neurons and also discuss the potential role of DNA damage and repair in the other cell types of the aging NVU. Novel therapeutic strategies targeting DNA damage and repair that may have the potential to combat the neuronal injury after ischemic stroke and neurodegenerative disorders such as PD and AD will also be introduced.

VULNERABILITY OF THE NVU IN THE AGING BRAIN

Changes of the Aging NVU

Living cells gradually exhibit features of senescence, which are characterized by sustained cell cycle arrest and release of senescence-associated secretory phenotype (SASP) throughout the body, including the brain (Mazeika and Doraiswamy, 2002; Lo and Rosenberg, 2009; Cai et al., 2017). Compelling evidence indicates that senescence cells in the brain are associated with multiple neurodegenerative diseases (Baker and Petersen, 2018). Meanwhile, dysfunction of NVU in the aging brain plays fundamental role in the pathology of ischemic stroke and also in the progressive neurological deterioration of neurodegenerative diseases (Cai et al., 2017). Since it was first proposed in 2001, the concept of NVU is attracting increasing research attention (Lo and Rosenberg, 2009). With aging, substantial changes occur in all components of the NVU, including neurons, glial cells, vascular cells as well as the basal lamina matrix within the brain vasculature (Mazeika and Doraiswamy, 2002; Lo and Rosenberg, 2009; Cai et al., 2017; **Figure 1**).

Aging related changes in the NVU usually result in the impaired BBB integrity and penetration of blood derived proteins, such as fibrinogen and plasminogen, which has recently been suggested to clot and form insoluble pro-inflammatory fibrin deposit in the brain (Cortes-Canteli et al., 2015; D'Angelo et al., 2018; Maugeri et al., 2018). Fibrin deposits are associated with amyloid plaques, pericyte loss, dystrophic neurites, and activated microglia in AD, demyelinated multiple sclerosis and stroke (Petersen et al., 2017; Ryu et al., 2018; Brait et al., 2019; Freeze et al., 2019). Fibrin deposits can damage the brain function via a variety of mechanisms: (1) it binds to the CD11b-CD18 integrin receptor and promotes cognitive deficits in a mouse model of AD (Merlini et al., 2019); (2) it can induce reactive oxygen species (ROS) production and the activation of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which increases the expression of proinflammatory genes (Ryu et al., 2018; Merlini et al., 2019); (3) it induces adaptive immune responses in the brain and inhibits oligodendrocyte precursor cells (OPCs) and suppresses remyelination (Ryu et al., 2015; Petersen et al., 2017; Lai et al., 2018); (4) it binds Aβ thus forming the Aβ-fibrinogen complex which blocks fibrin degradation and induces neurodegeneration by sustaining fibrin deposition and enhancing chronic CD11b-mediated microglia activation in the CNS (Cortes-Canteli et al., 2010; Zhao et al., 2010; Lai et al., 2018); (5) fibrinogen leads to axonal retraction (Schachtrup et al., 2007) and BBB damage, thus promoting neuroinflammation (Paul et al., 2007). Likewise, plasminogen, the blood protein synthesized in the liver is recently suggested as a regulator of brain inflammatory action and AD pathology (Baker et al., 2018). Depletion of plasminogen/plasmin in peripheral blood, but not in the brain, is highly protective from Aβ deposition and a neuroinflammatory response in a 5XFAD (Tg6799) AD mouse model (Baker et al., 2018; **Figure 2**).

Aging, with a plethora of mechanisms, affects all the components of the NVU. Aging may also impact the cell-cell interaction within the NVU and ultimately lead to NVU dysfunction and compromised BBB.

Aging Neurons in the NVU

In the NVU, neurons are the most susceptible cell type due to their high metabolic rate and are the most vulnerable to aging associated cell injuries (Cai et al., 2017). During aging, their capacity for ROS clearance reduces, making them more vulnerable to oxidative stress (Nicholls and Budd, 2000; Mattson and Magnus, 2006). Meanwhile, calcium dysregulation and decreased expression of calcium binding proteins further increase ROS production, exacerbating neuronal apoptosis and NVU injury in the aging brain (He et al., 1997). On the other hand, the regenerative capacities of neurons decline in an age-dependent manner, including neurogenesis (Smith et al., 2015), synaptic remodeling, synaptogenesis, axonal sprouting and dendritic remodeling (Skaper et al., 2017).

In addition to neuron itself, the interaction between neuron and glia cells may change with aging. There are a variety of neurotrophic factors that have been shown to play important roles in the neuron-glial interaction (Poyhonen et al., 2019). On one hand, the trophic factors produced from neurons, such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF), support the normal

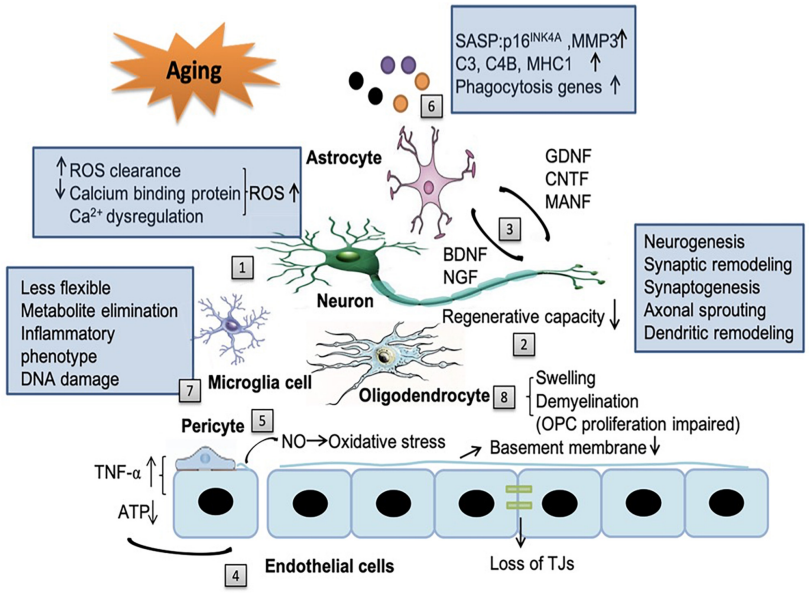

FIGURE 1 | The impact of aging on the neurovascular unit (NVU) components. Aging affects all the components of NVU. [1] In neurons, the capacity for reduced ROS clearance capacity, decreased expression of calcium binding proteins and Ca^{2+} dysregulation induced reactive oxygen species (ROS) production all contribute to the exacerbated neuronal injury. [2] The regenerative capacities of neurons decline in an age-dependent manner, including neurogenesis, synaptic remodeling, synaptogenesis, axonal sprouting and dendritic remodeling. [3] Aging reduces the release of neurotrophic factors from neurons, such as brain-derived neurotrophic factor (BDNF) and nerve growth factor (NGF) and also factors from astrocytes, such as glial cell-line derived neurotrophic factor (GDNF), ciliary neurotrophic factor (CNTF) and mesencephalic astrocyte-derived neurotrophic factor (MANF). The alteration of these factors in aging brain contribute to cognitive decline. [4] With aging, endothelial cells can secrete some noxious factors, such as tumor necrosis factor-α (TNF-α), consume increased amount of ATP, decrease the thickness of basement membrane and disrupt tight junction. In addition, the cross-talk among endothelial cells, astrocytes, and pericytes can modify the secretion of TNF-α. [5] Senile pericytes generate more nitric oxide (NO) and further increase the oxidative stress in the NVU. [6] Senescent astrocytes express senescence-associated secretory phenotype (SASP), such as $p16^{INK4A}$, matrix metallopeptidase 3 (MMP3), complement system genes (C3 and C4B), major histocompatibility complex 1 (MHC1) and upregulate phagocytosis genes, which enhance neuroinflammation and contribute to cognitive decline. [7] With aging, microglia become more rigid and less flexible in mobility. Their capacity to eliminate endogenous metabolites decreases. Aged microglia develop a more inflammatory phenotype and accumulates more DNA damages. [8] Senile oligodendrocytes have swelling morphology and lead to broad and irreversible demyelination which impair the ability of the proliferation of OPCs.

function of NVU (Budni et al., 2015). On the other hand, the factors produced from the glial cells, such as glial cell-line derived neurotrophic factor (GDNF), ciliary neurotrophic factor (CNTF), mesencephalic astrocyte-derived neurotrophic factor (MANF) and et al promote synaptic and neuronal growth, pruning, myelination and neuronal cell survival (Poyhonen et al., 2019). However, with aging, the alterations in their expression may contribute to cognitive decline in aging related neurodegenerative diseases (Budni et al., 2015). Astrocytes in the aging brain can also express characteristic SASP proteins, which may turn them into proinflammatory phenotypes and disrupt the functional neuron-glial interaction, thus progressively impair the neuronal functions (Salminen et al., 2011; Chinta et al., 2015).

Aging Brain Vasculature

Endothelial cells, one of the key components of the blood brain barrier and the NVU, maintain the integrity of the BBB and the hemostasis of the brain along with the tight junctions between endothelial cells, basement membrane, pericytes and astrocyte endfeet (Lo and Rosenberg, 2009). The cross-talk among endothelial cells, astrocytes, and pericytes of NVU may modify the cytokine secretion patterns of endothelial cells, such as tumor necrosis factor-α (TNF-α) (Banks et al., 2018). With aging, oxidative stress occurs in human endothelial cells and the permeability of BBB increases (Donato et al., 2007; Bake et al., 2009; Lee et al., 2012; Cai et al., 2017). Increased endothelial concentration of TNF-α, decreased thickness of basement membrane, loss of tight junctions (TJs), such as occludin and zonula occludens-1 (ZO-1), reduced secretion of trophic factors from brain pericytes have all been suggested as potential mechanisms underlying the aging associated injury of the NVU (Emerich et al., 2005; Bell et al., 2010; Elahy et al., 2015).

Central nervous system pericytes are embedded in the basement membrane. They generate diverse functional responses with neighboring cells, such as regulating BBB permeability, clearance of toxic metabolites, capillary hemodynamic responses, angiogenesis and neuroinflammation (Sweeney et al., 2016; Villasenor et al., 2017; Khennouf et al., 2018). During aging, the number of pericytes decreases in the brain and the loss of $NG2^{+}$ pericytes is associated with Aβ1-40 in AD patients (Bell et al., 2010). Mechanistically, fibril-enriched preparations (fibril-EP) Aβ1-40 exposure can reduce the cell viability of pericytes and it also increases caspase 3/7 activity, which may induce pericyte apoptosis (Schultz et al., 2018). The PDGF-BB/PDGFRβ (platelet-derived growth factor-BB/platelet-derived growth factor

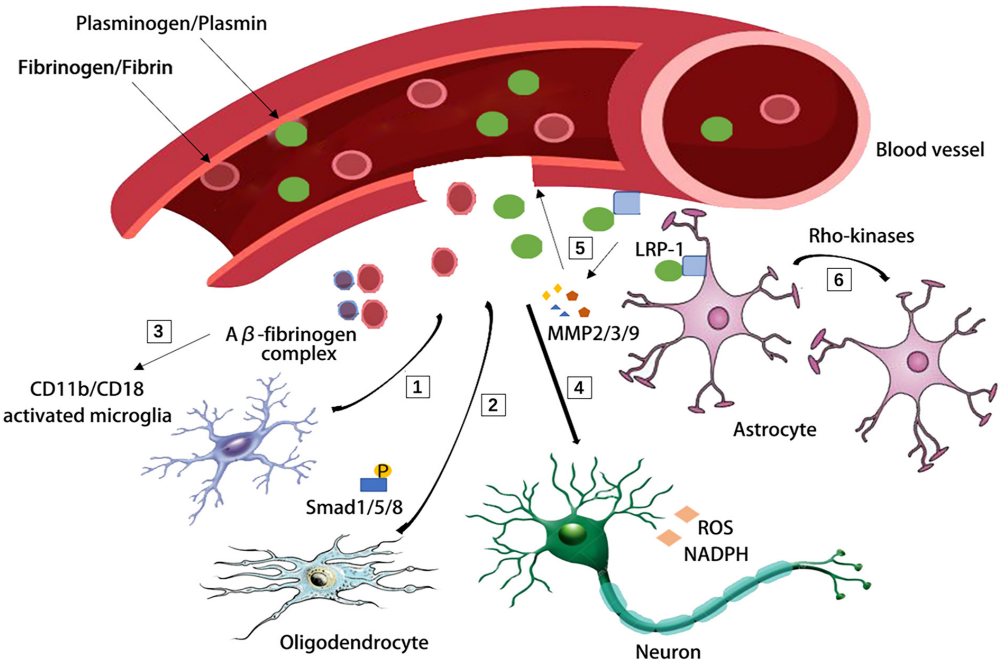

FIGURE 2 | Blood-derived fibrinogen and plasminogen mediated brain pathology through several different mechanisms. [1] Fibrin deposit causes CD11b-CD18 microglia activation in the 5XFAD mouse model of AD. [2] Fibrinogen causes phosphorylation of Smad 1/5/8 and inhibits oligodendrocyte progenitor cells. [3] Aβ-fibrinogen complex enhances chronic CD11b-mediated microglia activation. [4] Fibrin deposit induces reactive oxygen species (ROS) production and triphosphopyridine nucleotide (NADPH) oxidase activation and leads to axonal retraction. [5] The activation of low density lipoprotein receptor-related protein 1 (LRP-1) on endothelial cells was suggested to induce the degradation of tight junctions and base membrane by matrix metallopeptidase-9, matrix metallopeptidase-2, matrix metallopeptidase-3 (MMP-9, MMP-2, and MMP-3). [6] The LRP-1 on astrocytes activates the Rho kinases and mediates the retraction of astrocytic endfeet from vessel walls.

receptor β) signaling plays a pivotal role in the age-dependent pericyte regulation of the BBB integrity. Partially disrupted or deficient of the PDGF-BB/PDGFRβ signaling results in BBB breakdown in an age-dependent manner, which allows accumulation of neurotoxic blood-derived proteins in the brain (Armulik et al., 2010; Sweeney et al., 2016). Senile pericytes contain high smooth muscle actin and the smooth muscle cells generate more nitric oxide (NO), which can react with O^2-anions, causing severe oxidative stress (Hughes et al., 2006; Cai et al., 2017). Dysfunction of pericytes may ultimately result in comprised blood supply of the NVU due to contractile rigor (Sweeney et al., 2016).

The Impact of Aging on Brain Glial Cells

As the most numerous glial cells in the CNS, astrocytes not only provide structural and nutritional supports for neurons, but also participate in the composition of the NVU (Helms et al., 2017; Banks et al., 2018). In senile astrocytes, increased oxidative metabolism and disturbed glutamate regulation can impair their energy support capacity to neurons and cause neuronal excitotoxicity (Maragakis and Rothstein, 2006; Simpson et al., 2010; Cai et al., 2017). Senile astrocytes in the brain also express senescence-associated secretory phenotype (SASP), such as $p16^{INK4A}$ and matrix metalloproteinase 3 (MMP3), which enhances age-related neuroinflammation and exacerbates the functional decline of the aging brain (Salminen et al., 2011; Baker and Petersen, 2018). Recently, the accumulation of senile astrocytes were causally linked to neuronal cell loss and subsequent cognitive impairment (Bussian et al., 2018). Clearance of p16Ink4a-positive senescent astrocytes and microglia using INK-ATTAC transgenic mice prevents gliosis and deposition of neurofibrillary tangle in the cortex and hippocampus (Bussian et al., 2018). On the other hand, aging astrocytes activate the immune system and contribute to cognitive decline. It was recently demonstrated that the complement system genes in astrocytes, such as C3 and C4B were upregulated in the aging brain (Boisvert et al., 2018; Clarke et al., 2018). There's also an upregulation in antigen presenting genes such as major histocompatibility complex I (MHC I), and phagocytosis genes, such as *Pros1, Mfge8, Megf10, and Lrp1*, thus contributing to the low level inflammatory state characteristic of aging (Mangold et al., 2017; Clarke et al., 2018). However, the MHC I and the phagocytosis gene expression may not be detrimental all the time, they may also promote the clearance of the myelin debris and preserve the cognitive function during aging (Nag and Wadhwa, 2012; Lazarczyk et al., 2016).

Microglia has long been recognized as the main executor of inflammation after acute and chronic brain injuries (Perry and Holmes, 2014; Jin et al., 2017; Kluge et al., 2018). It has been recently shown that neocortical resident microglia are long-lived, with a median lifetime of well over 15 months. About half of the microglia can survive the entire lifespan in

mouse (Fuger et al., 2017). With aging, microglia become less flexible in mobility, which makes them become more rigid and less efficient during their daily patrol in the brain (Norden and Godbout, 2013; Perry and Holmes, 2014; Babcock et al., 2015). Their capacity to eliminate endogenous metabolites (e.g. amyloid-beta peptides) also decreases with aging (Norden and Godbout, 2013; Perry and Holmes, 2014; Babcock et al., 2015). Aged microglia develop a more inflammatory phenotype, which is primed, reactive or sensitized, and the activation is amplified and prolonged and more difficult to resolve compared to non-aged microglia (Norden and Godbout, 2013; Perry and Holmes, 2014). In addition, mutations and DNA damages accumulate in microglia with aging (Mrak and Griffin, 2005). Therefore, it's well recognized that microglial senescence may contribute to age-related neurodegenerative diseases. Although it does not directly participate in the composition of NVU, its interaction with the BBB after central nervous system disorders is getting increasing attention in the field.

Oligodendrocytes are one of the glial cells providing support and insulation to axons in the brain. Senile oligodendrocytes have swelling morphology which includes degenerated myelin sheaths in the cytoplasm (Peters, 2009). With aging, the injuries to myelin and the oligodendrocytes increase while the ability of the brain to repair and renew in response to these injuries declines, leading to broad and irreversible demyelination in various age-related CNS insults (Cai et al., 2017; Petersen et al., 2017). Demyelination results in exposure of unwrapped axons, which in turn stimulates the proliferation of OPCs and remyelination (Petersen et al., 2017). However, the remyelination efficiency is significantly impaired in the aged brain, causing a significantly lower axonal conduction velocity, which may also contribute to the progressive neurological deterioration in those aged individuals with neurodegenerative disorders (Peters and Sethares, 2002; Peters, 2009).

Collectively, the aging related changes in the NVU are illustrated in **Figure 1**.

Senile NVU and Cerebral Ischemic Stroke

As the fourth leading cause of death and the primary cause of disability worldwide, stroke poses enormous burden to the family and society (Donahue and Hendrikse, 2018). More than 80% of strokes occur in patients aged 65 or more (Ritzel et al., 2018). Aging is not only a risk factor of cerebral ischemic stroke, but also an indicator of poorer outcome (Cai et al., 2017; Yang and Paschen, 2017). Compared to younger patients, the elderly has higher rates of mortality and disability (Ritzel et al., 2018).

Aging can affect the NVU in a variety of ways (Salinet et al., 2018). Apart from the above mentioned direct impacts of aging on the NVU components, aging can also impair the systemic milieu and alter the immunological response and lead to further exacerbated brain injury after stroke (Pan et al., 2017; Ritzel et al., 2018; Wang et al., 2018). Reduced expression of sirtuin-1 in brain microvessels may also contribute to the increased brain permeability in aged mice after stroke (Stamatovic et al., 2018). However, the capacity of the aged NVU to recover from ischemic stroke is impaired (Jiang et al., 2018). Of note, with aging, BBB breakdown may occur before marked cognitive dysfunction occurs, which may predispose aged patient to post-stroke dementia (Nation et al., 2019). However, the causal link between aging-related NVU dysfunction and post-stroke dementia has not been well-established yet.

Intimate Association Between AD and NVU Dysfunction

Alzheimer's disease is a chronic neurodegenerative disease that constitutes 60–70% of dementia cases (Herholz et al., 2018). Emerging evidence suggests BBB disruption may serve as a critical pathway that initiates the onset of AD (Arvanitakis et al., 2016; Sweeney et al., 2018b). Using an advanced dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) protocol, it's demonstrated that compromise of the BBB is an early event in the hippocampus during aging and it may contribute to the progressive impairment of cognitive function. Thus, BBB breakdown can also serve as an early biomarker of human cognitive dysfunction (Montagne et al., 2015; Barry Erhardt et al., 2018; Nation et al., 2019).

Multiple lines of evidence suggest that there are pronounced NVU dysfunction in AD brains (Miners et al., 2018). BBB disruption has been found in the postmortem brain of AD patients, such as substantially reduced TJs proteins, occludin, claudin-5, and ZO-1 in capillaries, leading to increased fibrinogen leakages in the brain parenchyma (Carrano et al., 2011, 2012; Zlokovic, 2011). Aβ42 is likely to disrupt the organization of TJs and adherent junction between endothelial cells, thereby disturbing their barrier function (Carrano et al., 2011, 2012; Zlokovic, 2011). The receptor for advanced glycation end-products (RAGE)-mediated Aβ cytotoxicity is involved in damaging the BBB integrity (Kook et al., 2012; Wan et al., 2015). High degree of Aβ burden is associated with redistribution and even loss of aquaporin 4 (AQP4) on astrocytic end-foot membranes (Yang et al., 2011; Zeppenfeld et al., 2017). Retraction and swelling in astrocytic end-feet is involved in the Aβ mediated impairment of cerebral vascular function and cerebral metabolism (Merlini et al., 2011). Coverages of microvessels by pericytes are significantly reduced in AD brains and it inversely correlated with the extravasation of the blood-drived proteins including immunoglobulin G and fibrin (Sengillo et al., 2013; Winkler et al., 2014). Furthermore, reduced pericyte coverage in AD may further exacerbate cerebral hypoperfusion and Aβ clearance impairment (Dalkara et al., 2011). Deficiency of pericytes causes accelerated brain Aβ deposition and cerebral amyloid angiopathy formation in the brain of a mouse AD model (Sagare et al., 2013). With compelling evidence suggesting an intimate association of NVU dysfunction and AD, it's reasonable to envision that protecting the aging NVU may be a promising strategy to treat AD **(Figure 3)**.

Aging NVU and PD

Parkinson's disease is a progressive long-term neurodegenerative disorder in the aged population. It is characterized by degeneration of dopaminergic neurons in the substantia nigra

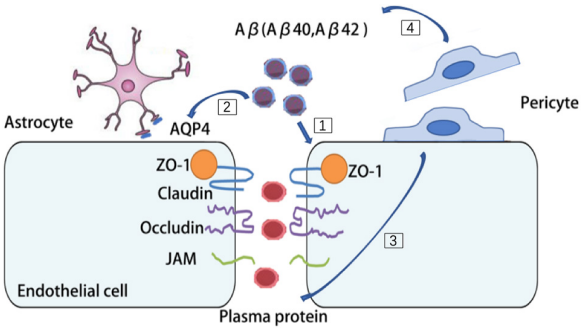

FIGURE 3 | Aβ burden contribute to multiple cell types dysfunction in AD brains. [1] Aβ42 disrupt the organization of tight junctions (TJs) and adherent junction in endothelial cells. [2] Aβ burden redistribute aquaporin 4 (AQP4) on astrocytes and cause retraction and swelling of astrocytic end-feet. [3] In AD brains, pericytes detach from microvessels and cause leakage of plasma protein. [4] Deficiency of pericytes cause accelerated brain Aβ deposition.

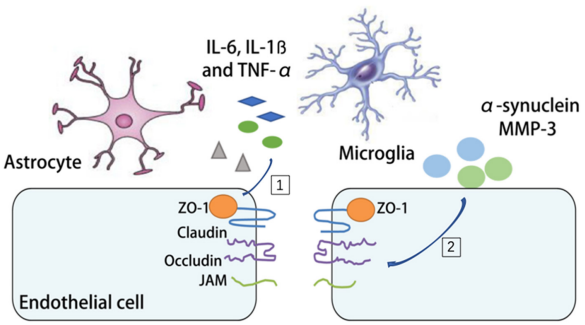

FIGURE 4 | The mechanism of BBB disruption in PD. [1] The release of interleukin 6 (IL-6), interleukin-1ß (IL-1ß) and tumor necrosis factor-α (TNF-α) by microglia and astrocytes during PD is associated with the rearrangement of tight junctions (TJs). [2] The deposition of α-synuclein and matrix metallopeptidase 3 (MMP3) increases BBB permeability and neuroinflammation in PD.

with accumulated α-synuclein. The relationship between the aging NVU and PD resides in two aspects. On one hand, increased oxidative stress, disturbed mitophagy, reduced energy support and impaired mitochondria repair with aging can all lead to dopaminergic neuronal cell injury and cell loss (Gredilla et al., 2010; Fivenson et al., 2017). On the other hand, the pathological changes of the PD brain, such as α-synuclein deposition and increased MMP-3 alter BBB permeability and neuroinflammation in PD (Chung et al., 2013; Jangula and Murphy, 2013). There is clinical evidence of BBB disruption during PD development (Ohlin et al., 2011; Lee and Pienaar, 2014). By measuring the albumin ratio, it's demonstrated that PD patients exhibit significant differences in albumin ratio, which indicates BBB dysfunction (Jangula and Murphy, 2013). Several mechanisms have been proposed to explain the BBB disruption in PD. Astrocytes have intimate contact with dopaminergic neurons, especially those with unmyelinated axons (Rodriguez et al., 2014). In the aging brain, instead of providing protection and support, the senile astrocytes along with microglia produce cytokines, chemokines (interleukin 6 (IL-6), interleukin-1ß (IL-1ß) and TNF-α) and ROS, which disrupt the integrity of the NVU, rearrange TJs ZO-1 and occludin and propel disease progression (Gredilla et al., 2010; Collins et al., 2012; Rodriguez et al., 2015; Fivenson et al., 2017). In addition, increased oxidative stress, neuroinflammatory processes and infiltration of peripheral immune cells have all been linked to BBB disruption in PD, although still controversial (Block et al., 2007; Appel, 2009; Chung et al., 2016). So far it still remains unknown whether NVU targeted therapy could be protective against PD (**Figure 4**).

ACCUMULATED DNA DAMAGE IN MULTIPLE CELL TYPES IN THE AGING NVU

Progressive DNA damage accumulation is linked to cellular senescence and organismal aging. Most DNA damage is referred to oxidative DNA damage, an endonuclease-independent process resulting from ROS attacks, posing a major threat for the genome stability in the aging brain (McKinnon, 2013). There are several types of DNA damage, such as DNA breaks, cross-links, and bases mismatch (e.g., oxidative lesions) (Hayflick, 2007), among which DNA strand breaks are the most frequently encountered and detrimental. When classified depending on their mechanisms of action, DNA damage can be divided into two distinctive types: active DNA damage and passive DNA damage. It's emerging that DNA damage accumulation underlies age-related neurodegenerative diseases, such as stroke, AD and PD [88]. Among the NVU cells, neurons are the most widely studied cell type in terms of DNA damage and repair. However, DNA damage in endothelial cells and glial cells are also getting increasing attention due to their fundamental role in the NVU. We summarize different types of DNA damages in different neuronal cells in the NVU following ischemic stroke, AD and PD in **Supplementary Table 1**.

Accumulated DNA Damage in the NVU and the Relationship With Neurodegenerative Diseases

Neurons are highly vulnerable to oxidative stress induced DNA damage due to its high metabolic and mitochondrial activity, oxygen consumption, as well as high rates of transcription and translation (Lu et al., 2014; D'apolito et al., 2018). This condition, together with the impaired DNA repair capacity, can lead to a high accumulation of DNA damage which ultimately result in neurodegenerative processes (Choi et al., 2012; Suberbielle et al., 2015; Hou et al., 2018). Persistent accumulation of DNA damages, including oxidative DNA damages, single-strand breaks (SSBs), and double-strand breaks (DSBs), have been found in neurons of both AD and PD patients and experimental animal models (Adamec et al., 1999; Abolhassani et al., 2017). Cortical neurons prepared from 8-oxodeoxyguanine/8-oxoguanine glycosylase (8-oxo-dG/OGG1) double deficient adult mouse brains exhibit increased 8-oxoguanine (8-oxoG) accumulation in mitochondrial DNA and significantly poor

neuritogenesis *in vitro* in the absence of antioxidants in AD (Abolhassani et al., 2017). In PD patients, a significant increase in 8-hydroxy-2'-deoxyguanosine (8-OHdG) levels was shown in mtDNA in nigrostriatal dopaminergic neurons [69]. After ischemic stroke, there are also pronounced formation of apurinic/apyrimidinic (AP) sites base modifications (e.g., 8-oxodG, 8-OHdG, and 8-oxoG), SSBs and DSBs in ischemic neurons (D'apolito et al., 2018). The DNA damages in neurons of different neurodegenerative diseases are summarized in **Supplementary Table 1**.

DNA damages also surface in brain vascular endothelial cells and lead to endothelial apoptosis and cell loss, which contributes to cognitive decline in AD and ischemic stroke via a number of mechanisms (Chen et al., 1997; Ou and Schumacher, 2018): (1) increased apoptosis in endothelial cells results in reduced cerebral blood flow due to stiffened vasculature; (2) compromised BBB integrity can cause unregulated passage of blood-derived protein into the brain and increased infiltration of peripheral immune cells; (3) generalized NVU dysfunction, which will impact both astrocytes and neurons, leads to reduced function of the NVU and a pro-inflammatory environment in the brain (Jadavji et al., 2015). Detailed DNA damage types identified in endothelial cells are also summarized in **Supplementary Table 1**.

Astrocytes play critical roles in the maintenance and protection of neurons especially acute or chronic injury encountered, they are also vulnerable to oxidative DNA damage (Fluteau et al., 2015). Astrocyte oxidative DNA damage and their response to oxidative DNA damage are related to the progression of cognitive impairment (Waller et al., 2018) and cerebral ischemic injuries (Chen et al., 1997; Matsuda et al., 2009). In addition, the activation of astrocytes has a profound impact on the glial scar formation and NVU remodeling after stroke (Nahirney et al., 2016; Yanev et al., 2017; Blochet et al., 2018). However, evidence of DNA damages in astrocytes in AD or PD is relatively limited. There is even conflicting data showing reduced DNA-dependent protein kinase expression and DNA-damage associated molecules H2A histone family member X (H2AX) in Alzheimer's disease (Simpson et al., 2010). Therefore, the role of astrocytic DNA damage in the development of neurodegenerative diseases remains obscure and warrants further investigation.

Pericytes are adjacent to capillaries and essential to the regulation and limitation of the transport of various substances, thereby play important roles in the regulation of the BBB permeability and NVU functions (Bell et al., 2010; Fernandez-Klett et al., 2013; Montagne et al., 2018; Sweeney et al., 2018a). The oxidative DNA damage and repair in pericytes are poorly understood comparing to neuronal cells and endothelia cells. However, pericyte loss has been evidenced as an important contributor for BBB disruption and NVU dysfunction in AD, white matter dysfunction and ischemic stroke (Bell et al., 2010; Fernandez-Klett et al., 2013; Montagne et al., 2018; Sweeney et al., 2018a). Pericytes incubated with Aβ express high levels of cyclin D1 and integrin alpha 5 (ITGa5), which represents disturbed cell cycle and increased cell apoptosis (Davis et al., 1999; Miao et al., 2005). Thymosin β10 (Thyβ10) is supposed to mediate the Aβ induced compromise of the actin network and increased expression of cyclin D1 and Thyβ10 in AD brain, may eventually lead to apoptosis in cerebrovascular cells (Gugliandolo et al., 2018; Knopman, 2019). However, whether different types of DNA damages participate in the pericyte loss during neurodegenerative diseases remains to be explored.

Collectively, there are compelling evidence showing that a variety of DNA damage molecules in neurons contribute to ischemic stroke, AD and PD, such as 8-OHdG, 8-oxodG, γ-H2AX and et al. as listed in **Supplementary Table 1**. While oxidative DNA damage and repair in other cell types of the NVU remains poorly understood and warrants further investigation.

Impaired DNA Damage Responses in the NVU in the Aging Brain

Once DNA damage occurs, it can be sensed by DNA damage responses (DDR), several signaling pathways can be triggered to initiate cell injury (Lee and Paull, 2005; Ciccia and Elledge, 2010; Shiloh, 2014; Lavin et al., 2015). Phosphoinositide 3-kinase (PI3K)-related kinases (PIKKs) can phosphorylate downstream proteins to activate DNA damage responses. There are three types of PIKKs DNA-dependent protein kinase that can be recruited to DNA damage sites, DNA-dependent protein kinase catalytic subunit (DNA-PKcs), Ataxia-telangiectasia mutated (ATM), and taxia-telangiectasia and Rad-3-related (ATR) (Blackford and Jackson, 2017). DNA-PKcs is required to form an active DNA-PK complex with Ku70/80 for DNA repair of double strand breaks, which is accompanied by non-homologous end-jointing (NHEJ), which will be discussed later. ATR is activated by single strand break and stalled DNA replication forks while ATM can be activated directly by oxidative stress and DNA damage, mainly double strand DNA damage (Li et al., 2011; Blackford and Jackson, 2017; D'apolito et al., 2018). Once ATM is activated, it phosphorylates a multitude of substrates, including nuclear respiratory factor 1 (NRF1), p53-binding protein 1 (53BP1), mediator of DNA damage checkpoint protein 1 (MDC1), breast cancer type 1 susceptibility protein (BRCA1) MRE11/RAD50/NBS1(MRN) and H2AX to activate cell cycle checkpoints and initiate DNA repair. When ATM phosphonates NRF1, it leads to enhanced electron transport chain and mitochondrial function (Chow et al., 2019). If the damage is too severe to be repaired, ATM can direct the cell to apoptosis (Lee and Paull, 2005; Ciccia and Elledge, 2010; Shiloh, 2014; Lavin et al., 2015).

Among the three PIKKs, both ATM and DNA-PKcs have been implicated to play fundamental roles in aging and neurodegenerative diseases (Chung, 2018; Gal et al., 2018). DNA-PKcs has been found in the amygdala of cognitively impaired patients (Gal et al., 2018). Both Aβ (1-42) oligomers and aggregated Aβ (25-35) have been shown to inhibit DNA-PK kinase activity, compromising double strand break repair (NHEJ) and sensitizing cells to non-lethal oxidative injury (Cardinale et al., 2012). ATM-centered DNA damage response has been shown to progressively decline with aging, but significantly increased phospho-ATM immunoreactivity has been found in dopaminergic neurons in PD mouse model (Cornelis et al., 2018; Milanese et al., 2018; Qian et al., 2018). Excessive ROS stimulates ATM-dependent phosphorylation of drebrin, a

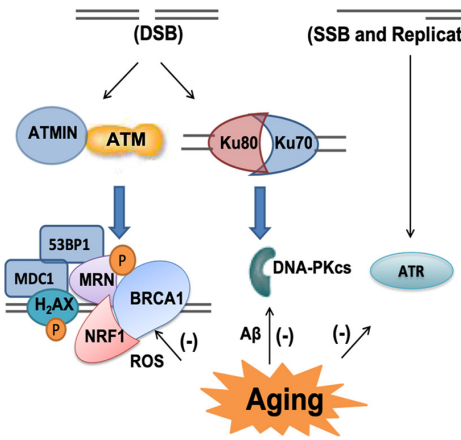

FIGURE 5 | PIKKs-related signaling pathway in the aging brain. There are three types of phosphoinositide 3-kinase (PI3K)-related kinases (PIKKs) DNA-dependent protein kinase including ataxia-telangiectasia mutated (ATM), DNA protein kinase catalytic subunit (DNA-PKcs) and taxia-telangiectasia and Rad-3-related (ATR). ATM can be activated by double-strand breaks (DSB) and it phosphorylates a multitude of substrates, including nuclear respiratory factor 1 (NRF1), H2A histone family member X (H2AX), mediator of DNA damage checkpoint protein 1 (MDC1), p53-binding protein 1 (53BP1), breast cancer type 1 susceptibility protein (BRCA1) and MRE11/RAD50/NBS1 (MRN). As an interactor of ATM, ATMIN plays important role in its response to oxidative stress and aging related DNA damage. DNA-PKcs is required to form an active DNA-PK complex with Ku70/80. ATR is activated by single-strand breaks (SSB) and replication arrest. In aging and AD brain, all these DNA damage response pathways have been shown to progressively decline.

regulator of cytoskeletal functions during neuronal development. The phosphorylation of drebrin improves structural and functional changes in the aging and AD synapse by enhancing the protein stability (Kreis et al., 2019). Depletion of ATM interactor (ATMIN), an interactor of ATM in the murine nervous system resulted in reduced numbers in dopaminergic neurons and increased mortality of aging mutant mice (Kanu and Behrens, 2008; Kanu et al., 2010; **Figure 5**).

Poly (ADP-ribose; PAR) polymerase-1 (PARP-1) is another enzyme that can be activated by oxidative stress and DNA damages, including single and double strand breaks. It belongs to NAD^+-dependent enzymes in eukaryotes. Cellular DNA damages, especially SSB, trigger overactivation of PARP-1, followed by NAD^+ depletion and lead to depletion of energy supply and mitochondrial impairment (Vosler et al., 2009; Fang et al., 2014). PARP-1 activation helps translocation of apoptosis-inducing factor (AIF) from the mitochondrion to the nucleus and also for the macrophage inhibitory factor (MIF) to translocate from the cytoplasm to the nucleus, where both of them can induce pro-death processes (Wang et al., 2016; D'apolito et al., 2018). Importantly, PARP-1 is not always detrimental, although overactivation of PARP-1 usually leads to pro-death cellular signals, its recognition of DNA damage is also important in initiating DNA repair (Vida et al., 2016). Of note, significant changes in the activity of PARPs have been detected in ischemic stroke (Andrabi et al., 2011; Nakajima et al., 2015), AD (Martire et al., 2016) and PD (Kam et al., 2018; Olsen and Feany, 2019; **Figure 6**).

As described above, mounting evidence suggests that aging not only results in accumulated DNA damages in the NVU comprising cells, but also affects the DNA damage response pathways, which contribute to the evolution of neuronal injuries in ischemic stroke and also neurodegenerative diseases. On the other hand, cells are equipped with delicate mechanisms to repair the DNA damages. However, with aging, the DNA repair capacities are impaired, which are associated with exacerbated ischemic brain injury and the progression of neurodegenerative diseases as we will discuss in the following part.

Impaired DNA Repair Capacities in Aging Brain

Although DNA damage is inevitable during aging, the cells have endogenous mechanism to repair these damages. The main DNA repair pathways include base excision repair (BER), nucleotide excision repair (NER), homologous recombination (HR), NHEJ and DNA mismatch repair (MMR) (Wyman and Kanaar, 2006; Iyama and Wilson, 2013; **Figure 7**).

Base excision repair is the primary nuclear and mitochondrial repair pattern for oxidative DNA damage, recognizing and replacing DNA modifications characterized by small base modifications (Li et al., 2011, D'apolito et al., 2018). BER is initiated by various DNA glycosylases, such as OGG1, endonuclease III-like 1 (NTH1), endonuclease VIII-like 1 (NEIL1) and endonuclease VIII-like 3 (NEIL3). These glycosylases excise the damaged bases and generate an AP site in DNA. The resulting AP site is then recognized by AP endonuclease 1 (APE1), which cleaves the phosphodiester backbone 5' to the AP site, leaving a nick with a 3'-OH group and a 5'-deoxyribose phosphate (dRP) residue. Next, the dRP is removed and filled in by "short-patch" repair or "long-patch" repair (D'apolito et al., 2018). Short patch repair involves sequential single-nucleotide gap-filling in which DNA polymerase beta (Polβ) synthesizes a single nucleotide to fill the gap and DNA ligase III-XRCC1 complex seals the nick between the newly synthesized nucleotide and the DNA template. Long patch repair is initiated by flap endonuclease-1 (FEN1) and usually produces a repair tract of at least two, most frequently four nucleotides (D'apolito et al., 2018).

With aging, the BER process becomes less effective (Niedernhofer et al., 2018), leading to accumulated DNA damage lesions that contribute to age-related degenerative diseases (Santos et al., 2013; Chow and Herrup, 2015). Firstly, the reduction in DNA damage recognition by reduced expression of DNA-PK and H2AX leads to impaired DNA damage recognition, which is associated with neuronal cell loss and glial responses in AD (Myung et al., 2008; Simpson et al., 2010). Secondly, the declined glycosylase activity and reduced DNA polymerase activity have been linked to aging related reduction of BER (Best, 2009). In the aged cerebellum, uracil DNA glycosylase (UDG) declined nearly 50% and OGG1 declined 90% (Best, 2009). In human studies, impaired BER function and the decreased BER capacity could be related to a reduction of Polβ activity and

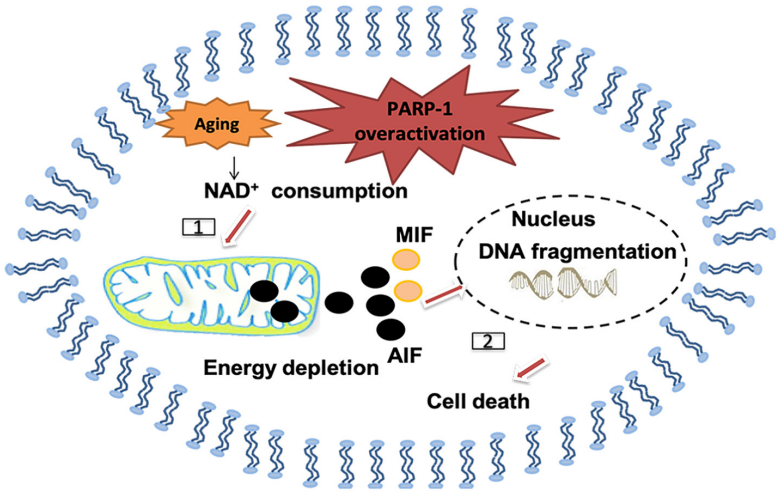

FIGURE 6 | Polymerase-1 over-activation causes cell death in the senile brain. [1] NAD^+ as the substrate for poly ADP-ribose polymerase (PARP) may be depleted and causes energy depletion in mitochondrial, especially in the senile brain. [2] PAR may directly cause the release of apoptosis inducing factor (AIF) from mitochondrial and transport into the nucleus, thus promoting macrophage migration inhibitory factor (MIF) to translocate from the cytoplasm to the nucleus and cause DNA fragmentation.

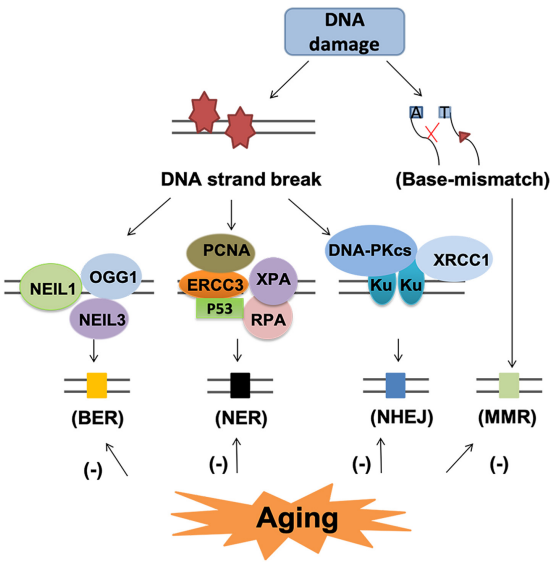

FIGURE 7 | DNA repair pathway and subsequent events in the aging brain. DNA repair pathway include base excision repair (BER), nucleotide excision repair (NER), non-homologous end-joining (NHEJ) and mismatch repair (MMR). Each pathway involved several various molecules. BER and NER are basic nuclear and mitochondrial DNA repair pathway for DNA strand break. NHEJ and MMR are two different pathways for the repair of base-mismatch. All the repair mechanisms become less effective with age, thus, may lead to accumulated DNA lesions and increase the risk of neurodegenerative diseases.

decreased glycosylase UDG in aging related neurodegenerative diseases (Sykora et al., 2013; Leandro et al., 2015). Recently, epigenetic events such as DNA methylation have also been identified to contribute to aging process and defective BER repair system (Dor and Cedar, 2018). Hypermethylation of the BER-related genes results in decreased expression these genes, especially OGG1, which is associated with reduced BER-related incision activity in AD and PD (Blanch et al., 2016).

The NER pathway is a versatile and complex system able to repair different types of DNA helix distorting lesions. In the aged humans, there are reduced expression of NER proteins, such as complementation group 3 (ERCC3), proliferating cell nuclear antigen (PCNA), replication protein A (RPA), xeroderma pigmentosum A (XPA) and tumor protein p53 (p53) (Gorbunova et al., 2007). However, the mechanism underlying this decline remains obscure. Treatment with short oligonucleotides that mimics DNA damage upregulated the levels of NER proteins in aged cells, suggesting decreased NER enzymes or altered induction of DNA damage response may underlie the decline of NER activity (Goukassian et al., 2002). The expression of NER proteins, such as ERCC1, is suggested to be associated with AD and PD (Sepe et al., 2016; Jensen et al., 2018).

Non-homologous end-jointing is a process to restore double stranded breaks of DNA. DNA-dependent protein kinase (DNA-PK) and its activator Ku play important roles initiating the NHEJ process upon binding to the DNA ends of DSBs (Kanungo, 2016). Reduced NHEJ activity as well as DNA-PKcs and Ku protein levels have been shown in aging and AD brains (Vyjayanti and Rao, 2006; Sharma, 2007; Kanungo, 2016). The level of Ku may be one of the mechanisms underlying the age-related decline of NHEJ (Rulten and Caldecott, 2013). Deficiency of Ku80 can induce Aβ generation, which in turn potentiates the degradation of DNA-PKcs and consequently reduced activity of NHEJ (Rulten and Caldecott, 2013).

Mismatch repair system provides two main genetic stabilization functions: correction of errors generated during replication and ensuring the fidelity of recombination. Mutations in MMR genes increase with aging but the function of MMR

declines (Bak et al., 2014). The mutagenic MMR has detrimental effects in neurodegenerative diseases for repeat expansions promotion (Bak et al., 2014). For AD patients, elevated DSB accumulation, reduction of DSB repair proteins such as DNA-PKcs and MRN complex proteins, and impaired BER activity all contribute to cell apoptosis or permanent cell-cycle arrest (Andreassi, 2008; Madabhushi et al., 2014).

Therefore, both increased DNA damage accumulation and defected DNA repair mechanisms have been identified in ischemic stroke, AD and PD. However, most of the above-mentioned studies focus the changes in neurons, but not other cell types of the NVU. Thus, it still remains unknown whether the above changes are directly associated with the NVU dysfunction in the aged brain. But, we envision that DNA damage and repair targeted therapy may help to preserve the NVU function and thus improve the outcome of these diseases. In the following part, we will introduce some potential therapeutic strategies that target DNA damage and repair in the treatment of ischemic stroke and neurodegenerative disorders.

POTENTIAL THERAPEUTIC STRATEGIES TARGETING DNA DAMAGE AND REPAIR IN AGE-RELATED VASCULAR AND NEURODEGENERATIVE DISORDERS

Several strategies have been proposed to combat the DNA damage in neurodegenerative diseases, such as prophylactically or therapeutically using antioxidants. Glutathione (GSH), vitamin E, selenium and superoxide dismutase have all been suggested to protect against oxidation and reduce DNA damage directly or stimulate the activity of DNA repair enzymes (Tomasetti et al., 2001; Mangialasche et al., 2010; Persson et al., 2014; Poprac et al., 2017).

Stimulating nuclear factors or increasing the activity of DNA repair enzymes can be another potential strategy to reduce the DNA damage and combat the neurodegenerative diseases. Forkhead box O3 (FOXO3a), the main isoform of FOXO transcription factors, has been shown to regulate the DNA repair genes. Inhibition of FOXO3a is associated with suppressed DNA damage response and attenuated Alzheimer-type pathology (Fluteau et al., 2015; Shi et al., 2016). In addition, there are a variety of DNA repair enzymes and proteins that can be targeted to combat the neuronal injuries, such as Apurinic/apyrimidinic endonuclease 1 (APE1), ATMIN, endonuclease VIII-like1 (NEIL1) DNA glycosylase, Polβ and DNA polymerase gamma (Polγ). APE1 is a critical BER enzyme that repairs AP sites. It has been shown to enhance neuronal survival after oxidative stress, provide neuroprotection against ischemic brain injury (Stetler et al., 2010; Leak et al., 2015) and also protect against Aβ25-35-induced neurotoxicity (Kaur et al., 2015). Administration of an endogenous small neuropeptide, pituitary adenylate cyclase-activating polypeptide (PACAP), is shown to induce APE1 expression and thus reduces oxidative DNA stress and reduce neuronal cell death after cerebral ischemia (Stetler et al., 2010). In addition, direct NAD repletion could markedly restore the DNA repair activity and reduce the accumulation of DNA damage (Wang et al., 2008). ATMIN is an essential component of the ATM signaling pathway (Kanu et al., 2010). ATMIN has same function in DNA repair system and deficiency of ATMIN will cause neurological disorders (Kanu and Behrens, 2008). Endonuclease VIII-like1 (NEIL1) DNA glycosylase is one of eleven mammalian DNA glycosylases that take part in the first step of the BER pathway (Prakash et al., 2016). Early research showed that NEIL1 function is important in brain-related diseases, such as AD (Canugovi et al., 2014). Polβ renders neurons vulnerable to reductions in cellular energy levels, sustain or elevate Polβ or DNA repair levels may protect neurons against dysfunction and degeneration in aging and AD (Sykora et al., 2015). Suitable supplement of Polγ may relieve PD syndrome (Gaweda-Walerych and Zekanowski, 2013). Collectively, these prophylactic or therapeutic DNA damage and repair targeting treatments appear to be a promising strategy to combat the DNA damage in neurodegenerative diseases **Supplementary Table 2**.

CONCLUSION

Aging related accumulation of DNA damage is emerging as important mechanism that underlies the neuronal injuries after ischemic stroke and neurodegenerative diseases like AD and PD. On the other hand, recent studies have highlighted the important role of NVU dysfunction and subsequent BBB damage and penetration of blood-derived substances, such as fibrinogen and plasminogen in the development of these diseases. In addition, aging related changes in the DNA damage responses and DNA repair signaling are also intimately associated with the progression of different types of age-related neurodegenerative diseases. Therefore, we envision that targeting DNA damage and DNA repair may serve as a promising strategy to combat the NVU dysfunction after ischemic stroke and neurodegenerative diseases. Although a variety of DNA damage and repair targeted treatments have been proposed to treat these neurological disorders, it still remains unknown whether these treatments can effectively improve the NVU function in these neurological disorders. Further investigations are warranted for a better understanding of DNA damage and repair related NVU dysfunction to explore new treatment ideas for multiple neurodegenerative disorders.

Neurological deficits and cognitive dysfunctions caused by acute ischemic stroke pose enormous burden to the stroke families and the communities. Restoration of the normal function of the neurovascular unit following ischemic stroke is critical for improving neurological recovery and cognitive functions after stroke. Recent evidence suggests that the myeloid cells including both the resident microglia and infiltrating monocytes/macrophages and neutrophils are highly plastic in response to the environmental cues. They intimately interact with multiple components of the neurovascular unit in response to the alarmins, danger associated pattern molecules (DAMPs) and other signals released from the ischemic brain. The aim of this review is to discuss the reciprocal interactions between the myeloid cells and the ischemic neurovascular unit during the late repair phase of cerebral ischemic stroke. We also summarize potential immunotherapeutic targets on myeloid cells and new therapeutic approaches targeting myeloid cells, such as cell transplantation, mitochondrial dynamic and extracellular vesicles-based therapy et al to enhance neurovascular repair for better stroke recovery.

Keywords: stroke, neurovascular unit, brain repair, myeloid cell, microglia, macrophage, neutrophil

INTRODUCTION

The neurovascular unit (NVU) is composed by neurons, endothelial cells, pericytes, smooth muscle cells, astrocytes, microglia and extracellular matrix components. It maintains brain homeostasis of the brain (Banks et al., 2018; Morrison and Filosa, 2019). All the components of NVU interact with each other to maintain the neuronal milieu that is required for proper neuronal functioning by balancing energy, preserving the integrity of the blood brain barrier (BBB), releasing neurotrophic factors, uptake and recycling of neurotransmitters and et al. (Halassa et al., 2007; Charveriat et al., 2017). In response to cerebral ischemic stroke, the integrity of the BBB compromises leading to leakage of harmful blood components into the CNS, immune cell infiltration, and aberrant transport and clearance of molecules. All these changes contribute to the dysfunction of the NVU which is associated with long term neurological impairments (Fisher and Saver, 2015; Villaseñor et al., 2017). The reconstruction of NVU and the remodeling of neuronal circuitry turns out as an essential player in long-term neurological recovery after stroke (Gurer et al., 2009; Lake et al., 2017). However, the repair of NVU is a complex

process involving clearing of neuronal debris, neurogenesis, angiogenesis, establishing the new neuronal circuitry, controlling neuroinflammation and et al. (Lake et al., 2017; Zhao Z. et al., 2017), thus it remains as a big challenge to promote the NVU repair after ischemic brain injury.

After ischemic stroke, both glial cells and peripheral immune cells can be activated by a variety of mechanisms, including neuronal "help me" signals, like lipocalin-2 (Xing et al., 2014; Blochet et al., 2018), interleukin 4 (IL-4) (Zhao et al., 2015), and a complex mixture of extracellular proteins functioning as damage associated molecular patterns (DAMPs), such as high-mobility group box 1 (HMGB1), hypoxia-inducible factor 1α (HIF-1α), S100B and et al. (Chamorro et al., 2012; Fu et al., 2015; Li et al., 2018b). Notably, myeloid immune cells are gaining increasing attention due to their unique function in anti-inflammation, clearing cellular debris and promoting neuronal plasticity (Iadecola and Anrather, 2011; Shichita et al., 2014; Fu et al., 2015; Zhao S. C. et al., 2017; Wang X. et al., 2018).

Myeloid cells are blood cells that arise from a large heterogeneous multipotent stem cell population, the hematopoietic stem cells (HSC) lineage (Kondo et al., 1997; Akashi et al., 2000) which resides in the bone marrow and possess the ability to give rise to diverse cell types in the immune system and the blood, including granulocytes, monocytes, erythrocytes and platelets (Paul et al., 2015). Some myeloid populations can develop directly from yolk sac progenitors without apparent bone marrow intermediates, such as tissue resident macrophages (Kondo et al., 1997; Akashi et al., 2000; Shibata and Suzuki, 2017). Although peripheral monocyte-derived macrophages and microglia can both be developed from the same yolk sac progenitors, they should not be considered as one cellular population in the injured brain (Greenhalgh et al., 2018). After injury, monocyte-derived macrophages can enter the brain and directly communicate with microglia and suppress the microglia-mediated phagocytosis and inflammation after spinal cord injury (Greenhalgh et al., 2018). In the central nervous system (CNS), the main tissue resident macrophages including perivascular macrophages (PVM), meningeal macrophages (MM), and choroid plexus macrophages (CPM) (Henning et al., 2009) and microglia migrate into the CNS during early neural development depending on transcription factor Pu.1 and Irf8 (Hanisch and Kettenmann, 2007; Kierdorf et al., 2013).

In the recent decades, microglia and monocytes/macrophages are intensively studied in the context of cerebral ischemic brain injury (Hu et al., 2012; Garcia-Culebras et al., 2018), with compelling evidence emerging, thus we mainly focused on these cells in this review. After cerebral ischemia, both residential microglia and macrophages can be activated within 24 h and the infiltration of monocyte-derived macrophages and activation of microglia peaks within 3–4 days after stroke onset (Lalancette-Hebert et al., 2007; Gelderblom et al., 2009; Wattananit et al., 2016). Polymorphonuclear neutrophil granulocytes (PMNs) are another myeloid cell population that can infiltrate into the ischemic brain and affect ischemic brain injury (Frijns and Kappelle, 2002). These innate immune cells play important roles in determining the ischemic infarcts. For example, PMNs release matrix metallopeptidase 9 (MMP-9) which degrades the BBB and exacerbates ischemic brain injury (Li et al., 2013a) and tissue-plasminogen activator related hemorrhagic transformation (Mao et al., 2017). Selective microglia elimination disturbed neuronal calcium responses, increased calcium overload and increased the incidence of spreading depolarization, thus significantly increased the infarct size by 60% (Szalay et al., 2016). Depletion of monocyte/macrophages in cerebral ischemic stroke reduced hemorrhagic infarct transformation or reduced brain injury in monocyte/macrophage depleted stroke mice (Gliem et al., 2012; Ma et al., 2016). However, there's also a recent study showed no impact on stroke outcome with monocyte/macrophages depleted (Schmidt et al., 2017).

Recent researches have highlighted that the impact of these myeloid cells on the ischemic brain injury largely depend on different phenotypes at different stages of stroke (Kurisu et al., 2018). As it's well-known that microglia and macrophages can be divided into different phenotypes depending on their functions on the inflammatory responses (Mantovani et al., 2013; Guruswamy and ElAli, 2017). Classically-activated (M1) microglia/macrophages usually secret pro-inflammatory cytokines, such as inducible nitric oxide synthase (iNOS), tumor necrosis factor α (TNFα), interleukin 23 (IL-23), interleukin 1β (IL-1β), interleukin 12 (IL-12) and et al. (Mills et al., 2000; Guruswamy and ElAli, 2017; Li et al., 2017), while alternatively activated (M2) microglia/macrophages are characterized by their production of anti-inflammatory cytokines, such as interleukin 10 (IL-10) and transforming growth factor β (TGF-β) (Gordon and Taylor, 2005; Guruswamy and ElAli, 2017) and they can be polarized with IL-4 via a signal transducer and activator of transcription 6 (STAT6)-dependent pathway (Stein et al., 1992; Gao et al., 2015). Recent studies further identified more specific subpopulation of M2 microglia/macrophages, such as M2a, M2b, M2c, and Mox (Hu et al., 2015). Importantly, the phenotypes and functions of these cells are highly dynamic after ischemic injury (Tsuyama et al., 2018). Likewise, PMNs may also have different phenotypes in different stages after ischemic stroke, a pro-inflammatory so called N1 and an anti-inflammatory N2 phenotype (Fridlender et al., 2009).

However, the terminology of microglial/macrophage polarization was questioned and believed to hinder research progress (Ransohoff, 2016). There are far more phenotypes of microglia/macrophages than M1/M2, such as amyotrophic lateral sclerosis specific microglia (Chiu et al., 2013), phagocytic monocyte-derived macrophages (Yamasaki et al., 2014), immunosuppressive $CD11c^{+}$ microglia and et al. (Kan et al., 2015). There are also cases that microglia/macrophage may concurrently display both pro- and anti-inflammatory phenotypes (Morganti et al., 2016). In addition, transcriptomics and genomic studies reveal that the function of microglia are versatile beyond immune responses, such as synaptic modulation and neurotrophic support (Wes et al., 2016). Single-cell RNA-sequencing gene profiling showed that macrophages in traumatic brain injury are not comprised of distinctly polarized cell subsets, instead, these macrophages are uniquely and broadly activated (Kim et al., 2016). Therefore, it is not rigorous to classify microglia/macrophages imprudently into M1/M2 classifications (Ransohoff, 2016).

Recently, compelling evidence is suggesting the role of the distinct "healing" myeloid cells during the restoration of NVU after stroke, including phagocytosis of damaged neuronal debris, promoting neurogenesis and angiogenesis, re-establishment of the neuronal circuitry, improving white matter repair and et al. during different phases after stroke (**Figure 1**).

In this review, we will summarize the distinct functions of different subsets of myeloid cells during the "repair" of NVU discuss the identified mechanisms underlying their restoration of the NVU after stroke.

DIVERGENT FUNCTIONS OF THE "HEALING" MYELOID CELLS DURING NVU REPAIR AFTER ISCHEMIC STROKE

Phagocytosis of Damaged Tissue Debris After Stroke

By removing necrotic tissues, myeloid cells may accelerate brain repair by enhanced phagocytosis after intracerebral hemorrhage (ICH) (Wan et al., 2016; Fumagalli et al., 2019). Using structured illumination microscopy, a super-resolution technique which helps study phagocytosis, it was shown that myeloid cells were encompassed with potent phagocytic abilities once they infiltrated into the ischemic brain (Fumagalli et al., 2019). There are several different receptors expressed on microglia/macrophages that mediate the phagocytosis of these cells, including class A, class B scavenger receptors, the surface receptor triggering receptor expressed on myeloid cells-2 (TREM2), complement receptors (CRs) (Dustin, 2016), mannose receptors (Galea et al., 2005) and the mer receptor tyrosine kinase (MerTK) (Healy et al., 2016, 2017). In addition, purinergic receptors, such as P2Y12 receptors as key regulators of microglia process extension, also contribute to their responses to brain injury (Kluge et al., 2017; Fukumoto et al., 2018). We will briefly summarize the phagocytic aspects of some recently studied receptors after stroke (**Figure 2**).

The Class A Scavenger Receptors

The class A scavenger receptor includes macrophage scavenger receptor 1(Msr1) and macrophage receptor with collagenous structure (Marco). Msr1 is also known as CD204. Both of these receptors are important for the clearance of DAMPs, including peroxiredoxins, high mobility group box 1 protein and S100 calcium-binding protein A8/9 from the ischemic brain (Milne et al., 2005; Shichita et al., 2017). Msr1 is up-regulated in infiltrating mononuclear phagocytes from day 1 to day 3 after stroke onset and is dependent on the transcription factor Mafb, which plays an important role in the regulation of lineage-specific hematopoiesis (Shichita et al., 2017). Combined Msr1 and Marco deficiency results in sustained inflammation, leading to impaired clearance of DAMPs and ultimately an enlarged infarct volume and exacerbated neurological deficits (Shichita et al., 2017). The expression level of Msr1 helps to distinguish the repairing macrophages from inflammatory ones, since $Msr1^{hi}$ macrophages express less inflammatory cytokines (TNF-α, IL-lβ, and IL- 23) and are instead the major sources of insulin-like growth factor-1(IGF-1), a neurotrophic factor (Shichita et al., 2017).

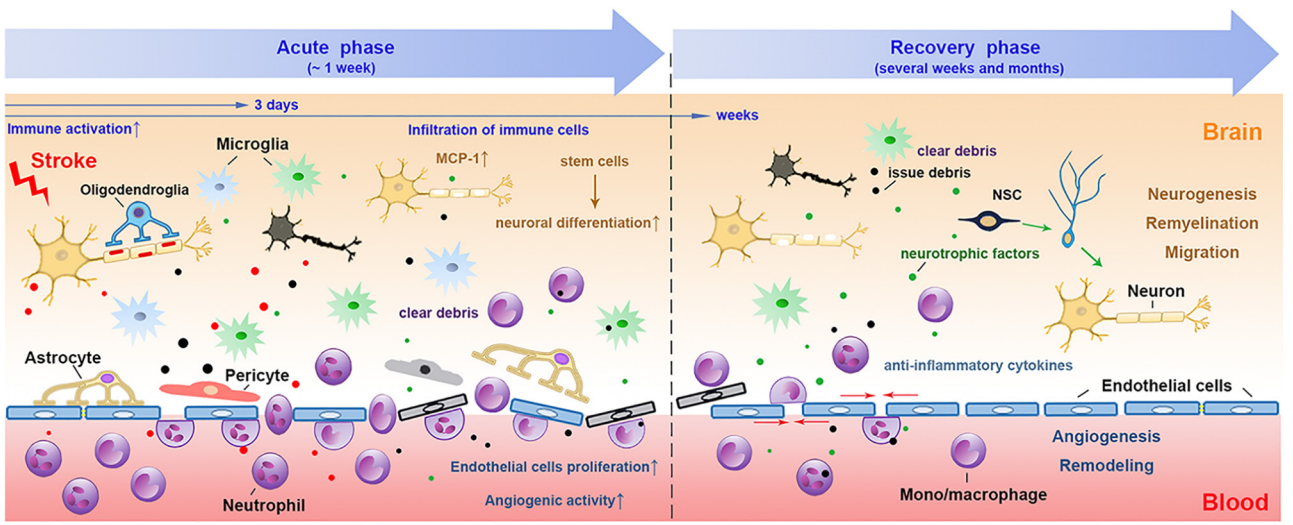

FIGURE 1 | The involvement of myeloid immune cells during the NVU repair after cerebral ischemic stroke. In the acute phase of ischemic stroke, the damaged associated signals from the ischemic brain activate resident and peripheral myeloid immune cells, such as microglia, peripheral mono/macrophages and neutrophils. These cells penetrate into the CNS through the disrupted BBB from 1 day after stroke, peaking at 2–3 days and may last for several weeks. The phagocytic function of myeloid cells enables them to remove tissue debris in both acute and repair stages. During the recovery phase after stroke, myeloid cells with strong plasticity could differentiate into different phenotypes and release several neurovascular nutritional factors, which may enhance neurovascular regeneration and remodeling up to weeks and months after stroke. NVU, neurovascular unit; CNS, central nervous system; BBB, blood brain barrier; NSC, neural stem cells.

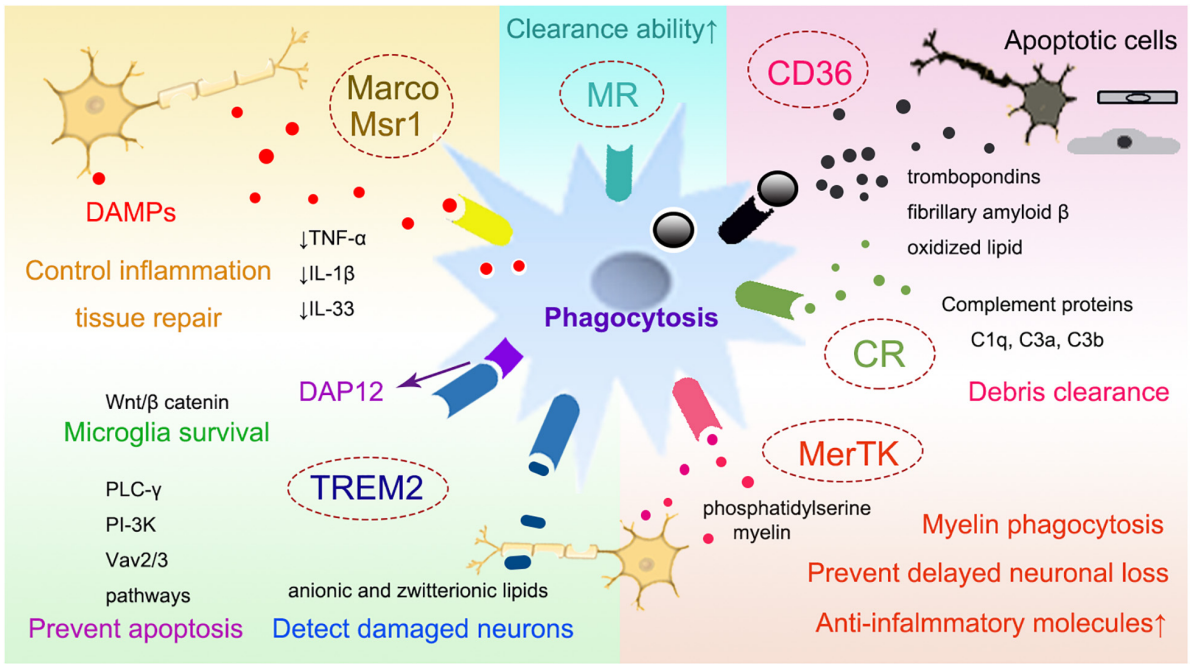

FIGURE 2 | The receptors that mediate phagocytosis of myeloid immune cells. Several receptors have been suggested to mediate the phagocytosis of myeloid cells, such as the class A scavenger receptor Marco and Msr1, the class B scavenger receptor CD36, TREM2, CRs, MRs, and MerTK. Myeloid cells can phagocytose the DAMPs released from damaged neurons with the receptors such as Msr1 and Marco, which subsequently downregulate the neurovascular inflammation and enhance brain repair. Through CD36, myeloid cells can also clear tissue debris from apoptotic cells, thrombospondins, oxidized lipid, et al. TREM2 is important for preventing microglia apoptosis, it also promotes the survival of microglia via the Wnt/β catenin pathway. Complement receptor, such as CR1 and CR3, may bind to apoptotic neuronal cells and contribute to clearing debris and limiting neuroinflammation. MerTK is associated with the myeloid phagocytosis of myelin, neurons and eryptotic erythrocytes, leading to prevent delayed neuronal loss after stroke. CD36, cluster of differentiation 36; TREM2, triggering receptor expressed on myeloid cells 2; CRs, complement receptors; MRs, mannose receptors; MerTK, the mer receptor tyrosine kinase; DAMP, danger associated molecular pattern; Msr1, macrophage scavenger receptor 1; Marco, macrophage receptor with collagenous structure.

The Class B Scavenger Receptor Cluster of Differentiation 36 (CD36)

The class B scavenger receptor CD36, is a highly glycosylated integral membrane protein expressed in microglia and monocytes/macrophages (Cho et al., 2005; Woo et al., 2016). With high affinity toward apoptotic cells and many ligands such as thrombospondins (TSPs), fibrillary amyloid β and oxidized lipids, CD36 has been suggested to play a pivotal role in the clearance of cell debris during the recovery phase in post-stroke brains (Cho et al., 2005; Woo et al., 2016; Stamova et al., 2018). Stroke induces increased mRNA expression of CD36 and TSP-1/2 mRNA levels in the ipsilateral hemisphere both during the acute and recovery phases (Woo et al., 2016). Deletion of CD36 results in poorer outcome due to lack of attenuation of nuclear factor-κB (NF-κB) mediated inflammation and diminished removal of apoptotic neuronal debris (Woo et al., 2012). CD36 deficiency or SS-31, a cell permeable tetra-peptide known to down-regulate CD36 pathway, significantly attenuated monocyte chemoattractant protein 1 (MCP-1), C-C chemokine receptor type 2 (CCR2) mRNA up-regulation and injury size in the transient ischemic stroke (Kim et al., 2015). Increased expression of CD36 expression in monocyte/macrophages has been associated with higher phagocytic indices in the brain immune cells after ischemic stroke (Woo et al., 2016).

The Surface Receptor TREM2

The surface receptor TREM2 is expressed exclusively on myeloid cells, including brain microglia (Hakola, 1972; Nasu et al., 1973). It was first identified as a genetic cause of neurodegenerative disease called Nasu-Hakola disease [or polycystic lipomembranous osteodysplasia with sclerosing leukoencephalopathy (PLOSL)] (Hakola, 1972; Nasu et al., 1973). It is characterized as axonal degeneration and white matter loss, as well as cortical atrophy in clinical patients (Sasaki et al., 2015). TREM2 binds anionic carbohydrates, anionic bacterial products and various phospholipids (Daws et al., 2003; Cannon et al., 2012). It transmits intracellular signals through the associated transmembrane adapter DNAX activation protein of 12 kDa (DAP12), an immune-receptor tyrosine-based activation motif (ITAM)-bearing adapter molecule that transduces activating signals in natural killer (NK) and myeloid cells (Peng et al., 2010). DAP 12 can recruit the protein tyrosine kinase Syk, which phosphorates phosphoinositide phospholipase C-γ (PLC-γ), phosphoinositide 3-kinases (PI3Ks) and Vav2/3 to induce the mobilization of intracellular calcium and the reorganization of actin and prevent apoptosis (Peng et al., 2010). TREM2 also stabilizes β-catenin by inhibiting its degradation via the Akt/GSK3β signaling pathway, thus promotes microglial survival (Zheng et al., 2017). TREM2 expression has been associated

with phagocytic activities of microglia in cerebral ischemia and Alzheimer's disease (AD) (Kawabori et al., 2015; Wu et al., 2017; Kurisu et al., 2018; Wei et al., 2019). Loss of TREM2 results in reduced phagocytosis of a variety of substrates, including apoptotic neurons (Hsieh et al., 2009), amyloid plaques and anionic and zwitterionic lipids on damaged neurons (Wang et al., 2015; Yuan et al., 2016). Using bone marrow chimeric mice, it has been shown that TREM2 on the brain microglia is more essential to post-stroke recovery compared to those on circulating macrophages (Kurisu et al., 2018).

CRs in Myeloid Cells

The complement system is emerging as an important player of cerebral ischemic brain injury. A variety of complement proteins have been shown to be induced after cerebral ischemic stroke, such as C1q, C3a and C3b (Fumagalli et al., 2019). It has been shown that C1q can bind to apoptotic neuronal cells and produce opsonizing C3b and C4b fragments, which are responsible for phagocytosis of apoptotic cells. Furthermore, C1q also binds to IgM, pentraxin-3 and serum amyloid P component during the C1q-mediated removal of apoptotic cells. $C1q^{-/-}$ mice exhibited impaired elimination of immune complexes and were more susceptible to neuroinflammation (Orsini et al., 2014). There are several CRs that have been linked to the phagocytic function of myeloid cells, such as CR1 and CR3 (Dustin, 2016). CR1 is a membrane-bound glycoprotein and is a receptor for C3b and C4b. It has been shown that the expression of CR1 on microglia was increased after lipopolysaccharide (LPS) induction and played a detrimental role in neuronal death after LPS stimulation or in the pathology of AD. However, the role of CR1 in the context of ischemic stroke remains unknown. CR3, also known as CD11b/CD18 or Mac-1(Ma et al., 2019) is a member of the integrin β2 subfamily. It is deeply involved in the innate immune responses and also the induction of phagocytosis by interacting with its ligand iC3b. The phagocytosis mediated by C3b is usually beneficial for clearing debris, apoptotic or necrotic neurons and limiting neuroinflammation after brain injury (Rotshenker, 2003; Fourgeaud and Boulanger, 2007).

Mannose Receptors (MRs)

The MRs, also known as cluster of differentiation 206, CD206, are C-type lectin which can express on microglia/macrophages, dendritic cells and et al. The extracellular region of MRs include an N-terminal cysteine-rich domain that is able to bind sugars with high affinity, such as mannose and fructose, thus scavenging unwanted high mannose N-linked glycoproteins from the circulation (Lee et al., 2002). The expression of MRs has been shown to increase after cerebral ischemic stroke in the phagocytic microglia/macrophages within the ischemic boundary (Giraldi-Guimaraes et al., 2012). Induction of increased MRs expression is believed to enhance the clearance ability of microglia/macrophages and thus provide neuroprotection against ischemic stroke (Giraldi-Guimaraes et al., 2012).

Tyrosine Kinase Receptor, MerTK

MerTK is a member of tyrosine kinase receptor family that plays important role in mediating phagocytosis by myeloid cells. The expression of MerTK is correlated with the myelin phagocytosis of myeloid cells not only in multiple sclerosis (Healy et al., 2016, 2017), but also the phagocytosis of ischemic neurons after cerebral ischemia (Neher et al., 2013). After ischemic stroke, the expression MerTK was transiently upregulated. Inhibition of MerTK may prevent delayed neuronal loss after stroke (Neher et al., 2013). In the model of ICH, loss of MerTK reduced hematoma clearance and exacerbated iron deposition, thus worsened neurological recovery (Chang et al., 2018). Therefore, MerTK is a receptor that is associated the phagocytosis of a variety targets, such as myelin, neurons and erythrocytes.

Collectively, there are multiple phagocytic receptors expressed on myeloid cells that are promising in clearing the debris and promoting brain repair after stroke. However, the roles and the underlying mechanisms of some phagocytic receptors remain largely unknown in the context of cerebral ischemia and thus warrant further investigation.

Anti-inflammatory Effect of Myeloid Cells and Brain Repair After Stroke

Mounting studies have suggested that the alternatively activated or anti-inflammatory phenotype of microglia/macrophages are characterized in their anti-inflammatory effects, with the signature proteins expressed, such as arginase-1, CD206 or macrophage MR, Ym1 and TGF β and IL-10 (Gordon and Taylor, 2005; Hu et al., 2015; Miro-Mur et al., 2016; Ge et al., 2017; Gaceb et al., 2018). Several mechanisms have been suggested to induce the anti-inflammatory effect of microglia and macrophages, such as the activation of chemokine (C-X3-C motif) ligand 1-CX3C chemokine receptor 1 (CX3CL1-CX3CR1) signaling, IL-33/ST2 signaling and IL-4/peroxisome proliferator-activated receptor γ (PPARγ) signaling (Mizuno et al., 2003; Lyons et al., 2009; Liu X. et al., 2016; Yang et al., 2017). High expression of endogenous CX3CL1 in neurons acts as an "on" signal to stop the quiescent state of microglia and leads to a tonic activation of CX3CR1 on microglia and acts as a neuronal "off" signal maintaining microglia in a quiescent state (Biber et al., 2007; Eyo and Wu, 2013). $CX3CR1^{+}Ly6C^{low}$ "patrolling" monocytes may play a role in repair processes in the ischemic brain (Garcia-Bonilla et al., 2016). However, there are also studies showing that $Ly6C^{hi}$ monocytes are protective in acute ischemic stroke by promoting macrophage polarization (Chu et al., 2015). IL-4 was able to induce peroxisome proliferator-activated receptor γ (PPARγ) activation thereby enhanced long-term functional recovery of cerebral ischemic stroke (Zhao et al., 2015). ST2, a member of the IL-1 receptor family, and its ligand interleukin-33(IL-33) play critical roles in immune regulation and inflammatory responses. ST2 deficiency aggravates neurological deficits up to 7 d after transient middle cerebral artery occlusion (Yang et al., 2017). The IL-33/ST2 signaling potentiates the expression of IL-10 and other anti-inflammatory genes in primary microglia and stimulates the production of IL-10 from microglia, which, in turn, enhances neuronal survival after ischemic insult (Yang et al., 2017).

Recent evidence suggests that similar to the concept of classically activated and alternatively activated macrophages, neutrophils also have pro-inflammatory and anti-inflammatory phenotypes, called N1 and N2 phenotypes

(Fridlender et al., 2009; Cuartero et al., 2013). Modulation of PPARγ with rosiglitazone results PMN to shift toward a more pronounced N2-phenotype after stroke (Cuartero et al., 2013). Notably, the anti-inflammatory N2 neutrophils were found to limit excessive immune response, promoting neuronal survival and successful brain remodeling after ischemic stroke and ICH (Hermann et al., 2018). Interleukin-27/lactoferrin is suggested to modulate neutrophil functions toward a "beneficial" phenotype in the treatment of ICH (Zhao X. et al., 2017).

Given the compelling evidence suggesting the association of anti-inflammatory phenotype of these myeloid cells with brain repair after stroke and ICH, the roles and mechanisms of the myeloid cell associated NVU repair remain to be further explored. Furthermore, it was recently demonstrated that lack of myeloid lineage cell autophagy could aggravate the inflammation after cerebral ischemic stroke, suggesting a conflicting role of myeloid cells in the neuroinflammation after stroke (Kotoda et al., 2018). In general, neuroinflammation is a complex and constantly evolving cellular process. However, we need to be cognizant of the fact that we still do not know which aspects of neuroinflammation are beneficial and which are detrimental. It is not by chance that there are no successful anti-inflammatory therapies to treat stroke patients, not least due to the risks surrounding immunosuppression (Smith et al., 2015; Siniscalchi et al., 2016), bringing other side effects like depression (Wium-Andersen et al., 2017).

Promoting Neurogenesis and Angiogenesis

Neurogenesis

Neurogenesis is a key step toward recovery from cerebral ischemic stroke (Sun et al., 2018). It is a natural process that occurs in the adult hippocampus everyday as was shown by a previous study measuring the concentration of nuclear-bomb-test-derived ^{14}C in genomic DNA (Spalding et al., 2013). After stroke, neurogenesis can be induced in the ipsilateral subventricular zone (SVZ) 1 to 2 weeks after the ischemic insult and cell proliferation returns to baseline 6 weeks later (Thored et al., 2006). In addition, stroke also induces neuroblasts to differentiate into neurons (Arvidsson et al., 2002) or to elicit a neurogenic program in striatal astrocytes in mice (Magnusson et al., 2014).

Microglia possess the ability to support neurogenesis after ischemic stroke through pleiotropic mechanisms (Ziv et al., 2006; Kettenmann et al., 2011). During 2, 6 and 16 weeks after middle cerebral artery occlusion, there are more activated microglia migrating from the ipsilateral SVZ to the striatum together with neuroblasts in rats (Thored et al., 2009). These microglia exhibit pro-neurogenic phenotypes with increased expression of IGF-1, which can promote proliferation and differentiation of neural stem cells (NSCs) (Thored et al., 2009) and contribute to neural repair and survival after ischemic injury (Zhu et al., 2009). Removal of proliferating microglia by ganciclovir treatment decreases the level of neurotrophic IGF1, leading to the exacerbation of ischemic neuronal damage and deteriorated stroke outcomes (Lalancette-Hebert et al., 2007). Therefore, microglia are believed to have a predominantly repairing function in promoting the survival of neurons in the resolution phase of ischemic brain injury (Szalay et al., 2016).

Brain-derived neurotrophic factor (BDNF) is another important neurotropic protein that can be produced by microglia after stroke (Cook et al., 2017; Verma et al., 2017). It has been shown to regulate synaptic function and promote multiple learning tasks performance (Coull et al., 2005; Parkhurst et al., 2013). The micro-environment of microglia/macrophage is critical for their pro-neurogenic properties. Microglia activated by IL-4 and interferon γ (IFNγ) promote neurogenesis, while LPS activated microglia block neurogenesis in hippocampal slice cultures (Butovsky et al., 2005; Liu et al., 2013). Modulation the polarization of microglia/macrophages with chronic metformin treatment is associated with enhanced angiogenesis and neurogenesis after cerebral ischemic stroke (Jin et al., 2014). Meningeal macrophage polarization induced by BCG vaccination is helpful for the neurogenesis and spatial cognition (Qi et al., 2017). In the neuron-macrophage co-culture, it has been shown that molecular factors secreted by macrophages can promote neurite outgrowth (Yun et al., 2018).

Angiogenesis and Vascular Remodeling

Remodeling of the cerebral vasculature after cerebral ischemic stroke involves angiogenesis and also the growth of new blood vessels from pre-existing vascular tree, both of which ultimately promotes the re-establishment of the microcirculation and the blood supply to the damaged brain tissue (Lapi and Colantuoni, 2015). Vascular remodeling can last for more than 3 weeks after cerebral ischemia. It has been associated with improved neurological outcome after stroke (Lapi and Colantuoni, 2015). Vascular endothelial growth factor (VEGF) and endothelium-released nitric oxide are important factors in the generation of new vessels and formation of new vasculature during microvascular remodeling (Lapi and Colantuoni, 2015). Monocytes/macrophages can express interleukin-8 (IL-8), VEGF, TGF-β, prostaglandin, and MMP-9, all of which can enhance the angiogenic process after stroke (Sanberg et al., 2010). In addition to secreting angiogenic factors, macrophages can also repair the ruptured vascular mechanically (Liu C. et al., 2016). Using i*n vivo* time-lapse imaging in zebrafish, it has been shown that macrophage arrive at the cerebral vascular rupture lesion and extend their filopodia or lamellipodia to physically adhere to both endothelial ends (Liu C. et al., 2016). Furthermore, these macrophages can promote the ligation and the repair of the rupture by generating mechanical traction forces to pull the endothelial ends (Liu C. et al., 2016; **Figure 3**).

Re-establishment of the Neuronal Circuit by Enhancing Axonal Sprouting and Synaptic Plasticity

To achieve functional recovery after stroke, the newly generated or differentiated neurons need reorganization and rewiring in the ischemic lesion. These remodeling processes are often

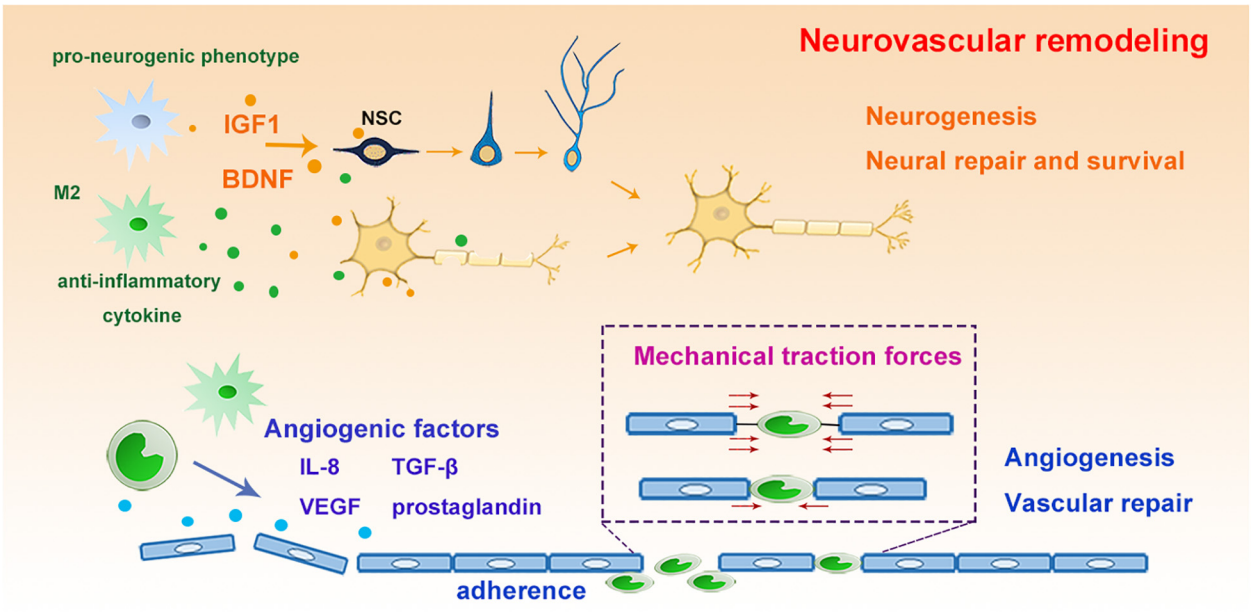

FIGURE 3 | The roles of myeloid cells for neurovascular remodeling. Microglia switch into pro-neurogenic phenotype and anti-inflammatory phenotype with increased release of IGF-1, BDNF and anti-inflammatory cytokines, which promote the proliferation and differentiation of NSCs, leading to enhanced neurogenesis, neural repair and NSC survival and differentiation. Furthermore, myeloid cells express angiogenic factors as IL-8, VEGF et al to promote vascular repair. Moreover, they could generate mechanical traction forces to pull the injured endothelial ends, rebuilding the ligation to enhance repair. IGF, insulin-like growth factor; BDNF, brain derived neurotrophic factor; NSC, neural stem cells; IL-8, interleukin 8; VEGF, vascular endothelial growth factor.

associated with the sprouting of spared axons and modifying the synaptic networks to establish new circuits (Chu et al., 2015). Interestingly, emerging evidence is suggesting that microglia can rapidly modify neuronal activity, modulate synaptic function and promote the integration of NPCs from endogenous neurogenic niches into functional networks after brain injury (Wake et al., 2013; Sandvig et al., 2018). In addition, recent evidence suggests that microglia/macrophages play an important role in the remyelination through protecting oligodendrocytes, augmenting oligodendrogenesis and promoting oligodendrocyte progenitor cell (OPC) differentiation both in stroke and other neurodegenerative diseases (Miron et al., 2013; Moore et al., 2015; Hagemeyer et al., 2017). By regulating the phenotypic switch of microglia with IL-4 or inducing iron-releasing phenotype with noggin, a bone morphogenetic protein (BMP) antagonist, the "healing" capacity toward remyelination of microglia can be significantly enhanced (Shin et al., 2018). Administration of iron-sulfur glutaredoxin 2, the oxidoreductase, inhibits peroxynitrite formation thus reduces the nitric oxide release from activated microglia and protects oligodendrocytes from myelin damage in experimental autoimmune encephalomyelitis (Lepka et al., 2017). Activation of microglia with IL-13 or IL-10 not only induces generation of OPCs from the SVZ after focal demyelination in the corpus callosum (Naruse et al., 2018), but also enhances the survival and differentiation of these cells during CNS remyelination (Miron et al., 2013; **Figure 4**).

POTENTIAL THERAPEUTIC STRATEGIES TARGETING MYELOID CELLS IN THE TREATMENT OF ISCHEMIC STROKE

Bone Marrow Derived Stem Mononuclear Cells Transplantation

Bone-marrow derived mononuclear cells (MNCs) based therapy is gaining increasing attention because of the pleotropic effects in improving neurological recovery after stroke (Brenneman et al., 2010; Vahidy et al., 2016; Yang et al., 2016). Interestingly, with increased expression of IL-10, IL-6, MCP-1, VEGF, and TNF-α, post-stroke MNCs treatment leads to a better recovery on neurological testing and reduces lesion size as compared to pre-stroke MNCs (Yang et al., 2012). In 2016, thirty-nine patients with subacute ischemic cerebral infarct due to large artery occlusion in the middle cerebral artery (MCA) territory were recruited to receive bone marrow mononuclear (BMMN) stem cell transplantation. The study suggests that it is safe to transplant autologous BMMN stem cell intra-arterially in subacute MCA ischemic stroke patients, but unfortunately, no significant improvement of motor, language disturbance, or infarction volume was detected in the stem cell-treated group as compared to the non-treated group within an observation period of 12 months (Deierborg et al., 2010).

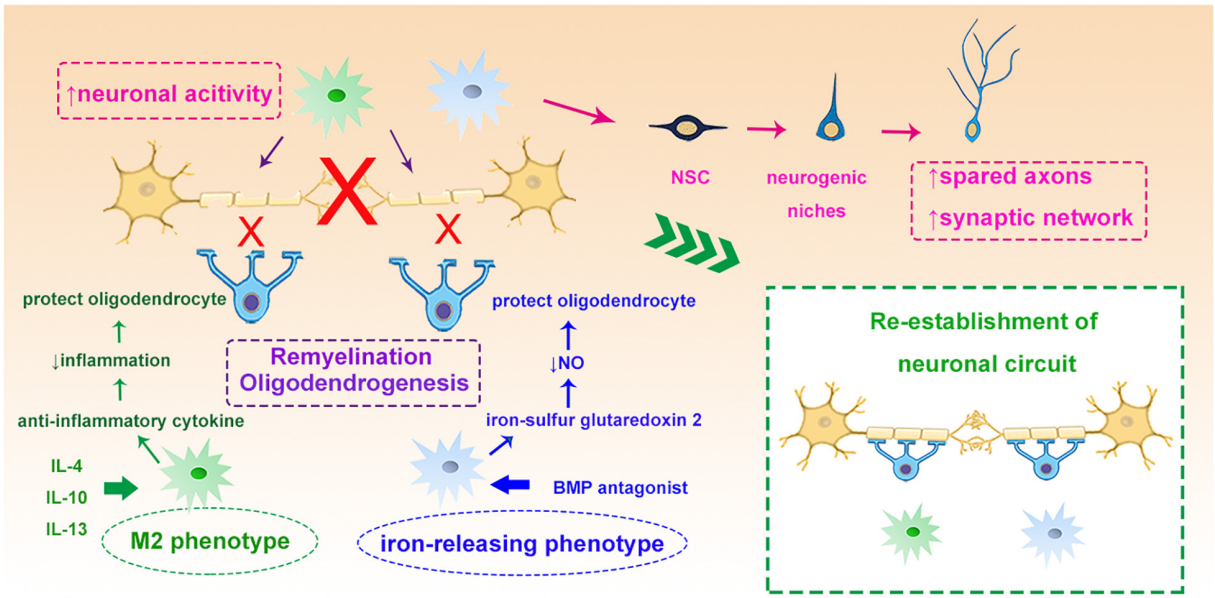

FIGURE 4 | Myeloid cells and neuronal circuit re-establishment. Myeloid cells such as microglia can modify neuronal activity and stimulate the NSCs to sprout axons and rebuild synaptic networks. IL-4 induced M2 myeloid cells and BMP antagonist induced iron-releasing microglia protect oligodendrocytes through different mechanisms, such as enhancing remyelination and oligodendrogenesis, which all contribute to the re-establishment of the neuronal circuit. NSC, neural stem cells; IL-4, interleukin 4; BMP, bone morphogenetic protein.

Adoptive Transfer of Monocytes/Macrophages

It's recently proposed that preconditioned monocytes/macrophages may play an endogenous protective role after ischemic brain injury (Garcia-Bonilla et al., 2018). Depletion of circulating monocytes/macrophages or selective targeting of CCR2 in bone marrow-derived cells exacerbated the BBB disruption and thus caused delayed clinical deterioration and hemorrhagic conversion of the infarctions after stroke (Gliem et al., 2012). On the other hand, transfer of splenic monocytes isolated from preconditioned mice into naive mice 7 h after transient MCAO reduced ischemic brain injury (Garcia-Bonilla et al., 2018). Mechanistically, gene expression and functional studies showed that IL-10, inducible nitric oxide synthase, and CCR2 in monocytes are essential for the neuroprotection (Garcia-Bonilla et al., 2018). Interestingly, a clinical study with 13 stroke patients and 13 case-control stroke patients showed that intrathecal injection of autologous M2 macrophages in stroke patients is safe and may lead to improved neurological recovery (Chernykh et al., 2016). Although the study is still preliminary with a small sample size, it opens up a new direction toward myeloid-cell based stroke therapy to protect the ischemic brain.

Nevertheless, when it comes to immune-cell based therapy, it's always important to consider the condition of the recipients. For example, in our previous study, we found adoptive transfer of regulatory T cells or *in vivo* expansion of regulatory T cells could protect against cerebral ischemic injury (Li et al., 2013b; Zhang et al., 2018) and meanwhile preserve the immune homeostasis after stroke (Li et al., 2013b). However, the immune suppressive regulatory T cells may be attracted to the tumor via the VEGF-neuropilin 1 signaling when the stroke recipient is complicated by cancer (Wang L. et al., 2018). Other critical issues related to immune cell-based therapy include availability or preparation of immune cells, major histocompatibility complex molecules which may initiate immune responses, preservation of purified immune cells and et al., all of which hinder the clinical translation of immune cell-based therapies.

Mitochondrial Dynamic of Myeloid Cells as Therapeutic Target

Mitochondria, a highly dynamic cellular organelle that plays pivotal role in metabolism and apoptosis is also deeply involved in the interplay between cellular metabolism and both innate and adaptive immune responses (Tur et al., 2017). They govern the dependence of cellular metabolism and the coordination of the tricarboxylic acid (TCA) cycle to modulate oxidative phosphorylation rates and adenosine triphosphate (ATP) production, as well as the important intermediates to support other metabolic processes (Tur et al., 2017). Therapeutically restoring mitochondrial function can reprogram inflammatory macrophages into anti-inflammatory cells by regulating cellular metabolic pathways (Van den Bossche et al., 2016). Alternatively activated or naive macrophages predominantly use oxidative phosphorylation for their energy support, whereas the aerobic glycolysis and pentose phosphate pathway can be robustly enhanced in classically activated macrophages (Liu and Ho, 2018), with significantly increased

glucose uptake. Whereas the fatty acids uptake is enhanced to support anti-inflammatory microglia/macrophage polarization and functions (Van den Bossche et al., 2016). As the central regulator of cellular metabolism, mitochondria are emerging as a pivotal therapeutic target to regulate the phenotype polarization of microglia/macrophages (Mehta et al., 2017). After cerebral ischemic stroke, enhanced glycolysis and fatty acid synthesis have been found in peripheral T cells, with increased expression of acetyl-coenzyme A (Wang et al., 2019). Hyper-glycolysis can induce the key glycolytic enzyme hexokinase 2 (HK2), which further results in accumulated acetyl-coenzyme A and subsequent histone acetylation and transcriptional activation of interleukin (IL)-1β and over-activation of the microglia-mediated neuroinflammation after cerebral ischemic stroke (Li et al., 2018a). However, it still should be kept in mind that the phenotypes of microglia/macrophages are far more complicated than pro-inflammatory or anti-inflammatory as we mentioned above. How does the mitochondria function and the metabolic process affect other phenotypes still remains largely unknown.

Immunological Effects of Extracellular Vesicles (EVs) on Ischemic Stroke

Extracellular vesicles (EVs) which can be released by almost all cell types can appear in all body fluids as membrane-surrounded vesicles. There are two distinct types of EV according to their origin: shedding microvesicles apoptotic bodies and exosomes. Because exosomes are able to cross the BBB and the blood-cerebrospinal fluid barrier, it allows crosstalk between the periphery and the brain. On one hand, damaged endothelium releases pro-inflammatory factors and EVs that pass through the compromised BBB after stroke. These EVs can activate microglia and astrocytes to release pro-inflammatory cytokines (TNFα, IL1β) (Zagrean et al., 2018). On the other hand, exosomes are emerging as a powerful diagnostic tool and a promising therapeutic shuttle of natural nanoparticles (Zagrean et al., 2018). It has been suggested that microglia-derived exosomes may contain microRNAs (miR-124-3p) that can inhibit neuronal inflammation and promote neurite outgrowth by transferring into neurons after traumatic brain injury (Ponomarev et al., 2013; Huang et al., 2018).

TABLE 1 | Potential immunotherapeutic targets on myeloid cells for NVU repair after stroke.

Cellular targets	Functions and underlying mechanisms	References
Msr1	Clearance of DAMPs; reduce the expression of inflammatory cytokines	Shichita et al., 2017
CD36	Clearance of cell debris; attenuation of nuclear factor-κB mediated inflammation;	Cho et al., 2005; Woo et al., 2012
TREM2	Promotes microglial survival by inhibiting β-catenin degradation *via* the Akt/GSK3β signaling pathway; phagocytosis apoptotic neurons, amyloid plaques and anionic and zwitterionic lipids on damaged neurons	Hsieh et al., 2009; Wang et al., 2015; Yuan et al., 2016; Zheng et al., 2017
CR1	Induction of phagocytosis by interacting with its ligands; clearing debris, apoptotic or necrotic neurons and limiting neuroinflammation	Rotshenker, 2003; Fourgeaud and Boulanger, 2007

EVs, exosomes, miRNA124-3p	Inhibit neuronal inflammation and promote neurite outgrowth	Ponomarev et al., 2013; Huang et al., 2018

NVU, neurovascular unit; Msr1, macrophage scavenger receptor 1; DAMP, damage associated molecular patterns; CD36, cluster of differentiation 36; TREM2, triggering receptor expressed on myeloid cells-2; CR, complement receptor; MR, mannose receptor; MerTK, mer receptor tyrosine kinase; PPARγ, peroxisome proliferator-activated receptor γ; CX3CL1-CX3CR1, chemokine (C-X3-C motif) ligand 1-CX3C chemokine receptor 1; IL-33, interleukin 33; IL-4, interleukin 4; ICH, intracerebral hemorrhage; IGF-1, insulin-like growth factor-1; NSC, neural stem cell; BDNF, brain-derived neurotrophic factor; IL-8, interleukin 8; VEGF, vascular endothelial growth factor; TGF-β, transforming growth factor β; MMP-9, matrix metallopeptidase 9; EVs, extracellular vesicles.

In addition, intravenous administration of macrophage exosomes can cross the BBB which serve as natural nanocarriers to deliver a cargo protein, the brain derived neurotrophic factor to the injured brain (Yuan et al., 2017). Treatment with exosomes secreted from LPS-stimulated macrophage or MNCs has been shown to reduce brain infarct volume and improve neurological function after focal cerebral ischemic stroke (Altmann et al., 2014; Zheng et al., 2019). In addition, exosomes derived from several different cell types, such as mesenchymal stromal cells, adipose-derived stem cells (ADSCs), embryonic stem cells (ESCs) and neural stem cells (NSCs) (Rufino-Ramos et al., 2017; Cunningham et al., 2018; Webb et al., 2018), and exosomes from these cells have been shown to reduce ischemic volume, promote white matter repair and help neurovascular restoration following ischemia-reperfusion injury (Xin et al., 2013; Otero-Ortega et al., 2017; Jiang et al., 2018; Venkat et al., 2018; Webb et al., 2018). Therefore, it's reasonable to envision that the exosome from the "healing" type of myeloid cells holds the promise to serve as an intriguing therapeutic strategy for future stroke therapy.

CONCLUDING REMARKS AND FUTURE PERSPECTIVES

As highlighted in this review, myeloid cells play an important role in tissue remodeling during the late stage of stroke via pleiotropic mechanisms, such as inhibiting immune inflammation, devouring harmful factors, removing tissue fragments, secreting neurotrophic substances, et al. Scavenger receptors such as Msf1, CD36, TREM2, CRs, MRs and MerTK all contribute to the clearing of necrotic debris and set the stage for NVU remodeling in the repair phase. Several mechanisms are involved in their anti- inflammatory functions to turn into potential protective phenotype through secreting anti-inflammatory cytokines such as IL-10 and TGF-β. With their "healing" effects during neurovascular renewal, myeloid cells are promising to provide novel therapeutic targets (**Table 1**). Meanwhile, myeloid cell-based therapy, such as bone marrow derived myeloid stem cell perfusion, mitochondrial therapy and EVs-based therapy are also gaining increasing attention for the stroke treatment. However, there are myriad unknown areas that warrant further investigation to foster novel therapeutic strategies, such as the complex mix of "help me" signals that initiate the activation and functional switching of myeloid cells, the interactions between the NVU repair processes and myeloid cells and the underlying mechanisms. As our understanding of the role of myeloid cells in the post-stroke NVU repair grows, we may have the potential to design better myeloid cell targeted treatments to improve the neurological outcome of stroke patients.

AUTHOR CONTRIBUTIONS

All authors listed have made a substantial, direct and intellectual contribution to the work, and approved it for publication.

The cerebral microcirculation holds a critical position to match the high metabolic demand by neuronal activity. Functionally, microcirculation is virtually inseparable from other nervous system cells under both physiological and pathological conditions. For successful bench-to-bedside translation of neuroprotection research, the role of microcirculation in acute and chronic neurodegenerative disorders appears to be under-recognized, which may have contributed to clinical trial failures with some neuroprotectants. Increasing data over the last decade suggest that microcirculatory impairments such as endothelial or pericyte dysfunction, morphological irregularities in capillaries or frequent dynamic stalls in blood cell flux resulting in excessive heterogeneity in capillary transit may significantly compromise tissue oxygen availability. We now know that ischemia-induced persistent abnormalities in capillary flow negatively impact restoration of reperfusion after recanalization of occluded cerebral arteries. Similarly, microcirculatory impairments can accompany or even precede neural loss in animal models of several neurodegenerative disorders including Alzheimer's disease. Macrovessels are relatively easy to evaluate with radiological or experimental imaging methods but they cannot faithfully reflect the downstream microcirculatory disturbances, which may be quite heterogeneous across the tissue at microscopic scale and/or happen fast and transiently. The complexity and size of the elements of microcirculation, therefore, require utilization of cutting-edge imaging techniques with high spatiotemporal resolution as well as multidisciplinary team effort to disclose microvascular-neurodegenerative connection and to test treatment approaches to advance the field. Developments in two photon microscopy, ultrafast ultrasound, and optical coherence tomography provide valuable experimental tools to reveal those microscopic events with high resolution. Here, we review the up-to-date advances in understanding of the primary microcirculatory abnormalities that can result in neurodegenerative processes and the combined neurovascular protection approaches that can prevent acute as well as chronic neurodegeneration.

INTRODUCTION

Cerebral microcirculation is a fundamental element for proper cerebral functioning since it is the main transport and distribution system for oxygen and nutrients that fuel the high and continuously changing metabolic demand of the brain tissue. The anatomical and physiological features of small vessels, which mainly consist of vasculature $<100\,\mu m$ in diameter (1), where most of the metabolic exchange takes place, are considerably different from large vessels and these differences make them difficult to study experimentally and virtually inaccessible in human beings. Over the last years, advances in imaging technologies and modeling made such investigations possible and increased the recognition of microcirculatory pathologies in acute and chronic neurodegenerative conditions, revealing novel mechanisms and potential therapeutic strategies. In this review, the structural and functional principles of cerebral microcirculation and its pathophysiological relevance will be discussed.

CAPILLARY DYSFUNCTION

The Complexity of Microcirculation

The brain is a vascular organ as much as it is neuronal. The anatomy of cerebral vasculature is unique and optimized to provide continuous blood supply to the brain. Extensive anastomoses between pial vessels on the surface ensure that extra blood can be shuffled to the activated brain area demanding more energy. As illustrated in **Figure 1**, progressive branching of penetrating arteries into a high-density meshwork of capillaries allows for adequate delivery of nutrients, such that there is a capillary within 10–20 μm of every neuron (4, 5). The density of capillary mesh correlates with neuronal density and differs between cortical layers or brain regions. Unlike simplified illustrations, capillary networks have a complex structure, branching in various directions, forming loops, and curls to optimally match the tissue demand.

Tissue blood flow is provided by the pressure gradient across the microcirculatory bed vascular resistance, which is largely determined by the vascular diameter and blood viscosity (6). The focal brain activity is highly variable; hence, regional metabolic requirements change fast and continuously. This requires a precise spatial and temporal control of the local blood flow. Consequently, flow changes are tightly coupled to neuronal activity through a set of mechanisms integrated within the *neurovascular unit* (7, 8). This *neurovascular coupling* can be mediated by both feed-forward (neuronal activity itself directly regulates blood flow) or feed-back (the metabolic consequences of increased activity regulates blood flow) mechanisms (8, 9).

Studying microcirculation is challenging in animals as well as humans because of the structural and functional complexity of the system. This has caused a delay in understanding role of microcirculatory dysfunction in neurological disorders, which is more relevant than previously thought. The microcirculatory dynamics are fast and heterogeneous, so we need tools that can acquire data with high spatial (in microns) and temporal (in milliseconds) resolution. Most of the available information on capillary flow and oxygenation is based on magnetic resonance imaging (MRI) as well as direct *in vivo* microscopic imaging that can be performed only in animals. Two-photon microscopy (TPM) through a cranial window in rodents provides high resolution angiogram of the capillary network and, red blood cell (RBC) flux and speed estimation within individual capillaries (12–14). Phosphorescence lifetime microscopy (PLIM) adds assessment of the oxygen with subcapillary resolution both in microvasculature and cerebral tissue (2, 15–22). Optical coherence tomography (OCT), which is sensitive to motion of scattering particles enable visualizing RBC flow label-free. Unlike TPM that images a limited area, OCT-angiography allows visualizing hundreds of capillaries simultaneously through the cortical mantle (10, 23–26). In MRI, a voxel of 1 mm^3 reflects merely an average of many capillaries but MRI has the advantage of imaging whole brain non-invasively (27).

Studies with these instruments have revealed that the increase in capillary blood flow occurs slightly before or in synchrony with upstream vessels, suggesting a direct role to the microcirculation to coordinate functional hyperemia response (29–32). Under resting state, most of the oxygen release into the tissue occurs at the precapillary arteriole level, while distal capillaries become an additional a site of oxygen extraction during functional hyperemia (2). Especially during baseline conditions, the capillary pO_2 distribution is highly heterogeneous, some capillaries have very low oxygen, while not necessarily making the tissue around them critically hypoxic but particularly vulnerable to fluctuations in blood flow and/or increase in metabolic demand (2, 16).

Microcirculation Plays an Active Role in Neurovascular Coupling

Models for blood flow simulation and oxygen transport / extraction (34–38) suggest that capillary flow patterns are important to determine tissue oxygen availability (37–39). While cerebral capillaries are normally almost always perfused with plasma during rest and activated conditions, the flow speeds of RBCs, like spatial oxygen distribution, are heterogeneous at baseline. This is caused by variability in capillary diameters, pressure gradients, and non-Newtonian fluid characteristics of blood, resulting in different RBC and plasma fractions in different capillaries that can affect the flow patterns (40) (**Figure 2C**). In a recent study, monitoring of capillaries frame-by-frame by OCT angiography revealed frequent temporary stalls that lasted for few seconds-minutes in individual capillaries (10) (**Figure 2A**). These temporal flow fluctuations can be caused by RBCs or white blood cells (WBCs) getting stuck or slowed down inside capillaries (10, 11, 41) because of their relatively large size compared to the capillary lumen (**Figure 2B**). They are more prevalent in capillaries closer to the distal end of the microcirculation, where pressure gradients are lower and RBCs are slower, and also where endothelial adhesion molecules like intercellular cell adhesion molecule-1 (ICAM-1) have higher expression (42). During functional activation, RBC flow speeds increase to make flow distribution in capillary bed more homogeneous and the dynamic stalls diminish (10) (**Figures 2D,E**). This homogeneous

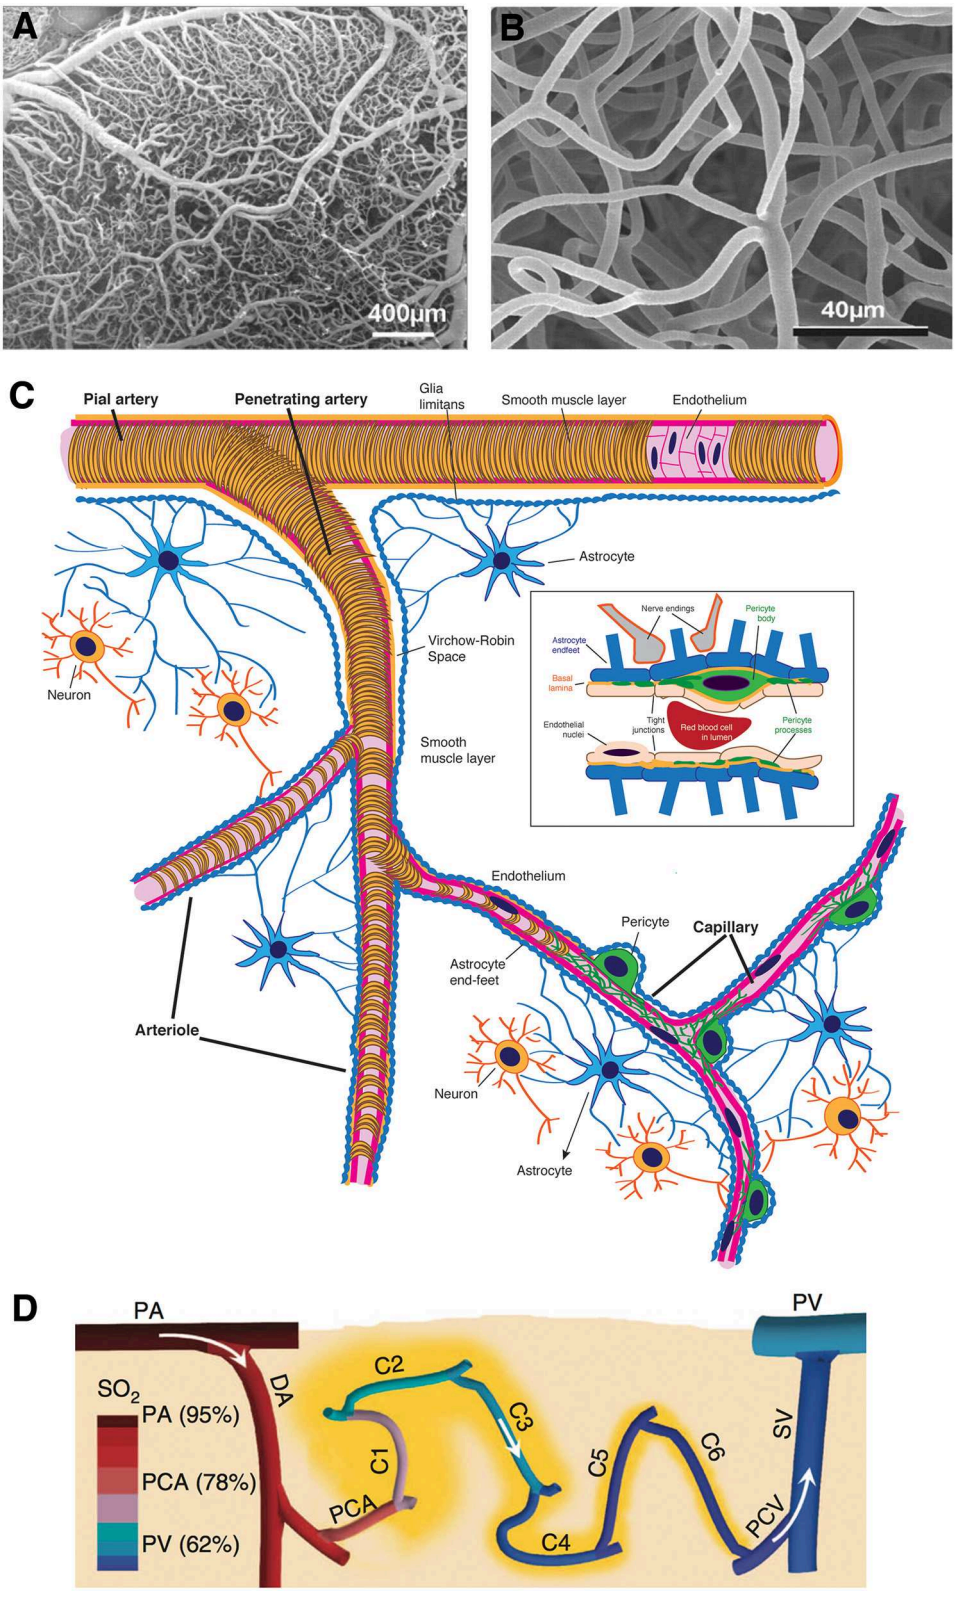

FIGURE 1 | Morphological features of cerebral microcirculation. **(A,B)** Dense external coverage of the surface by pial arteries and veins which are interconnected via anastomoses and collateral vessels then gives rise to a complex meshwork of capillaries, composed of segments about 60–70 μm in length. **(C)** Penetrating arteries

FIGURE 1 | originating from pial vasculature dive into the cortical tissue without forming any further anastomoses. Immediately surrounded by the cerebrospinal fluid-filled spaces called *perivascular spaces* or *Virchow-Robin spaces* along their course, penetrating arteries then give rise an extensive tree of small vessels as they branch into arterioles (30–100 μm diameter), precapillary arterioles (10–30 μm), and capillaries (<10 μm), respectively. As arterioles turn into capillaries, the perivascular space disappears, making the capillary wall adjacent to the parenchyma. **(D)** Capillaries branch out for 5–6 times on average (2) as they release oxygen into the tissue, until they converge on postcapillary venules that drain into ascending veins. transformation in oxygenation and flow speeds is essential for optimum oxygen extraction. Because, in case of heterogeneous flows, some capillaries have higher flow velocity compared to the neighboring vessels and they act as thoroughfare channels, shunting highly-oxygenated RBCs through the microcirculation to leave little time for oxygen release (37). This is important because it has been shown that increasing overall arterial blood flow to a capillary bed with heterogeneous flow distribution can paradoxically worsen oxygen availability to the tissue (38, 43, 44). For this reason, functional blood flow responses in the brain need to be actively regulated at the capillary level and not solely by dilating arterioles. This function is realized by structural and metabolic collaboration between neurons, endothelia, astrocytes and pericytes, the building blocks of the neurovascular unit.

Endothelium is the common inner lining of all types of vasculature, including capillaries. In the central nervous system (CNS) tight junctions between endothelial cells form the critical layer of the blood brain barrier (BBB) that controls material passage into the parenchyma. In the healthy setting, endothelium prevents paracellular plasma leakage by tight junctions and there is a low level of transcytotic vesicle trafficking through endothelial cells (45, 46). Oxygen and carbon dioxide, on the other hand, can freely diffuse across the capillary wall bidirectionally (46–48), allowing rapid gas exchange. The endothelium, basal membrane, and astrocyte end feet together form the capillary wall and the BBB (49). Degradation of BBB either due to basal lamina changes, endothelial or astrocyte damage is a common feature of many neurodegenerative disorders which have microcirculatory pathologies. While there is no smooth muscle layer in the capillary wall, there is another contractile cell, the pericyte located at the periphery of microvessel wall and embedded into the basal membrane layers (50). Pericytes have a contractile apparatus, which is similar to that of smooth muscle cells. Pericyte processes concentrically surround the capillaries, enabling them to regulate the capillary diameter (51, 52). Pericytes have also been shown to contribute to BBB formation and maintenance, to immunological modulation, angiogenesis, and capillary reorganization (53–55). Pericytes therefore are attractive candidates for capillary-level control of neurovascular coupling. Indeed, pericyte relaxation during functional activation has been shown to precede or being closely coincident with functional hyperemia (30, 51). The strong interactions between pericytes and endothelial cells and astrocytes further underline their strategic role in microcirculation (56, 57).

Astrocyte end-feet around microvessels are critical elements for neuron-microvessel communication. Nearby neuronal activity is sensed by astrocyte processes as extracellular adenosine triphosphate (ATP) and glutamate increase around synapses. Calcium signals triggered in astrocytes lead to cyclooxygenase activation and release of vasodilatory prostaglandins from end-feet surrounding the capillaries (58, 59). This is one of the basic mechanisms for translation of neuronal activity to vasoactive regulation. Other mechanisms involving metabolic and paracrine interactions within elements of the tightly integrated neurovascular unit are also present and contribution of each varies between brain regions. For example, astrocyte processes are also metabolically coupled to excitatory synapses; they rapidly breakdown glycogen to release lactate as an energy supply to neurons (60). An intriguing feature of the astrocyte network is the gap junctions between end-feet integrated to the capillary wall. Activity-induced calcium signaling can rapidly propagate around microvasculature to provide a coordinated response in a given area (59, 61–63). Capillary pericytes readily respond to the local release of vasodilatory prostaglandins (30). Endothelial cells, which are electrically coupled to other endothelial cells and to smooth muscle cells via gap junctions (64–67), have also been shown to propagate membrane depolarizations and calcium waves along the vasculature, releasing nitric oxide (NO) in consequence (68), adding to the coordinated microvascular regulation. Interneurons are also directly involved in vasoactive regulation. For example, stimulation of GABAergic interneurons has been shown to produce a biphasic blood flow response, hyperemia, followed by vasoconstriction, similar to the somatosensory activation response, by releasing NO and neuropeptide Y, respectively (69–72). Interestingly, red blood cells within the capillary lumen themselves can also take active role in capillary flow regulation by releasing ATP in response to focal acidosis, hypoxia, shear stress, or mechanical stimuli (73–76). The ATP release can be initiated by opening of pannexin channels or voltage-dependent anion channels in erythrocytes (75, 77). ATP, by binding to purinergic receptors can trigger NO or prostaglandin release from the endothelium (73) generating a local vasodilatory response to match the oxygen demand in the stagnated microenvironment (73).

The mechanisms of neurovascular regulation should be recognized in the setting of an integrated vascular network, where different levels of microcirculation may work in concert in addition to a tight compartmentalization. For example, arterioles appear to favor the vasoactive signals coming from interneurons coding the activity in a larger cohort of neurons in contrast to capillary regulation responding to very focal demand translated by adjacent astrocytes (69, 78). Arterioles also respond to signals coming up through the endothelia to accommodate the blood volume demand by the downstream microcirculatory bed (58, 59, 61–63).

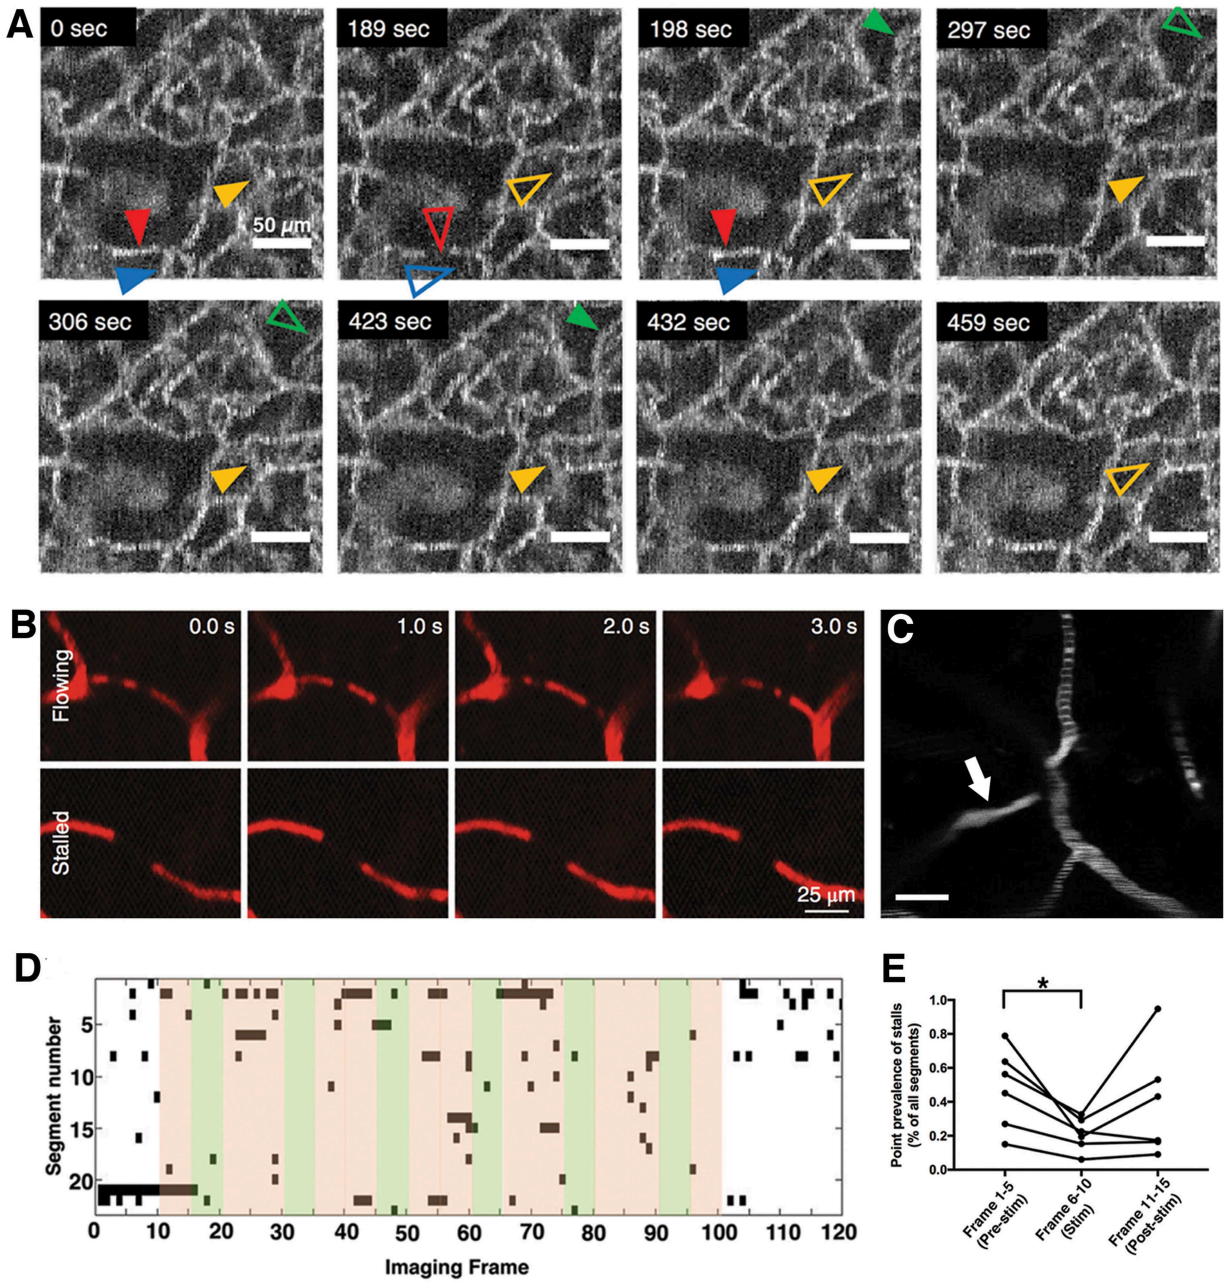

FIGURE 2 | Irregularity and heterogeneity in capillary flow **(A)** OCT angiogram time-series identify capillary segments with stalling red blood cells. Individual segments (arrowheads) with temporary interruptions of RBC flux simply lose OCT angiogram signal. Hollow arrowheads indicate a stalled capillary segment (10). **(B)** Two photon microscopy time series with fluorescent labeled plasma can identify flowing and stalled capillaries based on the motion of unlabeled cells as seen in black (11). **(C)** A single time-point two-photon angiogram of a set of capillary branches at ∼100 μm below cortical surface shows heterogeneous distribution of RBC flux. Segments with higher flow have thinner and denser RBC-bands whereas slower flow is indicated by thicker and more scarce bands. One segment (arrow) has no RBCs flowing but is still filled with fluorescent labeled plasma. Scalebar: 20 μm) **(D)** Matrix plot of individual stall events in a region of interest, acquired during a functional stimulation experiment, with a frame period of 9 s. Every black points denotes a stall in a particular capillary. Green shades indicate whisker stimulation. **(E)** The frequency of capillary stalls is dynamically modulated during functional stimulation; stall prevalence was significantly lower during functional hyperemia. *Statistical significance ($p < 0.05$). Microcirculatory Failure

Since oxygen availability in the tissue relies on the distribution of capillary flow patterns and their heterogeneity, the absolute quantitative level of cerebral blood flow (CBF) may not always reflect accurate supply-demand match at microscopic level. In routine clinical practice of cerebrovascular medicine, main focus

is on the evaluation of adequate arterial flow and luminal patency, as they can be easily imaged by widely available radiological techniques. In the setting of a CBF drop, particularly to ischemic levels (below ∼20 ml/100 g/min in humans) (79), there is a prominent decrease in tissue oxygen tension paralleled by a relative increase in oxygen extraction. However, experimental and computer simulation data indicate that the tissue oxygen availability may be compromised even in the absence of a flow-limiting condition (37, 38). This arises from "capillary dysfunction," causing excessive flow heterogeneity in the capillary bed and failing to homogenize in response to increasing functional demand. This heterogeneity causes certain capillary segments to transit oxygenated RBCs too fast for enough oxygen to be released to tissue (36, 44). A classic example of this phenomenon is the hyperperfusion syndrome (38, 80, 81), a temporary excessive hyperemia after recanalization of an occluded cerebral artery, which paradoxically results in low tissue oxygenation (38). Very slow flux rates in some capillaries may also lead to a reduced oxygen delivery due to insufficient number of RBCs transiting. Any factor introducing irregularity to the capillary flow, results in a higher standard deviation in distribution of RBC velocities and/or transit times across the microvascular bed, i.e., the capillary transit time heterogeneity (CTH). However, it should be noted that increased CTH may passively increase with high mean transit time (MTT), the average time that contrast bolus traverse between arterial and venous ends (43). Importantly, the relative transit time heterogeneity (CTH/MTT), i.e., the coefficient of variation of transit times, can distinguish between true microcirculatory heterogeneity and a passive increase in CTH with low CBF and elevated MTT. The relationship between CBF, CTH, oxygen extraction fraction (OEF), and tissue oxygen can be evaluated with computational models (36, 82, 83). These models show that, CTH is, counter intuitively; homogenized with very low flow rates to maximize O_2 extraction in poorly perfused tissue (37, 82). The detailed evaluation of mathematical models is beyond the scope of this review and the reader is referred to excellent papers on this subject (84, 85). MRI data can be used to prepare MTT, CTH, and OEF maps with use of appropriate mathematical models (27). These tools have been useful for evaluation of capillary dysfunction in acute ischemic stroke and Alzheimer's disease patients (36, 38, 43, 82, 86).

The capillary dysfunction can arise from almost any element within the neurovascular unit. A thin (0.5 μm) glycoprotein coating in the luminal side of the endothelium, called glycocalyx, facilitates passage of blood cells (87–89). Glycocalyx can degrade very fast with excessive inflammatory stimuli like lipopolysaccharides, hyperglycemia, ischemia, and oxidative stress (90). A degraded glycocalyx exposes underlying endothelium to physical interaction with blood cells. This usually results in a higher degree of cellular adhesion. Each cellular plug, whether permanent or transient, can then increase resistance in that particular segment, change pressure gradient, flux, and hematocrit distribution in nearby capillary bed and cause irregular hemodynamics. A relative increase in hematocrit in other capillaries within the same network may increase the tendency for plugging.

Endothelial cell dysfunction can significantly contribute to dysregulated capillary flow. This dysfunction includes a reduction in endothelium-derived nitric oxide availability. Moreover, gap-junction uncoupling between endothelial cells increases functional shunting by introducing irregularities to the microvascular cross-sectional profiles, caused by desynchronized regulation of smooth muscle or pericyte tone (91, 92). A dysfunctional endothelium is also more prone to leukocyte adhesion, as nitric oxide is a well-recognized modulator of leukocyte adhesion (92–94). Leukocyte plugs and resultant flow stalls in capillaries can unfavorably affect flow patterns and, the release of leukocyte-derived oxygen radicals or cytokines can damage the endothelium and overlying glycocalyx. BBB breakdown may accompany a damaged and dysfunctional endothelium. Endothelium, besides these barrier-forming and material exchange functions, is also involved in immunological regulation, leukocyte adhesion and regulation of thrombosis as well as vascular tone (95).

Pericytes maintain the BBB, interact with immune cells (96) and, since they are contractile, regulate capillary flow distribution within the microvascular network. Both constriction or dilation of capillaries mediated by pericytes can result in stalls in cellular flow or functional shunts (32). Pericytes contract or constrict with changes in oxygen tension, with exposure to reactive oxygen radicals, noradrenaline, ATP and endothelin (28, 30, 53, 97), while glutamate, adenosine, lactate, nitric oxide, and C-type natriuretic peptide cause relaxation (30, 97–99). Besides active contractile changes, loss of pericytes themselves can cause capillary dysfunction (100). Amyloid-beta has been shown to cause pericyte degeneration (101, 102), which may be a possible link between neurodegenerative disorders and microcirculatory dysfunction. Hyperglycemia directly causes pericyte death or migration, hence, leaky newly-formed microvessels are typical features of diabetic retinopathy (99, 103). Pericytes have been shown to migrate along or away from vasculature following traumatic injury (104, 105). With pathological stimuli, pericyte process coverage over capillary wall can decrease, further disrupting microvascular physiology (106, 107).

Finally, the physicochemical properties of plasma or blood cells themselves can introduce microcirculatory heterogeneity. As noted above, RBCs and WBCs have large diameters compared to capillaries therefore they need to squeeze through the narrow capillary lumen, significantly making passage challenging and vulnerable to disturbances (108). Even subtle capillary constrictions can therefore dramatically affect RBC perfusion distribution in a capillary network (36, 82). Changes in cell count, size, stiffness, flexibility, and adhesion can affect the capillary transit (8). In experimental models of polycythemia vera and essential thrombocythemia, it has been shown that individual capillaries are clogged by RBCs, and then platelets, affecting the CBF (41). Rheological properties, like deformability of RBCs can affect microcirculatory efficiency as seen in diabetes (109). Blockade of capillaries by activated neutrophils are also observed in cerebral ischemia (110–113). Dehydration and elevated homocysteine can increase plasma viscosity and/or hematocrit, causing formation of RBC aggregates, and capillary plugs (38, 114). It should be noted that plasma may continue to

flow though even when there is no cellular flow in a capillary, unfavorably affecting tissue survival as plasma provides glucose to the hypo-oxygenized tissue, promoting lactate production and tissue acidosis (28, 115–117).

The tissue can tolerate a certain degree of capillary dysfunction by regulating upstream arteriolar flow (either increasing or decreasing) to optimize oxygen extraction (37, 44, 118–120). A reduction in resting CBF and suppression of functional hemodynamic responses can be a part of this compensation (37, 121). But after a certain degree of CTH, usually accompanied by a higher level of capillary diameter irregularities, glycocalyx damage, elevated blood viscosity, leukocyte adhesion, and excessive red blood cell stalls, the supplied oxygen cannot sustain neuronal homeostasis any more (36). At this level of severe capillary dysfunction, where CBF is close to the ischemic threshold, slight changes in metabolic needs, systemic blood pressure, leukocyte count, or blood viscosity may cause appearance of hypoxic/ischemic neurological symptoms (36, 37). These events can also cause irreversible morphological changes in microcirculation, like capillary pruning, or appearance of string capillaries with no functional lumen (122–124). It should be noted that all these pathological events described above could occur in the absence of a flow-limiting condition, like arterial occlusion, or stenosis.

MICROCIRCULATORY DYSFUNCTION IN NEURODEGENERATION

Small Vessel Disease

Small vessel disease is a clinical and imaging phenomenon caused by different etiologies and characterized by pathological changes in vasculature with a diameter $<100\,\mu m$, including, arterioles, venules, and capillaries (1, 125). It is a common cause of cognitive impairment, gait problems and disability in the elderly (125). Uncontrolled hypertension or diabetes are among the leading risk factors for this chronic vasculopathy characterized with concentric smooth muscle thickening, especially in penetrating vessels as well as pericyte degeneration, basal membrane thickening, endothelial, and astrocyte end-feet swelling in capillaries (38, 126–129). Pro-inflammatory conditions in the endothelium increases tendency to leukocyte adhesion and activation in this pathologic setting (130–134). The slowly progressive worsening of microcirculatory structure and function may result in neuronal loss, brain atrophy, and the white matter changes detected as leukoaraiosis or diffuse white matter hyperintensities with MRI (135, 136). While capillary-level damage may insidiously progress over time, acute vascular events, like spontaneous rupture, or thrombosis of already damaged arteriolar branches (137–141), leading to stepwise clinical deterioration (1). It is not surprising that either the chronic progressive vasculopathy or acute ischemic events superimposed on this is a primary cause of microcirculatory dysfunction, the details of which are outlined in the next section.

Ischemic Stroke

Currently, the only approved treatment of an acute ischemic stroke is prompt recanalization within few hours either by mechanical thrombectomy or thrombolysis with intravenous or intra-arterial tissue plasminogen activator. At the present, this treatment approach only takes large vessel recanalization into account. However, tissue reperfusion is usually incomplete, hence oxygen extraction is not optimal even after complete recanalization (38). In the ischemic brain, pericytes contract in response to hypoxia and reactive oxygen species (28). This luminal narrowing and irregularities can easily block cellular passage, while plasma may continue to flow. Recanalization of the artery does not resolve this microvascular dysfunction as the capillary constrictions are sustained, leading to the no-reflow phenomenon (142, 143) (**Figures 3A–E**). The quality of capillary perfusion after recanalization is indeed a better indicator of functional outcome than recanalization itself (144, 145). If the capillary flow patterns are extremely dysfunctional and heterogeneous, the recanalization may in fact introduce more functional shunting, paradoxically reducing the oxygen availability (36, 38, 146).

In the ischemic brain, activated neutrophils can also temporarily plug capillaries with their large size and stiff cytoplasm, and can disturb the RBC transit (108). As a clinical evidence, leukocytosis and a high neutrophil fraction are bad prognostic factors in ischemic stroke (147–150). Stroke incidence as well as stroke-related mortality is higher during acute infections (36, 151). The dynamic microcirculatory dysfunction may continue after stroke onset, potentially contributing to infarct expansion over the subsequent days despite recanalization (152–155). One essential way to prevent infarct growth appears to reverse any capillary flow disturbance in addition to large artery recanalization. It is also becoming clear that the definition of ischemic tissue based solely on the level of CBF decrease is insufficient and the capillary flow patterns must also be taken into account (36).

The ischemia-induced microvascular dysfunction progresses in a graded fashion. With a temporary decrease in perfusion pressure in a normal and compliant microvasculature, the cells transiting the microvasculature slow down, since there is less driving force due to lower pressure gradient. Accordingly, MTT values increase. The CTH calculated based on the standard deviation of transit times in multiple pathways across the capillary bed proportionally increases as well. Thereby, the relative transit heterogeneity (RTH=CTH/MTT) remains unchanged and oxygen delivery to the tissue can still be sufficient to match the demand. However, with ongoing ischemia, structural irregularities, like constrictions, and glycocalyx damage in capillaries emerge, making cellular passage complicated (**Figures 3F–L**). This time, the increase in CTH will be higher than what can be mathematically expected from prolongation of MTTs. The disproportional increase in CTH will yield to higher RTH values, pointing to a specific dysfunction in microcirculation that can result in suboptimal oxygen extraction for the ischemic tissue. The above simplified progressive microcirculatory deterioration is the most likely scenario taking place in the ischemic penumbra, corresponding to a potentially salvageable tissue with timely and efficient recanalization, whereas it can also undergo permanent damage with increasing microvascular damage and oxygenation failure

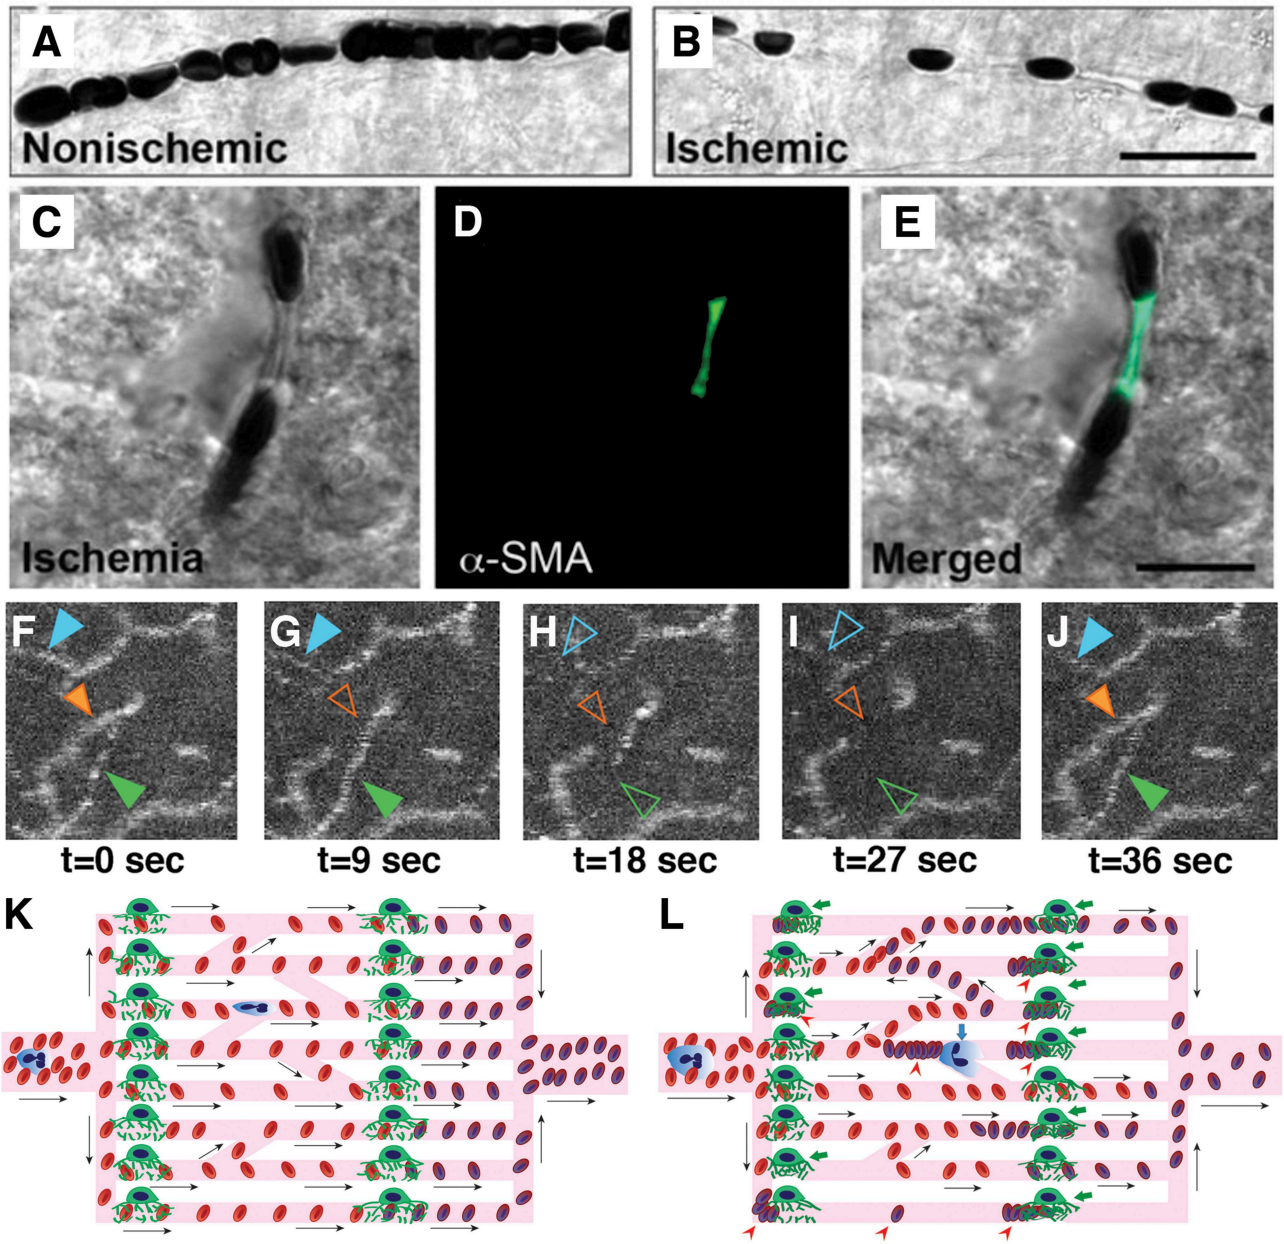

FIGURE 3 | Capillary dysfunction in ischemic stroke and flow-limiting conditions. **(A,B)** Differential interference contrast (DIC) microscopy images illustrate frequent interruptions in the erythrocyte column in an ischemic capillary contrary to a continuous row of erythrocytes flowing through a non-ischemic capillary. Scale bar: 20 μm. **(C–E)** The constricted segments colocalized with α-smooth muscle actin (α-SMA) immunoreactive pericytes. Scale bar: 10 μm. **(F–J)** Very high frequency of dynamic RBC flow stalls in ischemic penumbra shown with OCT angiogram time-series (Manuscript* in preparation). **(K)** Ideally, capillary flow should be homogeneous across a capillary bed to optimize oxygen extraction. Arrows indicate direction of cell motion. **(L)** Pericyte contractions, and increased plugging of leukocytes and red blood cells as a result of ischemia-induced capillary dysfunction, introduce severe heterogeneity into the microcirculation, resulting in redistributions of flow, and pathological shunting. This can profoundly reduce the oxygen delivery into the tissue, even if the total plasma-perfused capillary count and absolute arterial input is the same. Green arrows indicate constricted pericytes, red arrowheads indicate stagnant red blood cells, blue arrow indicates a plugged leukocyte. Deoxygenated RBCs are darker and bluish in color. (82). In the most severe form of ischemia, complete capillary occlusions that do not allow even passage of plasma emerge. This end-stage level of capillary dysfunction, paradoxically leads to homogenization of capillary transit times measured from remaining patent ones in the severely ischemic tissue that is destined to infarct regardless of recanalization (82). This low CTH probably reflects flow in maximally dilated flowing capillaries and does not take into account the occluded ones.

The phrasing may at first sound at odds with the capillary flow homogenization during normal functional hyperemia that provides optimal oxygen extraction (37). Although it may be a similar neurovascular coupling effort for the tissue to optimize blood flow using the capillaries left available (82), the absolute amount of blood passing through the tissue this time is simply very low, decreasing cerebral blood volume below the viability threshold (156).

Chronic cerebral hypoperfusion, even if it doesn't cause full-blown ischemia, can have long-term effects on microcirculatory structure. Experimental OCT data in mice with carotid artery occlusion show a local micro-heterogeneity of capillary flow and oxygen supply even at non-ischemic global blood flow levels (49). The functional changes are accompanied by histological signs of microglia and astrocyte activation along with capillary dilatation, remodeling, increased tortuosity, and even amyloid-beta accumulation (157–159). These structural pathologies can further contribute to the progression of capillary dysfunction. Recently, severity of carotid stenosis have been associated with accumulation of cortical cerebral microinfarcts and poor cognitive performance, even in patients who did not experience acute ischemic stroke (160). Preoperative capillary transit time heterogeneity measured by MRI, an indicator for capillary dysfunction, predicts the functional independency (i.e., Modified Rankin Scale) following endovascular treatment in patients with symptomatic bilateral high-grade carotid stenosis (161).

Subarachnoid Hemorrhage

Subarachnoid hemorrhage shares many common pathophysiological features with cerebral ischemia, because the blood products in cerebrospinal fluid (CSF) can trigger arteriolar and microvascular vasospasms (162). Hemoglobin breakdown products and concomitant formation of reactive oxygen species by iron released from hemoglobin (163) as well as release of vasoconstrictive mediators like endothelin-1 and thromboxane into the CSF may play roles in vasospasm (39, 164). Vasospasms emerge usually a few days after the initial hemorrhage. Like in cerebral ischemia, there is profound increase in capillary transit time heterogeneity after subarachnoid hemorrhage, caused by microarteriolar constrictions (165), reactive oxygen radicals, astrocyte end-feet swelling, leukocyte increase, and activation (39). There are numerous capillaries either without RBCs but with plasma, or with stationary RBCs in them (166). Capillaries with smaller diameters have been shown to have less probability to be perfused with RBCs (167). Because of these disturbances in microcirculation, attempts to relax the vasospasm in large arteries are not very effective. The microcirculatory pathology may begin even before gross vasospasm settles in. Within a few minutes after experimental subarachnoid hemorrhage, there is a heterogeneous slowing down of capillary flow with prominent irregularities, even though there is some dilation in penetrating vessels and precapillary arterioles (168, 169). Dilatory response to CO_2 is lost and an inverse neurovascular coupling response, i.e., constriction instead of expected hyperemia with sensory stimulation is observed 24 h after experimental subarachnoid hemorrhage (170). Whether this flow suppression is an outcome of pathologically high capillary heterogeneity or is a compensatory CBF decrease to optimize oxygen extraction is currently unknown (39).

Traumatic Brain Injury/Chronic Traumatic Encephalopathy

Ischemic injury is a well-known histological hallmark of traumatic contusion injuries (171). A reduction in global CBF almost always accompanies a contusion or traumatic hematoma. If the injury is severe, vasospasms in large vessels can emerge similar to subarachnoid hemorrhage, causing multifocal infarcts. Elevated intracranial pressure due to traumatic injury in animal models caused severely disturbed capillary flow and limited oxygen and solute extraction due to heterogeneity and shunts in the capillary bed (37, 172). This can be partly explained by a direct negative effect of increased intracranial pressure on cerebral perfusion pressure. The decrease in CBF can last for 12 h and functional blood flow responses are usually suppressed during this period (173, 174). Histologically, there is evidence of astrocyte end-feet swelling, pericyte contraction, and increased expression of smooth muscle actin (174). Also, pericytes have been shown to detach from the vessel wall early after the traumatic insult (105), which might contribute to blood-brain dysfunction in capillary bed (175). Capillaries have been shown to be the major site of vascular leakage in animal models after cortical trauma (176). Increased inflammatory protein expression and activation of leukocytes promote cellular adhesion, therefore limiting RBC passage and causing functional capillary stalls and shunts (108, 174). Leukocytosis, like in ischemic stroke, is associated with poor outcome following traumatic brain injury (172).

Interestingly, a gross contusion, hematoma, or intracranial pressure increase is not necessary for microcirculatory abnormalities to develop. A single mild concussion in mice can also decrease CBF 30–40% up to 24 h, as measured with diffuse correlation spectroscopy (177). With repetitive injuries, the oligemic response can extend to 72 h (177). The microcirculatory disturbances induced by mild injuries are independent of increases in intracranial pressure (178). Instead, cortical spreading depolarizations (CSD) multifocally triggered after such insults correlate with neuronal injury and cerebral microbleeds (172). CSDs are self-propagating waves of intense neuroglial depolarization, followed by prolonged suppression of neural activity. Whereas, CSDs associated with migraine aura are benign, repetitive CSDs can cause tissue injury in the setting of subarachnoid hemorrhage or cause infarct expansion during cerebral ischemia, in the form of peri-infarct spreading depolarizations (179–184). In a healthy brain, CSDs can initiate a hyperemic response followed by a long-term oligemia but, in an already ischemic brain, the hyperemia is reversed to oligemia during the depolarization phase (185). CSD waves cause sustained disturbances in capillary flow, causing massive, and heterogeneous changes in erythrocyte velocities (186). Pericytes contract during CSD in response to an increase in cytoplasmic calcium (187). Neurovascular coupling can disappear for hours, causing a supply-demand mismatch, contributing to tissue injury (186, 187). The reduced (inverse)

CBF response to increased metabolic load during massive depolarization could help increase O_2 extraction by slowing flux rates (186).

Repetitive concussions are associated with chronic traumatic encephalopathy (CTE), a cause of early onset dementia and psychiatric disorders especially in boxers or American football players and also in military veterans exposed to blast injuries (188). Autopsy brain samples from CTE patients and also rodent models have evidence of microcirculatory pathology, characterized with swollen astrocytic end-feet and processes forming tangles around capillaries, blood-brain barrier breakdown, and perivascular deposition of hyperphosphorylated tau especially in deep cortical regions (189–192). Even a single blast exposure or concussive cortical impact in mice has been shown to trigger a progressive tauopathy with evidence of microvascular injury and neurodegeneration, which started in the area of exposure first but spread distally over months (193–195).

Alzheimer's Disease

A reduction in CBF is observed early in Alzheimer's disease (AD) patients and this has been proposed as a predictor of progression to overt AD from mild cognitive impairment (196–198). Many vascular risk factors like coronary heart disease, dyslipidemia, hypertension are associated with AD (199). The underlying mechanisms and possible impact of the reduction in CBF and microcirculatory abnormalities in the pathogenesis of neurodegeneration are under investigation to better characterize the cause-effect relationship. In mouse models, impaired cerebral perfusion has been shown to stimulate amyloid-beta deposition. Tau protein can also be hyperphosphorylated under hypoxic conditions, even after brief and temporary episodes (200). After global brain ischemia, expression of tau protein increases in CA1 area of hippocampus in mice, one of the most severely affected areas in AD related to memory functions (201). Interestingly, perivascular zones around penetrating arterioles, the bottlenecks of the cerebral blood supply, are one of the initial areas showing tau and amyloid beta deposition (202).

Electron microscopy has identified capillary wall damage, basal membrane thickening and pericyte degeneration in autopsy brains from AD patients (203). In MRI studies, cognitive performance and level of cortical atrophy were found to be associated with low CBF, high CTH, and low oxygen extraction (86, 204). Similar dynamic abnormalities have also been found in transgenic AD mice, with insufficient flow homogenization, lower resting CBF, and reduced cortical oxygen availability (205).

A recent study using *in vivo* two photon microscopy in transgenic mice with excessive amyloid deposition demonstrated that an increased number of cortical capillaries had stalled blood flow due to neutrophils adhered to vessel wall (11) (**Figures 4A–C**). These stalls have also been found to correlate with amyloid deposition and, targeting neutrophil adhesion improved blood flow and cognitive performance (11). Another longitudinal study tracked obstructed capillaries and identified a VEGF-dependent pruning mechanism with regression of endothelial cells, causing uncompensated capillary loss (206). Perivascular macrophages, in response to amyloid-beta, can release reactive oxygen species that can aggravate microcirculatory dysfunction (207). Mouse models of increased hyperphosphorylated tau expression revealed capillary constrictions surrounded by swollen astrocyte processes (208), formation of abnormal spiraling capillary morphologies with impaired blood cell flux (33) (**Figures 4D,E**).

Transgenic mice with pericyte deficiency have been shown to have impaired capillary perfusion and neurovascular coupling, reduced oxygen supply, blood-brain barrier disruption, white matter degeneration and, importantly, progressive AD-like pathology (including progressive tauopathy and neuronal loss), resulting in accelerated cognitive decline (31, 100, 209–211). A recent study in AD patients showed reduced levels of platelet-derived growth factor-B, a pericyte marker, in precuneus, a cortical area affected in AD (101). We do not know exactly how pericytes degenerate progressively in those conditions, but there are some clues. For example, external introduction or overexpression of amyloid-β can damage pericytes directly (209, 212, 213) and conversely, pericytes can themselves be a zone of production of amyloid-β-associated proteins (214). Hypertension, dyslipidemia, and ApoE4 isoforms, all independent risk factors for AD, can also impair pericyte structure and function, that can potentially initiate a neurodegenerative phenotype (215–220). Pathogenic hyperphosphorylated tau, on the other hand, promotes BBB injury directly (221); the possibility that this injury may be related to pericyte damage, however, remains to be investigated.

Other Chronic Neurodegenerative Diseases

Accumulating evidence suggests that several other progressive neurodegenerative conditions may also involve primary microcirculatory pathologies, Like AD and CTE as discussed above, other tauopathies such as corticobasal degeneration (CBD), progressive supranuclear palsy (PSP) and amyotrophic lateral sclerosis (ALS) exhibit possible microvascular involvement (222).

In Parkinson's disease, both experimental and clinical data suggest microvascular involvement. Capillary loss and abnormal fragmented capillaries or endothelial clusters can be detected in substantia nigra, cerebral cortex and brain stem in pathological brain samples (223). There are also compensatory new vessel formations, which are possibly immature and leaky. In animal models produced by MPTP treatment, decreased capillary density or formation of abnormal endothelial clusters have been reported as observed in autopsy brains (224).

CBD and PSP are two atypical and rapidly progressive forms of parkinsonism. In postmortem brains of CBD and PSP patients, prominent accumulation of hyperphosphorylated tau in close proximity to vasculature, astrocytic proliferation, and hypertrophy as well as reduced capillary diameter have been detected (225, 226). These findings are difficult to test experimentally since there are no established animal models of these conditions. There are transgenic mouse models, however, available for another tauopathy, ALS, with mutations in superoxide-dismutase (SOD1) (227), tar DNA binding protein

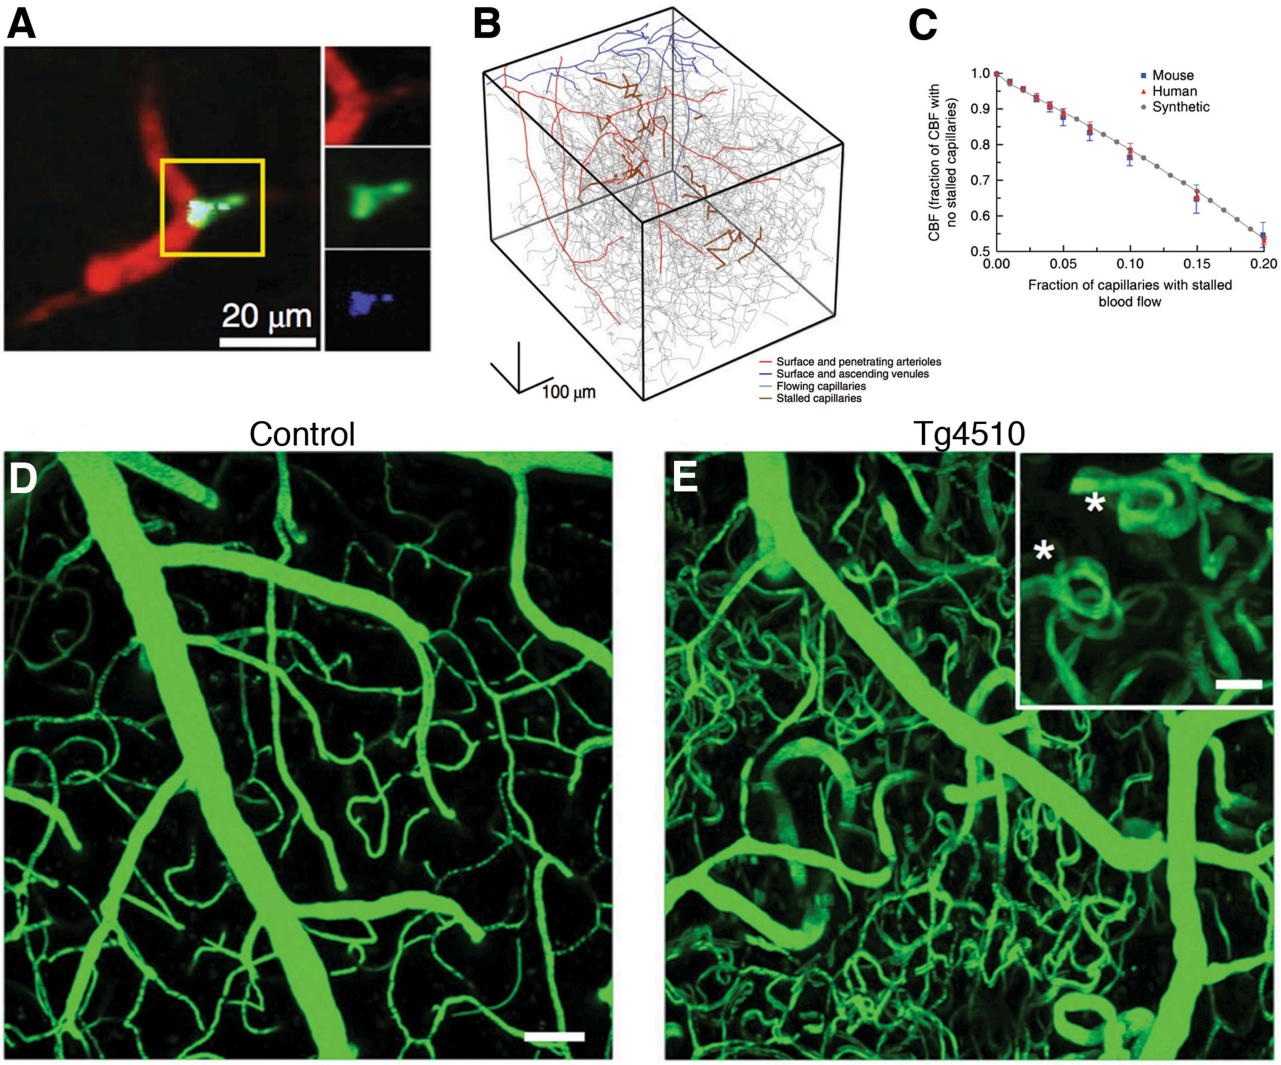

FIGURE 4 | Microcirculatory changes in experimental models of Alzheimer's disease. **(A)** There is increased fraction of stalled capillaries in double-transgenic mice overexpressing amyloid-beta (APP/SW1) due to increased plugging by leukocytes (Green: rhodamine-G labeled leukocyte, red: Texas-red labeled plasma). **(B)** Vascular network tracings show distribution of stalled capillaries. **(C)** Although the fraction of stalled capillaries may seem small, computer simulations on capillary networks show a prominent decrease in overall cerebral blood flow with gradual introduction of stalls. **(D,E)** In another model, 15 month-old mice overexpressing pathological form of hyperphosphorylated tau (Tg4510) show abnormal capillary morphology, number and density (spiral shapes as shown with asterisks(*)). Scale bar 50 μm (inset: 20 μm) There is increased number of stagnant of leukocytes also in these capillaries (not shown here). (TARDBP/TDP43) (228), fused in sarcoma (FUS) (229), or C9orf72 (230) genes. SOD1 mouse model exhibits progressive decrease in the anterior gray matter of the spinal cord, beginning from the presymptomatic stage before neuronal degeneration, and is accompanied by a reduction in capillary diameter and density as well as slowing down of RBC flow (231). The flow-metabolism coupling is also disrupted as glucose utilization in contrast to the oxygen availability is increased especially in early stages. These findings become more profound as the disease progresses (232). At present, there is no reported data on microvascular features of mice with other ALS-related mutations, however, future studies might provide deeper insight. In ALS patients, the cerebral blood flow is decreased especially in the prefrontal cortex (233, 234) and a clinical picture of frontotemporal dementia can accompany ALS (235). In ALS patients, the blood-spinal cord barrier is also damaged and extravasated hemoglobin and hemosiderin deposits can be detected in perivascular areas (236). In ALS transgenic mice, there is data showing capillary pericyte degeneration and blood-spinal cord barrier leakage, which can precede motor neuron degeneration (231, 237).

Finally in epilepsy, a group of disorders characterized with chronic repetitive seizures, progressive neurodegeneration can occur over time and also a single prolonged seizure can

initiate such degeneration (238, 239). This has previously been attributed to glutamate-induced excitotoxicity (240). Since there is usually increased blood flow in seizure foci (241–243), one would not readily suspect from impaired oxygenation as a possible cause of neuronal loss. But as discussed above, capillary dysfunction may occur in the setting of increased cerebral blood flow (38). An elegant study with *in vivo* two-photon microscopy, however, identified individual capillaries with pericyte contractions and accompanying stalls in blood flow in hippocampus of epileptic mice during seizures and those abnormal capillary vasodynamics created an environment with irregular capillary flow and possibly microscopic hypoxia, which was associated with neurodegeneration in close proximity of constricted capillaries (244).

POSSIBLE THERAPEUTIC APPROACHES TO IMPROVE CAPILLARY FLOW AND OXYGENATION

The above-discussed findings strongly suggest that, to slow down or to reverse the acute and chronic neurodegeneration, the microcirculatory structures and dynamics must also be taken into account. Interventions to improve the microcirculation need to have specific targets to homogenize capillary flow and optimize oxygen and glucose extraction that would meet the metabolic needs at all times. These approaches should complement interventions for the macrovessels. Any attempt to increase the cerebral blood flow without correcting microcirculatory disturbances may aggravate heterogeneous shunting and paradoxically worsen oxygen extraction (38).

Reactive Oxygen Species and Pericyte Contraction

Various scavengers can target reactive oxygen species that are responsible for vasospasms as well as capillary pericyte contraction and endothelial dysfunction. One of these, N-tert-Butyl-α-phenylnitrone (PBN), has been shown to improve microcirculation in a mouse model of cerebral ischemia, improving tissue injury and functional outcome (245). Since NO depletion may be contributory to capillary constriction, nitric oxide inhalation as well as nitrite infusion have been suggested to improve microcirculation and tissue oxygenation in various models of neurovascular disorders (246–252). Like nitric oxide, adenosine is involved in active physiological regulation of microvascular diameter and perfusion (58, 253). Adenosine is endogenously released as a metabolic end product of cerebral activity and external adenosine administration increases capillary diameter by relaxing pericytes in both myocardial and cerebral microcirculation, under ischemic conditions (99, 254–256). A major problem with nitric oxide donors and adenosine-based therapies is their systemic side effects, including systemic cardiovascular and respiratory changes (257–260). Novel strategies that allow targeted cerebral delivery of such potent drugs, like squalenoyl adenosine nanoassemblies (99), or nanoparticulated nitric oxide donors (261), and also inhaled nitric oxide that does not have systemic cardiovascular side effects, can be highly useful to promote clinical translation of this pharmacologic potential.

Capillary pericytes constrict in response to adrenergic receptor activation and with endothelin, therefore their antagonists could be considered as potential therapeutic targets (51, 262). Pericyte constriction is calcium-dependent as it involves actin machinery (30). Voltage-gated calcium channel blockers have been shown to decrease pericyte constrictions and also pericyte death, improving capillary transit time homogenization (262, 263). Ca^{+2}-activated chloride channels can also potentiate pericyte depolarization and constriction and can be another target (262, 264). Rho-kinase pathway inhibition can reverse abnormal pericyte contractions (265, 266) and this approach has been found to be neuroprotective in mouse models of cerebral ischemia (267–269).

Glycocalyx Integrity

Shedding of glycocalyx can impair homogeneities in RBC flux and increase endothelial-leukocyte adhesion. Glycocalyx has been protected by anti-thrombin administration in a rat sepsis model and this treatment decreased leukocyte adhesion, improving microcirculatory blood flow in mesentery (270, 271). Avoiding hyperglycemia is also beneficial for glycocalyx integrity (271). Similarly, a hydroxyethyl starch improved lung microcirculation by preventing experimental glycocalyx degradation by heparinase (90). Therefore, restoring glycocalyx integrity can be another potential treatment approach.

Blood Viscosity and Hematology

Since increased leukocyte count, activation, and increase in hematocrit (either due to higher RBC number or dehydration) increase capillary clogging, stalls and heterogeneity, blood viscosity, and endothelial adhesion could be one of the possible targets. Phosphodiesterase inhibitors like pentoxifylline increase RBC flexibility and decrease blood viscosity (272, 273) and they can indeed improve microcirculatory profile while their direct effects on augmenting NO activity might be another contributor to this (274). Prevention of dehydration and concomitant infections could also be beneficial for a regular and optimal capillary flow (38). These two factors are among the most common triggers of delirium and cognitive fluctuations in elderly patients with dementia (275).

Decreasing leukocyte count has been reported to provide a beneficial outcome in animal models of cerebral ischemia (276). A monoclonal antibody against Ly6G surface proteins on neutrophils has improved microcirculation by reversing neutrophil-mediated capillary stalls in mice, increased blood flow and behavioral scores acutely in mice, an effect attributed to modulation of neutrophil adhesion in capillaries (11). The same antibody has been found to be beneficial in mice with subarachnoid hemorrhage (277) and after stroke in hyperlipidemic mice (278). The exact physiological role and endogenous receptor of Ly6G is currently unknown (279) but these experimental data require further investigations.

Other innovative approaches to modulate rheological parameters of blood cells are continuously being developed.

Drag-reducing polymers improved flexibility of RBCs, decreasing cell stasis in capillaries, and plasma separation in capillary branching points, improving capillary flow heterogeneity in cerebral and myocardial ischemia models (280–282). Uptake of plasma-derived extracellular vesicles by RBCs have recently been shown to increase their deformability (283, 284).

CONCLUSION

Our review can help the recognition that many microvascular pathogenetic mechanisms are shared across a variety of acute and chronic neurological conditions and these mechanisms are not simply by-standers but are actually role-players, emerging in very early phases of neurodegenerative conditions. With advancement of optical microscopy, MRI-based imaging tools having higher spatiotemporal resolution as well as computer models, the physiology and vulnerabilities of the microcirculation will be better elucidated. Investigators in the field should not be surprised to see the introduction of previously unknown details, which will eventually lead to much better neuroprotectants for many neurological disorders within the next decades.

AUTHOR CONTRIBUTIONS

ŞE drafted the manuscript and prepared the figures. TD drafted and critically revised the manuscript.

FUNDING

TD work is supported by Turkish Academy of Sciences. ŞE work is supported by Turkish Neurological Society and The Science Academy, Turkey.

ACKNOWLEDGMENTS

The authors would like to thank Dr. David A. Boas (Boston University) and Dr. Sava Sakadzic (Massachusetts General Hospital) for their supervision of ŞE postdoctoral studies and helpful discussions.

Cessation of blood flow leads to a complex cascade of pathophysiological events at the blood-vascular-parenchymal interface which evolves over time and space, and results in damage to neural cells and edema formation. Cerebral ischemic injury evokes a profound and deleterious upregulation in inflammation and triggers multiple cell death pathways, but it also induces a series of the events associated with regenerative responses, including vascular remodeling, angiogenesis, and neurogenesis. Emerging evidence suggests that epigenetic reprograming could play a pivotal role in ongoing post-stroke neurovascular unit (NVU) changes and recovery. This review summarizes current knowledge about post-stroke recovery processes at the NVU, as well as epigenetic mechanisms and modifiers (e.g., DNA methylation, histone modifying enzymes and microRNAs) associated with stroke injury, and NVU repair. It also discusses novel drug targets and therapeutic strategies for enhancing post-stroke recovery.

Keywords: blood brain barrier, neurovascular unit, stroke injury, inflammation, DNA methylation, histone deacetylases, microRNA, non-coding RNA

INTRODUCTION

Stroke is defined as an abrupt onset of focal or global neurological symptoms caused by a blockage of cerebral vessels (ischemic stroke), rupture of blood vessels (hemorrhage), or transient occlusion of small blood vessels (transient ischemic attack). It is particularly prevalent in the aging population, with people over 65 years old accounting for ∼75% of all registered cases (Hollander et al., 2003). Ischemic stroke is further subdivided based on the caliber of occluded vessels into macro- and microvascular (i.e., lacuna stroke), and based on the origin of clot-causing blockage into (a) thrombotic stroke where clot form inside brain blood vessels, and (b) thromboembolic/embolic stroke where clots form elsewhere in the body and travel toward and lodge in brain blood vessels (Reed et al., 2014; Topcuoglu et al., 2018; Tsai et al., 2018).

Pathophysiologically, cessation of blood flow leads to a complex cascade of events at the blood-vascular-parenchymal interface which evolves over time and space, and results in damage to neural

cells and edema formation (Dirnagl et al., 1999; Allen et al., 2012). The central events in the hyperacute phase (within minutes and up to 6 h) include compromised mitochondrial function, anaerobic glycolysis, decreased pH (acid condition), impaired ATP production and reduced ion pump activity. As a consequence, cells swell and die, predominantly due to accumulation of lactic acid, ions (Ca^{2+} and Na^{+}) and increased water influx (Dirnagl et al., 1999; Ginsberg, 2008; Nagy and Nardai, 2017).

There follows a cascade of events in the acute and subacute phase (hours to 7 days), including blood-brain barrier (BBB), and neurovascular unit (NVU) damage characterized by mitochondrial failure, robust production of reactive oxygen species (ROS) (superoxide O_2, hydrogen peroxide, and peroxynitrite), excitotoxicity (release of glutamate from dying neurons), activation of matrix metalloproteinases (MMP2, astrocytes; MMP3, MMP9 endothelial cells and neutrophils), BBB damage triggering inflammation and blood cell infiltration (neutrophils, monocytes) that can lead to further cell death, and cellular and vasogenic edema (Enzmann et al., 2013; Posada-Duque et al., 2014; Sifat et al., 2017). The secondary damage mostly takes place in the penumbra surrounding the core infarct and its progression can extend into the chronic phase after stroke.

Paralleling these injury processes, there is activation of endogenous protective and repair mechanisms that include vascular remodeling, angiogenesis, and neurogenesis (Chopp et al., 2007; Venna et al., 2014). The degree of these ongoing repair processes on one side and persistent inflammation/damaging processes on the other determines stroke recovery and the potential risk of another stroke.

There is mounting evidence on the importance of epigenetic factors in stroke. The purpose of this review is to examine how such factors impact the cerebrovasculature in stroke injury and recovery, focusing on effects at the BBB, and NVU. There is debate over whether non-coding RNAs should be included as an epigenetic mechanism and this review will cover their effects as well as other epigenetic mechanisms.

THE BLOOD-BRAIN BARRIER AND NEUROVASCULAR UNIT IN STROKE

The blood-brain barrier is a highly complex and dynamic barrier, formed by an interdependent network of brain capillary endothelial cells, endowed with barrier properties. The BBB strictly regulates paracellular permeability due to the presence of tight junctions (TJs) between endothelial cells. Those TJs are built by intricate interactions between transmembrane proteins (claudins -5, -3, -1, -12, occludin, and JAM-A), important for paracellular space occlusion, scaffolding proteins (ZO-1, -2), and the actin cytoskeleton vital for physical support and TJ function (Daneman et al., 2010; Stamatovic et al., 2016). The transcellular interactions of claudin-5 play the major role in occluding the paracellular space (Nitta et al., 2003; Ohtsuki et al., 2007). Any loosening of its adhesive interactions directly affects BBB integrity and increases paracellular permeability. The BBB role of other claudins with lower expression is still uncertain and under investigation (Tietz and Engelhardt, 2015; Sladojevic et al., 2019). BBB function is also dependent on the perivascular microenvironment, which contains cells (e.g., pericytes, astrocytes, and perivascular macrophages), neuronal endings and tissue unique extracellular matrix (Mae et al., 2011; Muoio et al., 2014). Because of this functional integration, nearly two decades ago, the concept of a BBB was broadened to a new structure, the NVU.

The neurovascular unit is composed of BBB-endowed endothelial cells and a perivascular milieu composed from cells including pericytes, smooth muscle cells, astrocytes, perivascular macrophages/microglia, neurons/neuronal endings, and extracellular matrix. The NVU mediates neurovascular coupling, modulating vessel tone (Mae et al., 2011; Muoio et al., 2014). These intimately and reciprocally linked cells and matrix generate a complex structure that regulates exchange between blood and brain, oxygen and nutrient delivery, and regional cerebral blood flow. It is essential for maintaining circulatory and brain homeostasis.

In stroke, blood-brain barrier, and neurovascular unit dysfunction actively contributes to injury pathogenesis, being a "solid substrate" for ongoing injuring processes (oxidative stress, inflammation, and cytotoxicity), contributing to ischemic core (infarct) formation in the acute phase of stroke, and facilitating the progression of injury in the subacute and chronic phases. For example, in the early (acute) phase of stroke, NVU dysfunction is characterized by disruption of BBB integrity/BBB breakdown (disassembly of TJ complex, decreases in the TJ proteins claudin-5, occludin, and ZO-1) that leads to vasogenic brain edema, a life-threatening acute stroke complication (Bauer et al., 2010; Zehendner et al., 2011; Sladojevic et al., 2014). The cell components of the NVU undergo a series of transformations during injury. Brain endothelial cells, for example, are affected very early by cytotoxic effects with dysfunction of ion channels and transporters (e.g., Na^{+}-K^{+}-Cl^{-} cotransporter, and Na^{+}/H^{+} exchanger), release of extracellular vesicles and conversion of brain endothelial cells toward a proinflammatory and prothrombotic phenotype due to upregulation of protease-activated receptor 1 (PAR-1), tissue factor, and matrix metalloproteinases (MMPs) (Zhu et al., 2008; Bauer et al., 2010; Yamashita and Abe, 2011; Chen et al., 2015). The proinflammatory phenotype of brain endothelial cells involves an upregulation of endothelial adhesive molecules (ICAM-1, VCAM-1, P-, and E- selectins) that guide leukocyte infiltration in the acute inflammatory phase response and T and B cells infiltration in the late phase (Kleinschnitz et al., 2013; Zhou et al., 2013; Sladojevic et al., 2014). Overall, inflammation is thought to worsen acute ischemic injury, contributing to chronic focal inflammation and restricting functional recovery. However, inflammation is also involved in tissue repair.

In the hyperacute phase after stroke, pericytes may be involved in vasoconstriction, causing capillary occlusion (no-reflow phenomenon), while later, by switching to pro-inflammatory phenotype, they may enhance BBB permeability, and brain edema formation (Hall et al., 2014; Underly et al., 2017). Ischemia triggers a series of damaging reactions in astrocytes including mitochondrial dysfunction, energy depletion, ion

disequilibrium, increased glutamate and Ca^{2+}, aquaporin 4 (AQP4) channel activation, increased water permeability, and cell swelling (Friedman et al., 2009; Ito et al., 2009; Hertz et al., 2014; Mogoanta et al., 2014). It results in the release of oxidative stress products and inflammatory cytokines/chemokines (IL1, IL6, IL15, CCL2, CXCL1, CXCL10, CXCL12, and IP-10), proinflammatory associated small molecules [S100 Ca^{2+}-binding protein B (S100B) and nitric oxide (NO)] that enhance the inflammatory post-stroke response (Yamashita et al., 2000; Hill et al., 2004; Mori et al., 2008; Shin et al., 2014; Liu H. et al., 2015; Chen et al., 2018).

Perivascular macrophages and microglia play an important role in the stroke-induced inflammatory response via production of proinflammatory cytokines (IL1|*upbeta* TNFα IL6, IL12) and ROS (Drake et al., 2011; Liu H. et al., 2015; Wu et al., 2016; He et al., 2019). They trigger the first line of inflammation at the NVU in the acute phase of stroke. Notable changes also occur in the extracellular matrix. At early time points (within hours), there is MMP-related basement membrane degradation with reductions in agrin, SPARC, perlecan, laminin, and fibronectin (Sole et al., 2004; Castellanos et al., 2007; Lee et al., 2011; Ji and Tsirka, 2012; Lloyd-Burton et al., 2013). This ultimately leads to increased BBB disruption, accumulation of new extracellular matrix proteins (i.e., chondroitin sulfate proteoglycan neurocan and osteopontin) and leakage of plasma proteins, such as fibrinogen, into the CNS. This mediates inflammation, edema, and potentially hemorrhagic transformation (**Figure 1**).

THE BLOOD-BRAIN BARRIER AND NEUROVASCULAR UNIT IN STROKE RECOVERY

In post-stroke conditions, the NVU has the ability and capacity for remodeling, and this is becoming a very important therapeutic target for enhancing stroke recovery. Remodeling involves complex and tightly tuned interactions between neurons, glial and brain endothelial cells, recruitment of endothelial and neural progenitor cells, and inflammatory blood cells (monocytes, T and B lymphocytes), governing new blood vessel formation, glial cell remodeling of extracellular matrix, for augmented improvement of the NVU, and neurological recovery.

Blood-brain barrier recovery involves *de novo* synthesis of junctional proteins and reestablishing barrier integrity to reduce further brain damage. It is important to highlight that BBB recovery is limited and complete pre-stroke impermeability is difficult to achieve. Ongoing angiogenic processes, as well as defects in the structural repair (e.g., imbalance in the synthesis of claudins essential for TJ function) play a role in the prolonged BBB leakiness days after stroke (Yang Y. et al., 2015; Xu H. et al., 2017; Sladojevic et al., 2019). Whether there are benefits of BBB post-stroke leakage is still a controversial issue. From the perspective of stroke treatment, it may facilitate brain drug delivery. However, it may allow uncontrolled entry of blood components into brain fueling inflammation.

In neurovascular unit remodeling after stroke, cellular elements have important roles in recovery. Pericytes are a

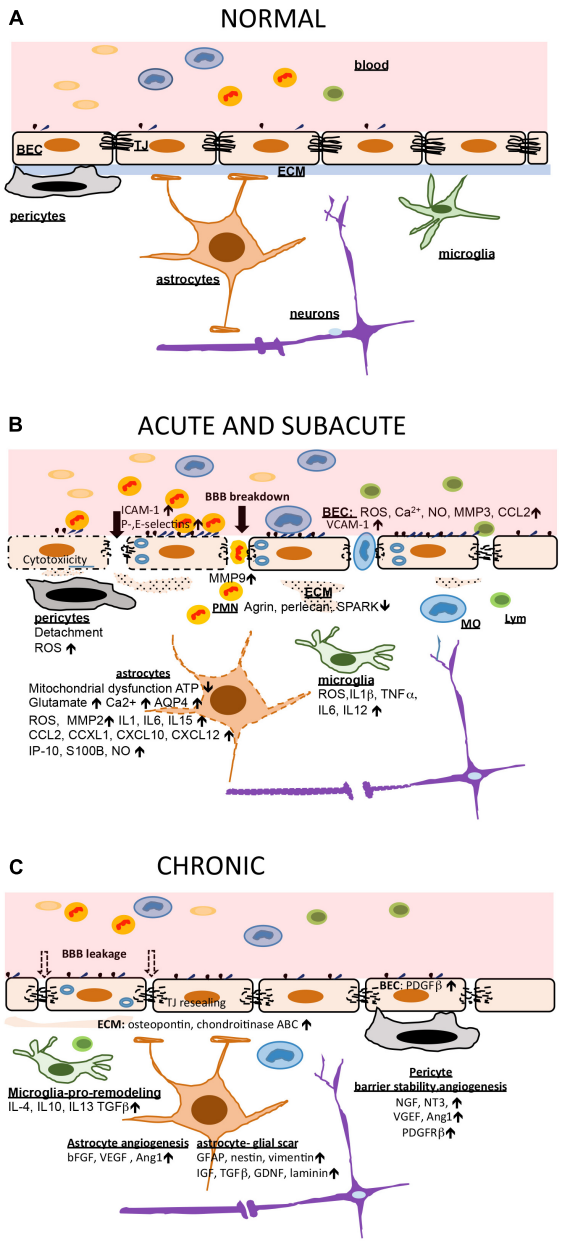

FIGURE 1 | Blood brain barrier (BBB) and neurovascular unit (NVU) in ischemic injury and post-stroke recovery. **(A)** In healthy conditions, the BBB is intact and other NVU components, including the extracellular matrix (ECM), support and preserve brain homeostasis. **(B)** Cessation of blood flow triggers a chain reaction at the BBB and NVU. The early events are mostly characterized by cytotoxicity, mitochondrial dysfunction and accumulation of ROS which further cause BBB breakdown (tight junction, TJ, disruption), neuronal injury guided by astrocytes, and triggering an acute inflammatory response. Brain endothelial cells (BEC) increase adhesion receptor expression allowing leukocyte (predominantly polymorphonuclear neutrophils; PMNs) entry which adds to BBB injury. Microglia and astrocytes produced large amount of proinflammatory cytokines and chemokines amplifying inflammation. Early pericyte detachment support BBB instability and breakdown. This support vasogenic brain edema formation. **(C)** The subacute and chronic phase of stroke is characterized by increased second wave of inflammation with monocyte (MO) and lymphocyte (Lym) entry but also

(Continued)

FIGURE 1 | Continued
ongoing repair processes (BBB recovery and angiogenesis). Microglia become source of anti-inflammatory cytokines and have a role in phagocytosing dead cells. Astrocytes are a source of growth factors supporting angiogenesis, and also source of extracellular matrix building a gliotic scar. Pericytes establish interactions with BEC, supporting barrier stabilization and new vessel formation. The BBB, with new TJ protein synthesis, undergo partial sealing.

source of neurotrophins and have a role in stabilizing the BBB and protecting brain parenchyma from leukocyte infiltration (Shimizu et al., 2012; Yang et al., 2017). They also promote angiogenesis and neurogenesis. Astrocytes undergo structural and functional transformation (reactive gliosis), manifested as increased expression of the intermediate filament protein glial fibrillary acidic protein (GFAP), cell proliferation, and synthesis of extracellular matrix to form the glial scar and demarcate the infarct necrotic core. Higher production of GFAP, nestin and vimentin in NVU negatively affect cell-cell communication at NVU during the subacute and chronic phase of stroke, while production of insulin-like growth factor, transforming growth factor β (TGFβ), and other growth factors as well as laminin by astrocytes enhance NVU recovery processes (Cekanaviciute et al., 2014; Yao et al., 2014; Okoreeh et al., 2017). During post-stroke NVU recovery, microglia transform to a M2 pro-remodeling phenotype, releasing anti-inflammatory cytokines (e.g., IL10) and growth factors. They switch astrocytes to anti-inflammatory phenotype, supporting clean-up phagocytosis, diminishing leukocyte-endothelial cells interaction, decreasing expression and activation of cytokine receptors, promoting NO-induced vasodilatation, and reducing ROS production and oxidative stress by inhibiting NADPH oxidase (Weston et al., 2013; Brifault et al., 2015; Yang Y. et al., 2015).

The extracellular matrix also plays an important role in NVU remodeling and stroke recovery. Interaction between the matrix and its receptors on NVU cells regulate cell survival, migration and focal bioavailability of growth factors essential for repair processes, including angiogenesis and neurogenesis. For example, while osteopontin is normally produced in development, its activity post-stroke, via αvβ3 receptors on astrocytes, promotes astrocyte migration and glial scar formation (Ellison et al., 1999; Suzuki et al., 2010). On the other hand, fibrinogen shifts its mechanism of action from the αvβ3 receptor to regulating transforming growth factor -β on astrocytes promoting reactive astrocytosis (Schachtrup et al., 2010; Beck and Schachtrup, 2012). Synthesis and upregulation of new extracellular matrix components like chondroitinase ABC may rescue the "injury type" of extracellular matrix by degrading proteoglycans (neurocan) that affect neuronal growth to further enhance the recovery processes (Hill et al., 2012; Chen et al., 2014; **Figure 1**).

Overall, targeting the NVU in stroke may have long lasting effects by preventing tissue damage in the early hours after stroke and enhancing ongoing recovery processes chronically after stroke. It is, however, very important to highlight that the functional response of NVU cells to stroke as well as the degree of recovery post-stroke will depend on the functional status of the NVU before the stroke which is affected by many co-morbidities (e.g., age, diabetes and hypertension).

EPIGENETIC REGULATION OF BBB AND NVU RECOVERY AFTER STROKE

An overview of decades of stroke research and a variety of identified targets, has unfortunately highlighted that current therapeutic approaches to limit ischemic brain injury have almost all failed, the exception being reperfusion. In recent years, approaches have started to shift toward preventing injury progression and enhancing repair and regeneration after stroke. Targets include inflammation and injury progression, neuronal repair to prevent ischemic cell-death and cerebrovascular remodeling that may prevent further injury progression. The NVU has a focal position in these new approaches to treat stroke.

How to approach treatment of stroke recovery when many conventional approaches (e.g., anti-oxidative, anti-inflammatory) have failed? It has to be taken into consideration that the recovery process is complex and tightly regulated. Many genes are involved in the temporal and spatial regulation of restoration of function with a high degree of individual variation that may depend upon multiple factors. An emerging field, epigenetics, holds promise for a better understanding of what regulates recovery after stroke and the potential success of modulating that process.

Epigenetics is defined as the interaction between environmental factors and the genome that may be heritable and modified gene expression or phenotype without changes in DNA sequences (Hendrich and Willard, 1995). Epigenetic mechanisms (e.g., DNA methylation, post-translational modification of histones) provide an additional level of tight control at the transcriptional level that differentially modifies gene expression and protein activity. In addition, cells possess a powerful machinery in non-coding RNAs, particularly microRNAs (miRs), that regulates gene expression at the post-transcriptional level. Coordinate and cooperative activity of epigenetics factors and miRs form circuits that regulate gene expression profiles and support cell function. Considering the far-reaching effects of epigenetics and miRs on gene regulation, these factors may have a key role in regulating plasticity during repair after stroke and be a key target for enhancing NVU recovery. In this review, we highlight some of the mechanisms that take place at the NVU and are involved in epigenetic and miRs remodeling of the NVU in stroke.

DNA METHYLATION

DNA methylation is an epigenetic mechanism characterized by covalent addition of methyl (CH_3) group to DNA that modifies gene function and expression. The best characterized methylation process occurs on the 5-carbon of the cytosine ring resulting in 5-methylcytosine (5-mC). 5-mC is found exclusively as paired

symmetrical methylation of a CpG site where cytosine nucleotide is located next to a guanidine nucleotide (Zeng and Chen, 2019). In genomic DNA, most CpG sites are methylated while CpG islands (clusters) located in proximity to promoter regions endure unmethylated allowing the regulation of gene expression, transcriptional repression (Bird, 1986). DNA methylation occurs via a family of enzymes, the DNA methyltransferases (DNMTs). Five types of DNA methyltransferases have been described: DNMT1- maintains existing methylation patterns following DNA replication, DNMT2 -which can act as a nuclear as well tRNA methytransferase, DNMT3a and DNMT3b responsible for establishing *de novo* methylation patterns and DNMT3L which does not mediate methylation but interacts with histone deacetylase 1 (HDAC1) (Hsieh, 1999; Aapola et al., 2002; Goll and Bestor, 2005; Goll et al., 2006; Ren et al., 2018). It is also important to highlight that DNMT may regulate the expression of certain miRs by direct methylation of miR promoter regions, adding additional layer of DNMT activity at the post-transcriptional level via miRs (Dakhlallah et al., 2013; Nicholson et al., 2017).

Early research investigating epigenetic changes following middle cerebral artery occlusion (MCAO) in mice demonstrated upregulated global DNA methylation within the brain, and genetic or pharmacologic DNMT inhibition decreased stroke severity (Endres et al., 2000). Within the NVU, altered DNA methylation is associated with both BBB injury and recovery, suggesting a biphasic pattern of post-stroke DNA methylation. Mouse MCAO leads to hypermethylation of the tissue inhibitor of metalloproteinase 2 (TIMP2) promoter. The resulting decrease in TIMP2 expression is associated with increased matrix metalloproteinase 9 (MMP9) activity and BBB hyperpermeability, with DNMT inhibition rescuing BBB permeability (Mondal et al., 2019). However, increased DNMT activity post-stroke is also implicated in angiogenesis. Oxygen-glucose deprivation (OGD) in cerebral endothelial cells promotes hypermethylation of the thrombospondin-1 promoter. As thrombospondin-1 inhibits angiogenesis, such promoter hypermethylation suggests DNMT activity promotes post-stroke angiogenesis (Hu et al., 2006). While research investigating post-stroke DNMT activity within the NVU is limited, current studies suggest a dual role of DNMTs within the NVU. An intriguing recent clinical study by Baccarelli et al. (2010) found that blood DNA hypomethylation was associated with a high risk stroke occurrence and total mortality, suggesting that DNMT activity could be a potential biomarker in post-stroke recovery.

To fully delineate the effects of post-stroke DNMT activity, future research must investigate: (1) specific genes with altered methylation patterns, and (2) the pattern of DNA methylation over time. As post-stroke DNMT activity is implicated in both BBB injury and recovery, investigating post-stroke methylation temporal patterns will begin to elucidate the complex roles of DNMTs in ischemic stroke.

HISTONE MODIFICATIONS

DNA wraps around histones forming nucleosomes and creating organized chromatin. Histones are octameric proteins containing modifiable N-terminal residues and post-translational histone modifications alter chromatin accessibility, leading to either transcriptional activation or repression. One well-characterized histone modification is the addition or removal of an acetyl group to lysine residues. Generally, histone acetyltransferases (HATs) add acetyl groups to lysine residues allowing transcription, as the acetyl group disrupts the interaction between the histone residue and DNA. Histone deacetylases (HDACs) remove acetyl groups, leading to transcriptional repression. Ultimately, a balance between HAT and HDAC activity regulates histone acetylation (Narlikar et al., 2002; Li et al., 2007; Kassis et al., 2017). Another form of histone modification is methylation. Methyl group are added on histone N terminal tails at either lysine or arginine residues (Klose and Zhang, 2007). The combination of methylation/demethylation pattern and interplay between lysine or arginine methylases and demethytransferases governs the transcriptional activation/repression of certain genes (Klose and Zhang, 2007; Migliori et al., 2010).

The HDAC superfamily consists of 18 different subtypes in four different classes. Expression of different HDACs within the brain varies by cell type, and mouse MCAO alters HDAC expression in a cell-specific manner (Baltan et al., 2011). Within the NVU, ischemic stroke upregulates astrocytic expression of HDAC2 and HDAC8 (Baltan et al., 2011; Demyanenko et al., 2018). Interestingly, ischemic stroke prominently upregulates HDAC2 in astrocytic processes and end-feet, suggesting HDAC2 affects the NVU post-stroke (Baltan et al., 2011). Current research has demonstrated that increased HDAC expression leads to BBB injury, as HDAC inhibition rescues BBB permeability observed in rodent models of ischemic stroke, including those with increased stroke severity (Park and Sohrabji, 2016; Shi et al., 2016). OGD upregulates endothelial HDAC9 expression and is associated with decreased expression of TJ proteins, such as ZO-1, claudin-5, and occludin. Genetically targeting HDAC9 pre-OGD rescues altered TJ protein expression in endothelial cells (Shi et al., 2016). Other studies indicate post-stroke HDAC expression induces inflammation and oxidative injury. Although contextualized within post-stroke neuroprotection, these studies potentially indicate a mechanism through which altered HDAC expression contributes to barrier injury as well (Wang et al., 2012; Patnala et al., 2017). HDAC inhibitors show a variety of effects after stroke. Valproic acid and sodium butyrate (class I, IIa and III inhibitor) repressed the nuclear translocation of NFκB subunit p65, mitigate MMP9 activity and restore the BBB integrity after stroke by regulating the expression of tight junction proteins, claudin-5, and ZO-1 (Wang et al., 2011; Park and Sohrabji, 2016). Non-specific HDAC inhibition also switches the pro-inflammatory microglial response to anti-inflammatory (Patnala et al., 2017). Likewise, pre-OGD HDAC inhibition promotes anti-oxidative enzyme expression in macrophages in a histone-independent manner (Wang et al., 2012).

While most studies focus on enzyme-mediated changes in histone acetylation, another mechanism through which histone acetylation may be altered in ischemic stroke is through histone eviction. Exposing endothelial cells to hypoxic conditions results in histone eviction from specific promoter regions, such as the eNOS promoter, and replacement with hypoacetylated histones

(Fish et al., 2010). Overall, studies investigating the role of histone acetylation in post-stroke recovery indicate that increased HDAC expression and histone hypoacetylation promotes BBB injury.

The specific pattern of histone methylation, and activity of histone lysine methylases and demethylases are important for stroke occurrence and regulation of stroke injury and recovery (Chisholm et al., 2015; Miao et al., 2015; Chakravarty et al., 2017). For example, the pattern of histone 3 methylation of lysine 4 or 9 residues in astrocytes, regulates different gene expression and may regulate the severity of stroke in rodents (Chisholm et al., 2015). The activity of histone lysine methylases (G9a lysine methylases) and demethylases (KDM4B lysine demethylases) was linked to inflammation by regulating TNFa mediated ICAM-1 and VCAM-1 expression in cerebral blood vessels and neutrophil infiltration (Choi et al., 2017). In addition, TNFa serum levels were closely correlated with H3K9Ac and H3K4me3 activity, suggesting an effect on stroke outcomes (Gomez-Uriz et al., 2014). Histone arginine methylation also plays a role in the inflammatory response after stroke. Hypomethylation of histone arginine residues and low asymmetric dimethylarginine (ADMA) levels are associated with increased inflammation and stroke risk in a hyperhomocysteinemia rodent model (Esse et al., 2013). Furthermore, ADMA and symmetric dimethylarginine (SDMA) expression levels were reported to be linked with inflammatory mediator expression (CCL2, IL6, S100B, MMP9, and tissue inhibitor of matrix metalloproteinase-1) and the expression of these mediators and inflammation closely correlated with histone arginine methylation (Chen et al., 2012). ADMA levels are potential biomarkers for stroke injury.

Multiple HDAC inhibitors have already undergone clinical testing for a variety of diseases, with vorinostat approved for treating T cell lymphoma and panobinostat for multiple myeloma (McClure et al., 2018). A non-specific HDAC inhibitor, valproic acid, has been used for many years in the treatment of epilepsy, although there are questions over whether those effects are mediated by HDAC inhibition. The knowledge from those clinical trials may help facilitate translation of HDAC inhibitors to the clinic, as may the generation of new inhibitors of specific HDAC subtypes that might lessen drug side effects (Cao et al., 2018).

Intriguing candidates for regulating BBB and NVU recovery after stroke are the sirtuins. Sirtuins are nicotinamide adenine dinucleotide (NAD^+) dependent class III histone deacetylases, first discovered in *Saccharomyces cerevisiae* as silent information regulator 2 (Sir2). There are seven mammalian sirtuins homologs (Sirt1-7) localized in nucleus (Sirt1, Sirt6, and Sirt7), mitochondria (Sirt3, Sirt4, and Sirt5), and cytoplasm (Sirt2). Generally, they are implicated in regulating aging, metabolism and cell cycle (Inoue et al., 2007). Besides targeting histones, sirtuins (i.e., Sirt1) can interact with specific DNA binding transcription factors and coregulators (i.e., FOXO, hypoxia inducible factor 1a, PGC1a) and deacetylation of these non-histone targets are responsible for transcriptional regulation and both negative and positive regulation of target gene expression (Andreou et al., 2012; Shukla et al., 2016; Chen et al., 2019).

Epigenetic roles of sirtuins, predominantly Sirt1 and 3, are described in stroke injury via acetylation/deacetylation of targets. Limited data highlight the role of Sirt1 in neuroprotection in the settings of stroke by deacetylation and subsequent inhibition of p53- and NFkB-induced inflammatory and apoptotic pathways, regulation of microglia activity via CX3CR1, brain endothelial cell protection by inhibiting nitric oxide synthesis, and balancing Sirt3 (mitochondrial Sirt) activation after stroke injury (Yang F. et al., 2015; Sellner et al., 2016; Chen T. et al., 2018). Resveratrol, a potent activator of Sirt1, has neuroprotective effects after stroke (enhancing neurite outgrowth and synaptogenesis) and vascular protective effects, reducing the chance of recurrent stroke (Tang et al., 2017). In addition, Sirt1 regulates BBB integrity in aging and CNS infection (Castro et al., 2016; Stamatovic et al., 2019). Although the role of sirtuins in NVU and BBB recovery after stroke is still largely unexplored, emerging data on sirtuin effects on the BBB, endothelial cells, and stroke, put these molecules, and particularly Sirt1, as important targets for epigenetic modification of NVU and BBB in stroke recovery (**Table 1**).

To determine the mechanisms leading to BBB injury in ischemic stroke, future research should determine which genes have altered expression due to aberrant HDAC activity. Because both HDAC and HAT activity determine histone acetylation patterns, post-stroke HAT activity within the NVU also needs to be determined.

NON-CODING RNAs (ncRNAs)

Non-coding RNAs represent a group of untranslated regulatory RNA molecules able to modify one or more genes/protein function affecting multiple cellular pathways in biological processes. Non-coding RNAs include ribosomal RNA (rRNA), transfer RNA (tRNA), small (<200 nucleotides), and long (>200 nucleotides) RNAs. Small ncRNA include large group of miRs, piwi-interacting RNAs (piRNA), small nuclear RNAs (snRNA), small nucleolar RNAs (snoRNA), and promoter associated small RNAs. Long ncRNAs are divided into long intergenic ncRNAs, long iontronic ncRNAs, telomeric ncRNAs, pseudogene transcripts, enhancer RNAs and promoter associated long RNAs. Small and long ncRNAs differ in origin, processing and mechanisms of action (Wei et al., 2017).

MICRORNAS

MicroRNAs are a class of short (∼20–25 nucleotides) non-coding RNAs capable of regulating gene/protein expression by inhibiting translation. Located in cytoplasm, miRs build RNA-induced silencing complexes (RISCs) by binding with Argonaute (Ago) proteins. Direct binding of miR-RISCs to complementary and unique 3′ UTR (untranslated) sequence motifs on target mRNAs, leads to sequestration or degradation of the target mRNA and translational silencing. miRs have multivalent properties, targeting multiple genes, and regulating protein expression in several key cellular processes (cell differentiation, cell cycle progression and apoptosis) (Ambros, 2001; Vishnoi and Rani, 2017). miR expression and function is closely associated with and dependent on interaction with epigenetic factors

TABLE 1 | NVU HDAC cell expression profile and effect in post-stroke recovery.

(DMNT and HDAC) (Dakhlallah et al., 2013; Lee et al., 2017; Nicholson et al., 2017). Together they form complex circuits for transcriptional and post-transcriptional regulation of genes. To date, ∼2000 miR family members have been identified in human, and it is assumed that miRs could regulate ∼60% of all mammalian mRNAs. The family classification is based on a common miR ancestor (Vishnoi and Rani, 2017). Family members share similar physiological function but not always primary sequence or secondary structure. miRs are linked to many disease conditions and represent both potential therapeutic targets but also biomarkers.

MicroRNA are highly differentially expressed in brain tissue and they play key roles in development, physiology, and disease. Cerebral ischemia triggers selective and temporally regulated miR expression that regulate stress responses (e.g., excitotoxicity, oxidative stress, and apoptosis) as well as a spectrum of other processes (e.g., transcription, inflammation, and angiogenesis) (Mirzaei et al., 2018). Intriguingly, miR expression in brain is mirrored by differential expression of miRs implicated in endothelial cell and vascular function, erythropoiesis, angiogenesis, neural function, and hypoxia, even several months after the onset of stroke. This suggests that miRs play role in the response to cerebral ischemia and can serve as clinical biomarkers of stroke and post-stroke injury/recovery. In stroke and post-stroke remodeling of the BBB and NVU, a spectrum of miRs are involved varying with time, cell-specific target and recovery process. Importantly, due to the ability of miRs to target multiple molecules, often one miR is found to be on the interface of ongoing angiogenesis, inflammation, and/or oxidative stress.

Several miRs play a critical role in regulating post-stroke inflammation at the NVU. miR126 is highly expressed and considered as endothelial specific. It is one of the most heavily studied miRs and it is a potent regulator of vascular inflammation. miR126 modulates/downregulates expression of an adhesion molecule, VCAM, and controls leukocyte extravasation into brain (Yuan et al., 2016). Similarly, miR31 and miR17-3p regulate/antagonize the expression of E-selectins and ICAM-1 reducing neutrophil adhesion and post-stroke leukocyte infiltration (Staszel et al., 2011). miR98 and let-7g decrease leukocyte adhesion to and migration across the BBB (Rom et al., 2015). Two other miRs, miR155 and let-7, also have anti-inflammatory effects. They regulate expression of molecules important in stroke recovery including IL4, IL10, and BDNF in microglia and down-regulate iNOS and IL6 (Rom et al., 2015; Xiang et al., 2017; Greco et al., 2018; Lu et al., 2018). Intriguingly, miR155 has proinflammatory effects in the brain after stroke. It regulates macrophage signaling, differentiation and proinflammatory phenotype by diminishing the balance between suppressor of cytokine signaling 1 (SOCS-1) protein,

and upregulating of inflammatory molecules such as iNOS (Lopez-Ramirez et al., 2014; Liu Y. et al., 2015; Cerutti et al., 2016). miR155 also stimulates expression of TNFα and IL1β via NFκB and toll-like receptor 4 (TLR4), and downregulation of myeloid differentiation primary response gene (MyD88) (Tarassishin et al., 2011). Furthermore, administration of miR155 antagomir decreased post-stroke inflammation, reduced neuronal apoptosis and improved neurological deficits (Pena-Philippides et al., 2016). Similar to the effect of miR155, an antagomir for miR210 decreased expression of proinflammatory cytokines IL6, TNFα, IL1β, CCL2, and CCL3 reducing the neurological impairment, putting miR210 as potent regulator of inflammation during stroke recovery (Huang et al., 2018).

Intriguingly, miRs are also associated with inflammasome activity. The inflammasome is a cytosolic complex that plays a role in ischemic stroke by promoting inflammatory and cell death mechanisms. miR223 has a role in suppressing the NLRP3 inflammasome by binding to its 3′ UTR sites and consequent inhibition of IL1β and caspase-1 activity, reducing brain edema and improving neurological score (Maitrias et al., 2017). The miRs, miR124, miR132a and 149-5a also have anti-inflammatory effects after stroke by inhibiting CCAAT/enhanced-binding protein (C/EBP-alpha) and downstream factor PU.1, promoting microglia quiescence, and suppressing activation of microglia and consequently reducing the expression of proinflammatory cytokines and suppressing proinflammatory mediators like NFκB, TNFα, and IL6 (Wanet et al., 2012; Yu et al., 2017; Wan et al., 2018).

Nuclear factor erythroid 2-related factor 2 (Nrf2) is a master regulator of anti-oxidant defense mechanisms that plays a critical role in limiting ischemia-induced brain injury, including BBB disruption (Alfieri et al., 2013). Papp et al. (2012) examined the Nrf2 interactome and identified 85 miRs involved in post-transcriptional regulation of Nrf2 (Wang et al., 2016). After transient MCAO in mice, Wang et al. (2016) found a marked increase in miR93 and that a miR93 antagomir reduced brain injury. The antagomir markedly increased brain Nrf2 levels as well as hemeoxygenase-1, a protein regulated by Nrf2; i.e., miR93 acts as a repressor of Nrf2, and antagonizing its actions may be a therapeutic approach for stroke (Wang et al., 2016).

Another miR, miR1 is indicated to have an important role in regulating neurotropic factors, apoptosis, neurogenesis and the generation of synapses (Talebi et al., 2019). Indicated as being an important target in treating neurodegenerative diseases as well myocardial infraction, miR1 suppression has a protective effect in stroke by reducing BBB permeability and brain edema and improving neurological deficits (Talebi et al., 2019). Similarly, miR15a is considered as a master regulator of cerebral vascular dysfunction after ischemic stroke. Intriguingly, after ischemic episodes, PPARγ and PPARd modulate miR15a expression at the cerebrovasculature, reducing injury and enhancing vascular recovery (Yin et al., 2010, 2013). Therefore, targeting miR15a is a promising strategy for protecting the BBB and the NVU after stroke.

Other processes regulated by miRs in post-stroke recovery include angiogenesis and BBB stability. In post-stroke associated angiogenesis, the miR expression profile is associated with the degree of post-stroke angiogenisis. Some miRs regulating angiogenic processes include miR225, miR335, miR139-5p, miR203, miR708, miR193 and miR494, which are predominantly downregulated, as well as miR224, miR210, miR204, miR322, miR100, miR450a, miR322, miR331 and miR101a which are upregulated in post-stroke angiogenesis (Lou et al., 2012; Yin et al., 2015). These miRs regulate expression of fibroblast growth factor (bFGF) and vascular endothelial growth factor (VEGF) in endothelial cells (miR15a and miR126), tube formation (miR139, miR335, and miR107), cell migration (miR210), targeting Dicer-1 and consequently VEGF (miR107) (Tome et al., 2011; Ye et al., 2014; Li et al., 2015; Zhu et al., 2017). One recent study indicated that functional polymorphism in the 3′ UTR site of angiopoietin-1 gene affects the binding sites of miR211, and can reduce the risk of stroke occurrence, while miR129-5p ameliorates inflammation and promotes revascularization after stroke (Chen et al., 2010; Li X.Q. et al., 2017).

Evidence indicates that several miRs are critical in regulating BBB integrity after stroke. A miR491-5p decrease leads to increased risk of cerebral ischemia and worsening stroke-induced BBB disruption by directly regulating expression of MMP9 (Yan et al., 2011). Suppression of miR155 2 days after ischemia in an experimental mouse stroke model decreased vascular leakage and promoted revascularization through stabilization of TJs and preservation of the BBB (Greco et al., 2018). Two recent studies showed that inhibiting miR130a in cerebral ischemia reduced BBB permeability, brain edema and enhanced neurological function by targeting Homeobox1 (Chen et al., 2010; Saito et al., 2011). A recent study by Yao et al. (2018) showed that miR21 suppresses MAP2K3 expression in brain endothelial cells regulating barrier permeability and exacerbation of brain edema and ischemic injury. miR149-5p also regulates BBB stability and NVU remodeling after cerebral ischemia. In addition, a miR149 polymorphism was reported to be associated with ischemic stroke pathogenesis (Jeon et al., 2013). A recent study by Wan et al. (2018) reported that miR149-5p targets the sphingosine phosphate receptor 2 (S1PR2) and regulates pericyte migration and N-cadherin expression. Thus, treatment with an agomir of miR149-5p attenuated BBB permeability and improved outcomes after transient MCAO.

A number of miRs are considered as cell specific. In the line with that, miRs mostly involved in regulating endothelial cell function include miR126, miR17-92, miR23-27-24, miR222-22, miR99, miR20b, miR101, and Let-7b (Mishra and Singh, 2013). Astrocytes at the NVU are regulated by miR29b, that regulates AQP4 expression, as well as by miR130a, and miR320a (Sepramaniam et al., 2012; Song et al., 2015; Wang et al., 2015). miR130a is expressed in brain endothelial cells and pericytes. It regulates occludin expression via HoxA5 as well MMP2 and -9 (Wang et al., 2018). Intriguingly, miR130a is downregulated after ischemic conditioning in astrocytes and pericytes which may indirectly affect TJ complex structure and brain endothelial barrier permeability. A summary of miR activities at the BBB and post-stroke NVU recovery is presented in **Figure 2**.

An important aspect of miRs in stroke and post-stroke recovery is whether changes in their circulating levels reflect the degree/type of injury and potential recovery. For example,

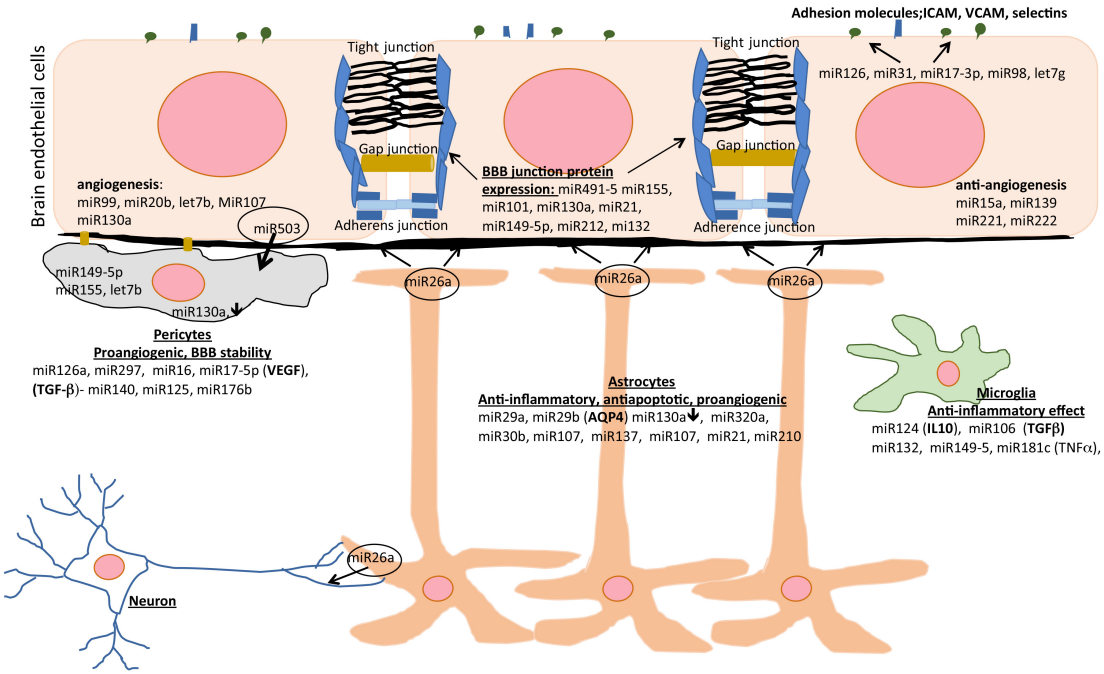

FIGURE 2 | The effects of miRs on different cell types of the NVU during post-stroke recovery. Different miRs modulate inflammation, angiogenesis, apoptosis, and blood-brain barrier (BBB) integrity and represent therapeutic area to enhance post-stroke recovery. AQP4, aquaporin-4; ICAM, intercellular adhesion molecule; IL-10, interleukin-10; TGF-β, transforming growth factor beta; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor.

blood levels of miR30a and miR126 in patients with ischemic stroke are reduced for 24 weeks (Long et al., 2013). Another example is a differential pattern of expression across different stroke subtypes for a miR, let-7b. Let-7b was lower in stroke patients of a large atherosclerosis subtype compared to non-stroke patients, whereas in other ischemic stroke subtypes, let-7b was higher than in healthy individuals (Long et al., 2013). Thus, screening of different types of miRs may serve as a useful tool to assess the risks and prognosis of specific stroke subtypes and stroke recovery.

It should be noted that while miRs have actions in the cells where they are produced, they can also have effects on other distant cells. One mechanism is via the cellular release and uptake of exosomes. That type of extracellular vesicle contains a wide range of molecules, including miRs. Exosomes are being examined both as biomarkers for stroke and as a therapeutic modality (Hong et al., 2018). Exosomes are produced and taken up by all cells of the NVU, having an important role in cellular crosstalk, including in stroke (Zagrean et al., 2018), potentially via the effects of miRs. Thus, Xu et al. recently found that exosomes released by neurons regulate BBB permeability in zebrafish (Xu B. et al., 2017; Zagrean et al., 2018). Those exosomes contained miR132 and delivery of that miR regulated adherens junction function in the cerebral endothelium (Xu B. et al., 2017).

Apart from the role of endogenous exosomes, there is interest in using exogenous exosomes as a delivery platform, including loading such exosomes with select miRs (Beuzelin and Kaeffer, 2018). Thus, bacterial-based mini-cells have been loaded with a miR16-based mimic and given to patients with malignant pleural mesothelioma (van Zandwijk et al., 2017). Such approaches might be used to limit stroke-induced NBVU/BBB injury or enhance recovery.

The above description suggests that miR agonists (agomirs) and antagonists (antagomirs) may be attractive targets for reducing ischemia-induced BBB and NVU dysfunction and improving post-stroke recovery, particularly as each miR many affect multiple processes. There are, however, hurdles that will need to be overcome. The ability of miRs to affect multiple pathways suggests that special attention may be required for potential side-effects of treatment. There is also the question of delivery of the therapeutic to the appropriate target. Targeting the cerebral endothelium may be easier than targeting other cells of the NVU where the miR, agomir or antagomir would have to cross the BBB. Progress has been made in adeno-associated viruses that will cross the BBB that might serve as a route for delivery.

OTHER NON-CODING RNAs

Currently, most studies have focused on the role of small ncRNA in regulating the BBB and NVU function in stroke. However, several recent studies have identified stroke-responsive piRNAs and lncRNAs (Alishahi et al., 2019). LncRNAs are not junk RNA but act as functional regulator elements in epigenetic regulation. They regulate gene function at different levels including but not limited to chromatin modification, and transcriptional and post-transcriptional mechanisms.

LncRNAs are longer than 200 nucleotides and have less sequence conservation than short ncRNA. Similar to short ncRNAs (miRs), lncRNAs regulate many important physiological processes including apoptosis, autophagy, immune response, and angiogenesis. LncRNAs may act as competitors to endogenous RNAs, acting as miR sponges or antagomirs (Alishahi et al., 2019). Recently, lncRNAs have been identified as being involved in human diseases. One lncRNA, Malat1 is involved in protecting against cerebrovascular ischemic injury. It is upregulated in brain endothelial cells by ischemia-like conditions and reduces injury. Malat1 acts by being a sponge for miR26b, regulating brain endothelial cell autophagy and survival under ischemic conditions (Li Z. et al., 2017).

CONCLUSION

The epigenetic mechanisms and the non-coding RNAs involved in BBB and NVU changes in stroke and stroke recovery are slowly emerging. That information holds great promise for better understanding of stroke pathology but also for developing new strategies for successful stroke recovery. In the future, both epigenetic factors and non-coding RNAs may have dual roles, as therapeutic targets and as biomarkers mirroring NVU injury and recovery processes. Epigenetic mechanisms are attractive targets as they affect multiple pathways. Histone deacetylase inhibitors are already used clinically for some disease states and more HDAC subtype-specific inhibitors are being developed. While the importance of miRs in a wide variety of disease states is recognized, there are still hurdles to cross in translating that to the clinic, particularly for neurological conditions such as stroke. However, the pleiotropic effects of epigenetic mechanisms and non-coding RNAs make them attractive and exciting therapeutic targets for limiting post-stroke NVU injury and enhancing recovery.

Serial Metabolic Evaluation of Perihematomal Tissues in the Intracerebral Hemorrhage Pig Model

Purpose: Perihematomal edema (PHE) occurs in patients with intracerebral hemorrhage (ICH) and is often used as surrogate of secondary brain injury. PHE resolves over time, but little is known about the functional integrity of the tissues that recover from edema. In a pig ICH model, we aimed to assess metabolic integrity of perihematoma tissues by using non-invasive magnetic resonance spectroscopy (MRS).

Materials and Methods: Fourteen male Yorkshire pigs with an average age of 8 weeks were intracerebrally injected with autologous blood to produce ICH. Proton MRS data were obtained at 1, 7, and 14 days after ICH using a whole-body 3.0T MRI system. Point-resolved spectroscopy (PRESS)-localized 2D chemical shift imaging (CSI) was acquired. The concentration of *N*-Acetylaspartate (NAA), Choline (Cho), and Creatine (Cr) were measured within the area of PHE, tissues adjacent to the injury with no or negligible edema (ATNE), and contralesional brain tissue. A linear mixed model was used to analyze the evolution of metabolites in perihematomal tissues, with p-value < 0.05 indicating statistical significance.

Results: The perihematoma volume gradually decreased from 2.38 ± 1.23 ml to 0.41 ± 0.780 ml ($p < 0.001$) over 2 weeks. Significant ($p < 0.001$) reductions in NAA, Cr, and Cho concentrations were found in the PHE and ATNE regions compared to the contralesional hemisphere at day 1 and 7 after ICH. All three metabolites were significantly ($p < 0.001$) restored in the PHE tissue on day 14, but remained persistently low in the ATNE area, and unaltered in the contralesional voxel.

Conclusion: This study highlights the potential of MRS to probe salvageable tissues within the perihematoma in the sub-acute phase of ICH. Altered metabolites within the PHE and ATNE regions in addition to edema and hematoma volumes were explored as possible markers for tissue recovery. Perihematomal tissue with PHE demonstrated a more reversible injury compared to the tissue adjacent to the injury without edema, suggesting a potentially beneficial role of edema.

INTRODUCTION

Intracerebral hemorrhage (ICH) often results in hemiparesis or hemiplegia. ICH accounts for about 10–15% of all strokes, and is associated with a high mortality and long-term disability rate (Feigin et al., 2009). ICH-induced deaths may occur within hours to days of the ictus (Feigin et al., 2009; Hemphill et al., 2015). The sequelae of ICH pathogenesis consist of primary injury with the rupture of blood vessels, physical compression, and disruption of brain tissues by the expanding blood mass. The secondary injury is associated with hematoma toxicity, oxidative stress, neuroinflammation, blood-brain barrier disruption, and consequent robust edema Perihematomal edema (PHE) (Wagner et al., 2003; Cherubini et al., 2005; Babu et al., 2012; Selim and Sheth, 2015; Lim-Hing and Rincon, 2017; Bernstein et al., 2018).

Initial cytotoxic edema progresses into mainly vasogenic edema, which is coupled with extravasation of blood fluid that contains plasma proteins, and has been proposed to contribute to additional injury (Xi et al., 2001; Keep et al., 2012a; Selim and Norton, 2018). One study reported a significant proportion of swollen cells in the inner and outer rims of the perihematoma with a small proportion of shrunken dark cells within 24 h after onset (Qureshi et al., 2001). ICH-induced neuroinflammation has been characterized by the presence of neutrophils, microglia, and macrophage/monocyte around the hemorrhagic foci (Castejon et al., 2005; Bakhshayesh et al., 2014; Zhao et al., 2007, 2017; Zhang et al., 2017). The location, expansion and retraction of hematoma and PHE volumes are used as a prognostic tool in humans and rodents (Aronowski and Hall, 2005; Falcone et al., 2013; Grunwald et al., 2017; Al-Shahi Salman et al., 2018; Klahr et al., 2018; Volbers et al., 2018). Because of the clinical importance of PHE, there is great interest to understand the pathophysiology and develop therapeutic agents targeting PHE. Serial and cross-sectional neuroimaging studies have reported a reduction of edema over time (Murthy et al., 2016; Ozdinc et al., 2016; Rodriguez-Luna et al., 2016; Liu et al., 2019), however, there is little known about the functional and structural restoration of those tissues after edema resolution.

N-acetylaspartate (NAA), choline (Cho), and creatine (Cr) are three major brain metabolites, seen on proton magnetic resonance spectroscopy (MRS) (^{1}H-MRS), which are often used as surrogate markers of neuronal health, cell proliferation, and cellular energy, respectively (Prado et al., 2002; Madhavarao and Namboodiri, 2006; Rigotti et al., 2007; Rackayova et al., 2017). Alterations in these metabolites were documented in patients with ischemic stroke, providing useful markers of tissue health (Fenstermacher and Narayana, 1990; Felber et al., 1992; Kang et al., 2000; Bivard et al., 2014). However, only a limited number of reports characterized these changes in patients with ICH (Kobayashi et al., 2001). Wagner reported a significant reduction in NAA in patients with a subarachnoid hemorrhage and Kobayashi reported a reduction in the ipsilesional NAA/Cr ratio in the motor cortex in patients with poor outcomes (Kobayashi et al., 2001; Wagner et al., 2013). Another study also demonstrated a significant reduction in NAA/Cr ratio in the primary motor cortices remote from the locus of injury (Yang et al., 2017). However, only few neuroimaging studies investigated metabolic changes in the PHE. Two studies by Carhuapoma et al. (2000, 2005) reported the presence of lactate and increased apparent diffusion coefficient in the PHE regions in ICH patients. In an animal study, Yin et al. (2006) showed significant apoptosis and reduction in NAA/Cr ratio in the PHE within 24 h of ICH onset. However, to the best of our knowledge, no study used spectroscopy to probe metabolic activities of the perihematoma region during post-ICH recovery, especially to understand the fate of peri-hematomal tissue regarding its functional recovery vs. irreversible damage.

The primary objective of this study was to assess the metabolic integrity of the perihematoma region over 2 weeks after injury using the ICH pig model. We used non-invasive MRS to probe neuronal viability/functionality in the perihematoma and the tissue adjacent to the injury with no apparent edema.

MATERIALS AND METHODS

Animal studies were approved by our institution's Animal Welfare Committee. The studies followed the guidelines outlined in the *Guide for the Care and Use of Laboratory Animals* from the National Institutes of Health.

Induction of ICH

Fourteen male Yorkshire pigs were studied with average age/weight of 8 ± 2 weeks/13.4 ± 2.4 kg. Procedural details were described elsewhere (Haque et al., 2018). Briefly, animals were sedated with ketamine (25 mg/kg, IM) and maintained under isoflurane throughout surgery. During the surgery, animals were wrapped in a blanket (to maintain body temperature), intubated, and catheterized to monitor physiological variables. To produce lobar ICH, a cranial burr hole was drilled 11 mm to the right of the sagittal and 11 mm anterior to the coronal suture. Hemorrhage was induced by pressure controlled infusion of autologous blood into the right frontal hemisphere, first 1.0 mL infused over 10 min followed by additional 1.5 ml after a 5 min interval.

Image Acquisition

Pigs were serially imaged on 1, 7, and 14 days after the surgery. During imaging, animals were ventilated with an average of 18 breaths-per-minute with maximum airway pressure of 20 cm-H_2O, oxygen saturation level (SpO_2) of 97%, typical end-tidal CO_2 of 47 mmHg, heart rate 120 beats-per-minute, and body temperature 98.6°C. Anesthesia was maintained with 2% isoflurane mixed with oxygen.

Animals were positioned prone in 3.0 Tesla Philips Ingenia MRI system (Philips, Best, Netherlands) and imaged using an eight-channel head coil. Anatomical imaging included: 3D T_1-weighted (TR/TE = 10/4.8 ms), 3D coronal T_2-weighted (TR/TE = 3500/267 ms), and 3D fluid attenuated inversion recovery (FLAIR, TR/TI/TE = 4800/1650/129 ms) with a field-of-view of 200 × 200 × 86 mm^3. Multivoxel spectral data were obtained using point resolved spectroscopy (PRESS)-localized two-dimensional chemical shift imaging (CSI) with

TR/TE = 2000/144 ms, matrix size = 9 × 9, bandwidth = 2000 Hz, and voxel size = 15 × 15 × 15 mm^3.

Spectral Analysis and Metabolite Quantification

All spectral integration and phase correction were performed manually using in-house software in Matlab (The Mathworks, Natick, MA, United States). The metabolite peaks at 2.01, 3.03, 3.19 ppm were referenced to NAA, Cr, and Cho, respectively, with respect to the unsuppressed water signal at 4.7 ppm. The absolute concentration of the metabolites was quantified using the unsuppressed water peak as an internal reference (Ernst et al., 1993; Kreis et al., 1993) with T_1 and T_2 correction for metabolite and water using the following equation:

$$C_m = \frac{A_m N_w (1-e^{-TR/T_{1w}}) e^{-TE/T_{2w}}}{A_w N_m (1-e^{-TR/T_{1m}}) e^{-TE/T_{2m}}} C_w \quad (1)$$

where C_m is metabolite concentration, A_m (A_w) is the area under the metabolite (water) peak, T_{1m} (T_{1w}) is the longitudinal relaxation time of metabolite (water), T_{2m} (T_{2w}) is the transverse relaxation time of metabolite (water), N_m (N_w) is the number of hydrogen atoms in the metabolite (water) molecule, TR is the repetition time, TE is echo time, and C_w is the reference water concentration in tissue. Previously reported T_{1m}, T_{1w}, T_{2m}, T_{2w}, and C_w at 3T systems were used in the calculation (Reyngoudt et al., 2010). Concentration is reported in milli-mole (mM) units.

To characterize biochemical events in brain tissue directly affected by ICH, we identified one voxel within the PHE, ATNE, and contralesional hemisphere and measured its absolute metabolite concentrations.

Lesion Volume Measurements

A semi-automated seed growing algorithm in Analyze 12.0 (Analyze Direct, Inc., KS, United States) was used to measure edema and hematoma volume on FLAIR images by a single rater. The rater selected two seed points within the hyperintense edema and hypointense hematoma and a region-growing algorithm automatically expanded the seed points within the 3D space of the image. Manual editing of the lesion volume was done when necessary.

Statistical Analysis

Cerebral metabolite concentrations were analyzed by the mixed model (Littell et al., 1998). The fixed effects in the model included brain regions (PHE, PHNE and contralesional), polychotomous time (1, 7, and 14 days), and interaction between hemisphere and polychotomous time. The random effects in the model included animal and interaction between animal and brain regions. These random effects led to a nested covariance matrix accounting for correlation of measurements due to the same animal and a different level of correlation for measurements due to the same hemisphere of the brain. The edema and hematoma volume were analyzed by the mixed models including polychotomous time as a fixed effect and animal as a random effect. Two-sided p-values of less than 0.05 were considered statistically significant. All statistical analyses were performed using the SAS software (version 9.4, the SAS Institute, Cary, NC, United States).

RESULTS

Twelve pigs completed all three imaging time points. One pig died during imaging on day 1 and was excluded from the analysis. Another pig died one day prior to the last imaging on day 14.

Representative MRI images demonstrating changes in the PHE region and hematoma volumes at three time points in a representative pig are shown in **Figure 1**. The computer calculated region of interest (ROIs) showing the boundaries were used to calculate the intracranial (ICV), hematoma, and edema volumes. There was no statistically significant change in ICV between day 1 (70.3 ± 6.5 ml), day 7 (72.9 ± 7.6 ml), and day 14 (74.2 ± 7.6 ml). ICH resulted in a 2.38 ± 1.23 ml PHE on day 1 that progressively resolved over the course of 2 weeks, reducing by 23.1% on day 7 and by 82.7% on day 14 ($p < 0.001$) (**Figure 1D**). Our model of ICH generated a hematoma volume of 1.00 ± 0.79 ml on day 1 after the surgery. The hematoma underwent progressive clearance and was reduced by 15.7% on day 7 and by 38.3% on day 14 ($p < 0.001$), as compared to day 1 (**Figure 1E**), indicating effective hematoma clearance.

Representative anatomical locations of MRS data collection are illustrated in **Figures 2A–C**. The locations were similarly applied across all 13 analyzed pigs and were selected on day 1 to signify presence of PHE, adjacent non-edematous tissues (ATNE), and the contralesional brain tissue. Our analyses demonstrate a clear pattern of metabolite loss around the hematoma at day 1 after ICH with strong restoration of NAA and Cho concentrations in the PHE, and unexpectedly poor restoration of all the metabolites in ATNE tissue, as assessed on day 7 and day 14 (**Figures 2D–L**). Specifically, the NAA concentration in both PHE and ATNE regions was reduced ($p < 0.001$) in response to ICH, as compared to contralesional tissue on day 1 and day 7 (**Figure 3A**), suggesting that ICH imposes dysfunction that affects neurons in the perilesional brain. The loss in NAA was transient in the PHE regions, as NAA was largely restored by day 14. Unexpectedly, NAA in the ATNE was still reduced 2 weeks after ICH, suggesting the more permanent nature of injury/dysfunction in the region containing no edema than in the regions spared by edema. The NAA concentration in PHE recovered from 9.70 ± 2.7 mM at day 1 to 14.79 ± 2.5 mM ($p < 0.001$) at day 14, values equivalent to NAA levels in the contralesional region. However, there was virtually no recovery in NAA content in the ATNE between day 1 and 14 (9.45 ± 3.1 vs. 9.99 ± 2.1 mM, $p = 0.51$). There was no change in NAA content in contralesional regions (13.7 ± 2.1 vs. 14.5 ± 2.0, $p = 0.36$) between the first and last time points.

As compared to the contralesional tissue, the Cr concentration in response to ICH was reduced ($p < 0.001$) within both the PHE and ATNE regions and remained reduced for 14 days, through the end of the experiment (**Figure 3B**). Unlike in the case of NAA, which was fully restored, Cr levels both in PHE and ATNE were only partially restored (3.62 ± 1.7 mM to 6.23 ± 2.9 mM; $p = 0.001$ for PHE and 3.46 ± 1.2 vs. 5.15 ± 2.4 mM, $p = 0.023$

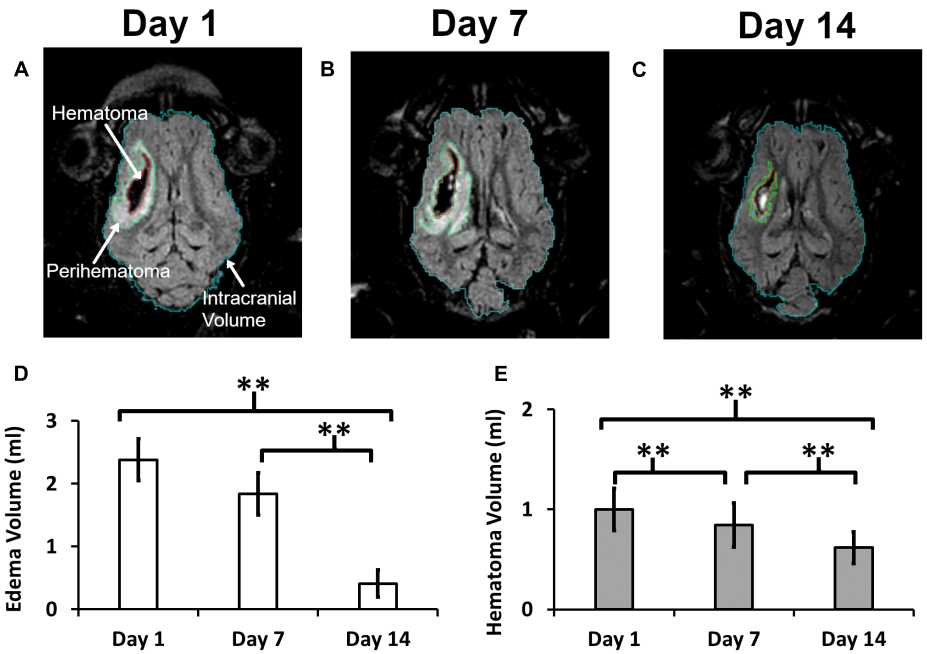

FIGURE 1 | A quantitative summary of the change in hematoma and edema volume in a post-ICH pig brain. Panels **(A–C)** illustrate a representative MRI image showing outlined boundaries of intracranial volume, perihematoma, and hematoma at days 1, 7, and 14, respectively. Panels **(D,E)** show Perihematoma edema **(D)** and hematoma **(E)** volumes. A double asterisk (**) denotes the significant temporal ipsilesional difference between the time point ($p < 0.05$). The error bars represent standard error in the mean.

for ATNE) 14 days after ICH as compared to contralesional tissue that was not affected by ICH (9.43 ± 2.2 mM vs. 10.7 ± 2.3 mM, $p = 0.08$).

Cho concentrations in the PHE and ATNE were also sharply reduced as determined on day 1 and 7 after ICH ($p < 0.001$), compared to the contralesional side (**Figure 3C**). The Cho levels were restored by day 14 in the PHE, but no signs of recovery were seen at this time point in ATNE. Cho concentration was unchanging in the contralesional side throughout the experiment.

There was no significant correlation between hematoma and edema volume with NAA, Cr, and Cho in all three spectroscopic voxel locations. No change was seen in the ratio of water signals between PHE, ATNE, and the contralesional side over time (P = NS), suggesting that the observed patterns of metabolic alterations are not due to changes in the reference tissue water content.

DISCUSSION

It is generally accepted that autologous blood infusion animal models provide a strong translational platform for studying the pathogenesis of ICH and testing therapeutic approaches (Wagner et al., 1999; Andaluz et al., 2002; Gu et al., 2009). The present study evaluated temporal metabolic changes in the perihematoma region using MRS in a piglet model of ICH. As compared to the rodent models of ICH, the larger brain size of piglets and thus ability to generate larger hematoma aids in the more qualitative and quantitative analyses of the changes in the perihematomal regions. Our present study compared metabolic heterogeneity in the perihematomal/ICH-adjacent tissue, sampled to capture metabolites within the edema-affected tissue (PHE) and the location devoid of edema (ATNE). We found that the concentrations of three measured metabolites (NAA, Cho and Cr) were reduced as early as day 1 after ICH in both PHE and ATNE regions. However, over the course of 14 days these metabolites were largely restored in the PHE, but not in the ATNE. These data suggest the potential of MR spectroscopy to identify salvageable tissue around the hematoma. Since perihematomal tissue demonstrating edema recovered more effectively from metabolic disturbances, our data may suggest that edema could play a homeostatic role regarding integrity of perihematomal tissue.

NAA and *N*-Acetylaspartylglutamate (NAAG) are both synthetized by neurons in the brain and upon secretion are internalized and metabolized by glial cells (Baslow, 2010). Both NAA and NAAG produce overlapping magnetic resonance spectral peaks at 2.01 ppm, not permitting differentiation between the individual metabolites. The consensus is that NAA concentration is a total (NAA ++ NAAG) concentration. Reduction of NAA concentration typically reflects some types of neuronal dysfunction or direct neuronal loss. Since ICH is known to produce extensive brain damage either through mass effect-mediated injury or through biochemical-mediated injury via toxic products of blood, blood-brain-barrier disruption, and brain edema (Aronowski and Zhao, 2011; Keep et al., 2012b; Bobinger et al., 2018), neurons surrounding the hematoma are

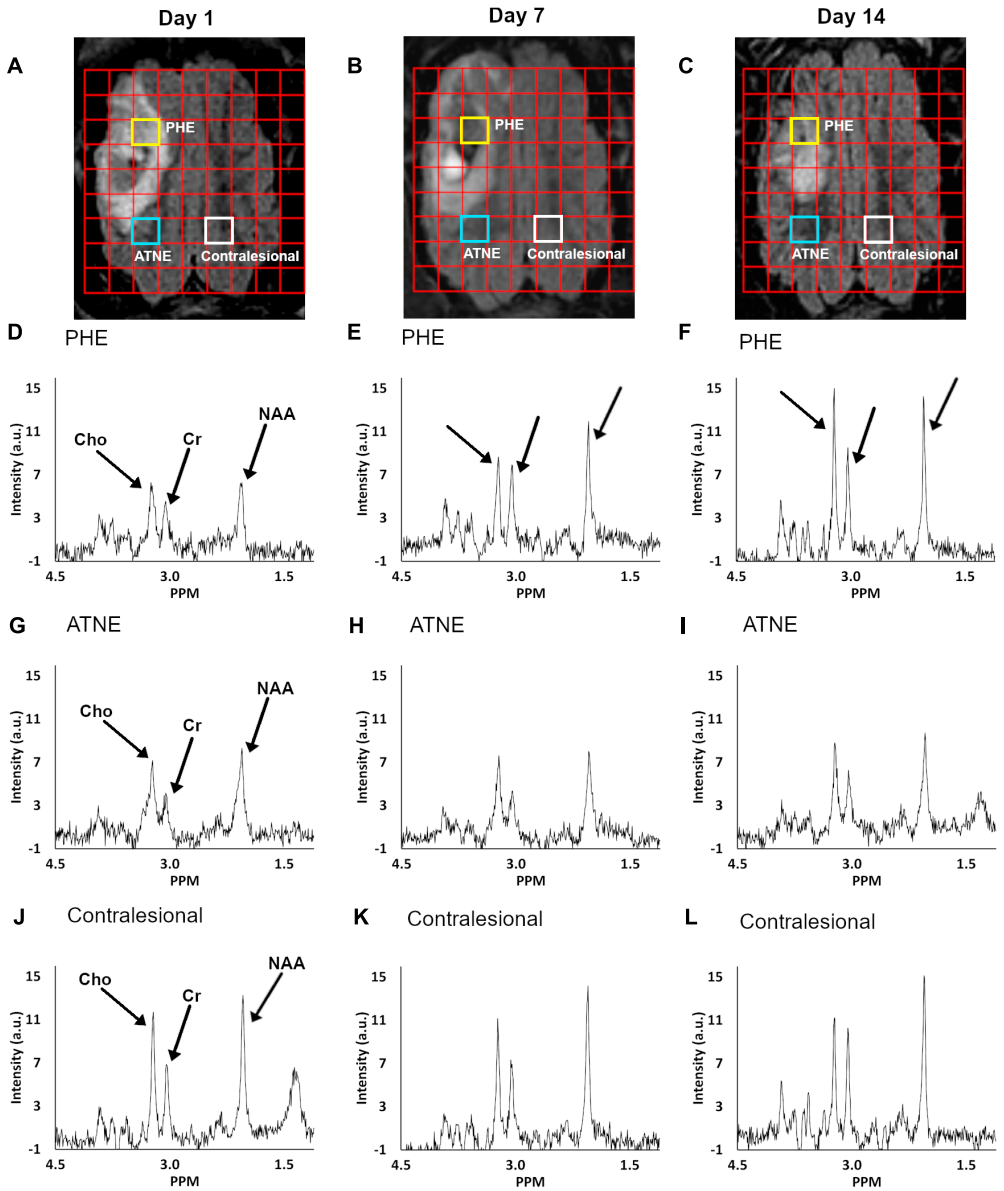

FIGURE 2 | Serial FLAIR MRI images overlaid with a multi-voxel grid of corresponding temporal spectra with highlighted voxels of interest **(A–C)**. Panels **(A–C)** show the PHE, ATNE, and contralesional voxel location at day 1, 7, and 14, respectively, from which the metabolite spectra were measured. MR spectroscopy graphs at days 1, 7, and 14 (columns) are shown for voxels from the PHE **(D–F)**, ATNE **(G–I)**, and the contralesional regions **(J–L)**.

adversely affected by ICH. Thus, it is not surprising that NAA levels in tissue close to the hematoma both in areas with and without edema show significant reduction at day 1 after ICH. However, the essential question is whether this early neuronal injury is transient and associated with reversible damage. Our results indicate that NAA gradually recovered in the PHE but not in the ATNE. Ultimately, these results suggest that neural tissue integrity, at least in the PHE region, is retained after ICH. The irreversible decline of NAA in the ATNE suggests more permanent metabolic dysfunction or neuronal loss. Our data also raise the possibility that the presence of edema could provide a protective cushioning from irreversible damage.

Creatine is a key molecule in the regulation of energy metabolism in the brain and is responsible for re-synthesis of ATP in glial cells (Rackayova et al., 2017). Here we found a significant loss of Cr levels in both the PHE and ATNE regions, suggesting either higher cellular energy demand-mediated depletion of (increased catabolism) Cr and/or its reduced synthesis. In contrast to the transient nature of NAA reduction in the PHE region, the Cr level decline was more sustained and still significantly reduced in both the PHE and ATNE regions at 14 days after ICH. However, over time a weak increasing trend of Cr concentration in both the PHE and ATNE regions suggests regional variance in metabolic dysfunction around the

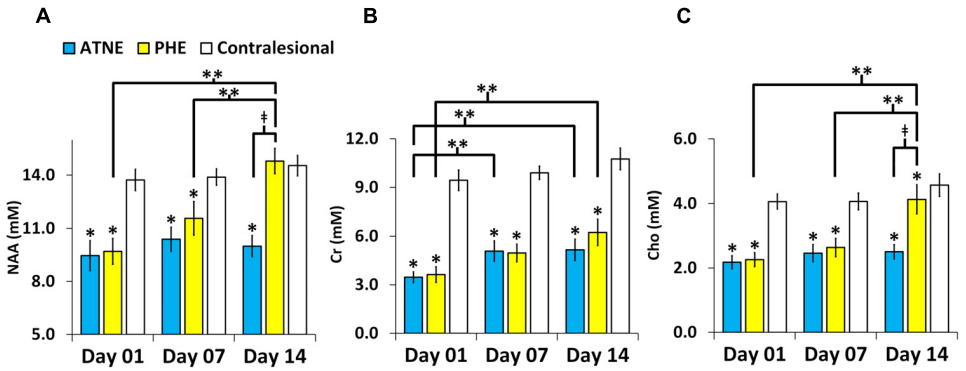

FIGURE 3 | Metabolite concentration in the perihematomal edema (PHE), adjacent tissues with no edema (ATNE), and contralesional voxels over two week follow-up post ICH. **(A–C)** Represent serial NAA, Cr, and Cho concentrations, respectively. The asterisk (*) denotes significant ($p < 0.001$) hemispheric differences, the double asterisk (**) denotes significant ($p < 0.001$) temporal difference and (‡) denotes significant ($p < 0.001$) change between PHE and ATNE. The error bars represent standard error in the mean.

injury. Often, Cr levels are presumed to be constant and have been utilized as a normalizing factor in reporting metabolite concentrations. While this assumption is valid for a healthy brain, under certain pathological conditions Cr levels are altered (Burklen et al., 2006; Andres et al., 2008), including in our study. Thus, appropriate caution must be taken using Cr as a constant value under pathological conditions and reporting metabolite concentrations relative to Cr.

Unlike other pathologies where an elevated concentration of choline has been recognized as a marker of progressive pathologies (Fayed et al., 2008; Karaszewski et al., 2010), here we are reporting a significant reduction in choline in both the PHE and ATNE during the first 7 days after ICH onset. By day 14, choline is restored in the PHE but not in the ATNE region, suggesting transient and sustainable metabolic dysfunction, respectively. Choline, which is localized in all types of cells, serves as a marker for overall membrane integrity, and as such in reference to our study, suggests that the integrity of cell membranes varies around brain tissue surrounding the hematoma. Previously in ischemic stroke animal studies an inverse relation between regional cerebral blood flow (CBF) and choline concentration had been documented (Scremin and Jenden, 1991). The relation between regional metabolic variation and CBF in the ICH model will be further investigated in the future. In addition, the changes in all three metabolite concentrations over time in the PHE, as compared to the absence of changes in the contralesional hemisphere, not only validate the methodology but also suggests a hemispheric rather than global compromise in response to ICH in this model.

In our piglet ICH model, we attempted to generate a modest size hematoma that results in a modest level of edema, which did not result in midline shift or cause too severe mass effect that inflicts irreversible injury and morbidity, as it happens in many humans with large bleeds. This approach allowed for more "uncontaminated" probing of the metabolic characteristics in the perihematomal zone, specifically edema-affected brain tissue vs. perihematomal non-edematous brain tissue. Here, we unexpectedly found the more effective reversal of metabolite levels in the PHE regions as compared to the non-edematous tissue. We certainly predict that the mild edema is beneficial and not detrimental compared to larger degrees of peri-hematoma edema, which leads to compression of local microvasculature resulting in hypoperfusion and compression of white matter tract resulting in anomalous nerve conduction. Collectively, this data may suggest potential beneficial function for mild edema in re-establishing homeostasis in peri-hematoma tissue after ICH.

Our study is limited by a small sample size and will need to be reproduced in larger studies. Another limitation is the variation in edema volume among animals induces partial volume effects in the PHE voxels with normal appearing tissues. In addition, the evolution of hematoma over time also complicates voxel placement and induces partial volume effects. Validation of our findings will require additional studies including PHE tissue histology and *in vitro* metabolite concentration measurements using mass spectrometry or High Performance Liquid Chromatography (HPLC).

In conclusion, this study demonstrated the possible application of MR spectroscopy in monitoring the sub-acute phase of ICH to identify salvageable tissue in the perihematoma region. Also, reversible metabolic recovery in the PHE as compared to the tissue adjacent to the injury without edema, suggesting the potentially beneficial role of edema.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

Animal studies were approved by our institution's Animal Welfare Committee. The studies followed the guidelines outlined in the Guide for the Care and Use of Laboratory Animals from the National Institutes of Health.

AUTHOR CONTRIBUTIONS

MH designed the study, carried out MRI quantitative analysis, and drafted the manuscript. RG wrote Matlab code for spectral integration and assisted in optimizing MRI acquisition. XiZ induced hematoma and supervised the surgery. SG and SB performed regions of interest analysis and generated final plots and figures. KH provided qualitative and quantitative quality assurance of data analysis. XuZ performed statistical analysis. S-MT and GS performed animal surgery. SS supervised the study, edited manuscript, and provided necessary resources. JA is the PI of the study.

FUNDING

This work was supported by National Institute of Health/National Institute of Neurological Disorders and Stroke 5R42NS090650-03.

ACKNOWLEDGMENTS

The authors thank Dr. Christopher Smith and veterinarian team for surgical and technical assistance and Mr. Vipulkumar Patel for help with MRI experiments.

Bolan F, Louca I, Heal C and Cunningham CJ (2019) The Potential of Biomaterial-Based Approaches as Therapies for Ischemic Stroke: A Systematic Review and Meta-Analysis of Pre-clinical Studies. Front. Neurol. 10:924. doi: 10.3389/fneur.2019.00924

Background: In recent years pre-clinical stroke research has shown increased interest in the development of biomaterial-based therapies to promote tissue repair and functional recovery. Such strategies utilize biomaterials as structural support for tissue regeneration or as delivery vehicles for therapeutic agents. While a range of biomaterials have been tested in stroke models, currently no overview is available for evaluating the benefit of these approaches. We therefore performed a systematic review and meta-analysis of studies investigating the use of biomaterials for the treatment of stroke in experimental animal models.

Methods: Studies were identified by searching electronic databases (PubMed, Web of Science) and reference lists of relevant review articles. Studies reporting lesion volume and/or neurological score were included. Standardized mean difference (SMD) and 95% confidence intervals were calculated using DerSimonian and Laird random effects. Study quality and risk of bias was assessed using the CAMARADES checklist. Publication bias was visualized by funnel plots followed by trim and fill analysis of missing publications.

Results: A total of 66 publications were included in the systematic review, of which 44 (86 comparisons) were assessed in the meta-analysis. Overall, biomaterial-based interventions improved both lesion volume (SMD: −2.98, 95% CI: −3.48, −2.48) and neurological score (SMD: −2.3, 95% CI: −2.85, −1.76). The median score on the CAMARADES checklist was 5.5/10 (IQR 4.25-6). Funnel plots of lesion volume and neurological score data revealed pronounced asymmetry and publication bias. Additionally, trim and fill analysis estimated 19 "missing" studies for the lesion volume outcome adjusting the effect size to −1.91 (95% CI: −2.44, −1.38).

Conclusions: Biomaterials including scaffolds and particles exerted a positive effect on histological and neurological outcomes in pre-clinical stroke models. However, heterogeneity in the field, publication bias and study quality scores which may be another source of bias call for standardization of outcome measures and improved study reporting.

INTRODUCTION

Stroke is a global health problem with limited treatment options. The World Health Organization reports stroke as the second leading cause of death worldwide accounting for around 6.7 million deaths annually (1). For patients surviving stroke, close to two thirds will have a disability (2). Despite the major societal impact, the only widely available therapy for ischaemic stroke is tissue plasminogen activator (tPA). However, due to the narrow time window of administration (<4.5 h of symptom onset), only around 12% of patients in the UK are eligible for treatment (3). In recent years, great advances have been made in the development of endovascular thrombectomy as an alternative treatment (4, 5). While clinical trials have demonstrated thrombectomy is effective up to 6 h after stroke onset, it has been estimated that only 10% of patients would be eligible even with national coverage in the UK, which is presently not the case (6). Both thrombolysis and thrombectomy aim to restore reperfusion and limit further damage to the ischaemic brain and there are currently no approved regenerative medicine therapies available for promoting repair and regeneration.

In recent years, interest in regenerative medicine approaches to increase neuronal tissue repair following ischaemic stroke has increased. Notably, over 20 early phase clinical trials have been conducted assessing the safety of cell therapies including mesenchymal stem cells (MSCs) (7), neural stem cells (NSCs) (8), and haematopoietic stem cells (9). A number of studies have used cell-based therapies and growth factors to promote endogenous brain repair or tissue replacement in animal models of stroke with limited success. For this reason, biomaterials are now being investigated as potential agents to enhance the therapeutic efficacy of such interventions as scaffolds for tissue regeneration or vehicles for drug release (10, 11). For example, cell transplantation in the brain may be facilitated by the use of engineered scaffolds, which mimic native extracellular matrix (ECM) properties and provide adhesion sites for native cell attachment, aiding graft cell retention in the infarct cavity (12, 13). Alternatively, scaffolds may be used to aid recruitment and survival of endogenous stem cell populations for tissue restoration. Examples of scaffolds studied for cell delivery in stroke models include natural and synthetic hydrogels, electrospun fibers, sponges, and glue. Particulates are another class of biomaterials commonly used as delivery systems for targeted and controlled release of therapeutic agents. A wide variety of particulates have been tested for ischaemic stroke repair including nanoparticles, microparticles, micelles, liposomes, nanocarriers, and microspheres (14, 15).

To date, there is no systematic review or meta-analysis available investigating the potential of biomaterial-based approaches in pre-clinical models of ischaemic stroke. Given that biomaterial-based interventions are currently attracting great interest it is timely therefore to provide such a review, with the hope of averting the "translational roadblock" (16) and poor predictive validity of previous studies of neuroprotective agents for stroke (17, 18). Our systematic review and meta-analysis aims to assess the methodological quality of current research into biomaterial-based interventions for ischaemic stroke repair and to determine the efficacy of such approaches, helping to inform future research directions.

MATERIALS AND METHODS

Search Strategy

We searched PubMed and Web of Science for (stroke OR cerebral ischemia OR cerebral ischemia) AND (biomaterial OR tissue engineering OR hydrogel$ OR scaffold$ OR *particle$ OR sponge$). No restrictions were placed on date of publication and the last search was conducted on 4 February 2019. We also searched reference lists of review articles for additional articles. Titles and abstracts were initially screened by two authors (CC and FB).

Data Sources, Studies Selections, and Data Extraction

Full texts of the identified publications were screened (CC, FB, and IL) for studies assessing the efficacy of biomaterial-based strategies in pre-clinical models of cerebral ischemia. Studies were included if lesion volume and/or neurological score were reported as outcome measures. Studies in which the method of induction of cerebral ischemia was not stated were excluded. After screening full texts for suitability, study design information was extracted from each publication (CC and FB). Information extracted included the species and stroke model used, type of biomaterial investigated and whether the material was combined with another therapeutic agent (such as growth factors or a drug), the time of administration and any functional tests conducted.

The risk of bias of each publication was assessed using the CAMARADES (Collaborative Approach to Meta-analysis and Review of Animal Data in Experimental Studies) study quality checklist (19): (1) peer reviewed publication; (2) control of temperature; (3) random allocation to treatment or control; (4) blinded induction of ischemia; (5) blinded assessment of outcome; (6) use of anesthetic without significant intrinsic neuroprotective activity; (7) animal model (aged, diabetic, or hypertensive); (8) sample size calculation; (9) compliance with animal welfare regulations; and (10) statement of potential conflict of interests. All information extracted was independently cross-checked by a second reviewer (CC, FB, and IL).

For both lesion volume and neurological score, mean values, ± standard deviation (SD) or standard error of the mean (SEM), and group sizes for treatment and control groups were extracted. Publications that did not specify specific group sizes and reported variance as SEM or did not include control groups were excluded from the meta-analysis. Where variance was reported as SEM, this was converted to SD in Microsoft Excel in order to calculate standardized mean difference (SMD) for analysis. Since the effect of biomaterial administration on stroke recovery was the main focus of this analysis, control groups chosen for comparisons were either stroke only or vehicle. In cases where the material was combined with additional therapeutic agents, stroke or vehicle were also used as controls. In two cases (20, 21), the control

group was biomaterial alone so these papers were excluded from the meta-analysis.

Two publications which presented lesion volumes and neurological scores as median ± interquartile range (IQR), were also excluded from the meta-analysis (22, 23). One paper expressed the neurological score inversely to the convention (higher scores indicate a higher degree of impairment) so the data were inverted relative to the stated baseline measure (24). Where multiple treatments were assessed, we selected the treatment identified by authors in the publications as the primary focus. When publications reported multiple outcome measures from multiple timepoints, the data for the final end point was chosen. Where publications included multiple administration timepoints, data from each group was extracted separately.

Where possible, raw values were extracted from the text of the publication. When data was presented only graphically, the online tool WebPlotDigitizer (https://automeris.io/WebPlotDigitizer/) was used to estimate mean and variance from graphs. Estimate measures were independently cross-checked by a second reviewer and any conflicts (>10% difference) were resolved by a third reviewer (CC, FB, and IL). For analysis of effect size, the publications were split into subgroups by type of biomaterial (scaffolds and particles). The scaffolds subgroup included publications using hydrogels, extracellular matrix scaffolds, fibrin glue, and sponges. The particles subgroup included publications using nanoparticles, microparticles, nanocarriers, microspheres, liposomes, nanoemulsions, nanotubes, and micelles. The selected publications were also

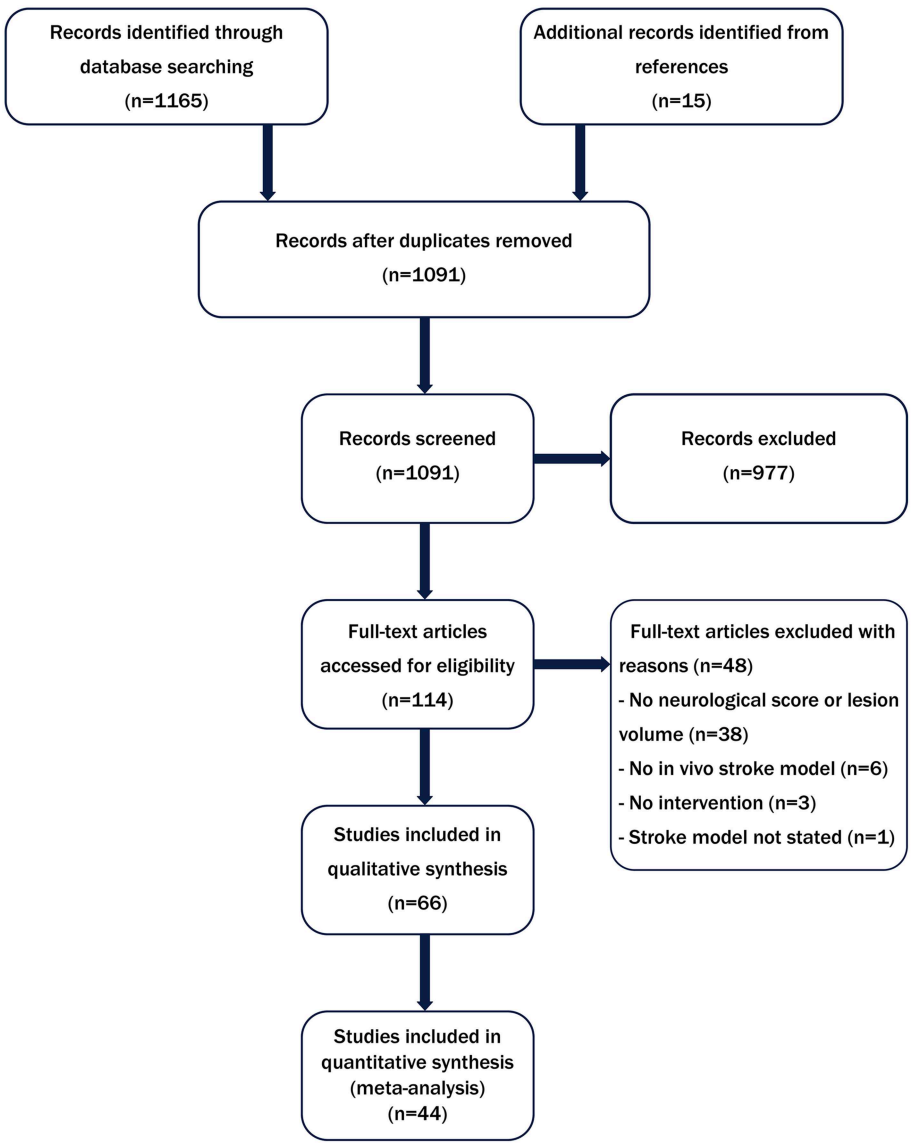

FIGURE 1 | Flow diagram summarizing the literature search strategy and number of studies included in the systematic review and meta-analysis.

divided into subgroups according to the time of administration. The groups were as follows: administration prior to stroke and up to time of reperfusion; from reperfusion to 24 h post-stroke; >24 h to 1 week post-stroke; >1–3 weeks post-stroke and multiple administrations spanning these timepoints.

Statistical Analysis

For both the lesion volume and neurological score outcomes, the SMD between the trial arms and accompanying 95% confidence intervals were calculated using DerSimonian and Laird random effects meta-analysis. Studies were weighted based on animal number. The presence of heterogeneity in the data sets was assessed using the I^2 statistic. Due to very high heterogeneity in the data ($I^2 = 82.8$ and 84.3% for lesion volume and neurological score, respectively), random effects were chosen. Forest plots were used to visually present the results. The analysis was stratified by type of biomaterial and time of administration although for brevity, only the former are presented graphically. The extent of publication bias was assessed graphically using funnel plots and confirmed with Egger's regression test. The trim and fill approach was also used to estimate an effect size accounting for publication bias. Stata 15 (StataCorp, USA) was used for all statistical analyses with the exception of the trim and fill analysis which was conducted in RStudio version 1.1.463 (RStudio Inc., USA) using the metafor package (http://www.metafor-project.org/doku.php).

RESULTS

Study Selection and Characteristics

As shown in **Figure 1**, 1,091 publications were identified from our literature search of which 66 met the inclusion

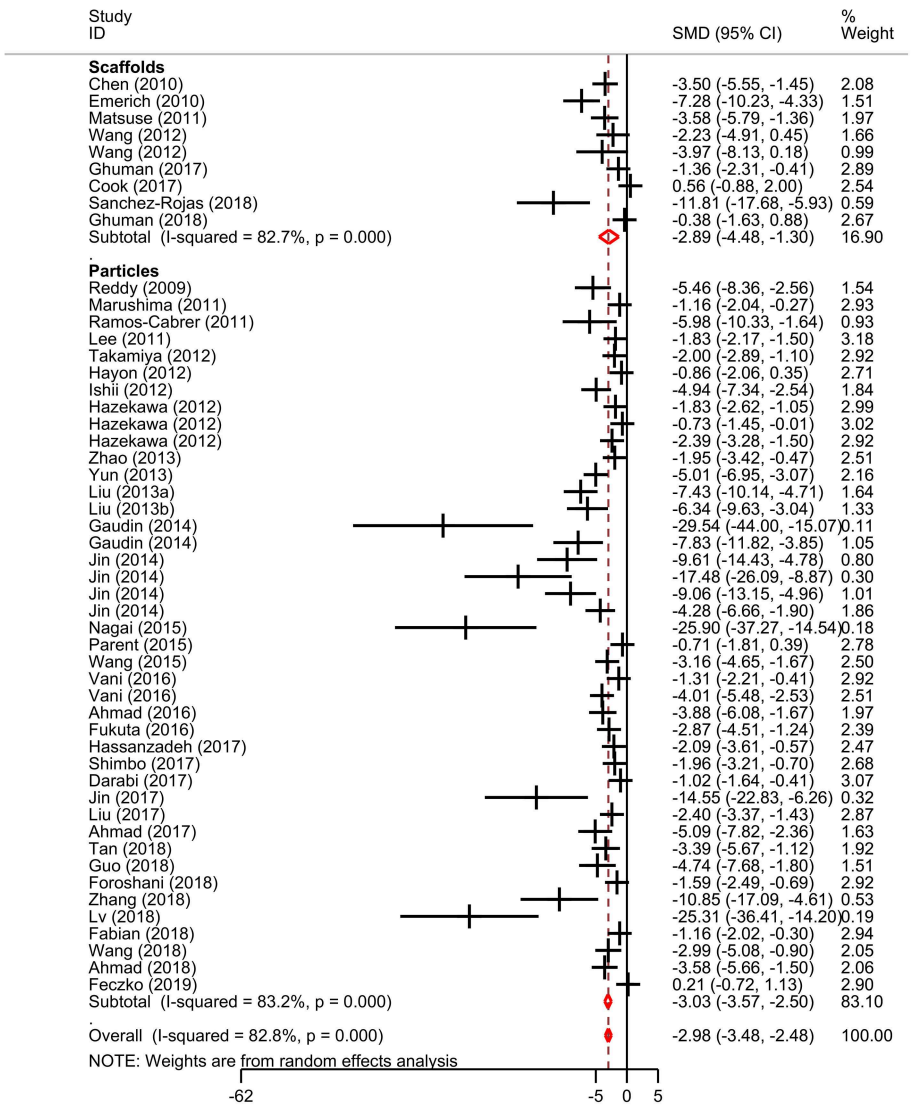

FIGURE 2 | Effect sizes for biomaterial-based interventions for lesion volume. Forest plot of standardized mean difference and 95% CI. CI, confidence interval; SMD, standardized mean difference.

criteria for the systematic review. The characteristics of these studies including stroke model, animal numbers and type of biomaterial intervention are shown in **Supplementary Table 1**. All of the included studies were conducted in rats ($n = 49$) or mice ($n = 16$) or both rats and mice ($n = 1$). The most commonly used model was the transient intraluminal filament model of middle cerebral artery occlusion (MCAO) ($n = 46$). Only two studies used comorbid animals. Hayon et al. (25) used spontaneously hypertensive rats and Fabian et al. (26) induced acute hyperglycemia in Sprague-Dawley rats using streptozotocin. As shown in **Supplementary Table 1**, there was high variation in the functional outcome measures employed (23 different behavioral tests). Furthermore, several different neurological scores were reported including modified neurological severity score (both 14 and 18 points), Bederson, modified Bederson and Longa (27, 28). A total of 44 studies including 1,075 animals (control $n = 522$, treatment $n = 553$) were then included in the meta-analysis reporting 86 comparisons. Of these, 51 assessed lesion volume and 35 assessed neurological score. There was

Median quality (/10) (IQR)	5.5 (4.25–6)	6 (4–7)	5 (4–6)

substantial heterogeneity in the datasets from both lesion volume and neurological score outcomes (I^2 = 82.8 and 84.3%, respectively).

Synthesized Findings

Meta-analysis was performed on lesion volume and neurological score data. Overall, treatment with biomaterial-based interventions led to improvements in lesion volume (SMD: −2.98, 95% CI: −3.48, −2.48). Both the scaffolds (SMD: −2.89, 95% CI: −4.48, −1.30) and particles subgroups (SMD: −3.03, 95% CI: −3.57, −2.50) had comparable effect sizes (**Figure 2**). There was high variability in the reported effect sizes in the particles groups ranging from –29.54 to −0.21. Similarly, biomaterial-based approaches were also associated with overall improvements in neurological score (SMD: −2.3, 95% CI: −2.85, −1.76; **Figure 3**). Administration of the biomaterial-based therapies within 24 h of stroke onset appeared to be most effective leading to the most marked improvement in lesion volume (SMD: −3.94, 95% CI: −5.19, −2.69; **Table 1**).

Risk of Bias and Study Quality

Risk of bias was assessed using the CAMARADES checklist (19). Overall, the median score was 5.5/10 (IQR 4.25-6). Studies within the scaffolds (6/10, IQR 4-7) and particles (5/10, IQR 4-6) subgroups had very similar scores (**Table 2**). Reporting of randomization (56%), blinding (35% to stroke and 50% to outcome) and sample size calculations (9%) was low.

Publication bias was then assessed. From visual inspection of the funnel plot for lesion volume (**Figure 4**), there was pronounced asymmetry denoting publication bias. This was confirmed by Egger's regression test ($p < 0.001$). Similarly, there was asymmetry in the funnel plot of neurological score ($p < 0.001$; **Figure 4**). Trim and fill analysis estimated 19 "missing" studies on the right side of the funnel plot of lesion volume outcome (**Figure 5**) which adjusted the effect size to −1.91 (95% CI: −2.44, −1.38). Conversely, trim and fill analysis did not report any "missing" studies for neurological score.

DISCUSSION

Summary of Findings

In this study we assessed the efficacy of biomaterial-based approaches in pre-clinical models of ischaemic stroke. A total of 66 publications met our inclusion criteria for the systematic

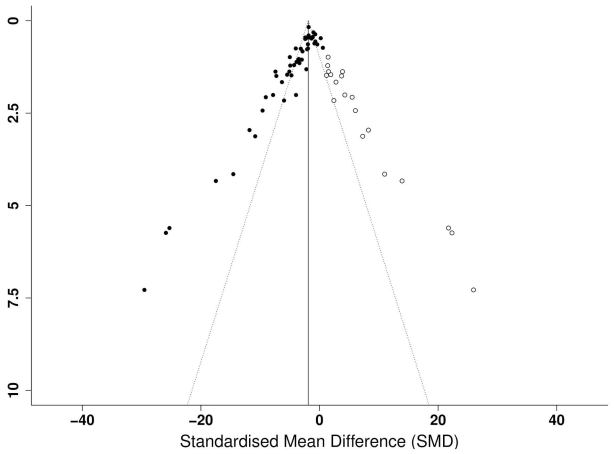

FIGURE 5 | Trim and fill analysis of lesion volume showing published studies (filled circles) and estimated unpublished studies (unfilled circles). The solid vertical line indicates the adjusted effect size.

review with 44 studies (86 comparisons) included in the meta-analysis. Overall, our findings show that biomaterial-based interventions improved both lesion volume and neurological score. Treatment within 24 h of stroke onset appeared to be the most effective timepoint. We next assessed risk of bias using the CAMARADES checklist (19) and showed the median score was 5.5/10. We also identified pronounced asymmetry in the funnel plots of both the lesion volume and neurological score dataset, indicating publication bias. Trim and fill analysis indicated there were 19 "missing" studies reporting negative or neutral lesion volume data which when adjusted for, greatly reduced the effect size.

Variability in Outcome Measures

In agreement with a recent systematic review on animal models of stroke and vascular cognitive impairment (29), we reported very high variability in the choice of functional outcome measures. A limitation of the pre-clinical stroke field is the lack of consensus on the optimal test or battery of tests for assessing functional recovery (30). We selected neurological score as one of our outcome measures as it is by far the most widely used assessment of recovery (29). While there are a number of advantages including being fast to perform and requiring no specialist equipment, a large drawback of neurological scores is that they are highly subjective (31). Additionally, we noted there was no standardization in the scale used and a number of publications neglected to report the scoring system used. A further limitation is that as rodents have a great capacity for spontaneous recovery, simpler assessments such as neurological scores often cannot detect deficits at later timepoints (30). These scores may therefore have limited use in studies where scaffold materials are administered at chronic timepoints after stroke (1–2 weeks) (32–34). In addition, neurological scores are not able to adequately distinguish compensatory strategies from true motor recovery (35) which as previously suggested, could lead to false positives (36, 37). Future studies should therefore aim to use tasks such as skilled reaching and gait analysis which can differentiate between the two.

Additionally, we noted that all but two publications identified in our systematic review reported neurological score as mean ± SD/SEM. This is surprising given that these data are ordinal and thus should be expressed as median ± IQR. The calculated effect sizes of individual studies should therefore be approached with caution. Nevertheless, given that the central limit theory states that the mean of a large number of observations will tend toward a normal distribution, our overall effect size for neurological score are robust.

Lesion volume was also chosen as an outcome measure in our meta-analysis given its wide use in the pre-clinical stroke field. The vast majority of the included studies assessing the efficacy of nanoparticles chose acute end points (24–48 h) with lesion volume as the primary outcome measure of neuroprotection. However, most studies assessing the capacity of scaffolds to promote brain regeneration elect to administer during the sub-acute and chronic phase of stroke. In these instances, it is currently unclear whether lesion volume assessment at chronic timepoints is a measure of tissue atrophy, repair or a combination of the two (33, 38, 39). Future work should therefore focus on developing standardized methods for evaluating tissue regeneration. For example, Ghuman and colleagues have chosen to focus on host cell infiltration into ECM hydrogels as an outcome measure (32, 38). Furthermore, it is worth noting that many studies that focused solely on material characterization or assessment of administration at the tissue level were excluded from our systematic review and meta-analysis as lesion volume and neurological scores were not included as outcome measures.

Both histological techniques (including 2,3,5-triphenyltetrazolium chloride (TTC), cresyl violet or haematoxylin & eosin (H&E) stains) and magnetic resonance imaging (MRI) were used to measure lesion volume. The variation in choice of method likely reflects the availability of MR scanners or preference of researchers toward a certain method. However, this may introduce inter-study variability into lesion volume measurements. A meta-analysis comparing measurements obtained from T2-weighted MR images and histological sections found a strong correlation between the two methods ($p < 0.001$) (40). Nevertheless, lesion volume measurements from MR images were larger than for histology and there was considerable variation in the reporting and use of MR methods (40). Despite this, as our study compares the SMD of treatment and control group measurements obtained using the same method, the differences in methodology is unlikely to have an effect on the conclusions of our study.

Study Quality and Risk of Bias

To improve the quality of pre-clinical research, a number of guidelines have been published in recent years including the National Centre for the Replacement, Refinement and Reduction of Animals (NC3Rs) published the Animal Research: Reporting of *in vivo* Experiments (ARRIVE) guidelines (41). This consists of a checklist of 20 items which should be reported including full details of allocation to experimental groups, sample size calculations and reporting of exact animal numbers. While most

of the studies included in our systematic review were published after the ARRIVE guidelines (2011 onwards), reporting of these items remained low. This is in agreement with a recent position paper which shows compliance with the guidelines so far has been low (42). We noted that several publications had extremely large effect sizes (SMD >-10) of which a number reported >80% reductions in lesion volume following treatment. Previous systematic reviews of *in vivo* studies have shown that studies reporting the greatest efficacies often have the lowest compliance with such checklists (43). It is possible that limitations in study design could account for an overestimation in effect size and reduced reliability of the results. It has been suggested that the lack of blinding and randomization has led to false positives in neuroprotection studies or over-estimates of efficacy which may have contributed to the translational roadblock in the field (16).

As previously mentioned, our results indicated the presence of publication bias. In particular, trim and fill analysis predicted there was a substantial number of "missing" unpublished studies reporting neutral or negative lesion volume outcomes. Publication bias is an issue not limited to pre-clinical stroke research (19, 44, 45) which can lead to overestimation of efficacy. For example, a number of studies has shown that conference abstracts reporting positive results are more likely to be published later (46–48). To avoid another translational roadblock, greater emphasis should be placed on publishing negative and neutral data.

Limitations

This systematic review and meta-analysis is the first to collate the pre-clinical literature on biomaterials for ischaemic stroke. As such, we believe the synthesized findings and conclusions are important for the field. Nevertheless, there are a number of limitations. Firstly, only summary data obtained from the publications was used for the meta-analysis and in many cases, values had to be estimated from graphs. As such, our measurements may differ marginally to the raw values. However, we did not contact authors to obtain these data. A study by the Cochrane Library compared meta-analyses using summary or "aggregate" data to those using raw data and found the difference in results and conclusions to be minimal (49). As our aim was to provide a succinct summary of the current field, we reason that the use of summary data for meta-analysis has negligible impact on the conclusions of the review.

Additionally, the considerable heterogeneity in the types of biomaterials used made identifying suitable subgroups problematic. We reasoned that all of the publications could be classified broadly as either scaffolds (administered at the lesion site for *in situ* tissue engineering in the sub-acute to chronic phase of stroke) or as particles (usually delivered systemically before or acutely after stroke). We acknowledge the wide range of material types within the chosen subgroups and an alternative option may have been to include a greater number of specific subgroups. However, we reasoned that this would decrease the statistical power of the meta-analysis and the main objective was to give an overview of the efficacy of biomaterial-based approaches in pre-clinical stroke.

We acknowledge our search criteria only identified studies relating to ischaemic stroke. A separate search containing the keywords intracerebral hemorrhage and subarachnoid hemorrhage, returned seven relevant publications (50–56). Based on the small number of publications and the heterogeneity in outcome measures used, we chose not to include these studies. Given our findings concerning risk of bias and study quality, a future systematic review and meta-analysis should investigate this in the emerging field of biomaterial therapies for hemorrhagic stroke.

CONCLUSIONS

Our meta-analysis revealed that studies assessing biomaterial-based interventions for ischaemic stroke report overall positive results leading to reductions in lesion volume and neurological improvements in rodent models. Additionally, our systematic review regarding study quality showed CAMARADES checklist score was 5.5/10. Our findings provide insight into the field of biomaterials for stroke therapeutics and the quality of studies conducted. We believe the results highlight the need for improved study design and reporting to ultimately support translation of biomaterial-based therapies to the clinical setting.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

AUTHOR CONTRIBUTIONS

CC: conception. CC, FB, and IL: design, literature search, study screening, data extraction, and manuscript writing. CH and CC: data analysis. CC, CH, FB, and IL: interpretation.

FUNDING

This work was supported by an Engineering and Physical Sciences Research Council (EPSRC) Doctoral Prize Fellowship grant EP/N509565/1 and EPSRC and Medical Research Council (MRC) Centre for Doctoral Training in Regenerative Medicine studentship grant EP/L014904/1.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Emily Sena (University of Edinburgh) and Dr. Raymond Wong (University of Manchester) for their advice on data extraction. We would also like to thank Dr. Jack Rivers-Auty (University of Manchester) for his advice on statistical analysis. We also acknowledge the contribution to study design and manuscript editing by Dr. Catherine Lawrence, Dr. Emmanuel Pinteaux, and Prof. Stuart Allan, who are also supervisors of CC, FB, and IL.

Liu J, Zhang B, Wilson G, Kong J and the Alzheimer's Disease Neuroimaging Initiative (2019) New Perspective for Non-invasive Brain Stimulation Site Selection in Mild Cognitive Impairment: Based on Meta- and Functional Connectivity Analyses. Front. Aging Neurosci. 11:228. doi: 10.3389/fnagi.2019.00228

Background: Non-invasive brain stimulation (NIBS) has been widely used to treat mild cognitive impairment (MCI). However, there exists no consensus on the best stimulation sites.

Objective: To explore potential stimulation locations for NIBS treatment in patients with MCI, combining meta- and resting state functional connectivity (rsFC) analyses.

Methods: The meta-analysis was conducted to identify brain regions associated with MCI. Regions of interest (ROIs) were extracted based on this meta-analysis. The rsFC analysis was applied to 45 MCI patients to determine brain surface regions that are functionally connected with the above ROIs.

Results: We found that the dorsolateral prefrontal cortex (DLPFC) and inferior frontal gyrus (IFG) were the overlapping brain regions between our results and those of previous studies. In addition, we recommend that the temporoparietal junction (including the angular gyrus), which was found in both the meta- and rsFC analysis, should be considered in NIBS treatment of MCI. Furthermore, the bilateral orbital prefrontal gyrus, inferior temporal gyrus, medial superior frontal gyrus, and right inferior occipital gyrus may be potential brain stimulation sites for NIBS treatment of MCI.

Conclusion: Our results provide several potential sites for NIBS, such as the DLFPC and IFG, and may shed light on the locations of NIBS sites in the treatment of patients with MCI.

Keywords: mild cognitive impairment, non-invasive brain stimulation, stimulation site, meta-analysis, resting state functional connectivity

INTRODUCTION

Mild cognitive impairment (MCI) is defined as subjective memory impairment without dementia or loss of function (Bruscoli and Lovestone, 2004). Literature suggests that MCI can be the early expression of Alzheimer's disease (AD) and that up to 14.9% of MCI patients older than 65 will develop dementia. However, pharmacologic treatment for MCI is far from satisfactory (Petersen et al., 2018).

Recently, non-invasive brain stimulation (NIBS), such as repetitive transcranial magnetic stimulation (rTMS) and transcranial direct/alternating current stimulation (tDCS/tACS), has been widely used in the treatment of MCI (Brunoni et al., 2014; Nardone et al., 2014; Birba et al., 2017; Padala et al., 2018; Rajji, 2019). While most NIBS studies have targeted brain areas such as the dorsolateral prefrontal cortex (DLPFC), inferior frontal gyrus (IFG), inferior parietal lobule (IPL), and superior temporal gyrus (STG) (Elder and Taylor, 2014; Cappon et al., 2016; Birba et al., 2017), no stimulation location has been universally agreed upon (Pievani et al., 2017).

With the aid of cutting edge brain-imaging tools, investigators have found that many brain regions and networks are involved in the pathology of MCI (Cai et al., 2017; Melrose et al., 2018). These findings provide a basis for exploring new stimulation locations for NIBS. However, some of these regions pose a challenge for NIBS application, as they are located beneath the brain surface and are therefore difficult to access (Pievani et al., 2017).

In past decades, resting state functional connectivity (rsFC) has been widely used in brain research and in identifying NIBS locations. Functional connectivity is defined as the temporal correlation or coherence of a neurophysiological index measured in different brain areas that may show similar functional properties among these brain regions (Friston et al., 1993; Biswal et al., 1997). In a previous study, Fox used a connectivity-based approach to explore the underlying mechanisms of different TMS targets, which demonstrated the potential of using a connectivity-based targeting strategy to optimize TMS locations and increase clinical response (Fox et al., 2012).

In this study, we combined brain imaging meta- and rsFC analyses to explore brain locations for NIBS treatment of MCI. Specifically, we first performed a meta-analysis to identify surface brain areas associated with MCI and then selected these regions as potential NIBS targets. Further, we selected the key MCI-associated brain areas (including both superficial and deep structures) as regions of interest (ROIs) based on the meta-analysis. These ROIs were then used as seeds in the following rsFC analysis to further identify the functionally connected brain regions that are proximal to brain surface cortex in a cohort of MCI patients. We hypothesized that areas on the brain surface that are functionally connected with the deep brain structures involved in MCI pathology (meta-analysis map) may also be used as NIBS target locations in MCI treatment.

MATERIALS AND METHODS

In the present study, we first used Neurosynth[1] to conduct a forward inference meta-analysis at the threshold of $p < 0.01$ FDR-corrected and identify key brain regions involved in the pathophysiology of MCI. Neurosynth is a platform for automatically synthesizing the results of many different neuroimaging studies. Using the Neurosynth framework, a researcher can conduct large-scale automated neuroimaging meta-analyses of broad psychological concepts. The ability of Neurosynth to quantitatively distinguish forward inference from reverse inference allows researchers to assess the specificity of mappings between neural and cognitive functions (Yarkoni et al., 2011).

We then used three different pipelines (methods) to explore potential locations for NIBS in MCI patients. In Pipeline 1, we directly selected clusters on the brain surface of the original forward inference map from the meta-analysis as potential NIBS target regions. In Pipelines 2 and 3, we applied seed-based rsFC analysis to further explore the potential brain surface locations for NIBS in MCI patients. To do this, we first chose 20 ROIs from the meta-analysis map. In Pipeline 2, the group-level correlation maps of each ROI were saved to a binary mask (with positive and negative functional connectivity separated). The 20 positive and 20 negative correlation maps were added to obtain third level maps, and 4–6 surface clusters were selected from the third level maps as potential stimulation locations. In Pipeline 3, after 20 ROIs were picked, we combined them into a single ROI. The group-level seed-based functional connectivity map was created, and 4–6 surface clusters were chosen as potential stimulation locations.

Meta-Analysis (Pipeline 1)

In the Neurosynth platform, we used "MCI" as the search term to conduct forward inference analysis on all neuroimaging studies in the database that were available until February 2018. The forward brain maps were downloaded from the platform. Potential NIBS locations were chosen based on the report, and they were visually confirmed using BrainNet view[2](Xia et al., 2013), as well as MRcon_GL and MRcron_ice toolboxes. These potential locations were mapped onto a standard brain map and standard head map with the international 10–20 system in MNI space (Cutini et al., 2011).

Resting State Functional Connectivity Analysis

fMRI Data Acquisition

The structural and resting state functional MRI data of MCI patients used in the present study were obtained from large multicenter Alzheimer's Disease Neuroimaging Initiative (ADNI) studies[3]. The ADNI was launched in 2003 as a public-private partnership, led by Principal Investigator Michael W. Weiner, MD. The primary goal of ADNI has been to test whether serial magnetic resonance imaging (MRI), positron emission tomography (PET), other biological markers, and clinical and neuropsychological assessments can be combined to measure the progression of MCI and early AD. A total of 45 MCI patients were included.

The inclusion and exclusion criteria for MCI patients are available at: http://adni.loni.usc.edu/methods/documents/ (ADNI 1 Procedures Manual). Inclusion criteria was as follows: memory complaint by subject or study partner that is verified by a study partner; abnormal memory function documented by scoring below the education-adjusted cutoff on the logical

[1]http://neurosynth.org/

[2]https://www.nitrc.org/projects/bnv/

[3]http://adni.loni.usc.edu/

memory II subscale (delayed paragraph recall) from the Wechsler memory scale-revised (the maximum score is 25): (a) less than or equal to 8 for 16 or more years of education, (b) less than or equal to 4 for 8–15 years of education, (c) less than or equal to 2 for 0–7 years of education; mini-mental state exam score between 24 and 30 (inclusive) (Exceptions may be made for subjects with less than 8 years of education at the discretion of the project director); clinical dementia rating = 0.5 Memory Box score must be at least 0.5; General cognition and functional performance sufficiently preserved such that a diagnosis of AD cannot be made by the site physician at the time of the screening visit."

The data of Mild cognitive impairment patients from 55 to 90 years old with the same fMRI scanning parameters (TR = 3000 ms, TE = 30 ms, phases = 140 with eyes opened) was used in the present study. Eligibility criteria included MCI at any stage.

Resting State Functional Connectivity Analysis

Seed-to-voxel correlational analysis were calculated in MATLAB by applying the functional connectivity (CONN) toolbox v17.C[4]. Similar to our previous studies (Tao et al., 2016, 2019; Liu et al., 2019a,b), the images were preprocessed with slice timing, realigned, co-registered to subjects' respective structural images, normalized, and smoothed with a 6 mm full width at half maximum kernel. Segmentation of gray matter, white matter, and cerebrospinal fluid for the removal of temporal confounding factors was employed. Band-pass filtering was performed with a frequency window of 0.01 to 0.089 Hz.

To eliminate correlations caused by head motion and artifacts, we identified outlier time points in the motion parameters and global signal intensity using ART[5]. We treated images as outliers if the composite movement from a preceding image exceeded 0.5 mm or if the global mean intensity was greater than three standard deviations from the mean image intensity. In addition, the 12 motion regressions (three rotation and three translation parameters plus six first-order temporal derivatives) were used in the preprocessing of BOLD time courses. Outliers were included as regressors in the first level general linear model along with motion parameters (Tao et al., 2016; Wang et al., 2017).

Based on the results of the meta-analysis, we chose the key peak MNI coordinates from the brain map (see details in section "Results" and **Table 2**) as ROIs. To ensure only voxels that were part of the original Neurosynth map were included, and to maintain regional specificity within the mentioned peak coordinates, the mask was derived by taking the overlap of the original forward inference Neurosynth map and a 6 mm radius spherical mask centered on the identified peak coordinates. This methodology is similar to that of a previous study conducted by Goldstein-Piekarski et al. (2018). The ROIs were further defined and refined by WFU-Pick Atlas software (Maldjian et al., 2003, 2004) to ensure that the regions were within the specific structure identified. The BOLD time course from these ROIs was then extracted, and Pearson's correlation coefficients were computed between that time course and the time courses of all other voxels in the brain. Correlation coefficients were Fisher transformed into *Z* scores.

Before the rsFC group analysis, we created a brain cortex mask to exclude sub-cortex brain regions from the AAL template using WFU-Pick Atlas software. The mask included bilateral pre and postcentral, superior and middle frontal, superior and inferior and middle occipital, superior and inferior parietal, supramarginal, angular, superior temporal, superior temporal pole, middle temporal, middle temporal pole, inferior temporal, oper inferior frontal, oper Rolandic, tri inferior frontal, superior medial frontal, calcarine, orbital middle and superior and inferior frontal, orbital medial frontal, supplementary motor area, paracentral lobule, precuneus, and cuneus.

Pipeline 2

For every seed in the subject-level correlation maps, the residual BOLD time course was extracted for each subject, and Pearson's correlation coefficients were computed between ROIs and all other brain voxels. The resulting correlation coefficients were subsequently transformed into *Z* scores to increase normality and thus conform to the assumptions of generalized linear models. In the group-level seed-to-voxel analysis, all subject-level seed maps of seed-to-voxel connectivity were included in a one sample *t*-test to obtain a group-level correlation map (positive and negative separated; *Z* values greater than or less than zero). A threshold of voxel-wise $p < 0.001$ uncorrected and cluster-level $p < 0.05$ family-wise error (FWE) corrected were applied within the cortex mask in data analysis.

After all whole-brain rsFC results of all ROIs above threshold had been extracted (binary mask), we calculated the sum of all brain masks using DPABI[6] to form a correlation map. The intensity of this correlation map represented the number of ROIs, and a higher intensity indicated a greater number of overlapping ROIs in the brain region. The 4 to 6 clusters on the brain surface with the largest peak intensity based on the report, visually confirmed using BrainNet view (Xia et al., 2013) and MRconGL and MRcron_ice toolboxes, were identified as potential stimulation locations.

Pipeline 3

We also calculated group functional connectivity using the seed that combined all above seeds into one seed. A threshold of voxel-wise $p < 0.001$ uncorrected and cluster-level $p < 0.05$ FWE corrected were applied within the cortex mask in data analysis.

RESULTS

Patient Demographics and Characteristics

Demographic and clinical characteristics of the study group are summarized in **Table 1**. Of the 45 enrolled MCI patients (24 female), the score of mini mental state examination (MMSE), clinical dementia rating-sum of boxes, and Alzheimer's disease assessment scale-cognition 12 (ADAS-Cog 12) were 27.64 (1.88), 0.95 (0.78), and 8.68 (3.66), respectively [mean (SD)], with

[4]http://www.nitrc.org/projects/conn

[5]http://www.nitrc.org/projects/artifact_detect

[6]http://rfmri.org/dpabi

33.33% APOE4 positive. The average age of MCI patients was 69.32 with a standard deviation of 8.07.

Meta-Analysis Results (Pipeline 1)

A total of 67 studies were included in the meta-analysis, and 20 clusters had a size greater than 30 continuous voxels. With the BrainNet viewing software, we visually determined that the left orbital IFG (F7) and left angular gyrus (P3) are proximal to the brain surface and can thereby serve as brain stimulation sites directly (**Figures 1B,C**, **Table 2**, and **Supplementary Figure S1A**).

Seed-to-Voxel rsFC Results

To further investigate potential surface locations of brain stimulation, we selected the peak coordinates from the meta-analysis maps as ROIs (seeds) (**Supplementary Figure S2**) and performed a rsFC analysis. The 20 seeds of MNI coordinates (*X*, *Y*, and *Z*) are shown in **Table 2**.

We used the above 20 seeds and applied rsFC analysis separately. The brain surface regions that showed overlap positively correlated with seed regions are listed in **Figures 1B,C**, **Table 3**, and **Supplementary Figure S1B**. These regions include the left inferior temporal gyrus, right inferior temporal gyrus, bilateral medial orbital frontal gyrus, right middle temporal gyrus/temporoparietal junction (TPJ), left middle occipital gyrus/TPJ, and left DLPFC. The left inferior temporal gyrus (T3), right supramarginal gyrus (between C4 and P4), and bilateral medial superior frontal gyrus (T3 and T4) were found to be negatively associated with seed regions applied in this study (**Figures 1B,C**, **Table 3**, and **Supplementary Figure S1C**; Pipeline 2).

When combining all seeds into one large seed, we only found positive rsFC with the right inferior occipital gyrus (between T6 and O2) proximal to the brain surface (**Figures 1B,C**, **Table 3**, and **Supplementary Figure S1D**; Pipeline 3).

DISCUSSION

In this study, we combined a meta-analysis and rsFC analysis to explore potential stimulation locations at the brain surface in patients with MCI. Our results suggest that the left DLPFC, left inferior orbital frontal gyrus, bilateral inferior temporal gyrus, TPJ, medial superior frontal gyrus, medial orbital prefrontal gyrus, right middle temporal gyrus, and inferior occipital gyrus should be considered as potential brain stimulation sites for MCI.

Location is a critical component in the treatment of MCI via NIBS (Fox and Greicius, 2010; Bergmann et al., 2016). In a previous study, Birba et al. (2017) used a meta-analysis method to test the effects of NIBS techniques on patients with MCI. They found that the DLPFC and IFG are brain stimulation areas commonly used in studies (**Figure 1A**). These findings are consistent with our results, indicating that these regions should be preferentially selected in the treatment of MCI with NIBS.

In further support of the important role of the DLPFC in patients with MCI, Yang et al. (2009) found that the BOLD response of the DLPFC is weaker in patients with MCI when compared with normally aging individuals. This finding suggests that a functional abnormality of the DLPFC may be an early indicator of the disease. In addition, results from neuroimaging studies suggest that the IFG plays an important role in cognitive functions such as memory processing (Thompson-Schill et al., 1997). For instance, Bell reported that, compared with amnestic MCI patients, patients with MCI-multiple cognitive domain had significantly reduced volume of the right IFG

(Bell-McGinty et al., 2005). Lin found that IFG activities may protect the memory function of individuals with MCI (Lin et al., 2017). These studies demonstrate the functional alterations of the DLPFC and inferior prefrontal gyrus in MCI and provide support for using these regions as treatment targets.

The temporal gyrus/TPJ was an overlapping brain region of both the meta-analysis and rsFC analysis, suggesting that it may be another important stimulation site for patients with MCI. A previous study reported that, compared with healthy elderly subjects, amnesiac MCI (aMCI) patients showed increased ALFF values in the left TPJ (Xi et al., 2013). The TPJ has been implicated across a broad range of cognitive areas, such as attention, social cognition, decision making, and episodic memory reconsolidation (Simon et al., 2017). Olichney reported that there was a significant suppression in amplitude of the late positive potential in the TPJ during a 3-choice vigilance task in individuals with MCI, and this change in amplitude may be a potential biomarker for early dementia (Olichney et al., 2011). Further, a study from Griffith et al. (2010) reported that the volume of the angular gyrus, a brain area within the TPJ, can predict cognitive function in MCI patients. Herholz also found that non-pharmacological interventions like recreational activity can yield an increase in cortical thickness of the right angular gyrus in patients with early stage AD (Herholz et al., 2013).

Our results suggest that the bilateral orbital prefrontal gyrus, inferior temporal gyrus, medial superior frontal gyrus, and right inferior occipital gyrus are potential stimulation sites based on rsFC analysis. Previous studies have suggested that the

orbitofrontal cortex is important in cognitive processes such as learning, decision making (Wilson et al., 2014), and maintaining appropriate social behavior (Jonker et al., 2015). Sacuiu showed that cortical atrophy in the frontal lobe, including the orbital prefrontal gyrus, can hasten the conversion of MCI to AD (Sacuiu et al., 2016).

In addition, studies suggest that the inferior temporal gyrus plays an important role in verbal fluency processing (Scheff et al., 2011) and serial visual recognition (Baylis and Rolls, 1987). For instance, investigators found that synaptic loss in the inferior temporal gyrus is a prominent pathological defect in the early stages of AD, and individuals with aMCI have significantly fewer synapses compared to those with no cognitive impairment (Scheff et al., 2011). The current literature suggests that increased activity of the superior frontal gyrus may be closely related to attentional shift between object features (Nagahama et al., 1999), cognitive control, working memory, and execution (Zhang et al., 2012).

Moreover, the medial superior frontal is an important node within the default mode network (DMN). Zhou et al. (2015) found several important nodes within the DMN that are involved in MCI, including the medial superior frontal gyrus. Huang et al. (2016) suggested that the DMN may indeed be a crucial target for interventions of MCI. Fink et al. (1996) found that the left inferior occipital cortex was activated in a local directed attention task, and Belleville suggested that attentional control deficits occur in patients with MCI (Belleville et al., 2007). Taken together, these studies provide further support for the aforementioned brain regions as targets for MCI treatment with NIBS.

It is worth noting that identifying these locations may also help to advance other interventions such as scalp acupuncture. Unlike traditional acupuncture, where needles are inserted into acupuncture points, scalp acupuncture stimulates the area of scalp corresponding to brain regions believed to be involved in the pathology of the disorders (Hao and Hao, 2012). Thus, results obtained from this study may facilitate the development of acupuncture and therapeutic modalities such as transcutaneous electrical nerve stimulation for the treatment of MCI.

Further, the aim of this preliminary study was to investigate potential stimulation locations for NIBS treatment using a unique approach that combined meta- and functional connectivity analyses. However, different stimulation techniques may have different intensities and reach different depth. How to apply and optimize these different treatment modalities to target the brain areas identified in our study is beyond the scope of this manuscript. Investigators should consider the characteristics of different tools when attempting to stimulate these areas.

CONCLUSION

Our results suggest that the DLPFC, IFG, and TPJ should be preferentially recommended as locations for NIBS treatment of MCI. Furthermore, the bilateral orbital prefrontal gyrus, inferior temporal gyrus, medial superior frontal gyrus, and right inferior occipital gyrus may also be potential brain stimulation sites. Our results ultimately shed light on possible NIBS sites in the treatment of MCI and other cases of age-related cognitive decline.

LIMITATIONS

There are several limitations to our study. First, while we provide several potential stimulation sites for NIBS treatment, we cannot predict the specific effects of such stimulation. For instance, we do not know whether the effect of the stimulation will be excitatory or inhibitory in nature. Another limitation is that the results of the connectivity analysis were strictly functional in the present study (i.e., rsFC). Future studies combining anatomical and functional connectivity analyses may yield stronger evidence for stimulation sites. Furthermore, our present study provided only a starting point for brain stimulation location selection via meta- and rsFC analysis methods. Determining the best brain region for NIBS remains a challenge. One option is to apply stimulation to multiple regions simultaneously. Stimulation paradigms are beyond the scope of this manuscript, and future studies are needed to explore these paradigms based on the specific NIBS modalities and, most importantly, the condition of the individual. In addition, due to the database limitation, we included patients within the age range of 55–90. Future studies with a smaller age range should be conducted to reduce the effects of standard deviation of age.

DATA AVAILABILITY

All datasets generated for this study are included in the manuscript and/or the **Supplementary Files**.

ETHICS STATEMENT

Data used in preparation of this article were obtained from the Alzheimer's disease ADNI database (adni.loni.usc.edu). As such, the investigators within the ADNI contributed to the design and implementation of ADNI and/or provided data but did not participate in analysis or writing of this report. A complete listing of ADNI investigators can be found at: http://adni.loni.usc.edu/wp-content/uploads/how_to_apply/ADNI_Acknowledgement_List.pdf.

AUTHOR CONTRIBUTIONS

JK designed the experiments. JL, BZ, and JK analyzed and interpreted the data. JL and GW prepared the manuscript. All authors prepared the manuscript, and read and approved the final manuscript.

FUNDING

JK was supported by grants R01 AT008563, R33 AT009310, R33AT009341, R34DA046635, and R21AT008707 from NIH. JL was supported by the Science and Technology Platform Construction project of Fujian Science and Technology Department (Grant No. 2015Y2001). Data collection and sharing for this project was funded by the Alzheimer's Disease

Neuroimaging Initiative (ADNI) (National Institutes of Health Grant U01 AG024904) and DOD ADNI (Department of Defense award number W81XWH-12-2-0012). ADNI was funded by the National Institute on Aging, the National Institute of Biomedical Imaging and Bioengineering, and through generous contributions from the following: AbbVie, Alzheimer's Association, Alzheimer's Drug Discovery Foundation, Araclon Biotech, BioClinica, Inc., Biogen; Bristol-Myers Squibb Company, CereSpir, Inc., Cogstate, Eisai Inc., Elan Pharmaceuticals, Inc., Eli Lilly and Company, EuroImmun, F. In the present study, we assessed efficacy of exosomes harvested from human and mouse stem cell cultures in protection of mouse primary astrocyte and neuronal cell cultures following *in vitro* ischemia, and against ischemic stroke *in vivo*. Cell media was collected from primary mouse neural stem cell (NSC) cultures or from human induced pluripotent stem cell-derived cardiomyocyte (iCM) cultures. Exosomes were extracted and purified by polyethylene glycol complexing and centrifugation, and exosome size and concentration were determined with a NanoSite^{TM} particle analyzer. Exosomes were applied to primary mouse cortical astrocyte or neuronal cultures prior to, and/or during, combined oxygen-glucose deprivation (OGD) injury. Cell death was assessed *via* lactate dehydrogenase (LHD) and propidium iodide staining 24 h after injury. NSC-derived exosomes afforded marked protection to astrocytes following OGD. A more modest (but significant) level of protection was observed with human iCM-derived exosomes applied to astrocytes, and with NSC-derived exosomes applied to primary neuronal cultures. In subsequent experiments, NSC-derived exosomes were injected intravenously into adult male mice 2 h after transient (1 h) middle cerebral artery occlusion (MCAO). Gross motor function was assessed 1 day after reperfusion and infarct volume was assessed 4 days after reperfusion. Mice treated post-stroke with intravenous NSC-derived exosomes exhibited significantly reduced infarct volumes. Together, these results suggest that exosomes isolated from mouse NSCs provide neuroprotection against experimental stroke possibly *via* preservation of astrocyte function. Intravenous NSC-derived exosome treatment may therefore provide a novel clinical adjuvant for stroke in the immediate post-injury period.

Keywords: glia, iCM, iPSC, pluripotent, MCAO, cerebral ischemia

INTRODUCTION

Stroke remains the second-leading cause of death worldwide, with ischemic/embolic stroke accounting for ∼87% of total stroke occurrence (Benjamin et al., 2019). To date, early restoration of cerebral blood flow with thrombolytics remains the only effective intervention to minimize the evolution of injury. The failure to develop novel adjuvant therapies may lie in a historical focus on genes and cell-signaling pathways that are predominant in terminally differentiated cells. Neural progenitor cells persist in the adult brain and recent evidence (Peron and Berninger, 2015) describes latent neurogenic pathways re-activated after ischemic injury that act to preserve and restore neuronal function. Stem-cell targeted therapies have more recently been studied intensely as a therapeutic option to translate the developmental capacity of embryogenesis to treat a wide array of adult diseases and injuries. However, early promising results with directly transplanted stem cell lines (Hao et al., 2014) have been offset by immune-rejection, and tumorigenesis (Solter, 2006; Kawai et al., 2010). Most recently, in the setting of stroke therapy, the beneficial outcomes of stem cell therapy have been localized to their paracrine effects, and not mediated by cell replacement or transplanted cell differentiation (Chen et al., 2014; Xin et al., 2014). Therefore, a more immediate focus has been delineating the cellular mechanisms of the stem cell *secretome*.

Exosomes are nanoscale vesicles (≈30–130 nm in diameter) released by most cell types after multivesicular bodies (MVBs) fuse with the plasma membrane (Colombo et al., 2014). Exosomes are present in the circulation and contain a variety of proteins, nucleic acids and lipids derived from their host cells, facilitating intercellular communication and regulating recipient cell function (Robbins et al., 2016). Exosomes can cross the blood-brain barrier (BBB), and are transported into brain cells *via* pinocytosis, direct fusion with the plasma membrane, or binding to cell surface proteins and cell adhesion molecules (Colombo et al., 2014). Recent work utilizing exosomes for ischemic stroke therapy have attributed improved functional outcome to their cargoes, which includes microRNAs, DNAs, lipids, proteins and RNAs (Chen and Chopp, 2018). Deng et al. (2018) recently demonstrated that human neural stem cell (NSC)-derived exosomes had the best effect on neuronal recovery after *in vitro* ischemia compared to exosomes derived from terminally differentiated neurons or glia. These observations suggest that application of NSC-derived exosomes may be a promising new avenue for stroke therapy, however, their cellular targets remains poorly defined. Specifically, whether there are species-, organ- or cell-type specific effects of stem cell-derived exosomes on neuroprotection remains a critical gap impeding therapeutic implementation.

Notably, re-activation of latent embryonic pathways in the brain following ischemic injury have been shown to be regulated by astrocytes (Gotz et al., 2015), specialized glia critical in maintaining neuronal homeostasis in health and in response to injury (Clarke and Barres, 2013). Our lab and others have demonstrated that preserving astrocyte survival and function can translate to neuronal protection and reduced injury (Ouyang et al., 2013; Stary and Giffard, 2015), further supporting their potential as therapeutic targets for stroke. Therefore, in the present study, we assessed the effect of exosomes derived from mouse NSC cultures on primary mouse astrocyte and neuronal cultures subjected to *in vitro* ischemic injury. To assess inter-species exosome protection we also assessed the effect of exosomes derived from human induced pluripotent stem cell-derived cardiomyocytes (iCM) on primary mouse astrocyte cultures subjected to *in vitro* ischemic injury. After observing marked protection primarily by mouse NSC-derived exosomes in primary mouse astrocyte cultures, we then assessed their efficacy with post-injury intravenous application in an *in vivo* model of ischemic stroke.

MATERIALS AND METHODS

Primary Mouse Neural Stem Cell Cultures

All animal experiments were approved by Stanford University Animal Care and Use Committee (Stanford, CA, United States) and conducted according to the National Institutes of Health guidelines for animal welfare. Mouse NSCs were isolated from newborn mice within 24 h as previously described (Sun et al., 2015) (**Figure 1**). In brief, brains were removed, freed of meninges, and diced with a sterile razor blade in dissociation buffer [DMEM (Thermo Fisher Scientific, Waltham, MA, United States) containing 2.5 U/ml papain, 250 U/ml DNase I (Thermo Fisher Scientific), and 1 U/ml Dispase II (Roche Diagnostics, Indianapolis, IN, United States)]. After 1 h incubation the cells were washed three times with DMEM plus 10% fetal bovine serum (FBS, HyClone, Logan, UT, United States). The cells were then resuspended in plating medium, Neurobasal A (Thermo Fisher Scientific), with 2 mM L-glutamine, 100 U/ml penicillin, and 100 ug/ml streptomycin (Thermo Fisher Scientific), B-27 without vitamin A (Thermo Fisher Scientific), 20 ng/ml fibroblast growth factor-2 (Peprotech, Rocky Hill, NJ, United States), and 20 ng/ml epidermal growth factor (Peprotech), and plated at a density of one brain per six-well plate. Neural precursor cells proliferated and started to form neurosphere morphology (NSCs) in 2–3 days.

Human Induced Pluripotent Stem Cell-Derived Cardiomyocytes

Human induced pluripotent stem cell (iPSC)-derived cardiomyocytes (iCMs) were generated from human amniotic mesenchymal stem cells (hAMSCs), as previously described (Ge et al., 2012) (**Figure 1**). In brief, human placental tissue was obtained from healthy subjects at the Stanford Healthcare Center. All donors provided written informed consent before collection. Placental tissue underwent serial enzymatic digestion with trypsin-EDTA (Thermo Fisher Scientific) in phosphate-buffered saline and HBSS (Thermo Fisher Scientific) containing 50 mg type I collagenase (Thermo Fisher Scientific), 0.01% papain (Sigma, St. Louis, MO, United States), and 10% FBS (HyClone). After digestion, the suspension was filtered and the cells were collected by centrifugation at 200 g for 5 min.

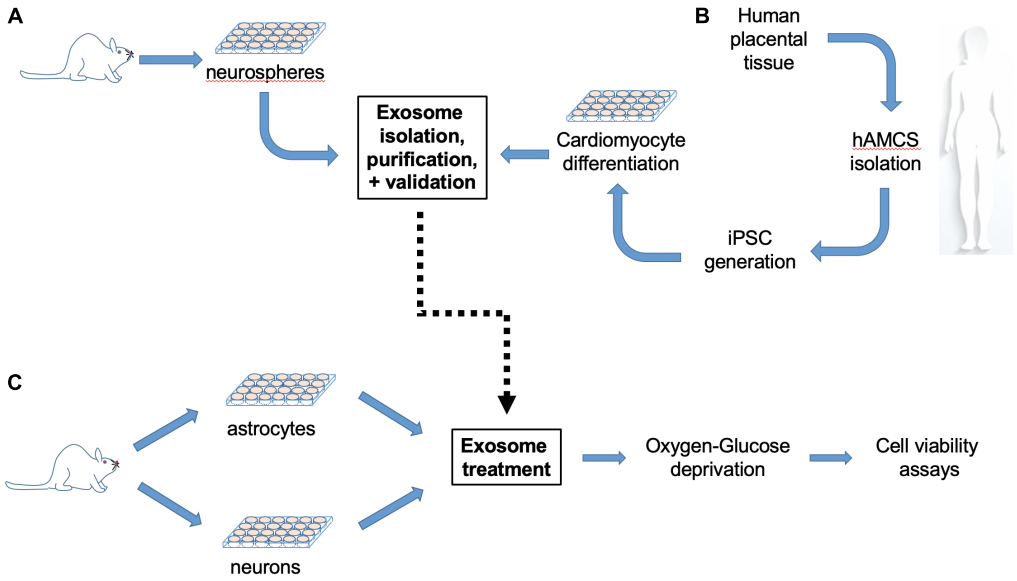

FIGURE 1 | Experimental workflow. **(A)** Mouse neural stem cells (NPCs) isolated from newborn mice were cultured for 2–3 days until proliferation to neurospheres, and then processed for exosome extraction, purification and size validation. **(B)** In parallel, exosomes were isolated from cultured human induced pluripotent stem cell (iPSC)-derived cardiomyocytes (iCMs) generated from human amniotic mesenchymal stem cells (hAMSCs). **(C)** Primary cerebral cortical astrocyte cultures were prepared from post-natal day 1–3 mice, plated for 21 days and then subjected to 6 h combined oxygen/glucose deprivation (OGD) with or without exosome treatment, followed by 24 h reperfusion prior cell viability assay. Neuronal cultures prepared from the cortices of embryonic day 15–16 mouse fetuses were plated for 12–13 days and then subjected to 70 min OGD with or without exosome treatment, followed by 24 h reperfusion prior to cell viability assay.

hAMSCs were seeded in 6-well plates and infected with 150 μL of pHAGE2-EF1α-OKSM (courtesy of Mostoslavsky, G, Ph.D., Boston University) virus in the presence of polybrene (10 mg/mL; Sigma). On day 6 post-infection, the cells were trypsinized (trypLE; Thermo Fisher Scientific), and pre-seeded with irradiated mouse embryonic fibroblasts (MEF-irr; GlobalStem). The resulting iPSCs were identified and verified as spontaneous colonies forming in human embryonic stem cell (hESC) culture media. iPSCs were then differentiated toward cardiac lineage with small molecules as previously described (Tachibana et al., 2017).

Exosome Extraction and Characterization

Exosome extraction was performed using a modified protocol by Chen et al. (2013). Briefly, Cell culture supernatant was centrifuged at 300 g for 10 min and passed through 0.2 um pore bottle top filter (BD Falcon, #352340, Thermo Fisher Scientific). One quarter volume of PEG (polyethylene glycol 8000, Thermo Fisher Scientific) stock solution [(20 g PEG8000 in 20 ml 0.5 NaCl phosphate-buffered saline (PBS, Sigma)] was added, then the total volume was brought to 50 ml with deionized H_2O and incubated overnight at 4°C. Samples were then centrifuged at 1500 g for 30 min, then at 300 g for 5 min after removal of most supernatant. The final pellet was then resuspended in PBS. Protein concentrations were determined *via* the bicinchoninic acid method (BCA Protein Assay Kit; Pierce, Rockford, IL, United States). The Malvern Panalytical NanoSight^{TM} instrument (which utilizes Nanoparticle Tracking Analysis to characterize nanoparticles from 10 to 2000 nm) was used to define exosome size and concentration.

Primary Mouse Astrocyte Cultures and Neuronal Cultures

Primary cerebral cortical astrocyte cultures were prepared from postnatal days 1–3 Swiss Webster mice (Charles River, Wilmington, MA, United States) as previously described (Dugan et al., 1995). Briefly, cortices freed of meninges were incubated in 0.05% trypsin/EDTA (Thermo Fisher Scientific) for 30 min at 37°C, mechanically dissociated, and plated in Falcon Primaria 24-well plates (Becton Dickinson, Lincoln, IL, United States) at 1–2 hemispheres per plate, in Eagle's minimal essential medium, high glucose (Glutamic, Thermo Fisher Scientific) supplemented with 10% fetal bovine serum, (Hyclone, Logan, UT, United States), 100 u/ml penicillin, 100 ug/ml streptomycin (Thermo Fisher Scientific). Cultures were maintained at 37°C in 5% CO_2, and medium was changed every 2 days before cell confluence, then twice/week after confluence, and utilized at day-*in-vitro* (DIV) 21. Relatively pure neuronal cultures, containing <1% astrocytes (Dugan et al., 1995), were prepared from the cortices of embryonic day (ED) 15 or 16 Swiss Webster mice. Cortices collected in ice-cold Eagle's minimal essential medium (Thermo Fisher Scientific) were digested with 0.05% trypsin/EDTA for 15 min at 37°C, triturated, then plated in medium containing 5% FBS and 5% ES (Hyclone). The culture medium was replaced with glial-conditioned medium containing 5% ES and 2% B-27 (Thermo Fisher Scientific). Cytosine arabinoside (3 mol/liter, Sigma) was added 24 h after plating to

inhibit glial proliferation. Cultures were used after 12–13 days (DIV 12,13) for oxygen-glucose deprivation (OGD) experiments.

Cell Culture Injury and Exosome Treatment

Combined OGD was employed as *in vitro* ischemic injury as we have previously done (Volobouева et al., 2008). Briefly, primary astrocyte and neuronal cultures were transferred to an anaerobic chamber (Coy Laboratory Products Inc., Grass Lake, MI, United States) with atmosphere gas partial pressure maintained of 5% CO_2, 5% H_2, and 90% N_2. The culture medium was replaced by three washes with deoxygenated, glucose-free balanced salt solution (BSS0), pH 7.4, containing phenol red (10 mg/liter) and (in mM) NaCl 116, $CaCl_2$ 1.8, $MgSO_4$ 0.8, KCl 5.4, NaH_2PO_4 1, $NaHCO_3$ 14.7, HEPES 10. BSS5.5 contains 25 mM glucose in BSS0 and is the medium used for wash controls. Cultures were kept at 37°C in the anaerobic chamber for 6 h for astrocyte cultures (Sun et al., 2013) and 70 min for neuronal cultures (Wang et al., 2004). Oxygen tension was monitored with an oxygen electrode (Microelectrodes, Bedford, NH, United States) and was kept under 0.02%. OGD was terminated by adding glucose to the culture medium to a final concentration of 5.5 mM and returning the cultures to the normoxic incubator for 24 h prior to assessment of cell death. In separate (unpublished) results, we have observed protection by iPSC-derived exosomes in cardiomyocytes at doses of at 10, 25, 50, 100, 200, 500 μg with an optimal dose at 50 μg. In the present study, we assessed doses *in vitro* of 30, 60, and 90 μg.

Cell Viability Assays

Extracellular release of lactate dehydrogenase (LHD) was measured to assess the extent of cell death as we routinely perform (Stary et al., 2017). LDH is an intracellular enzyme that catalyzes the conversion of lactate to pyruvate with the reduction of NAD to NADH which can be detected fluorescently (Decker and Lohmann-Matthes, 1988). LDH activity in the medium was assessed at 24 h of reperfusion and compared with maximum LDH release in medium after cells were frozen/thawed. The percentage death (% of LDH release) was calculated by dividing the experimental time point by the maximum LDH release values ×100. In parallel experiments propidium iodide (PI, 1 mg/ml) and Hoechst33258 (Sigma, 1 mg/ml) fluorescence were used to determine the percentage of cell death (Stary et al., 2017). Automated fluorescent image capture was performed at 200× using a Lumascope^{TM} 720 (Etaluma, Carlsbad, CA, United States) as we have previously performed (Xia et al., 2018). The number of PI-positive and Hoechst-positive cells were quantified using ImageJ software (v1.49b, National Institutes of Health, United States) and expressed as percentage of total cells.

In vivo Transient Focal Cerebral Ischemia and Exosome Treatment

All experimental protocols using animals were performed according to protocols approved by the Stanford University Animal Care and Use Committee and in accordance with the NIH guide for the care and use of laboratory animals. Adult male CB57/B6 mice (n = 16, 25–30 g from Jackson Lab) were anesthetized with 2% isoflurane in balance O_2 by facemask and focal cerebral ischemia was produced by 1 h of middle cerebral artery occlusion (MCAO) using a silicone-coated 6-monofilament (Doccol Co. Redlands, CA, United States) followed by reperfusion as we have previously performed (Stary et al., 2015, 2017). Rectal temperature was maintained at 37 ± 0.5°C controlled by a homeothermic blanket control unit (Harvard Apparatus, Holliston, MA, United States). Temperature and respiratory rate were monitored continuously. Mice were randomized to surgery, and mice with evidence of hemorrhage (n = 1 each group) were excluded from analysis and further treatment. Mice received treatment 2 h after reperfusion, a time point similar to when most stroke patients receive intervention (144 mins, (Saver et al., 2013)). Animals were re-anesthetized and either exosomes (10 ug total protein diluted in 100 μl saline, n = 7) or sterile saline alone (10 μl, n = 7) was administered into the surgically re-exposed internal jugular vein. This dose was chosen based on a prior study by Otero-Ortega et al. (2018) which administered 100 mg IV to rats, and scaled down to mice by body weight. Neurological status was assessed by neurologic deficit score 24 h after reperfusion (Xiong et al., 2011) using the following scoring system: 0 – no observable neurological deficits, 1 – failure to extend right forepaw; 2 – circling to the right; 3 – falling to the right; and 4 – cannot walk spontaneously. Cerebral infarction volume was determined after 4 days with 2,3,5-triphenyltetrazolium chloride (TTC, Sigma) staining of brains. Four sections/mouse were analyzed by a blinded observer and corrected for edema as described previously (Han et al., 2009) using ImageJ (v1.49b). Percent brain infarction was calculated as the area of the contralateral hemisphere minus the ipsilateral heather portion/contralateral hemisphere × 100, averaged for the sections.

Statistical Analysis

All values are presented as mean ± SD. For comparisons with more than two groups (i.e., **Figures 2**, **3**), one-way ANOVA was used. For comparison of two groups (i.e., **Figure 4**), student's t-test was used; Bonferroni *post-hoc* analysis was applied for statistical significance. GraphPad Prism 7.0 was used for statistical analysis and to plot graphs.

RESULTS

To investigate whether exosomes-derived from human or mouse stem cells had any effect on astrocytic cell death induced by OGD-reperfusion, we applied exosomes from either human iCMs or mouse NSC cultures immediately prior to and during OGD to confluent primary mouse astrocyte cultures. Both exosomes from human iCMs (**Figure 2A**) and exosomes from mouse NSCs (**Figure 2B**) exerted a neuroprotective effect. Exosomes derived from human iCMs reduced astrocytic LDH release from 47 to 32.9% at 30 ug/well, and then significantly ($p < 0.05$) reduced injury to 23.8% at 60 ug/well and to 21.6% in 90 ug/well. Comparatively, mouse NSC-derived exosomes treatment significantly ($p < 0.0005$) reduced LDH release

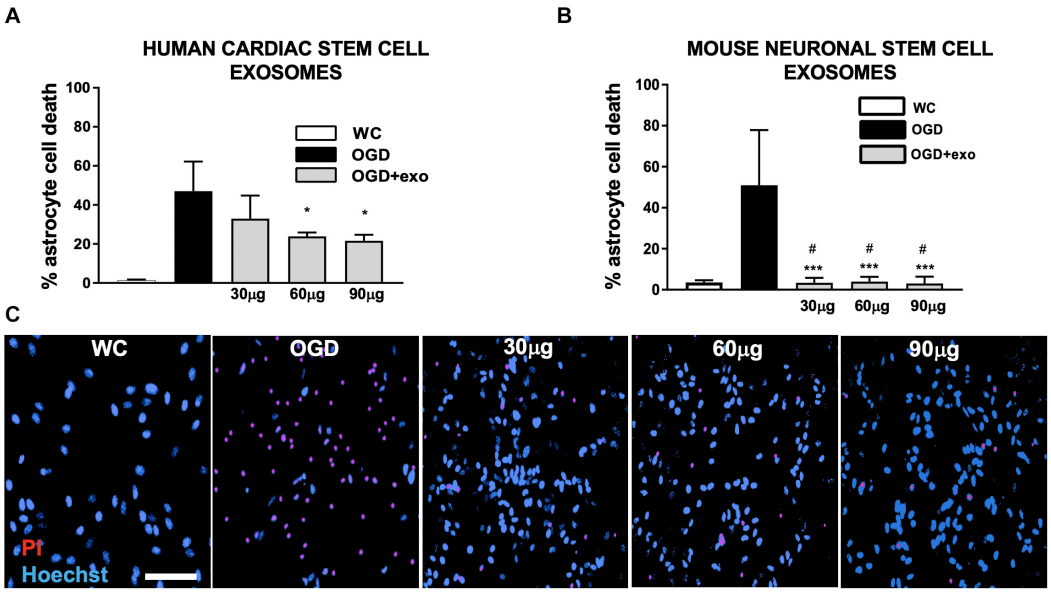

FIGURE 2 | Protection of mouse primary astrocytes against ischemic injury with exosomes derived from human iCMs and exosomes derived from mouse NSCs. **(A)** Cell death assessed by lactate dehydrogenase (LDH) release from mouse primary astrocyte cultures after oxygen/glucose deprivation injury (OGD) with/without exosomes derived from human iCMs. **(B)** Cell death assessed by LDH in mouse primary astrocyte cultures after OGD with/without exosomes derived from mouse NSCs. **(C)** Examples of astrocyte cultures stained to assess cell death with propidium iodide (PI, red) after OGD and treated with varying concentrations of exosomes derived from mouse neuronal stem cells. Cells are counterstained with Hoechst (blue) which stains all nuclei. Data are expressed as mean ± SD, all graphs represent pooled data from three individual experiments (n = 4–6 per treatment group for each individual experiment). *$p < 0.05$, ***$p < 0.0005$, compared with the control group. $^{\#}p < 0.05$ versus same dose exosomes derived from human iCMs. WC = wash control.

Data are expressed as mean ± SD, graphs represent pooled data from three individual experiments, (n = 4–6 per treatment group for each individual experiment). ***$p < 0.0005$, ****$p < 0.0001$. WC = wash control.

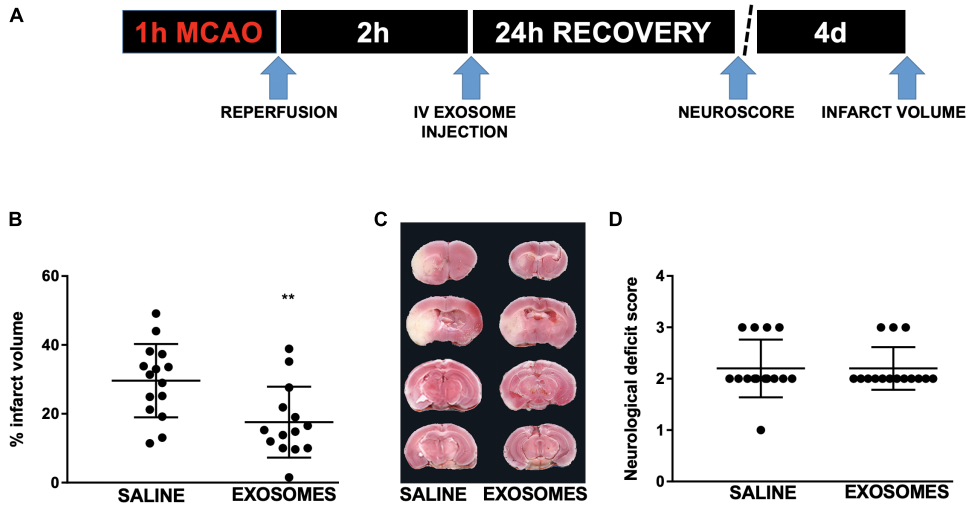

FIGURE 4 | Effect of post-injury intravenous treatment with exosomes from mouse NSCs on *in vivo* injury from transient middle cerebral artery occlusion (MCAO). **(A)** Injury and treatment workflow. Mice were subjected to 1 h MCAO and treated after 2 h reperfusion with either intravenous (IV) saline or exosomes derived from mouse NSCs. **(B)** Quantification of infarct volume 4 days after MCAO in mice treated with either saline or mouse NSC-derived exosomes. **(C)** Representative TTC-stained brain sections with saline or exosome treatment (infarcted areas are lighter in color). **(D)** Neurological deficit 24 h following MCAO in mice treated with saline or NSC-derived exosomes. Data are expressed as mean ± SD, $^{**}p < 0.0046$ versus saline (control) and exosome; n = 15–14/treatment group. TTC = 2,3,5-Triphenyltetrazolium chloride.

from astrocyte cultures at all doses: from 50.9 to 3.34% with 30 ug/well, 3.9% with 60 ug/well and 3% with 90 ug/well. In comparison with the same dose human iCM-derived exosomes, mouse NSC-derived exosomes provided significantly ($p < 0.05$) greater protection against *in vitro* ischemia in these astrocyte cultures. Protection was confirmed in parallel *via* propidium iodide/Hoescht co-staining (**Figure 2C**).

To further validate these observations, we tested the protective effect of exosomes isolated from three additional culture dissections of mouse NSCs. Exosome quality and concentration from each dissection were first independently validated (**Figure 3A**) and were similarly significantly protective when applied at 60 ug/well during OGD, as assessed either by LDH release (**Figure 3B**: 46.32 to 6.5% for exosome 1, 5.53% for exosome 2 and 5.93% for exosome 3) or PI/Hoescht staining (data not shown).

Next, to assess whether protection by stem cell-derived exosomes is cell-type specific, we assessed their effect in primary neuronal cultures subjected to OGD. We observed that while NSC-derived exosomes were protective neuronal cultures were sensitive to trace amounts of the purification agent PEG 8000 and required an additional purification step (**Figure 3C**). Treatment with 60 ug/well NSC-derived exosomes during OGD reduced neuronal cell death significantly ($p < 0.05$) only when subjected to additional purification: from 56.58% to 30.97 for exo1-P, and to 37.18 by exo2-P (**Figure 3D**). We failed to observe any significant protection in primary neuronal cultures treated with human iCM-derived exosomes (data not shown).

Finally, to advance the clinical application of NSC-derived exosomes we assessed the effect of post-injury application in a mouse model of ischemic stroke. Mice were treated 2 h after reperfusion following 1 h of MCAO with an intravenous injection of NSC-derived exosomes (**Figure 4A**) or with saline alone. Relative to saline control, NSC-derived exosome treatment resulted in a significantly reduced infarct volume from 29.62 ± 2.755 to 17.59 ± 2.75% ($p < 0.005$; **Figures 4B,C**) 4 days after injury. However, we did not observe a significant difference in neurological deficit score (**Figure 4D**) at 24 h reperfusion.

DISCUSSION

In the present study, we first assessed *in vitro* the protective effect of mouse NSC- and human cardiac iCM-derived exosomes in primary mouse astrocyte cultures subjected to ischemic injury. Interestingly, we observed that application of human cardiac iCM-derived exosomes was protective in primary mouse astrocytes. These observations validate the clinical utility of utilizing rodent models of cerebral ischemia for pre-clinical testing human-derived exosomes, which will likely be available for clinical therapy in the near future, and also highlight that xenotransplantation of exosomes derived from other species may be a possible therapeutic route for human neuroprotection. However, comparatively, treatment with mouse NSC-derived exosomes resulted in near-perfect preservation of mouse astrocyte viability. Subsequently, we observed that mouse NSC-derived exosomes applied to mouse primary neuronal cultures also had a more modest (but significantly) protective effect against *in vitro* ischemia compared with the marked protection of NSC-derived exosomes applied to primary astrocyte cultures. Together these findings suggest that *in vivo* exosome-mediated neuroprotection may be primarily mediated by astrocytes in a species and/or organ-dependent manner.

Astrocytes play a key role in neuroprotection by maintaining cellular ion homeostasis and pH, sequestering excess neurotransmitter, and in neuronal synaptic signaling (Clarke and Barres, 2013; Liu et al., 2017). Astrocytes also mediate neuronal energy homeostasis by providing energy substrate and regulating neuronal mitochondrial biogenesis and degradation (Davis et al., 2014). Notably Hayakawa et al. (2016) recently demonstrated that astrocytes are capable of direct transfer of functional mitochondria to neurons, and that suppression of this process worsens ischemic injury. Relevant to the results from the present study, Xin et al. (2017) recently demonstrated that improved functional recovery after MCAO from *in vivo* treatment with exosomes derived from microRNA 133b-overexpressing mesenchymal stem cells was dependent on secondary exosome release from astrocytes. Both embryonic and adult neurogenesis is an astrocyte-mediated process (Sultan et al., 2015; Platel and Bordey, 2016), and specific to stroke, reactive astrocytes have been observed to behave as neural progenitor cells, an effect tied to latent activation of embryonic neurotrophic pathways in astrocytes (Gotz et al., 2015). Building on our observations from the present study of enhanced astrocyte protection with NSC-derived exosome, future investigations should assess *in vivo* whether NSC-derived exosome administration can recapitulate astrocyte-mediated neuro-restoration after stroke.

Exosomes are also central to embryonic intercellular communication in the developing nervous system and play a major role in brain development and function (Sharma et al., 2013). Exosomes released by glia regulate neuronal signaling and plasticity (Wang et al., 2012a; Fruhbeis et al., 2013; Gosselin et al., 2013) and astrocyte-derived exosomes have been demonstrated to promote neurite outgrowth and neuronal survival after oxidative stress (Wang et al., 2011). Xin et al. (2013a) originally demonstrated that systemic treatment of stroke with cell-free exosomes derived from mesenchymal stem cells significantly improved neurologic outcome and contributed to neurovascular remodeling. They noted that exosome-based therapies represented a safer therapeutic approach than cell-based therapies, as exogenously administered cells have the potential to generate emboli and to self-replicate (Wang et al., 2012b), and that protection and enhanced recovery of stem cell-based therapies are mediated by exosomal trafficking (Xin et al., 2012, 2013b). One aim of the present study was to demonstrate proof-of-principle whether clinical administration of exosomes derived from NSCs could minimize the evolution of injury from stroke. We observed that NSC-derived exosomes provided significant protection against ischemic stroke injury when given as post-MCAO IV therapy. Clinically, approximately 65–70% of stroke patients receive care within 3.5 h after onset of stroke symptoms to be treated with thrombolysis (Saver et al., 2013; Benjamin et al., 2019). The results from the present study with IV exosome treatment at 2 h post-stroke represents a realistic clinical scenario whereby exosomes could be co-administered as an adjuvant therapy with thrombolytics. Future investigations should extend these observations to assess the efficacy of direct (intracerebroventricular or intrathecal) NSC-derived exosome therapy on both acute and extended injury phases and clinical outcomes, with and without thrombolytic therapy.

One limitation of the present study was that we did not see improvement in gross motor function at 24 h post-MCAO with exosome treatment. This may be related to the short interval between post-injury exosome intervention (2 h) and our assessment of post-injury neuroscore (24 h), and/or the relative insensitivity of a 4-point test of gross motor function, although we have utilized this test to reliably demonstrate neuroprotection at 24 h in the past (Xiong et al., 2011; Xia et al., 2018). Another contributing factor may have been organ sequestration of circulating exosomes given IV or possibly secondary to inadequate dosing, however, in this mouse ischemic stroke model we employed a similar dosing regimen scaled to prior studies in rats (Xin et al., 2013b, 2017). Future studies would benefit from assessing long-term neurobehavioral outcome with repeated IV exosome dosing to more accurately assess the clinical potential of NSC-derived exosome therapy.

Another caveat is that we did not demonstrate the presence of the exosomes within the brain with IV treatment, leaving the possibility that protection from systemic exosome administration may have been mediated by systemic responses, possibly immune-mediated. Indeed, recent studies (Zagrean et al., 2018) indicate that altered immune system signaling in response to stroke may be communicated *via* exosome-mediated glial-neuronal crosstalk. Future studies should seek to develop methods to assess cell-type specific and sub-regional localization of exogenously applied exosomes which would provide additional insight into their therapeutic mechanism of action and expand their potential as a novel adjuvant stroke therapy.

Finally, in order to advance clinical relevance future pre-clinical studies should fully implement the stroke therapy academic industry roundtable (STAIR) and the stem cell therapies as an emerging paradigm in stroke (STEPS) recommendations (Lapchak et al., 2013). Combined, these recommendations include: randomized and blinded studies; efficacy in two or more laboratories; replication in a second species; consideration of age and gender; consideration of route of administration, and useful therapeutic window and dose response; defining inclusion/exclusion criteria; conducting full power analysis and sample size calculations; disclosing potential conflicts of interest; extended functional outcome (minimum of 1 month); and stratifying ischemic and hemorrhagic stroke subgroups. While the present study employed several of these criteria (randomization and blinding, clinical route of administration, etc.), future studies should assess exosome efficacy in females and in aged animals, with a focus on extended functional recovery.

DATA AVAILABILITY

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

All animal experiments were approved by Stanford University Animal Care and Use Committee (Stanford, CA, United States)

and conducted according to the National Institutes of Health guidelines for animal welfare.

AUTHOR CONTRIBUTIONS

XS performed experiments and acquired the data. J-HJ prepared biological reagents and the manuscript. OA prepared the manuscript. MS prepared biological reagents. RG and PY assisted in experimental design and data analysis and provided funding. CS assisted in experimental design and data analysis, prepared the manuscript, and provided funding.

FUNDING

This work was supported by the National Institutes of Health (NIH) grant NS 084396 to RG, NIH grant HL113456, NIH grant HL130553, and California Institute for Regenerative Medicine grant DISC1-08650 to PY, and American Heart Association grant 14FTF19970029 to CS.

Neurons Induced From Fibroblasts of c9ALS/FTD Patients Reproduce the Pathology Seen in the Central Nervous System

Peter O. Bauer[1,2,3], Judith H. Dunmore[1], Hiroki Sasaguri[1] and Vaclav Matoska[3]*

[1] Department of Neuroscience, Mayo Clinic, Jacksonville, FL, United States, [2] Bioinova, Ltd., Prague, Czechia, [3] Department of Clinical Biochemistry, Hematology and Immunology, Na Homolce Hospital, Prague, Czechia

Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are incurable neurodegenerative conditions. A non-coding hexanucleotide (GGGGCC) repeat expansion in the *c9orf72* gene is the most common genetic cause of ALS/FTD. We present a cellular model of c9ALS/FTD where induced neurons (iNeurons) are generated within 2 weeks by direct conversion of patients' dermal fibroblasts through down-regulation of polypyrimidine-tract-binding protein 1 (PTB1). While sense (S) and anti-sense (AS) intranuclear RNA foci were observed in both fibroblasts and iNeurons, the accumulation of (S) and (AS) repeat-associated non-ATG translation (RANT) products were detected only in iNeurons. Importantly, anti-sense oligonucleotides (ASOs) against the (S) repeat transcript lead to decreased (S) RNA foci staining and a reduction of the corresponding RANT products without affecting its (AS) counterparts. ASOs treatment also rescued the cell viability upon stressful stimulus. The results indicate that iNeurons is an advantageous model that not only recapitulates c9ALS/FTD hallmark features but can also help uncover promising therapeutics.

INTRODUCTION

Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are devastating neurodegenerative diseases with significant genetic, neuropathological, and clinical overlap (Lillo and Hodges, 2009; Walsh and Hochedlinger, 2010). ALS is characterized by selective degeneration of upper and lower motor neurons causing muscle weakness, spasticity, atrophy, and death within 1–5 years after disease onset (Cleveland and Rothstein, 2001; Bruijn et al., 2004). FTD is one of the most common early onset dementias (Ratnavalli et al., 2002) characterized by neuronal degeneration in the frontal and temporal lobes causing a progressive deterioration of behavior, language, and personality (Bozeat et al., 2000). An expanded non-coding hexanucleotide repeat expansion [r(GGGGCC)$_{exp}$] in the chromosome 9 open reading frame 72 (*c9orf72*) gene has been identified as the most common genetic cause underlying FTD and ALS (c9ALS/FTD) (DeJesus-Hernandez et al., 2011; Renton et al., 2011). Normal length is considered less between 2 and 30 hexanucleotides while 65 repeats are regarded as the limit for the pathogenic range [r(GGGGCC)$_{exp}$] (Loy et al., 2014; Van Mossevelde et al., 2017). Approximately 40% of

FTD patients develop motor neuron dysfunction (MND) (Lomen-Hoerth et al., 2003) and as approximately 15% of ALS patients also meet the criteria for FTD (Giordana et al., 2011; Phukan et al., 2012) while up to 50% of cases displaying frontotemporal dysfunction features (Montuschi et al., 2015).

The repeat expansion may cause c9ALS/FTD through three potential pathomechanisms. Firstly, RNA transcripts containing the expansion of sense (S) r(GGGGCC)$_{exp}$ or anti-sense (AS) r(CCCCGG)$_{exp}$ can form nuclear foci in the CNS of c9ALS/FTD patients (Gendron et al., 2013; Lagier-Tourenne et al., 2013; Taylor et al., 2016; Liu et al., 2017) which may lead to RNA-mediated toxicity by sequestering RNA-binding proteins (RBP) impairing their ability to interact with their physiological RNA targets (Lee et al., 2013; Gendron et al., 2014). Secondly, (S) and (AS) RNA transcripts can be processed by repeat associated non-ATG translation (c9RANT) resulting in dipeptide repeat proteins (S: poly GP, GA, GR; AS: poly PR, PA, GP) production that are prone to form neuronal inclusions in the CNS (Ash et al., 2013; Gendron et al., 2013; Mori et al., 2013). Thirdly, reduction of *c9orf72* mRNA levels in brain and other tissues of repeat expansion carriers were first reported in 2011 (DeJesus-Hernandez et al., 2011; Renton et al., 2011) in which several other groups and we subsequently have reported this reduction may largely due to histones hypermethylation in the vicinity of the *c9orf72* gene (Belzil et al., 2013), indicating that loss of yet unknown function of the C9orf72 protein may also play a role in disease pathogenesis (Belzil et al., 2014; Bauer, 2016; Shi et al., 2018). The haploinsufficiency of the C9orf72 protein, however, seems to be not sufficient to cause the disease, as has been shown in a C9orf72 knock out mouse model (Koppers et al., 2015; Sudria-Lopez et al., 2016). Nevertheless, it is thought to affect the inflammatory response during the disease course (O'Rourke et al., 2016).

Several cellular models of c9ALS/FTD have been generated, however, most of them have limitations. For example, although overexpression of the expansion results in robust RNA foci formation and c9RANT products accumulation (Wen et al., 2014; Molliex et al., 2015; Webster et al., 2016; Gendron et al., 2017), it does not result in reduced expression of *c9orf72* mRNA and protein as seen in c9ALS/FTD patients (DeJesus-Hernandez et al., 2011; Renton et al., 2011). It may also bypass potentially important events resulting from the presence of the repeat in genomic DNA. Moreover, it is very challenging to clone repeat sequences with lengths similar to those in patients.

So far, the most accurate cellular models have been considered neurons generated from induced pluripotent stem cells (iPSCs) derived from c9ALS/FTD patients. In these cells, RNA foci and accumulation of inclusions composed of c9RAN proteins, mainly poly GP, have been observed while maintaining the reduction of *C9orf72* mRNA (Almeida et al., 2013; Donnelly et al., 2013; Sareen et al., 2013). Although robust, the preparation of this type of cell model can be costly and time-consuming. Here we present a method involving direct conversion of human dermal fibroblasts (HDFs) into induced neurons (iNeurons). We used a previously described vector encoding short hairpin RNA targeting polypyrimidine-tract-binding protein 1 (PTB1) (Xue et al., 2013). PTB1 has been shown to inhibit neuronal differentiation triggered by miR-124 while miR-124 can reduce PTB1 resulting in a cascade including proneuronal alternative splicing events (Makeyev et al., 2007). Xue et al. (2013) generated neurons from different types of cells including HeLa, NT2, Neuro2a, or mouse embryonic fibroblasts (Xue et al., 2013). We developed a modified protocol for direct transformation of HDFs to iNeurons within 2 weeks compared to 12–16 weeks through conventional iPSC differentiation. Characterization of these iNeurons generated from c9ALS/FTD patients showed expression of all six (S) and (AS)-c9RANT products detected by polyclonal antibodies against each individual protein addition to the presence of intranuclear (S) and (AS) RNA foci in all tested cell lines. Moreover, the usefulness of iNeurons in *in vitro* modeling of ALS has been shown recently (Lim et al., 2016). In this study, iNeurons generated from fibroblasts of three ALS patients with mutations in fused in sarcoma (FUS) gene recapitulated all key features of FUS pathology found in the patient brain and spinal cord motor neurons.

Several groups have recently shown that anti-sense oligonucleotides (ASOs) therapy targeting the r(GGGGCC)$_{exp}$ RNA sequence in iPSC differentiated neurons can significantly reduce (S) RNA foci and mitigate cellular toxicity with little effect on c9RAN products detected with a polyclonal antibody preferentially detecting poly GP (Donnelly et al., 2013; Sareen et al., 2013). Therefore, we tested antisense oligonucleotides (ASOs) targeting the sense transcript containing repeat expansion r(GGGGCC)$_{exp}$ in our model and observed significant reduction of (S) RNA foci and c9RANT products accumulation without affecting (AS) RNA foci and c9RANT products. Thus, our c9ALS/FTD iNeuron model may be an efficient tool for validating therapeutic screenings.

MATERIALS AND METHODS

Standard Protocol Approvals, Registrations, and Patient Consents

Protocols were approved by the Mayo Clinic Institutional Review Board and Ethics Committee on human experimentation. Skin biopsies were collected after the participants gave written informed consent.

Human Samples

Punch skin biopsies were performed on the anterior aspect of the forearm from six individuals visiting Department of Neurology of Mayo Clinic, which included three control participants (control 1: female diagnosed with sixth nerve palsy, 61 years old at the time of biopsy; control 2: healthy female, 64 years; control 3: healthy female, 38 years) and three repeat expansion carriers (carrier 1: female, asymptomatic, 28 years old; carrier 2: female diagnosed with ALS at 49 years of age, 50 years; carrier 3: male diagnosed with ALS/FTD at 41 years of age, 43 years). Fibroblasts were generated by ReGen Theranostics Inc., (Rochester, MN). The presence or absence of the *c9orf72* repeat expansion was determined by PCR method as previously described (DeJesus-Hernandez et al., 2011). These studies were approved by

Institutional Review Board and all participants provided written informed consent.

Cell Culture and Differentiation of iNeurons

Fibroblasts were maintained in Dulbecco's modified Eagle's medium (DMEM; Lonza) supplemented with 10% heat-inactivated fetal bovine serum (Sigma), 100 units/ml penicillin, and 100 μg/ml streptomycin (Gibco) at 37°C, in an atmosphere containing 5% CO2 and 95% air. The shRNA against human PTB1 (shPTB) cloned into lentiviral plasmid pLKO.1 was a kind gift from Dr. Fu (University of California, San Diego, CA, United States). Both shPTB and non-silencing shRNA in the pLKO.1 vector (Sigma) were packaged in HEK293FT cells using Virapower (Invitrogen). Viral particles were collected 48 and 72 h after transfection.

For iNeurons production, our previously modified method (Su et al., 2014) was further optimized. Fibroblasts were seeded on a poly-D-lysine-coated surface and were transduced with lentiviral particles with shPTB for 16–18 h in the presence of 5 μg/ml polybrene. We selected the infected cells with 1.5 μg/ml puromycin for 48 h starting 2 days after transduction. At day 5, 10 ng/ml basic fibroblast growth factor (bFGF; GenScript) was added to the medium for 2 days. Cells were then maintained in DMEM/F12 medium containing 5% FBS (reduced to 2% after 2 days), 25 mg/ml insulin, 100 nM putrescine, 50 mg/ml transferrin, 30 nM sodium selenite (all Sigma), and 15 ng/ml bFGF. After 4 days, we added B27 supplement (Gibco) and 10 ng/ml each of brain-derived neurotrophic factor (BDNF), glial cell-derived neurotrophic factor (GDNF; both R&D Systems), neurotensin-3 (NT3; Peprotech), and ciliary neurotrophic factor (CNTF; Sigma). The cells were used for experiments 2–4 days later.

Immunocytochemistry

Cells were fixed with 4% paraformaldehyde, permeabilized with 0.5% Triton X-100/PBS and blocked with 5% skim milk in TBS-Tween20 (TBS-T) buffer. All antibodies were diluted in 5% skim milk/TBS-T. For neuronal markers analysis, following antibodies were used: mouse anti-MAP2 (Sigma; 1:2,000 dilution), mouse anti-Neurofilament H (Smi-32; 1:2,000), mouse anti-neuronal nuclei (NeuN; 1:500), rabbit anti-Synapsin 1 (Syn1; 1:500), rabbit anti-MAP2 (all Millipore; 1:2,000), mouse anti-Tuj1 (Cell Signaling, 1:2,000), rabbit anti-postsynaptic density protein 95 (PSD95; 1:250), rabbit anti-Drebrin (both Abcam; 1:500), rabbit anti-pan voltage-gated Na2 + channels (pan Nav; Alomone; 1:250), anti-vesicular glutamate transporter 1 (vGlut1; Synaptic Systems; 1:500), and goat polyclonal anti-PTB1 (Abcam; 1:200). Rabbit antibodies against c9RANT products, anti-poly(GP), anti-poly(GA), anti-poly(GR), anti-poly(PA), and anti-poly(PR), were generated as described previously (Gendron et al., 2013; Mann et al., 2013) and used at 1:1,000 dilutions. Secondary fluorescent antibodies (Invitrogen) were used at 1:1000 dilutions. Nuclei were stained with Hoechst 33258 (Invitrogen). Confocal microscopy was performed using Zeiss LSM 510 microscope.

Western Blot Analysis

Fibroblasts were transduced with shPTB1 or non-silencing control shRNA. Cells were collected and lysed 5 days later and the samples were run on 4–20% Tris–glycine polyacrylamide gel. Proteins were then transferred from the gel to nitrocellulose membranes following standard protocols and the immunoblot was completed using goat polyclonal anti-PTB1 (1:1,000) and mouse monoclonal anti-β-actin (Sigma; 1:10,000).

Cell Treatment

Control anti-sense oligonucleotides (ctrl ASO; sequence: CCTTCCCTGAAGGTTCCTCC) and ASOs targeting the $r(GGGGCC)_{exp}$ (ASOs; sequence: CCGGCCCCGGCCCCGGCCCC) (Donnelly et al., 2013) in final concentration of 5 μM were added to the cells at day 5, after the puromycin selection. Modified 2′ *O*-methyl RNA/DNA ASOs were generated by Integrated DNA Technologies (IDT). For quantification experiments, iNeurons were induced in 96-well plates and serial pictures were generated with BD Pathway Bio-imager (BD Biosciences). For each cell line and condition, the percentage of cells containing c9RANT inclusions was calculated from 6 wells in 4 independent experiments.

RNA Fluorescence *in situ* Hybridization (FISH)

RNA FISH on fibroblasts and iNeurons to detect RNA foci consisting of the sense (S) transcript was performed using a modified method described previously (Lagier-Tourenne et al., 2013). Briefly, cells on coverslips were fixed in 4% PFA/DEPC-PBS, permeabilized with 0.2% Triton X-100/DEPC-PBS and washed twice with DEPC-PBS. The samples were then dehydrated by 70 and 100% ethanol and air dried. This step was followed by incubation in hybridization buffer (10% dextran sulfate, 50% formamide, 50 mM sodium phosphate buffer (pH 7), 2xSSC) at 66°C for 20–60 min. Prior to use, the locked nucleic acid (LNA) probe (5′TYE563-CCCCGGCCCCGGCCCC-3′, Batch #612968, Exiqon) was denatured at 80°C for 75 s and diluted to 40 nM with hybridization buffer. The hybridization with probe was performed in a sealed, light-protected chamber at 66°C for 16–24 h. RNA FISH of fibroblasts and iNeurons to detect RNA foci consisting of the (AS) transcript were performed as above with slight modifications. The incubation with hybridization buffer (10% dextran sulfate, 50% formamide, 50 mM lithium phosphate buffer (pH 7), 2xSSC) changed to 60°C for 16–24 h with LNA probe (5′TYE563-GGGGCCGGGGCCGGGG, batch #614784, Exiqon). The coverslips were subsequently washed with 0.1% Tween-20/2xSSC for 5 min followed by three 10 min stringency washes in 0.1xSSC at 66°C. The cells were stained with Hoechst 33258, rinsed with DEPC-treated water, dehydrated through 70 and 100% ethanol and air dried. Coverslips were then mounted with Prolong Gold anti-fade reagent (Life Technologies) and the RNA foci were visualized and quantified using a Zeiss Axiovert Fluorescence Microscope with apotome module. For each cell line, three experiments were performed with three fields consisting of at least 100 cells each were randomly selected per condition.

For each field, the number of foci-positive nuclei and the total number of nuclei were counted to determine the average percentage of foci-positive cells.

Cell Toxicity Assay

The iNeurons were grown in 96-well plates and treated with increasing concentrations of tunicamycin (Sigma) for 24 h or 10 μM glutamate (Sigma) for 8 h. Medium was collected and lactate dehydrogenase (LDH) levels using Cyto-tox 96 (Promega) were measured with Spectra Max M5e Microplate Reader (Molecular Devices).

Statistical Analysis

We used paired student's *t*-test for comparison between two sample groups. Two-way ANOVA Fisher's test was used for multiple comparisons with a 95% confidence level. We considered the difference between comparisons to be significant when $P < 0.05$ for all the statistical analyses.

RESULTS

Knock-Down of PTB1 in Human Dermal Fibroblasts Leads to Induction of Neural Phenotype

Effect of PTB1 downregulation in several cell types has been shown to result in direct conversion to neuron-like cells (Xue et al., 2013). In an attempt to develop human neuronal disease models with endogenous mutation, we extended this finding to adult human dermal fibroblasts (HDFs). HDFs obtained by skin biopsies were transduced with pLKO.1-shPTB1 packaged into lentiviral particles. Interestingly, cells started to acquire neuron-like morphology as early as 4 days after transduction and with further differentiation process, the cells continued to develop into iNeurons (**Figure 1A**). The iNeurons with down-regulated PTB1 (**Figure 1B**) also expressed neuronal marker MAP2 (**Figure 1C**). In addition, differentiated cells expressed multiple neuron-specific markers including cytoskeletal, synaptic, nuclear, and other markers after 12–14 days after transduction (**Figure 1D**). Of note, HDFs transduced with non-silencing shRNA did not exhibit neurite outgrowth or neuronal markers expression.

iNeurons Derived From c9ALS/FTD Patients Form RNA Foci and Accumulate RANT Products

To see whether iNeurons could serve as a useful cellular model for *c9orf72*-related pathologies, we analyzed them for the presence of RNA foci, usually found in c9ALS/FTD patients. As reported previously, HDFs of c9ALS/FTD patients contain intranuclear RNA foci (Lagier-Tourenne et al., 2013). (S) and (AS) foci were detected in both fibroblasts and iNeurons by RNA fluorescent *in situ* hybridization (RNA FISH) by utilizing fluorescently labeled locked nucleic acid (LNA) oligonucleotides probes against the (S) and (AS) repeat RNA expansion (**Figure 2**). RNA foci were not detected in non-c9orf72 (C9-) HDF cell lines. The fraction of cells containing intranuclear (S) foci varied between ∼20% and 30% in HDFs whereas after differentiation into iNeurons, the fraction of cells containing (S) foci varied between ∼30 and 50% among the three c9ALS/FTD patient cell lines (**Figures 2C,D**). Interestingly Patient 3 had more than 50% of the cells accumulating intranuclear (AS) RNA foci in HDFs (**Figure 2C**) but is reduced by half in iNeurons. Majority of the c9ALS/FTD fibroblasts and iNeurons had 1 to 4 (S) or (AS) foci per cell with less than 5% exhibiting more than 10 nuclear foci (**Supplementary Figure 1**). The percentage of cells with 5–10 (S) foci/cell increased whereas the numbers of >20 (AS) foci/cell decreased in iNeurons compared to HDFs (**Supplementary Figure 1**). The variability of RNA foci observed in our three iNeurons cell lines generated from *c9orf72* expansion carriers (C9 +) are consistent with results previously reported in iPSC derived neurons from *c9orf72* ALS fibroblasts (Donnelly et al., 2013; Sareen et al., 2013).

In contrast to the RNA foci, we were not able to detect RANT products in HDFs (**Figure 3A**). We were curious whether we could detect some of the RANT products in iNeurons. Surprisingly, we observed all RANT products from the (S) [poly-(GA) and -(GR)], or (AS) repeat [poly-(PR) and -(PA)]; poly-(GP) is translated from both strands (**Figure 3B**). Interestingly, different RANT peptides displayed distinct distribution and pattern of inclusions (**Figure 3C**). Moreover, partial translocation of TAR DNA-binding protein 43 (TDP-43) from its normal nuclear location to cytoplasm of the C9 + iNeurons was observed (**Supplementary Figure 2**). These results indicate that C9 + iNeurons recapitulate main pathological hallmarks of c9ALS/FTD and can be used as an accurate cellular model obtainable quickly and easily.

RNA Foci Staining and RANT Is Reduced by Antisense Oligonucleotides Treatment

To examine, whether our iNeuron model could be utilized as a tool for research related to experimental therapies, we treated the cells with ASOs. Specifically designed antisense oligonucleotides have been proven to mediate the target RNA molecules degradation through RNase H-based mechanism. Previously, it has been shown that a 3-day treatment with ASOs efficiently reduced the RNA foci formation, however, did not significantly affect poly(GP) accumulation (Donnelly et al., 2013).

Control ASO or ASOs (5 μM) were applied to the cells 4 days post-transduction. Further differentiation steps including the media changes remained unmodified. ASOs reduced the staining of RNA foci formed from the (S) strand by more than 90% in three different C9 + iNeuron lines (**Figures 4A,B**). The RNA foci staining from the (AS) strand, on the other hand, was not inhibited (**Figures 4A,B**). Similar effects of ASOs were observed in the fibroblasts (**Supplementary Figure 3**).

Importantly, we also observed effect on c9RANT products translated from the (S) strand. The quantification was performed by counting cells containing inclusions by BD Pathway Bio-imager. In case of poly(GR) and poly(GA) peptides, the peptides translated only from the (S) strand, the inclusion formation was reduced by more than 85 and 75%, respectively, in all three C9 + iNeuron lines (**Figures 4C,D**). Accordingly to (AS) RNA

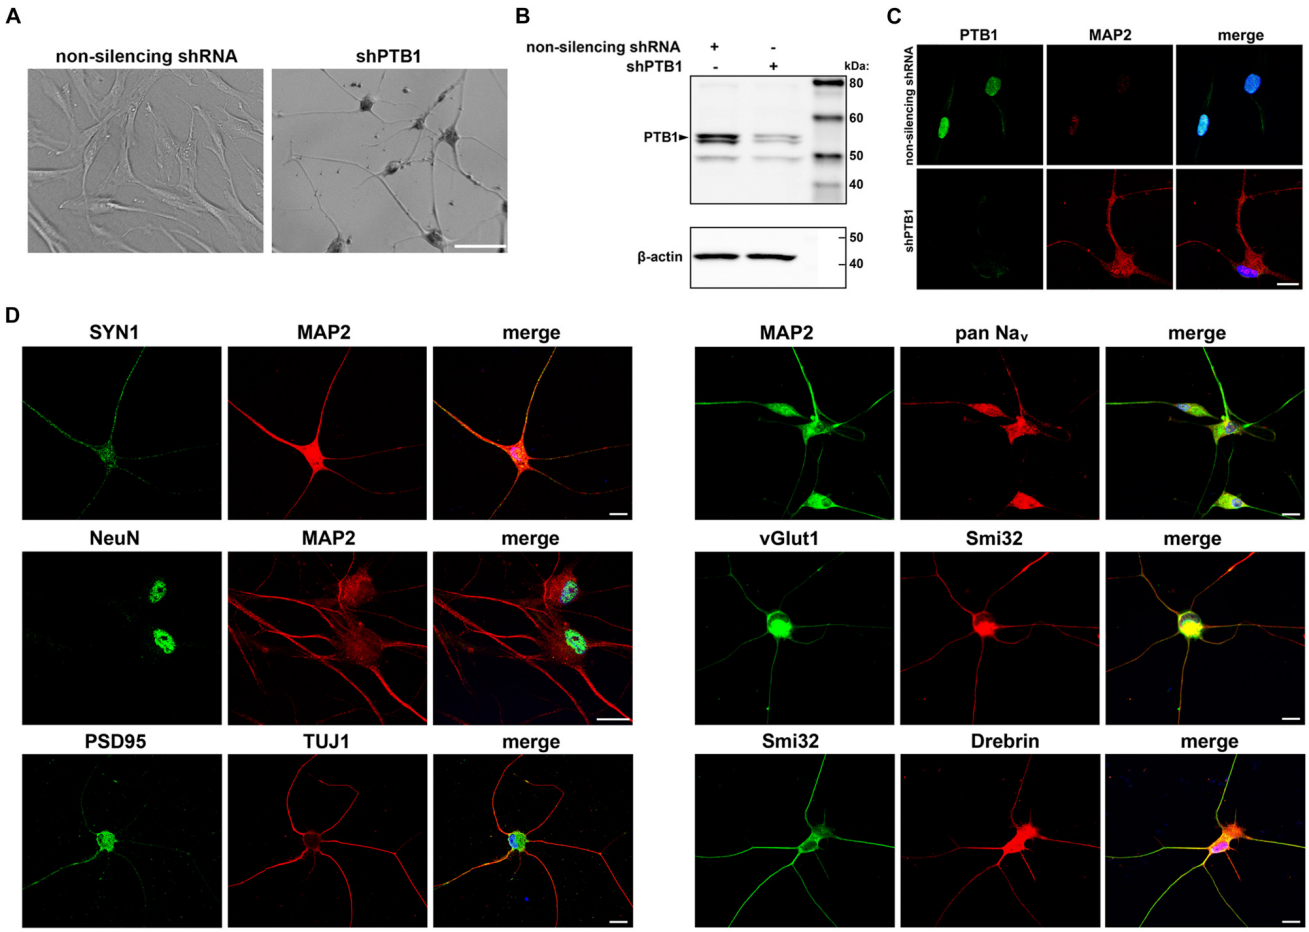

FIGURE 1 | Generation and characterization of c9ALS/FTD patient-specific induced neurons (iNeurons). **(A)** Representative bright field images show cell morphology upon non-silencing shRNA and shPTB1 transduction of human fibroblasts. While the cells infected with control shRNA retained their fibroblast-like shape, shPTB1-transduction induced a neuronal morphology with reduced size of cell soma, and neurite outgrowth. Scale bar, 400 μm. **(B)** Western blot analysis of fibroblasts transduced or not with shPTB1. **(C)** Immunofluorescence staining of cells transduced with non-silencing shRNA or shPTB1 for PTB1 and the neuronal marker, MAP2. Scale bar, 20 μm. **(D)** Expression of cytoskeletal (MAP2, TUJ1, Smi32), synaptic (SYN1, PSD95) and other neuronal markers in iNeurons. These cells also express Drebrin, which plays a role in the formation and maintenance of dendritic spines in neurons. Scale bars, 20 μm.

foci, the inclusion formed by (AS) c9RANT products were not affected by ASOs treatment. Poly(GP) inclusions were reduced only by about 52–54% likely due to the fact that it is translated from both (S) and (AS) repeat sequence.

Solely the presence of the r(GGGGCC)$_{exp}$ did not cause cytotoxicity in iNeurons. However, the C9 + cells were more sensitive to the treatment with a well-known endoplasmic reticulum stress inducer, tunicamycin (**Figure 4E** and **Supplementary Figure 4**). This is similar to a previous study showing no difference in cell viability in iPSC-derived neurons with or without r(GGGGCC)$_{exp}$. The C9 + iPSC-derived neurons were, however, more sensitive to the proteotoxic stress (Haeusler et al., 2014). Importantly, ASOs treatment was able to reduce the toxicity of tunicamycin, as determined by LDH test and by propidium iodide staining (**Figure 4E** and **Supplementary Figure 4**). Similar effect of ASOs was observed in C9 + iNeurons treated with glutamate (**Supplementary Figure 5**), that has previously been shown to be more toxic to C9 + iPSC-derived neurons (Donnelly et al., 2013). Our results suggest, that blocking the (S) RNA strand leading to reduction of c9RANT products accumulation represents a promising therapeutic strategy for c9ALS/FTD.

These results confirm that iNeurons are a suitable cellular disease model system for screening and performing experimental therapies for c9ALS/FTD.

DISCUSSION

In this study, we characterize a cellular model of c9ALS/FTD and provide evidence that this model is suitable for experimental therapeutic attempts. Studying neurological diseases is very challenging as compared to other medical fields due to the inaccessibility of the CNS neurons affected by diseases. Most of the human brain studies in neurological patients have been performed on post-mortem tissues often depicting the

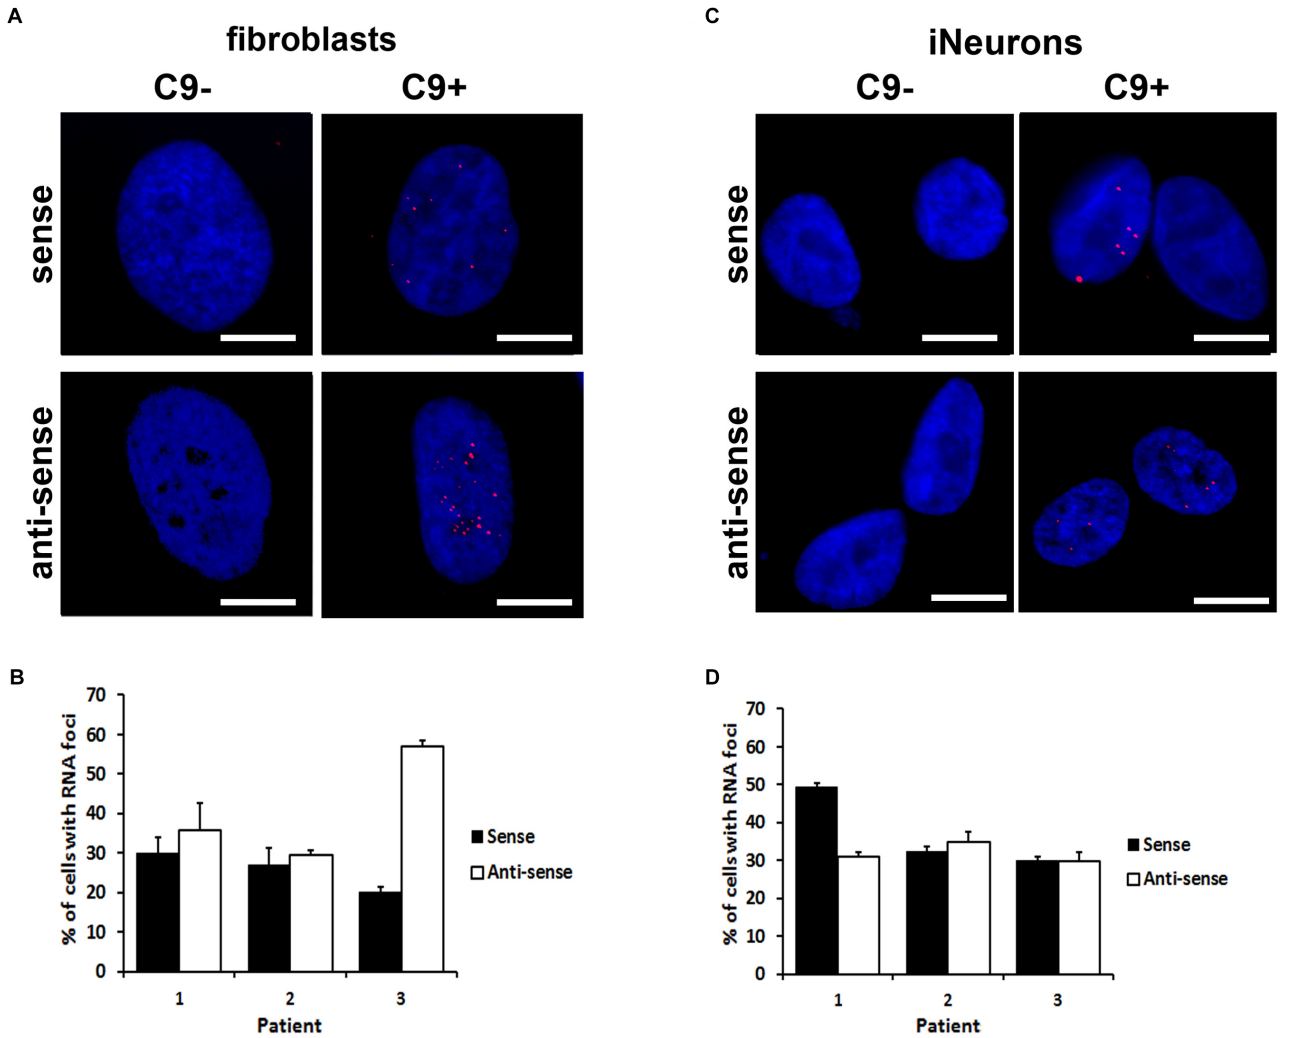

FIGURE 2 | Formation of sense and anti-sense (AS) RNA foci. **(A)** RNA foci in fibroblasts. Blue staining: Hoechst 33258. Scale bars, 20 μm. **(B)** Quantification of fibroblasts with RNA foci. end-stage of the disease. With improving cellular and animal models of the GGGGCC repeat expansion, we can uncover the pathomechanism related to c9ALS/FTD. Traditional approaches in modeling disease have multiple limitations often due to overexpression of the disease gene. Moreover, cellular and animal models often partially imitate the disease leading to limited phenotypic correlations between the genetic models and human diseases. Consequently, most of the successful experimental treatments fail to be introduced to clinics.

New approaches in disease modeling are not only vital to recapitulate human neuropathologic conditions but also can reveal unknown aspects, which could greatly improve the benefits for patients. It is particularly true in disorders without definitive causative genes and mutations (e.g., sporadic cases of AD, PD, ALS) as well as in sporadic neurological disorders caused by interactions of environmental and (multi)genetic risk factors. Another category comprises disorders where the cloning of the causing genes is problematic (e.g., CG-rich sequence, repeat expansions). The cell reprograming technology for producing iPSCs allows studying the development and progression of neurological diseases in human systems with the disease-specific pathways investigated before and during disease onset. Several reports have been published on employing iPSC technology in modeling neurological diseases, including PD, AD, spinal muscular atrophy or familial dysautonomia (Yung et al., 2013).

Direct conversion of somatic cells bypassing the iPSC stage is an alternative approach which considerably shortens the process patient-specific neurons generation. There have been several methods published using various cocktails of transcription factors (e.g., Ascl1, Brn2, or Myt1l, etc.) (Qiang et al., 2013). These methods appear to be more efficient with as much as 10% of cells conversion rate when compared with those involving iPSC generation (Pfisterer et al., 2011). The strategy of direct conversion has been even more simplified after the discovery of

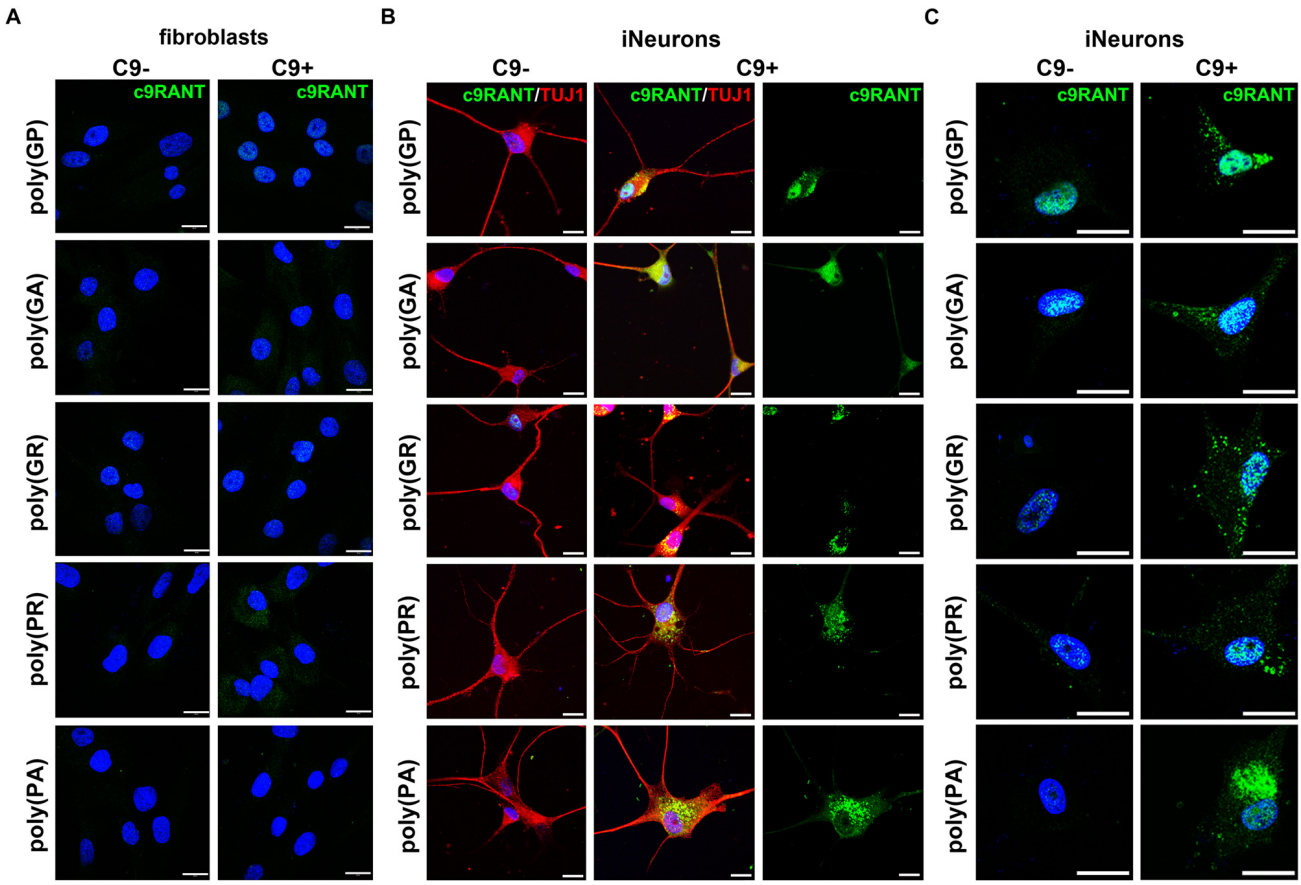

FIGURE 3 | iNeurons express c9RANT products. **(A)** c9ALS/FTD patients' fibroblasts do not accumulate RANT peptides. **(B)** Accumulation of c9RANT products can be detected in iNeurons generated from c9ALS/FTD patients. **(C)** Distribution of c9RANT products in iNeurons generated from c9ALS/FTD patients. miR-124 (a microRNA highly expressed in neurons which plays an important role in neural development) being able to efficiently contribute to induction of neurons (Ambasudhan et al., 2011) and that the down-regulation of PTB1 by shRNA, leading to an activation of miR-124-related proneuronal expression cascade, was sufficient to transdifferentiate multiple cell lines to neurons (Xue et al., 2013). The delivery of a single factor to the cells enables an extremely simple strategy in changing the fate of differentiated cells.

We extended this finding and used shPTB1 in HDFs obtained from c9ALS/FTD patients. Within 2 weeks, we were able to generate iNeurons which expressed multiple neuronal markers (**Figure 1**). Importantly, iNeurons displayed both main pathological hallmarks seen in c9ALS/FTD patients: accumulation of RNA foci and c9RANT products (**Figures 2, 3**). Inclusions formed by c9RANT products were present only in the C9 + iNeurons while not detected in the C9 + fibroblasts (**Figure 3**). These findings are consistent with our prior observation that poly(GP) inclusions are restricted to neurons in c9ALS/FTD patients (Ash et al., 2013). We also observed a partial translocation of TDP-43 from nucleus to the cytoplasm in the C9 + iNeurons (**Supplementary Figure 2**). The presence of the repeat expansion did not appear to interfere with the neuronal differentiation process and did not lead to decreased viability of the iNeurons. With additional stressful stimuli, the vulnerability of iNeurons was exposed and displayed increased cytotoxicity associated with $r(GGGGCC)_{exp}$ (**Figure 4E**). To test the suitability of our model for experimental therapeutic testing, we treated the cells with ASOs targeting the (S) repeat sequence (Donnelly et al., 2013). We found that ASOs the c9RANT products accumulation (**Figures 4A–D**). Importantly, the viability of the ASOs-treated C9 + iNeurons also increased after treatment with tunicamycin (**Figure 4E** and **Supplementary Figure 4**) and glutamate (**Supplementary Figure 5**).

Reduction of the *c9orf72* mRNA has been shown to be one of the pathological hallmarks of the c9ALS/FTD disease (DeJesus-Hernandez et al., 2011; Renton et al., 2011), probably affecting the inflammatory response (O'Rourke et al., 2016). We have previously observed such reduction in fibroblasts from patients with *c9orf72* mutation, including those involved in this study (Belzil et al., 2013).

The simplicity of the direct conversion strategy enables rapid production of iNeurons, as the whole procedure routinely takes 2–3 weeks. As the primary fibroblast cultures from

Magnification, 20 ×. **(B)** Quantification of iNeurons containing RNA foci. Data represents mean ± standard error of the mean (SEM; $n = 4$, each with at least 300 cells from 12 wells in 96-well plates). (***$p < 0.001$). **(C)** Treatment with ASOs reduced the number of cells with inclusions formed by sense RANT peptides: poly(GP),(GA), and (GR) while products translated only from the anti-sense strand, poly(PR) and (PA), remained unchanged. Blue staining: Hoechst 33258. Scale bars, 20 μm. **(D)** Quantification of iNeurons containing inclusions formed by RANT products. Data represents mean ± standard deviation (SD; $n = 3$). (***$p < 0.001$). **(E)** ASOs reduce the dose-dependent tunicamycin toxicity in C9 + iNeurons. Data represents mean ± standard error of the mean (SEM; $n = 4$, each with data from two wells). (*$p < 0.05$, **$p < 0.005$, ***$p < 0.001$).

punch biopsies can be established in 4–6 weeks, the patient-specific iNeurons can be generated within 2 months after the patient's visit. Therefore, this model represents a powerful tool not only for accurately recapitulating the pathology of c9ALS/FTD but also for individualized testing of potentially effective drugs in the future.

AUTHOR CONTRIBUTIONS

POB conceived and designed the experiments. POB, JHD, and HS performed the experiments. POB and VM analyzed the data. POB and VM wrote the manuscript.

FUNDING

This work was supported by Amyotrophic Lateral Sclerosis Association (POB; No. 2137) and Center for Regenerative Medicine, Mayo Clinic (POB, HS; No. FP00076246).

ACKNOWLEDGMENTS

We are grateful to all the patients who agreed to donate skin samples. We thank Dr. Leonard Petrucelli for the valuable discussions and providing materials. We acknowledge the expert technical assistance of Dr. Jeannie Chew for the help with FISH.

SUPPLEMENTARY MATERIAL

The Supplementary Material for this article can be found online at: https://www.frontiersin.org/articles/10.3389/fnins.2019.00935/full#supplementary-material

Small Vessel Disease

Antoine M. Hakim [1,2,3]*

[1] Ottawa Hospital Research Institute, Ottawa, ON, Canada, [2] Faculty of Medicine, Brain and Mind Research Institute, University of Ottawa, Ottawa, ON, Canada, [3] Division of Neurology, University of Ottawa, Ottawa, ON, Canada

Small vessel disease (SVD) refers to conditions where damage to arterioles and capillaries is predominant, leading to reduced, or interrupted perfusion of the affected organ. Data suggest that when this condition is evident in any organ, it is already systemic in its occurrence and consequences. SVD affects primarily organs that receive significant portions of cardiac output such as the brain, the kidney, and the retina. Thus, SVD is a major etiologic cause in debilitating conditions such as renal failure, blindness, lacunar infarcts, and dementia. The factors that lead to this devastating condition include all the known vascular risk factors when they are not strictly controlled, but lifestyles that include sedentary existence, obesity, and poor sleep patterns are also recognized drivers of SVD. In addition, depression is now recognized as a vascular risk factor. Inflammation is a mediator of SVD, but it is not known which factor(s) predominate in its etiology. This article emphasizes the need for more investigations to define this link further and suggests clinical and societal responses that might reduce the major impacts of this condition on populations.

Keywords: SVD, vascular risk factors, inflammation, dementia, lifestyle

INTRODUCTION

Small vessel disease (SVD) refers to any pathologic process that damages small end arteries, arterioles, venules, and brain capillaries (1). Although this condition was described pathologically more than a century ago (2), its pervasive nature and its association with clinically relevant conditions have been increasingly appreciated as imaging technologies advanced and became more accessible (3).

PATHOLOGY AND PATHOPHYSIOLOGY OF SVD

The main target of SVD is the endothelium, the organ that is a barrier between circulating blood and the vessel wall. Healthy endothelial cells control vascular permeability to components in plasma, limit aggregation of platelets and leucocytes, and regulate vascular tone, all of which is essential if blood flow will match metabolic demand (4). The main task of the endothelial cells is therefore to integrate information scanned constantly from the vessel wall, the blood flowing through the arterioles, and from the physiological parameters defining vascular health, and respond by varying vasomotor tone in the arterioles and maintaining an adequate antithrombotic surface.

While the endothelial cells are the main contributors to the properties of the blood brain barrier, their capabilities are induced and maintained by their interactions with mural cells (pericytes and vascular smooth muscle cells), immune cells, and glial cells—predominantly astrocytes (5). As a result, SVD results in lipohyalinosis and arteriolosclerosis.

Several animal models have been studied to shed light on the physiological processes leading to and accompanying SVD, and most involve sustained hypoperfusion of the brain as a result of bilateral stenosis of the common carotid arteries (6). This results in multiple small infarcts and hemosiderin-like regions in subcortical nuclei, with the eventual appearance of cerebral atrophy.

INFLAMMATION AND SVD

There is a growing appreciation that endothelial cells may become damaged when the environment is inflammatory (7). Inflammatory markers have been associated with periventricular white matter hyperintensities (WMH), the main MRI signature of SVD in the brain (8). Reports have linked a number of abnormalities in the interleukin (IL) pathways to SVD including IL-1beta, tumor necrosis factor, IL-10, IL-21, and IL-23 (9), confirming earlier findings by Flex et al. linking proinflammatory gene polymorphisms to one of the major consequences of SVD, dementia (10). C-reactive protein (CRP), a non-specific marker of inflammation, is considered an endothelial toxin, and CRP is both predictive of SVD and is elevated when the condition is evident (11). A relationship between midlife systemic inflammation and late-life SVD has also been reported (12).

NEUROIMAGING OF SVD

The damage caused by SVD impacts both deep gray and white matter structures in the brain (13). While CT scans can reveal the presence of SVD, the ideal method for visualizing the full spectrum of SVD is structural MRI. This includes FLAIR, T1 and T2-weighted as well as gradient echo MRI sequences (14). More recently, whole-brain magnetic resonance spectroscopy has also been used to study markers of brain inflammation (15). These brain imaging modalities reveal in SVD recent small subcortical infarcts, hyperintensities in the periventricular and deep white matter, lacunes, microbleeds, and enlarged perivascular spaces, located predominantly in the basal ganglia and the subcortical white matter (16). As well, the blood-brain barrier is impaired in small vessel disease (17). Eventually, brain atrophy becomes evident (18). Combining MRI studies with measurements of cerebral blood flow and metabolism using positron emission tomography is allowing new insights linking the progression of physiological and imaging abnormalities to the development of cognitive deficits (19, 20).

HEALTH CONSEQUENCES OF SMALL VESSEL DISEASE

In 2016 a report from experts in the field sponsored by the National Institutes of Neurological Diseases and Stroke titled: "Small Blood Vessels: Big Health Problems," highlighted the systemic nature of the disease and its neurological consequences (21). The current review unequivocally confirms the conclusion that the presence of SVD in any organ implies that the patient is suffering from a "systemic" condition.

In the brain, SVD is strongly associated with stroke (22), and the presence of SVD in the brain hampers recovery in patients who have suffered a stroke (23). SVD in the brain is also associated with declines in psychiatric (24), and gait functions (25). As might be expected from these statements, and as already noted, SVD is a major etiologic factor in dementia (26).

If brain imaging modalities reveal SVD, there is a high probability that the condition is also affecting in variable combinations the retina (27), the kidneys (28–31), the heart (32), the lungs (33), and the musculoskeletal system (34)—in fact, every organ that is perfused at a high rate of flow. Although it is possible that all these organs are impacted by the same vascular risk factors, there is nonetheless multi-organ involvement with SVD, and the link appears multidirectional. Thus, it was reported recently that retinal neurodegeneration can predict cognitive impairment (35, 36), and small vessel disease as well as retinal microvascular abnormalities are now confirmed to be associated with an increased risk of renal failure (30, 31). Consequently, in addition to damaging the brain, SVD is perhaps the main etiology for blindness, renal dysfunction, and cardiac insufficiency, making it the etiology for major medical, and neurological conditions.

WHO IS A CANDIDATE FOR SVD?

A paper published in 2007 by Vermeer et al. outlined the conditions associated with MRI-defined silent brain infarcts (37). The highest associations were noted with prior stroke, cardiovascular risk factors, and the presence of renal failure (37). This article also identified depression as having a strong association with silent brain infarcts, a link that has been confirmed subsequently (38). A 2014 study that specifically tested the association of total SVD score with vascular risk factors confirmed that smoking, hypertension, male sex, and advancing age were conditions that promoted brain SVD (39). In a separate study, SVD was observed in 3% of 40–49-year-olds but 18.9% of 70-year-olds, highlighting the association of SVD with aging (40).

In terms of the cardiovascular risk factors, hypertension is a major driver of SVD (41), and ambulatory measurements of blood pressure are better predictors of WMH than self-reported measurements (42). In the setting of hypertension, the risk of accumulating WMH rises rapidly above a resting systolic blood pressure of approximately 120 mmHg (43). Systolic blood pressure sustained above this threshold also predicts a growing risk for dementia and strokes (42, 44). Despite this overwhelming evidence in favor of maintaining at-rest systolic blood pressure at 120 mmHg, concern is often expressed that this may lead to increased mortality in the elderly, perhaps contributed to by falls and hip fractures due to orthostatic hypotension and dizziness (45). The implications of these new guidelines and the challenges they represent merited an entire issue of Circulation Research (46). It is important to note that in the SPRINT trial, among patients aged 75 or older, primary outcomes of myocardial infarction, acute coronary syndrome, stroke, congestive heart failure and cardiovascular death were all significantly lower in

those whose systolic blood pressures were maintained at or below 120 mmHg (47). Despite this, Canada's hypertension guidelines still define hypertension as systolic blood pressure of more than 135 mm Hg (48).

Obesity's impact on the development of brain small vessel disease is now well-documented (49). A 2017 review concluded that obesity and its comorbidities were associated with impaired cognitive performance, accelerated cognitive decline and dementia in later life (50), confirming the conclusion of a systematic review by Pedditzi et al., published a year earlier (51). In the setting of obesity there is a significant rise in the factors promoting inflammation, leading to the conclusion that accumulated fat, particularly in its abdominal location, is a source for inflammatory cytokines (52). It is perhaps not surprising therefore that obesity has been associated with smaller brain volumes (53).

Another reason for referring to obesity's negative impact on brain function is its high prevalence in our societies. In the United States, in 2010, 35.5% of men and 35.8% of women satisfied the criteria for obesity (Body Mass Index (BMI) of 30 or more) (54), with a clear trend for increasing prevalence of abdominal obesity between 1999 and 2012 in both men and women (55). In 2009, 24% of Canadian men and women satisfied the criteria for obesity (56).

Several other vascular risk factors have been associated with greater occurrence of SVD. These include prediabetes (57), untreated diabetes (58, 59), and hyperlipidemia (60, 61). In diabetes, microvascular complications are associated with proinflammatory cytokines and with both vascular and intracellular cell adhesion molecules (62). It is now also clear that gut microbiota can impact brain health through immune influences that can lead to cerebral endothelial dysfunction. In this context, new evidence suggests that dietary salt may promote neurovascular and cognitive dysfunction through a gut-initiated TH17 response (63).

A newly emphasized risk factor for SVD is a poor sleep pattern (64). Those who chronically cheat themselves out of sufficient sleep suffer from increased systemic inflammation (65) and are at risk for SVD and eventually develop cortical atrophy (66). The most likely reason for this is that metabolic clearance from the brain occurs preferentially during sleep (67). Unfortunately, it is estimated that a large segment of the population lives daily with inadequate sleep (68), particularly in school aged children (69).

As noted above, depression was identified by Vermeer as a factor promoting silent brain infarcts (37), and depression has been confirmed to be associated specifically with SVD (70, 71). The importance of this association arises from the disturbing statistics about the prevalence of loneliness in society, a state of mind that is highly correlated with depression (72). In the United States, it has been estimated that 40% of Americans felt lonely (73), and a survey by Statistics Canada in 2012 reported that 20% of older people declared feeling lonely (74). Thus, several societal factors associated with loneliness and depression may be promoting SVD.

SVD AND THE RISK FOR DEMENTIA

Since the prevalence of SVD increases with age, it is the consensus that the prevalence of dementia will increase over time as life expectancy lengthens (75). SVD is associated with both a reduction in cerebral blood flow (CBF) (76), and impaired CBF autoregulation (77), making it a key player in the etiologic mix that leads to dementia. Alzheimer's disease, where beta-amyloid and tau proteins accumulate in the brain, does lead to dementia, but the genetically inherited Alzheimer's variant becomes apparent early and impacts patients in their 50's and 60's. When individuals live past that age with normal cognitive function, the physiological profile that leads to dementia is very different. As mentioned above, data from the ADNI cohort (Alzheimer's Disease Neuroimaging Initiative) have clearly shown that when individuals are still cognitively intact, the sequence of pathophysiologic events that eventually leads to a decline in cognitive function starts with a reduction in cerebral blood flow (20), an association that was confirmed in a population-based study (78). This results in both reduced energy supply and reduced ability to clear accumulated waste. The important point to remember is that the reduction in CBF occurs before glucose dysregulation, before the abnormal accumulation of A-beta and other molecular biomarkers in the CSF, and before any impairment in cognition is evident. This new appreciation for the role of cerebral blood flow in delivering energy to the brain and removing the accumulated toxic molecules is perhaps one explanation for the failure of drugs designed to improve symptoms of cognitive decline by reducing the cerebral load of beta-amyloid (79, 80). Consequently, protecting CBF from decline and securing the brain's energy supply are crucial to our ability to defend against dementia.

The powerful message in all of this is that we need to explore the premise that individuals and societies may succeed in lowering their risk for dementia by reducing vascular risk factors and changing potentially harmful lifestyles. A review of advances in stroke research accomplished during 2018 confirms the impact of adverse lifestyle exposures on brain health and on cognition (81). Decades ago the lesson was established that a successful cure is dwarfed in its societal impact by a reduction in risk, and books intended for the public are now available with advice on how to achieve the goal of reducing the risk for dementia (82, 83).

SVD DESERVES MORE RESEARCH ATTENTION

Because SVD represents a major and growing threat to vascular health, it deserves more focused research attention. Addressing the specific pathophysiology of SVD is urgently needed. Several endothelial toxins associated with SVD are already known (84), but if we knew which played predominant roles, then it might be possible to test in SVD therapeutic tools to decrease the concentration of the most harmful inflammatory molecules. Another approach may arise from our knowledge that sustained activation of certain pro-angiogenic signaling factors studied in cancer biology can promote the generation of new blood vessels

(85). Could one or more of these factors be tested as repair paradigms in the setting of SVD?

IDEAL RESPONSE TO SVD AT THE CLINICAL LEVEL

The patient with SVD keeps many subspecialists occupied. He or she sees the neurologist for failing memory function and for other consequences of lacunar infarcts, the ophthalmologist for failing vision, the nephrologist for failing kidney function, the cardiologist for heart failure, and the family physician and geriatrician for control of vascular risk factors. Each specialist is focused on how to protect his or her subspecialty organ from damage. As a result, there is enormous duplication of effort, when a centralized "Vascular Clinic" that focusses on optimizing the function of the small blood vessels may be effective. In addition to monitoring and treating the vascular risk factors, such a clinic would also help patients with the lifestyle changes they need to bring about to reduce further SVD and provide support to accomplish these goals.

IDEAL SOCIETAL RESPONSE

SVD puts a very heavy burden on our individual and national health care budgets. Add to that the unpaid labor of caregivers to patients afflicted by the consequences of SVD, and the cost increases further. Society needs to respond with a cohesive and integrated set of actions.

When we became convinced that smoking was the cause of some lung cancers, clinicians, and scientists developed a discourse with our patients and the public emphasizing the serious consequences of smoking. Eventually society took on the industry—and it was not easy. To reduce the incidence of SVD we need to regenerate that energy, educate the public by talking about the damaging consequences of untreated high blood pressure and all the other vascular risk factors we know. Like there was in smoking, there are industries that will oppose us. Focused taxation may be one solution as it is now proven to limit the consumption of items known to contribute to SVD (86).

CONCLUSION

We now recognize that small vessel disease is a major health threat, aggravated by the current lifestyle trends in our society. We need to understand the disease better and mobilize energies to improve its prevention and treatment.

It is well-known that hyaluronic acid (HA) as a component of brain extracellular matrix (ECM) plays a pivotal role in the nervous system and is involved in synaptic plasticity changes in vascular cognitive impairment and dementia. HA breakdown is a feature of the acute stage of stroke injury and may be detrimental through enhancement of the inflammatory response. Recent studies have shown that knockout mice lacking hyaluronic acid synthetase demonstrates epileptic phenotype *in vivo* and removal of HA leads to delayed development of epileptiform activity in cultured hippocampal neurons *in vitro*. Here, we studied whether digestion of hyaluronic acid in the hippocampus in early postnatal period can trigger seizures. Hyaluronidase (Hyal) (5 U/μl) was bilaterally injected into C57BL/6j mice (P17) CA1 field of hippocampus using the stereotaxic method to remove hyaluronan-based ECM. Transcriptome analysis of hippocampal tissue 2 h after enzymatic digestion of hyaluronan-based brain ECM revealed increased gene expression of proteins involved in inflammation reactions (TLR2, CCL2,3,5), neuroinflammation, axonal guidance and ephrin receptor signaling, versus the vehicle group. Mice injected with hyaluronidase exhibited delayed audiogenic seizures and improvement in working memory 72 h after injection, while there were no changes in locomotor activity, anxious level and exploratory behavior due to the open field test. The obtained results point to a link between the activation of neuroinflammation by enzymatic digestion of hyaluronan-based brain ECM during the neonatal period and their subsequent reactivity to seizures, which may play an important role in the functional features of the developing brain, including its seizure propensity.

INTRODUCTION

Brain extracellular matrix (ECM) is a multicomponent complex. Members of the lectican family, chondroitin sulfate proteoglycans (CSPGs) such as neurocan, brevican, versican, and aggrecan with tenascins are anchored on hyaluronic acid (HA) backbone. HA is a unique non-sulfated glycosaminoglycan. It has a lot of physiological and biochemical properties including providing

biomechanical integrity, altering tissue hydration and facilitating tissue assembly which are dependent on its size, concentration, and localization (George and Geller, 2018).

Hyaluronic acid is distributed throughout the ECM but the highest density of HA is detected around neuronal bodies and myelinated fibers (Perkins et al., 2017). ECM in the brain has two main states: (1) diffuse ECM, which is represented throughout the brain, and (2) densely packed matrix, forming so-called perineural networks (PNNs) (George and Geller, 2018). In the adult brain, PNNs generally surround parvalbumin-expressing GABA-ergic neurons by forming a lattice structure around synapses on the body and proximal dendrites, which may affect the development and stabilization of synapses in neonatal period (McRae et al., 2012). Moreover, depending on the proteoglycan component, PNNs prevent the formation of new synaptic connections by inhibiting axonal growth (Ueno et al., 2019). There is evidence that PNNs can also protect neurons from oxidative stress and glutamate-stimulated excitotoxicity (Ueno et al., 2019).

The formation of PNNs is a long activity-dependent process. *In vitro* studies have shown that formation of PNNs requires the activity of alpha-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA) receptors and L-type voltage-dependent calcium channels (L-VDCC). During the period from the second to the third week after birth, the expression of crucial molecules of immature ECM such as tenascin-C and neurocan decreases, whereas expression of CSPGs such as aggrecan, brevican, versican V2, phosphacan, as well as tenascin-R and hyaluronan-binding protein Hapln1, are increased (Song and Dityatev, 2018). Rowlands et al. (2018) recently found that mice with knock-out of a gene responsible for aggrecan synthesis (*Acan*) has a significantly lower level of aggrecan, as well as phosphacan, neurocan, brevican, versican, and tenascin-R together with the reduced density of PNNs. This finding points to the crucial role of aggrecan in the formation of functional perineuronal nets.

Hyaluronic acid plays a pivotal role in synaptic plasticity during vascular cognitive impairment and dementia (Dityatev et al., 2009). Extracellular remodeling is a common response to different types of injuries and diseases. Upregulation of HA synthases (Has1 and 2) and hyaluronidases (Hyal1 and 2) in the cells from both stroke and peri-infarcted regions of the brain were demonstrated (Sherman et al., 2015). Recent studies have shown that knockout mice lacking hyaluronic acid synthase demonstrates epileptic phenotype (Arranz et al., 2014).

For most types of epilepsy, it is unknown how the hippocampus becomes hyperexcitable and how hyperexcitable cells integrate into a pathological circuit, resulting in the generation of spontaneous recurrent seizures. Subsequent transcriptional and translation alterations can induce changes in neuronal circuits, which predispose to development of seizures (Kim et al., 2017). Assessing the role of particular genes and pathways through the analysis of genome-wide gene expression is a promising tool to identify key trigger genes or pathways of epileptogenesis and other neurologic conditions (Younus and Reddy, 2017).

Previously, we have found that enzymatic digestion of hyaluronic acid by exogenous enzyme Hyal leads to the delayed development of epileptiform activity in cultured hippocampal neurons *in vitro* (Vedunova et al., 2013). In this study, we performed behavioral tests to identify seizure-like activity following Hyal intrahippocampal injections in C57BL/6j mice (P17). The ability for learning was assessed with a fear conditioning test. Open field exploratory test was used to estimate locomotor activity, anxiety and exploratory behavior. Transcriptome analysis of hippocampal tissue was carried out 2 h after enzymatic digestion of hyaluronan-based brain ECM to reveal changes in gene expression of different proteins. Immunohistochemical staining with anti-aggrecan antibodies was carried out to assess the integrity of PNNs.

MATERIALS AND METHODS

Animals

Animals were housed in a specific pathogen-free animal facility at 20 ± 2°C with 60% humidity, a 12 h/12 h light/dark cycle, and *ad libitum* access to food and tap water until the surgery procedures. Animals were transferred into animal cages after surgery and maintained at the same environment with their male-littermates for 2–9 days. All experiments were carried out with an effort to minimize the number of animals used and the suffering caused by study procedures.

Ethics Statement

All animals were treated in strict accordance with ethical animal research standards defined by the Russian law and approved by the Ethical Committee on Animal Health and Care of Lobachevsky State University and Privolzhsky Research Medical University of the Nizhny Novgorod.

Hyaluronidase Injection

17-day-old C57BL/6J mice were divided among two groups: hyaluronidase-treated (Hyal) and phosphate-buffered saline (PBS) treated (Vehicle). Animals were deeply anesthetized with 1.5% isoflurane and the scalp was incised. For hyaluronidase injection, a 1 mm diameter portion of the skull was removed with a drill bit at stereotactic coordinates −2.06 mm anterio–posterior, 1.89 mm medio-lateral relative to bregma. 1.25 mm diameter glass capillary with open tip 5–10 μm diameter were used for injections. The glass capillary tip was placed 1.8 mm dorso-ventral to the skull surface. The speed of the liquid flow was maintained at 3–4 nl/s. The coordinates of the injection were calculated individually for each animal based on the ratio of the distance between bregma and lambda from those mentioned above. Animals in the experimental group (Hyal) were injected with 1 μl of Hyaluronidase from bovine testis (Sigma) diluted in 0.1 M phosphate buffered saline (PBS) at a concentration of 5 U/μl. Animals in vehicle group were injected with equal volume of 0.1 M PBS.

Behavioral Tests

All the behavioral tests (n = 10/group) were carried out on second and third days after hyaluronidase injection.

Open Field Exploration Test

Mouse was placed in an open field chamber or arena (PanLab, Spain) and allowed to explore freely for 5 min. The locomotor activity (such as mean and max speed and traveled distance) in the whole arena was monitored and analyzed by an automated system (Smart v.3.0, PanLab, Spain). The distance traveled and the time spent in different parts of the arena (center and periphery) were estimated in a same way.

Anxiety (the duration of rearing and grooming in both compartments) was made in open field test.

Passive Avoidance Test

The short-term memory of experimental animals was evaluated by Passive Avoidance test (PanLab, Spain). The Passive Avoidance test is a behavioral model of conditioned reflex, consisting of the stages of training and reproduction of the reflex. The equipment was "Shuttle Box" divided into a dark and light compartment. Assessment of acquisition and retention of the passive avoidance task was carried out using identical illuminated and non-illuminated compartments containing a 50 W bulb. In brief, the animals underwent two separate trials: an acquisition trial and a retention trial, conducted 24 h after the acquisition trial. For the acquisition trial, the mouse was initially placed in the light compartment; the door between the two compartments was opened. When the mouse entered the dark compartment, the door automatically closed and an electrical foot shock (0.5 mA, 3 s) was delivered through the grid floor. The time before entering the dark room (latency) was registered. For the retention trial, the mice were placed in the light compartment as well as in acquisition trial and the time taken to enter the dark compartment was recorded again. If the mouse did not enter the dark compartment within 180 s, it was assumed that the mouse remembered the foot shock from the acquisition trial. The difference in time spent by an animal before entering dark chamber during retention and acquisition trials (delta time) was calculated.

Audiogenic Stimulus Assay

The animals were placed individually in the chamber (a glass cylinder 15 cm diameter, 25 cm height and video camera were placed a sound-proofing box) and were habituated for 5 min. Audiogenic stimulus was performed by a bell sound (100 dB) inside of box∼15 cm above the test subject. The stimulus lasted 60 s or until tonic-clonic seizure was observed visually. The behavior of the animal was recorded in three categories: wild running, tonic-clonic seizures, and death. If an animal displays the single wild run bout and stopped, thus displaying the low intensity fit score (Krushinsky–Molodkina, or KM, arbitrary unit "1"). The last stage of seizures goes through wild run which is followed first by clonic and then by tonic/clonic and tonic "full" seizure with extension of extremities and death (KM arbitrary unit "6").

Immunohistochemistry

Staining

The animals were transcardially perfused with 0.1 M PBS (pH = 7.4) at 2 h, 2 and 3 days after surgery, and subsequently followed by 4% paraformaldehyde (PFA) in PBS. Brains were then removed and fixed overnight in PFA, washed in PBS and dehydrated through a series of graded ethanol baths, and then infiltrated with paraffin; infiltrated tissues were embedded into paraffin blocks. Sections from paraffin blocks 5 um thick were made with semi-automated rotary microtome (Leica Biosystems, Germany). Every third slice was placed on an adhesive slide and dried. Paraffin sections were deparaffinized, rehydrated, treated with antigen retrieval buffer and washed in tris-buffered saline (TBS) (pH = 7.4). Permeabilization were made with 0.2% Triton X-100 (Sigma 93443-100ML) solution in TBS and was followed by blocking in 10% fetal cow serum (FCS), 1% bovine serum albumin (BSA) in TBS for 2 h. After that, sections were incubated overnight at 4°C with primary antibodies. The next day, sections were incubated with the appropriate species-specific fluoroconjugated secondary antibodies (Alexa Fluor 647 and Alexa Fluor 488; 1:400; Abcam) for 1 h. Primary antibodies used were rabbit polyclonal anti Aggrecan (ab36861; 1:100; Abcam), and chicken polyclonal anti NeuN as a neuronal marker (266006; 1:100; Synaptic Systems). The secondary antibody was goat polyclonal secondary antibody to rabbit IgG – H&L (Alexa Fluor® 488) (ab150077; 1:400; Abcam) and goat polyclonal secondary antibody to chicken IgY – H&L (Alexa Fluor® 647) (ab150171; 1:400; Abcam). Stained sections were mounted using Fluoroshield Mounting Medium with DAPI (ab104139, Abcam) and examined by fluorescence microscopy using a ZEISS LSM 880. Images were acquired controlling for equal exposure times using Zen 2.1 SP3 software. 1.2 Pl-Apo objective, pinhole 0.8 μm. Data from three channels (DAPI 405, Alexa Fluor 488, and Alexa Fluor 647) were collected by sequential scanning. Single confocal planes were analyzed to determine co-localization of signals in tissue sections.

We assessed the fluorescence intensity of anti-aggrecan antibody to assess the integrity of PNNs in four 212.5 × 212.5 μm fields of view from each slice. The average cell area and average area of extracellular space was also estimated using ImageJ. $N = 3$ animals/group, three slices from each animal.

RNA Extraction

For RNA extractions, hippocampi were dissected on ice 2 h after injections and immediately frozen via liquid nitrogen with subsequent transfer into −80°C freezer.

Total RNA was extracted from hippocampi of animals from both Hyal and Vehicle groups. RNA extraction was performed with the RNeasy mini kit (Qiagen, Valencia, CA, United States). A NanoDrop® NP-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE, United States) was used to measure the quantity of the RNA samples. The quality of the RNA samples was checked using a 2100 Bioanalyzer (Agilent Technologies Inc., Santa Clara, CA, United States), RNA integrity of each sample was assessed using ratio of 18S/28S RNA and RNA integrity number (RIN).

Agilent Microarray Analysis

The synthesis of cDNA followed by the synthesis of cRNA with fluorescent labels was performed using the Agilent Low RNA Input Fluorescent Linear Amplification Kit (Agilent

Technologies Inc., Santa Clara, CA, United States). 3-CTP or 5-CTP nucleotides with fluorescent labels (Agilent Technologies Inc., Santa Clara, CA, United States) were used for detection.

After determining the concentration of cRNA and evaluating the efficiency of fluorescent labels incorporating, the samples (750 ng each) were mixed in one tube and fragmented using reagents from the *in situ* Hybridization kit-plus kit (Agilent Technologies Inc., Santa Clara, CA, United States). After the end of fragmentation, 500 μl of the mixture was applied to Sure Print G3 Mouse Gene Expression v2 8 K× 60K Microarray Kit (Agilent Technologies Inc., Santa Clara, CA, United States) expression chips. These microchips contain 60,000 of 60 nucleotide probes immobilized on a glass and designed to analyze gene expression of the complete mouse genome (annotated genes with known and unknown function) in a given volume. Hybridization was performed in a rotary incubator (Agilent Technologies Inc., Santa Clara, CA, United States) at 65°C for 17 h. The chips were washed in an SSC buffer with the addition of Triton X102 according to the protocol of the manufacturer, then chips were scanned on a G2505B confocal laser scanner (Agilent) with a resolution of 10 μm. Extraction of DNA chip data and their primary processing were performed using the Feature Extraction 9.1 (Agilent Technologies Inc., Santa Clara, CA, United States) program.

The background signal was calculated and the fluorescence intensity in the red and green channels was calculated for each sample (spot). After determining the background signal level, all genes which are not expressed both in the Vehicle and Hyal samples were excluded from further analysis. Finally, the degree of difference in the signal of certain genes in different samples was evaluated (Vehicle, $n = 4$; Hyal, $n = 4$).

Microarray Analysis

A microarray analysis was performed using BRB-ArrayTools[1] to identify probe intensity values developed by Dr. Richard Simon and the BRB-ArrayTools Development Team that were significantly affected by hyaluronan digestion. Intra-array LOWESS normalizations were performed. The BRB-ArrayTools "Random Variance Model" option was used.

To identify the direct effect of hyaluronidase injection we compare Vehicle and Hyal groups. For this analysis two-sample *t*-test were used and *q*-value was 0.05 this resulted in 25 genes passed this filter (0.089%).

Pathway Analysis

Ingenuity pathway analysis (IPA, Qiagen, Valencia, CA, United States) was used to perform "Core Analysis" to discover biological pathways that were significantly affected by hyaluronidase treatment. Data from microarray analysis were first uploaded into Qiagen's IPA system for core analysis and then overlaid with the global molecular network in the Ingenuity Pathway Knowledge Base (IPKB).

Ingenuity pathway analysis was performed to identify canonical pathways, functions, upstream regulators that are most significant to microarray outcomes and to categorize differentially expressed genes in pathways and upstream regulators.

Establishment of Protein–Protein Interaction Network

Search Tool for the Retrieval of Interacting Genes/Proteins (STRING) database[2] was used to analyze protein interactions (Szklarczyk et al., 2014). We modeled a network of 22 genes where the interaction scores above 0.4 was considered as *de facto* interaction with the high confidence (≥0.700). After modeling the interactions network, we performed the *k*-means clustering (number of clusters = 3).

Statistical Analysis

All data quantification is presented as the mean ± standard error of the mean (SEM). Statistical analysis was performed using GraphPad Prism 6.0. Normality test was performed using Shapiro–Wilk criterion. The Mann–Whitney test and 2-way ANOVA multiple comparison test with Bonferroni's correction were used to quantify behavioral test results. The difference between groups was considered significant if the p value was less than 0.05.

RESULTS

Locomotor Activity, Anxiety, and Exploratory Behavior

Hyal animals in Open field test were shown neither increase nor decrease in anxiety and exploratory behavior versus vehicle group on time points 2 and 3 days. Locomotor activity wasn't changed after hyaluronidase injection as well (**Figures 1**, **2**).

Short-Termed Memory Changes

At the following time point: 48 h after hyaluronidase injection, animals from the Hyal group remembered foot shock in 90% of cases, while animals from Vehicle group remembered aversive stimuli only in 60% of cases. However, the difference between latency time before entering the dark room in acquisition and retention sessions (delta time) in two groups were not significantly different. 100% of animals in Hyal group avoided entering the dark chamber during retention trial versus 70% of animals in Vehicle group, delta time were significantly higher in Hyal group (Mann–Whitney test, $p < 0.05$). Delta time for both time points is shown in **Figure 3**.

Audiogenic Seizures

It was shown that hyaluronidase injection can promote audiogenic seizures in neonatal animals. 20% of animals in Hyal group demonstrated wild running, 10% showed nearly complete tonic extension except hind feet (KM arbitrary unit "4"), and 10% of animals underwent all the stages of KM scale and died (KM arbitrary unit "6") after audiogenic stimuli at the time point of 48 h. In the vehicle group, 10% of animals demonstrated wild running during stimulation.

[2] http://string-db.org/

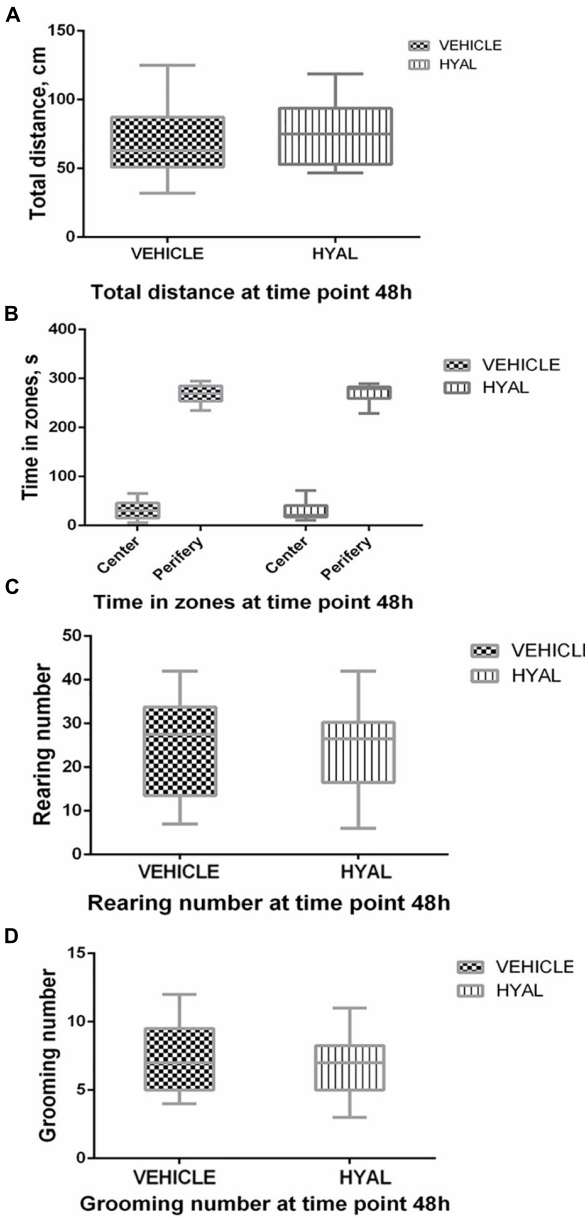

FIGURE 1 | Open field test results at the time point 48 h. Hyal animals in Open field test show neither increase nor decrease in anxiety and exploratory behavior versus vehicle group on time points of 48 h. There was no difference in locomotor activity of animals as indicated by traveled distance **(A)**. Time spent by animals in center and periphery of Open field didn't differ as well **(B)**. Anxiety level of Hyal animals didn't differ refer to Vehicle group as was shown by rearing and grooming analysis **(C,D)**. Figures show mean ± SEM, $N = 10$ per group. Two-way ANOVA and Mann–Whitney test didn't reveal any significant difference ($p > 0.05$).

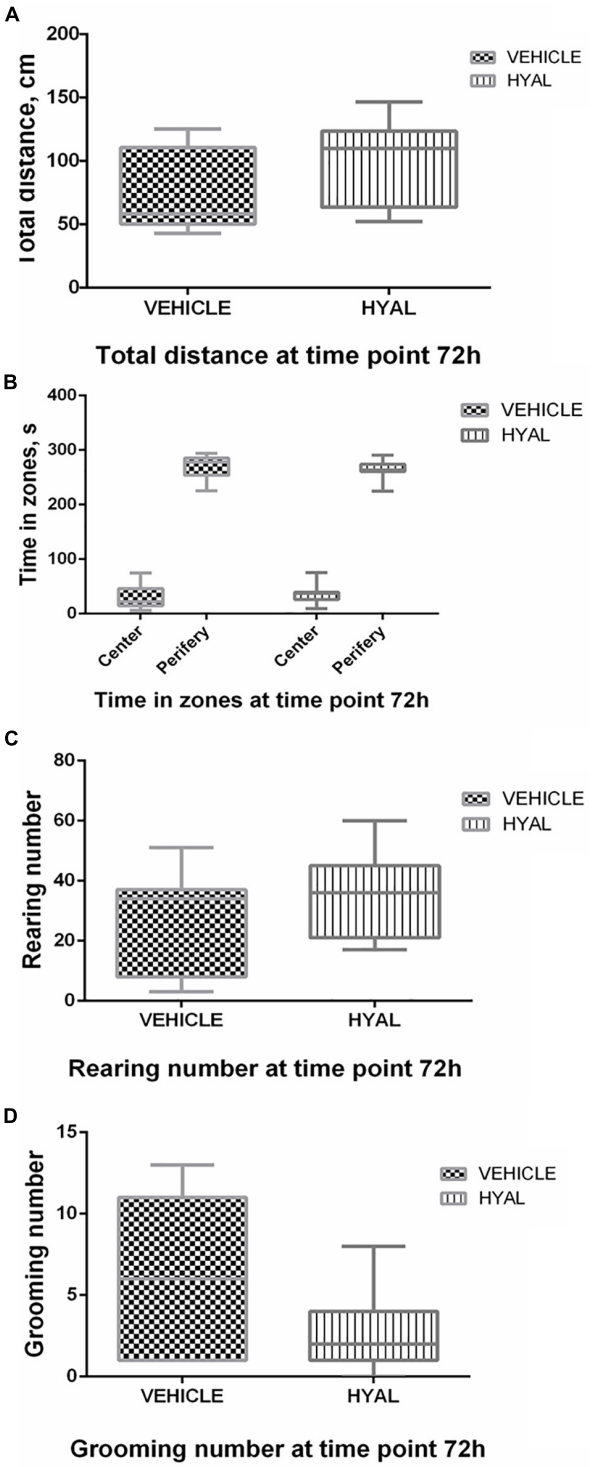

FIGURE 2 | Open field test results at the time point 72 h. There was no difference in locomotor activity of animals as was shown by traveled distance **(A)**. Hyal animals exhibited normal aversion to brightly lit open areas as well as Vehicle animals did, as was shown by time spent by animals in center and periphery of Open field **(B)**. Anxiety level of Hyal animals didn't differ refer to Vehicle group as was shown by rearing and grooming analysis **(C,D)**. Figures show mean ± SEM, $p < 0.05$. $N = 10$ per group. Two-way ANOVA and Mann–Whitney test didn't reveal any significant difference.

The number of animals with audiogenic seizures was even higher at the time point of 72 h in the Vehicle group; 40% of animals demonstrated wild running and 10% of animals demonstrated seizures of KM arbitrary unit "4," while in Vehicle group situation stayed the same (**Figure 4**).

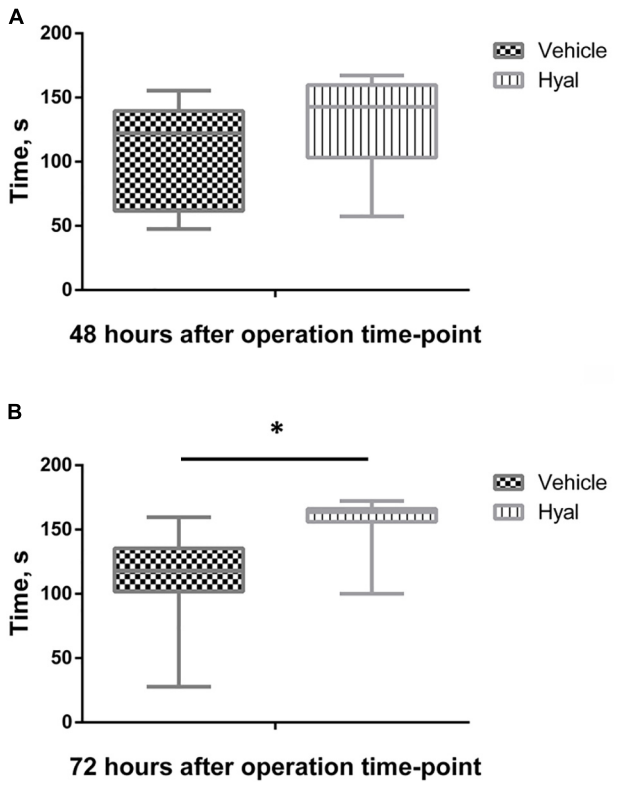

FIGURE 3 | Passive avoidance test results. Time before enter dark compartment in acquisition and retention trials at time points of 48 h **(A)** and 72 h **(B)**. *Y* axis indicates the difference between latency time before entering the dark room in acquisition and retention sessions (delta time). All the animals entering dark compartment during acquisition trial. At the time point of 48 h after hyaluronidase injection animals from Hyal group remembered foot shock in 90% cases, while animals from Vehicle group remembered aversive stimuli only in 60% cases, but Mann–Whitney test showed no significant difference. At the time point of 72 h 100% of animals in Hyal group avoided entering the dark compartment during retention trial versus 70% of animals in Vehicle group, delta time in two groups significantly differs. Figures show mean ± SEM, $N = 10$ per group, $^*p < 0.05$.

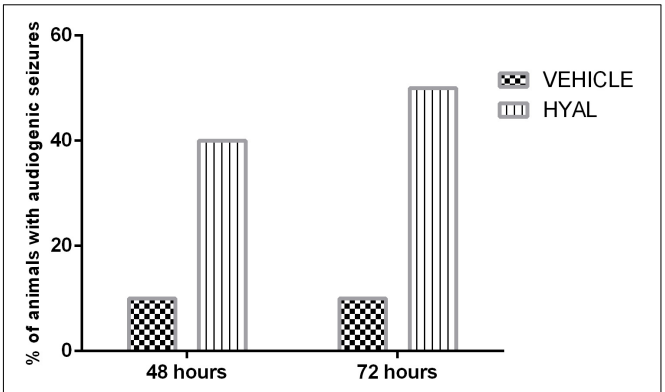

FIGURE 4 | Audiogenic seizures test results. Data shown in the diagram represents the percent of animals demonstrating audiogenic seizures. $N = 10$. The percent of animals in Vehicle group demonstrating wild running during audiogenic stimuli stayed at the level of 10% on the time points of 48 and 72 h. 40% of animals in Hyal group in total demonstrated audiogenic seizures at the time point of 48 h. 20% of animals demonstrated wild running, 10% showed nearly complete tonic extension except hind feet (KM arbitrary unit "4") and 10% of animals underwent all the stages of KM scale and died (KM arbitrary unit "6") after audiogenic stimuli at the time point of 48 h. At the time point of 72 h in vehicle group number of animals with audiogenic seizure was even higher – 50% in total. 40% of animals demonstrated wild running and 10% of animals demonstrated seizures of KM arbitrary unit "4."

PNN Immunostaining

It was shown that, 2 h after hyaluronidase injection, there was no detectable aggrecan agglomerates surrounding pyramidal neurons in hippocampal regions of injections in Hyal group in comparison with the Vehicle group. The trend persisted in both Hyal and Vehicle groups 48 and 72 h after injection (**Figures 5A,B**). The analysis of the area of extracellular space and an average cell area didn't reveal any significant differences between Hyal and Vehicle groups (**Figures 5C,D**). Fluorescence intensity analysis showed that the level of aggrecan in Hyal group reached its minimum at the 48 h after injection (**Figure 5E**) and started to restore at 72 h time point.

Analysis of Differential Expressed Genes and Their Interactions

The data expression matrix was processed with BRB-array tools, whole gene expression data presented in **Figure 6**.

According to the heat map (**Figure 7**), hyaluronidase treatment resulted in strong difference in comparison to vehicle control (PBS). The total number of DEGs were 25 (FDR = 0.05, *P* value ≤ 0.05, Benjamini–Hochberg correction).

Data from the STRING database revealed that several of the genes interacted with each other. In total, 25 genes were used to form the network complex (**Figure 8**). The network contained 27 nodes and 70 edges. Among them, seven nodes were the most significant (node degree ≥ 5). These were CCL2, CCL4, CCL5, CXCL1, CXCL10, CCR5, and TNF. Among seven nodes, TNF exhibited the highest node degree ($n = 10$).

Functional Analysis

To obtain an elementary investigation of the molecular mechanisms underlying disruption of hyaluronan matrix, microarray data were submitted to IPA core analysis. The differentially expressed genes were categorized to related canonical pathways based on IPKB. The top enriched categories of canonical pathways with *P* value < 0.05 are listed in **Figure 9**. Among pathways with $-\log_{10}$ *P* value, 3 include the Axonal guidence signaling, Neuroinflammation signaling pathway and Ephrin signaling pathway (Yu et al., 2016).

As hyaluronidase-treatment changed the profile of DEGs and signaling pathways, upstream regulators can also be changed. To investigate this issue, we tested DEGs identified upon Hyal treatment for enrichment of known key transcriptional regulators using the Upstream Regulator Analysis within the IPA Knowledgebase contains information about known regulators targets and can predict which transcriptional regulators are

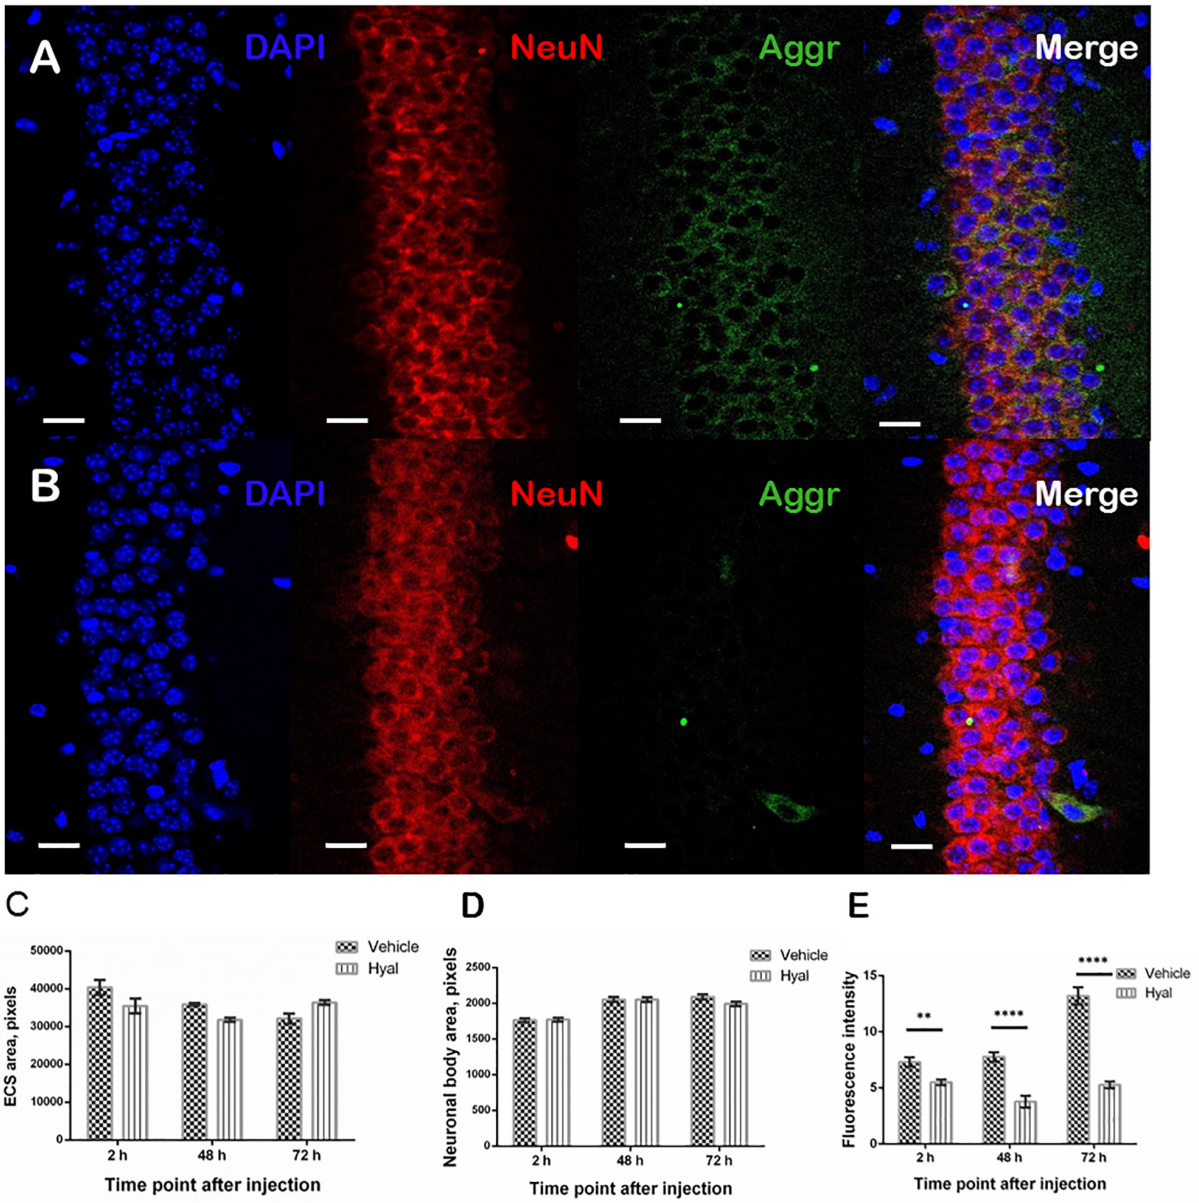

FIGURE 5 | Immunohistochemical staining of paraffin embedded brain slices. Images obtained by fluorescence microscopy at the 48 h after injection time point from Vehicle **(A)** and Hyal **(B)** animals brain slices. The nuclear marker DAPI is shown in blue. Aggrecan, the component of perineuronal nets, is shown in green, neuronal marker NeuN is shuwn in red. The scale is 20 μm. We measured ECS area **(C)** and average neuronal body area **(D)** at the 2, 48, and 72 h after injection time points. Mann–Whitney test didn't reveal any differences. The presence of aggrecan was measured by fluorescence intensity of green channel **(E)**. There is significant decrease in aggrecan component at all the time points but the minimum was fixed 48 h after injections. At the time point of 72 h the level of aggrecan starts to restore. $^{**}p < 0.005$, $^{****}p < 0.0001$.

responsible for certain biological processes or it can suggest pathways and the potential impact regulators may have on those pathways.

Analysis identified five genes upregulated in hyaluronidase-treated hippocampal tissues (**Figure 10**) with a significant number of their targets ($p < 10^{-5}$) changed in a direction which indicates an activated regulator status on a protein level (positive Z-score > 2).

DISCUSSION

Epilepsy is a most common neurological disorder all around the world. There are a lot of people suffering secondary epilepsy after brain infections or non-infectious (sterile) inflammatory response, traumatic brain injury or brain tumors (for review see Lowenstein, 2009; Vezzani et al., 2016). There is a large amount of mechanisms leading to seizure appearance and lots of it needs

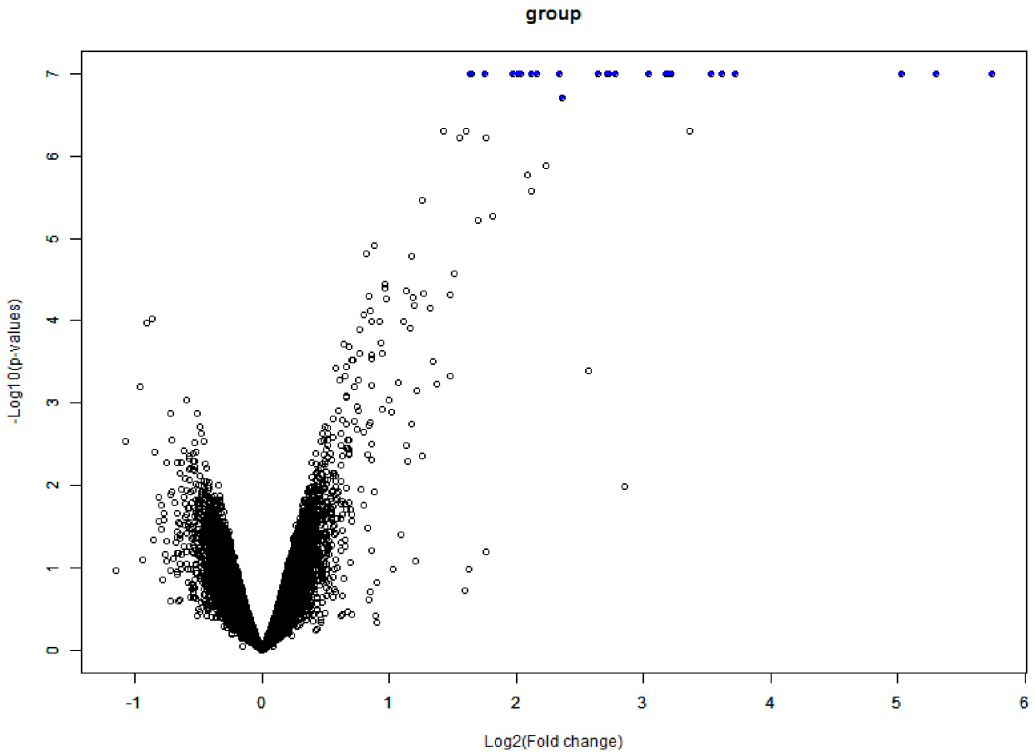

FIGURE 6 | Volcano plot of DEGs. The *x*-axis is logFC and the *y*-axis represents –log10 (adjusted *P*-value). The blue dots represent the DEGs, while the black dots represent genes that were not differentially expressed. DEGs, differentially expressed genes; FC, fold change.

further investigation (Klein et al., 2018). The reasons for seizure occurrence in early postnatal development is the less studied subject in the field.

Brain ECM was shown to affect the maturation of central nervous system during early developmental stages (McRae et al., 2012; Ueno et al., 2019). We assumed that the destruction of ECM molecules during the early postnatal period may lead to the occurrence of some pathological states. Indeed, it was shown that 40 and 50% of animals after bilateral intrahippocampal hyaluronidase injections at the 48 and 72 h time points, respectively, exhibited seizures. The mechanism of epileptogenesis after ECM digestion during early development is not known so we decided to make a full transcriptomic analysis to unveil the possible pathways and detect target molecules for a further correction. Our transcriptomic analysis with further analysis of interacting genes/proteins revealed activation of a number of genes implicated in inflammatory responses (as far as cytokine-cytokine receptor interaction pathway was activated) in the Hyal group. Enzymatic digestion of hyaluronan produces a lot of low molecular weight fragments (<500 kDa), which can trigger an inflammatory response. During the inflammation, chemokines such as CCL2, CCL3, and CCL 5 can activate pathways leading to status epilepticus (Arisi et al., 2015; Cerri et al., 2016; Tian et al., 2017). In the current study, transcriptomic analysis showed the activation of the chemokine pathway due to upregulation of TLR2. Activation of TLR2 by short fragments of hyaluronan and disruption of CD44 can induce an inflammatory response (Jiang et al., 2011). Signals from these receptors can be transmitted through NF-κB transcription factor upregulating the expression of chemokines (CCL2,3,4,5,7,10,12, CXCL 1,10), which can act through $ERK_{1,2}$ enhancing the production of

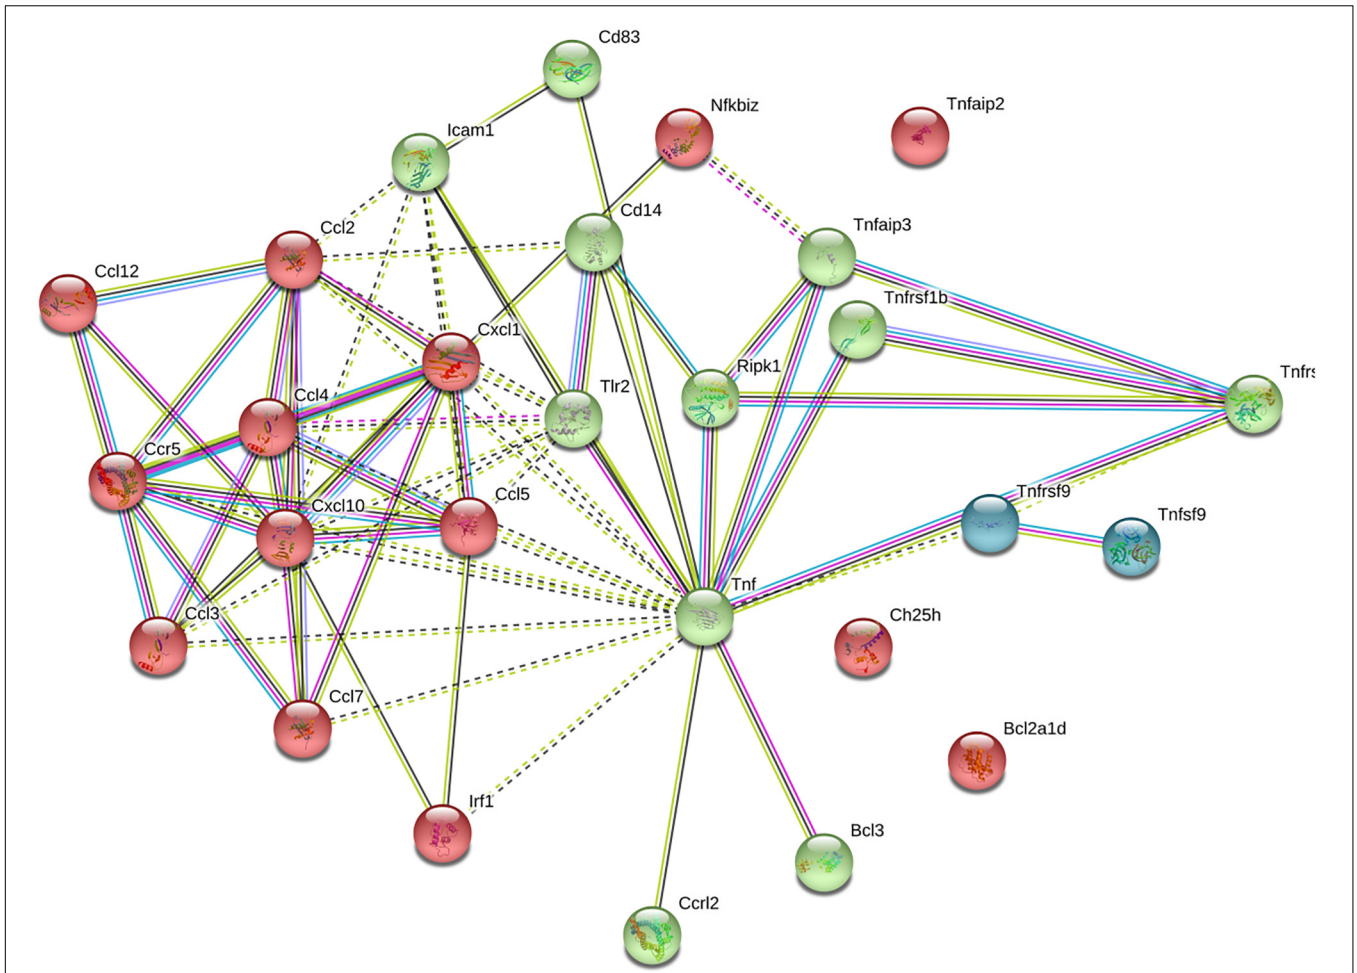

FIGURE 8 | Protein–protein interaction networks of differentially expressed genes upon hyaluronidase treatment. Using STRING database 25 genes were used to construct the PPI network. PPI, protein–protein interactions. Colors of nodes indicate result of clustering. Nodes represent proteins, edges represent protein–protein associations. Dotted lines indicate insignificant link, solid lines indicate significant interactio, pink lines indicate experimentally determined interaction, blue lines from curated database, black lines indicate co-expression, yellow lines indicate text mining, and gray lines indicate protein homology.

TNF and activating CREB1 expression (Bose and Cho, 2013; Cekanaviciute and Buckwalter, 2016). Activation of CREB and glial-mediated production of TNF-α may led to enhancing the release of glutamate. Imbalance of glutamate production can cause excitotoxicity and seizures (Li and Ransohoff, 2008; Vezzani et al., 2016). These findings coincide with the opinion that at least 40% of all epilepsies have structural or metabolic causes as a consequence of diverse brain injuries and the most common risk is inflammation during infections and sterile inflammation during stroke and autoimmune encephalitis (Vezzani et al., 2016).

However, animals in the Hyal group didn't show any differences in locomotor activity and anxiety level. This finding correlates with the previously made by Hosseini et al. (2018) where the overexpression of inflammatory factors didn't affect the activity of animals in open field test, although the chronic inflammation can lead to a memory loss (Zhou et al., 2016). In contrast, we demonstrate that hyaluronidase-treated animals showed elicited ability for learning. At the time point of 48 h after surgery, 90% of animals in Hyal group learnt aversive stimuli versus 60% of animals in Vehicle group. The percentage of animals that learnt the task 72 h after surgery was 100 and 70, respectively, although Mann–Whitney test revealed the significant difference in delta time only at the 72 h time point. According to transcriptome analysis, this memory improvement might be due to an activation of *BCL3* and *IRF1* genes directly interacting with CREB, which is tightly connected with long-term potentiation and memory (Silva et al., 1998). Facilitation of working memory can also be explained by the fact that ECM modification leads to the formation of a new structural and functional connections between neurons, changes the ratio of inhibitory and excitatory neurons leading to changes of plasticity (Morellini et al., 2010). It had also been shown that some matrix proteins have a particular importance for the behavior, spatial, and contextual memory. For example, decreased expression of reelin is a common characteristic among neurological and mental

FIGURE 9 | Significantly enriched pathways of significant genes in response to hyaluronan digestion. Green bars represent number of downregulated genes, red bars represent number of upregulated genes, gray bars represent no change of expression, orange curve with dots represent ($-\log_{10}$ (*P* value) – FDR), numbers in right border reflect number of genes including in canonical pathway.

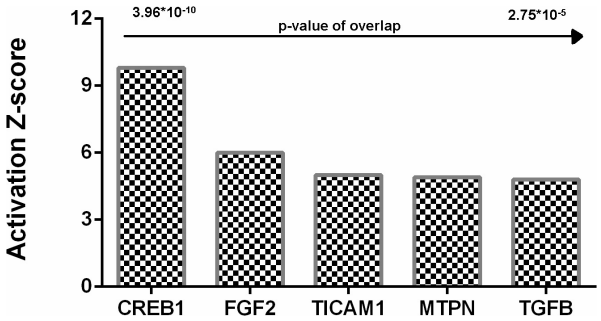

FIGURE 10 | Upstream regulators identified by Ingenuity Pathway analysis for hyaluronidase dependent treatment. Positive activation *Z*-score (>2) indicates activation of these upstream regulators. CREB1, cAMP response element-binding protein; FGF2, fibroblast growth factor 2; TICAM1, TIR domain-containing adaptor molecule 1; MTPN, myotrophin; TGFB, Transforming growth factor beta.

disorders such as autism, schizophrenia, depression and bipolar disorder (Ferrer-Ferrer and Dityatev, 2018), and knock-out mice lacking aggrecan demonstrated improvement in memory in spontaneous object recognition test (Rowlands et al., 2018).

There are pathways activated after several types of cerebral insults, which are associated with epileptogenesis or epilepsy progression such as Janus Kinase/Signal Transducer and Activator of Transcription (JAK/STAT) and mammalian Target of Rapamycin Complex (mTORC) (Klein et al., 2018). These signaling pathways mediate cellular physiological mechanisms that are critical for memory formation, long-term depression (LTD) and long-term potentiation (LTP). The JAK/STAT pathway is activated after many types of epileptogenic injuries in experimental models, including TBI, SE and stroke (Satriotomo et al., 2006; Lund et al., 2008; Zhao et al., 2011). It regulates expression of genes critical for multiple essential functions including cell proliferation, differentiation, neurogenesis, learning and memory. We found the elevation in *NFKBIZ*, *IRF1*, and *BCL3* genes, which tightly interact with members of the JAK/STAT pathway. Structural or dysplastic lesions associated with infantile spasms in rodents or humans also demonstrate overactivation of the mTORC1 pathway in the epileptogenic area (Galanopoulou et al., 2012). We found an upregulation of TNF, which is involved in this pathway and TLR2, TNFAIP3, and CD14, which directly interact with other members of mTORC1 signaling pathways.

Brain tumors are the other pathological process that can cause seizures. One of the factors which contribute to peritumoral seizures is glioma-released glutamate, which presumably acts through chronic overactivation of neuronal glutamate receptors enhancing the excitatory drive in the cortex (Buckingham et al., 2011; Yuen et al., 2012). A recent study demonstrates that seizures can appear as a result of the loss of fast-spiking interneurons concomitant with a significantly reduced firing rate of those that remain due to the degradation of PNNs that surround fast-spiking interneurons, resulting in alterations of its membrane capacities (Tewari et al., 2018). It also should be noted that treatment with a GM6001, a broad-spectrum inhibitor of MMPs, leads to retention of the PNN's structure and, most importantly, membrane properties of FSNs in GM6001-treated mice were essentially identical to the control group. The alteration of membrane capacities may also contribute to epileptogenesis after hyaluronidase injections.

There is an idea that seizures appearing in mice with ECM deficiency are linked with the reduction of ECS (Arranz et al., 2014). However, our immunohistochemical

analysis didn't reveal any significant differences in ECS area and in average neuronal body area at all time points, which means that seizures appeared after digestion of HA during postnatal stages were not a result of changes in osmotic parameters of cell environment.

Brain ECM is known to play a pivotal role in the functioning of the nervous system, especially during ontogenesis, but some of mechanisms by which it regulates neuronal activity are still hidden from the scientist's eye. Therefore, our study provides new insight into the mechanisms of epilepsy development in early postnatal period, showing the role of hyaluronic acid in the stabilization of morphology and neural network activity. These mechanisms can become potential targets for the correction of seizures during early postnatal development. Proteomic analysis is needed to reveal the precise mechanism of epileptogenesis in neonatal animals after ECM digestion. It also remains unknown how long the hyperexcitable state of the brain is preserved after hyaluronan digestion.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

The animal study was reviewed and approved by the Ethical Committee on Animal Health and Care of N. I. Lobachevsky State University of Nizhny Novgorod and Privolzhsky Research Medical University, Nizhny Novgorod.

AUTHOR CONTRIBUTIONS

IM initiated the study. AB, VP, and MG generated a detailed plan of the experiments and supervised the research. AB, OZ, NT, and AM performed the behavioral and immunocytochemistry experiments. VP, EG, LK, and MG performed the transcriptome analysis. AB, VP, MG, and IM analyzed the data and wrote the first draft. All authors edited the manuscript.

FUNDING

The reported study was funded by RFBR (research project No. 18-44-520016) and the state project "Provision of scientific research" (No. 6.6379.2017/8.9).

Whole-brain volumetric microscopy techniques such as serial two-photon tomography (STPT) can provide detailed information on the roles of neuroinflammation and neuroplasticity throughout the whole brain post-stroke. STPT automatically generates high-resolution images of coronal sections of the entire mouse brain that can be readily visualized in three dimensions. We developed a pipeline for whole brain image analysis that includes supervised machine learning (pixel-wise random forest models via the "ilastik" software package) followed by registration to a standardized 3-D atlas of the adult mouse brain (Common Coordinate Framework v3.0; Allen Institute for Brain Science). These procedures allow the detection of cellular fluorescent signals throughout the brain in an unbiased manner. To illustrate our imaging techniques and automated image quantification, we examined long-term post-stroke motor circuit connectivity in mice that received a motor cortex photothrombotic stroke. Two weeks post-stroke, mice received intramuscular injections of pseudorabies virus (PRV-152), a trans-synaptic retrograde herpes virus driving expression of green fluorescent protein (GFP), into the affected contralesional forelimb to label neurons in descending tracts to the forelimb musculature. Mice were sacrificed 3 weeks post-stroke. We also quantified sub-acute neuroinflammation in the post-stroke brain in a separate cohort of mice following a 60 min transient middle cerebral artery occlusion (tMCAo). Naive e450^{+}-labeled splenic CD8^{+} cytotoxic T cells were intravenously injected at 7, 24, 48, and 72 h post-tMCAo. Mice were sacrificed 4 days after stroke. Detailed quantification of post-stroke neural connectivity and neuroinflammation indicates a role for remote brain regions in stroke pathology and recovery. The workflow described herein, incorporating STPT and automated quantification of fluorescently labeled features of interest, provides a framework by which one can objectively evaluate labeled neuronal or

INTRODUCTION

In the United States, nearly 800,000 people have a stroke annually, making it the 5th leading cause of death and the leading cause of adult disability (Benjamin et al., 2018). More than half of all stroke survivors experience persistent motor deficits that impair daily function, underscoring the significant need for a better understanding of the mechanisms of injury and repair after stroke (Dobkin, 2005). Spontaneous recovery of function is associated with a higher capacity for neuroplasticity in homologous brain regions after stroke (Brown et al., 2009). These regions, which are both remote and adjacent to the infarcted tissue, undergo changes in order to assume the functions of the lost neuronal networks (Furlan et al., 1996). Preclinical models of stroke have been instrumental in understanding the complexity of post-stroke responses and how they relate to functional recovery (Nudo, 2007). Using these models, plasticity which underlies circuit remodeling has been repeatedly shown to be correlated with improved recovery from stroke (Jones and Adkins, 2015). These forms of circuit plasticity involve recruitment of homologous neuronal pathways, inhibition of aberrant electrical signaling, and formation of new connections through synaptogenesis and axonal sprouting throughout the brain and spinal cord (Murphy and Corbett, 2009). However, in some cases, post-stroke neuroplasticity can impede recovery. The degree of functional recovery is heavily dependent on the regions in which the plasticity occurs (Dancause et al., 2005; Kim et al., 2005), emphasizing the need for pre-clinical studies that investigate changes in axonal connectivity in the whole brain after stroke.

In addition to alterations in brain architecture after stroke, the immune system plays a major role in post-stroke pathology and recovery. In particular, the critical role of the immune system in both the acute and chronic phases of post-stroke recovery is becoming increasingly apparent (Jin et al., 2013). Within hours of the onset of injury, damage-associated molecular patterns (DAMPS) are released from dying neurons, astrocytes, and endothelial cells, recruiting immune cells to the brain (Rubartelli and Lotze, 2007). Blood-brain barrier (BBB) disruption, upregulation of cell adhesion molecules, and activation of resident microglia enhance the post-stroke neuro-immune interactions (Abulrob et al., 2008; Patel et al., 2013). Within 24 h of stroke onset, adaptive immune cells, including T cells, can be detected in the ipsilesional hemisphere (Gelderblom et al., 2009). Migration of these cells peaks around 3–4 days post-stroke, but helper $CD4^+$ and cytotoxic $CD8^+$ T cells persist in the perilesional tissue for weeks after injury, implicating this leukocyte subset in long-term recovery (Xie et al., 2018). Many of these studies rely on flow cytometry, a technique that requires the dissociation of brain tissue, and therefore the loss of information of spatial dynamics of leukocyte diapedesis. Even research using spatially-sensitive techniques like immunohistochemistry often overlook the possibility of recruitment of immune cells into remote brain areas. Given that leukocytes modulate axonal growth after injury through the secretion of cytokines and growth factors (Wang et al., 2018), it is possible that migration of immune cells, such as $CD8^+$ T cells, to remote brain regions could affect post-stroke plasticity far from the stroke lesion. This highlights the need to understand where neuroplasticity and neuroinflammation occur in the brain after stroke, and if the two phenomena are interconnected. To visualize post-stroke responses that directly involve neuroplasticity or occur on the larger scale, systematic analysis of the entire brain must be incorporated into preclinical studies of stroke recovery.

Advances in the field of functional imaging have greatly enhanced the ability to study global post-stroke alterations in brain connectivity (Bauer et al., 2014). However, few studies currently exist which incorporate the use of high resolution, whole brain volumetric microscopy techniques to assess changes in brain architecture in the context of stroke (Lugo-Hernandez et al., 2017). In the current study, we used serial two-photon tomography (STPT) (Ragan et al., 2012; Oh et al., 2014; Amato et al., 2016; Kim et al., 2016; Whitesell et al., 2018; Ramirez et al., 2019), a block-face automated imaging technique, to acquire volumetric image datasets comprising entire mouse brains. A custom-developed image analysis pipeline incorporating supervised machine learning (ML)-based methods to isolate relevant fluorescent signals of interest and registration of the images into the Allen Institute Common Coordinate Framework version 3.0 (CCF 3.0) was then employed to quantify stroke-induced neural connectivity and neuroinflammation throughout the mouse brain. We found robust changes in connectivity in the corticospinal tract, as well as $CD8^+$ T cell migration into motor and somatosensory brain regions affected by stroke. Taken together, our results indicate that mesoscale whole-brain imaging reveals important information about region-specific changes in both neural connectivity and neuroinflammation that may be key to developing long-term therapies to promote functional recovery after stroke.

METHODS

Animal Approval

Experiments involving corticospinal tract tracing with PRV-152 used 8–11-week old adult, male C57BL/6 (wild type; WT) mice from Jackson Laboratories. For neuroinflammation experiments involving $CD8^+$ T cells, 10–15-week-old male WT mice were

randomized for the isolation of donor $CD8^+$ T cells or to receive the donor T cells following stroke. Animals were housed in a 12 h light/dark cycle with access to food and water *ad libitum*. All protocols were approved by the University of Texas Southwestern Medical Center Institutional Animal Care and Use Committee.

Photothrombotic (PT) Stroke

Cortical stroke was induced using the photothrombotic stroke model previously described (Yanev et al., 2019). Mice ($n = 6$) were anesthetized using 1–4% isoflurane, 0.7% nitric oxide, and 0.3% oxygen and temperature and breathing rates were monitored. Mice were placed on a stereotaxic frame and an incision was made down the midline of the scalp. Mice were administered 1.5 mg of Rose Bengal (Sigma Aldrich, St. Louis, MO, USA) dissolved in 0.3 cc of saline via intraperitoneal injection. One minute later, we aimed a 45 mW laser (Coherent Sapphire, Santa Clara, CA, USA; 561 nm; 2.7 mm collimated beam diameter) 1.7 mm lateral to Bregma as the forelimb representation of the motor cortex for 15 min. Buprenorphine was administered post-operation for pain management, and moist food was provided for the first 24 h following stroke. All mice that received a PT stroke had a successful surgery.

Transient Middle Cerebral Artery Occlusion (tMCAo)

Mice ($n = 7$) were anesthetized (2% isoflurane/ 70% NO_2/30% O_2) and their body temperatures were maintained at 37°C while the left middle cerebral artery (MCA) was exposed for transcranial Laser Doppler flowmetry (TSI, Inc.) as previously described (Monson et al., 2014; Ortega et al., 2015). A blunted suture (6.0-gauge nylon, 12 mm) was advanced to block the MCA (>80% reduction relative to baseline blood flow) by surgeons blinded to condition, between 8 and 14:00 h. Animals were placed in an incubator (34°C), re-anesthetized after 60 min, and suture withdrawn. Flowmetry confirmed reperfusion (CBF > 50% baseline) and animals were monitored. All animals met blood flow criteria and were included in analysis.

Intramuscular Injections of Pseudorabies Virus (PRV)

An incision was made on ulnar border of forelimb on anesthetized mice using a standard scalpel (Liu et al., 2009). After the forelimb flexor muscle was identified, mice were given an intramuscular injection using a 27 G needle and 10 μL syringe of PRV-152, a generous gift from Dr. Lynn Enquist (Princeton University, Princeton, NJ), a trans-synaptic pseudorabies virus expressing green fluorescent protein (GFP). PRV-152 injections were divided into multiple injections of 2 μL of virus in multiple locations in the forelimb flexor muscle (Ganzer et al., 2018). All standard viral handling precautions were followed during this procedure. Animals recovered in a standard recovery chamber. A single administration (0.2 ml) of subcutaneous buprenorphine (0.05 mg/kg) and lidocaine was given immediately after the procedure for pain relief. Mice that were injected with PRV that received a stroke had a 50% morality rate (3/6 mice) while mice that received a sham surgery all survived (6/6 mice) to the 6-day sacrifice time point.

Sample Preparation for Imaging on TissueCyte 1000

All mice were transcardially perfused with 1X Phosphate Buffered Saline (PBS) followed by 4% paraformaldehyde (PFA) to fix brain tissues. Extracted tissues were further post-fixed in 4% PFA at 4°C for 24 h and transferred to 0.01% NaN_3 in 1X PBS for storage at 4°C until embedding. 4.5% (w/v) agarose (Type 1A, low EEO, Sigma #A0169) solution in 50 mM phosphate buffer was first prepared and oxidized by adding 10 mM $NaIO_4$ (Sigma #S1878) while stirring gently for 2 to 3 h in the dark. The agarose solution was filtered with vacuum suction and washed 3 times with 50 mM phosphate buffer. The washed agarose was resuspended in the appropriate volume of phosphate buffer to make a 4.5% agarose solution. The oxidized agarose solution was heated to boiling in a microwave, then transferred to a stirring plate and allowed to cool to 60–65°C. Brains were embedded by filling a cryoembedding mold (VWR #15560-215) with oxidized agarose, placing the filled mold on a flat frozen ice pack, and then quickly submerging the brain using forceps into the bottom of the block with the cerebellum touching the bottom of the block (olfactory bulbs facing upward). The agarose block was allowed to fully solidify on a frozen ice pack in the dark. Once the agarose blocks were fully hardened, the agarose blocks including the specimens were removed from the molds and placed in small glass jars, where they were treated overnight at 4°C in the dark in sodium borohydride buffer (50 mM sodium borohydride, 50 mM borax, 50 mM boric acid, pH 9.0–9.5). After overnight crosslinking, the agarose blocks were transferred to phosphate buffer for storage at 4°C until TissueCyte imaging.

Serial Two-Photon Tomography

The agarose blocks containing the brain samples were attached to a custom magnetic slide with superglue and placed on a magnetized stage within an imaging chamber filled with phosphate buffer. STPT imaging is a block-face imaging technique in which a series of 2-dimensional (2-D) mosaic images in the coronal plane is acquired just below the cut surface of the brain (within ∼100 μm), followed by physical sectioning with a built-in vibrating microtome to cut away the imaged tissue, preparing a new cut surface for imaging (Ragan et al., 2012). For this study, three optical planes were imaged at 25, 50, and 75 μm below the cut surface, followed by a vibrating microtome cut at 75 μm (blade vibration frequency of 70 Hz, advancement velocity 0.5 mm/s). The excitation laser (MaiTai DeepSee, SpectraPhysics/Newport, Santa Clara, CA) wavelength was tuned to either 920 nm to excite GFP (PRV experiments) or 850 nm to excite e450 ($CD8^+$ T cell experiments). Three image channels of emission fluorescence (pre-set bandpass filters encompassing red, green, and blue fluorophores) were collected with a predetermined photomultiplier tube voltage of 700 V. This process produced 190 physical sections and 570 2-D stitched coronal section images (9 by 13 mosaic collected for each coronal section) with a lateral resolution of 0.875 μm/pixel and axial resolution of 25 μm (∼280 gigabytes of raw data per brain). The

raw image tiles were first trimmed and subjected to flat field correction, then stitched into 2-D mosaic coronal section images using the Autostitcher software (TissueVision, Inc.).

Image Analysis Pipeline

We used an automated pipeline (as described in Ramirez et al., 2019) to analyze and extract quantitative results from raw STPT-generated data. The image analysis pipeline is depicted in **Figure 1** and consists of three main components: image registration, pixel classification and numerical quantification. The red channel 2-D stitched images are used to register the dataset into the Allen Institute Common Coordinate Framework (CCF 3.0) using SimpleElastix (an extension of SimpleITK that combines elastix and transformix) (Lowekamp et al., 2015). A multi-step registration process was chosen using rigid, affine, and b-spline registration components. At each step, optimization was performed on a 6-resolution multi-grid (pyramid) schedule, with Mattes Mutual Information as the optimization metric. To balance local/global optimization across the whole dataset, the "Random Coordinate" Image Sampler was used with sample regions of $2 \times 2 \times 4$ mm. Final b-spline grid dimensions were $0.5 \times 0.5 \times 0.5$ mm. The optimized registration parameters identified for the red channel images were then applied to the other raw image channels and ilastik probability maps using transformix.

Relevant signals of interest were identified in the images using the "Pixel Classification" plugin for the Interactive Learning and Segmentation Toolkit (ilastik), which implements a random forest supervised machine learning (ML) classifier (Somner et al., 2011). To support the supervised ilastik training, a maximum intensity projection (MIP) was first created for each physical section from its three optical planes and the resultant MIP image was downsampled to a pixel size of $1.5\,\mu m \times 1.5\,\mu m$ in the x-y dimension. This resulted in a set of 16-bit 3-color compressed

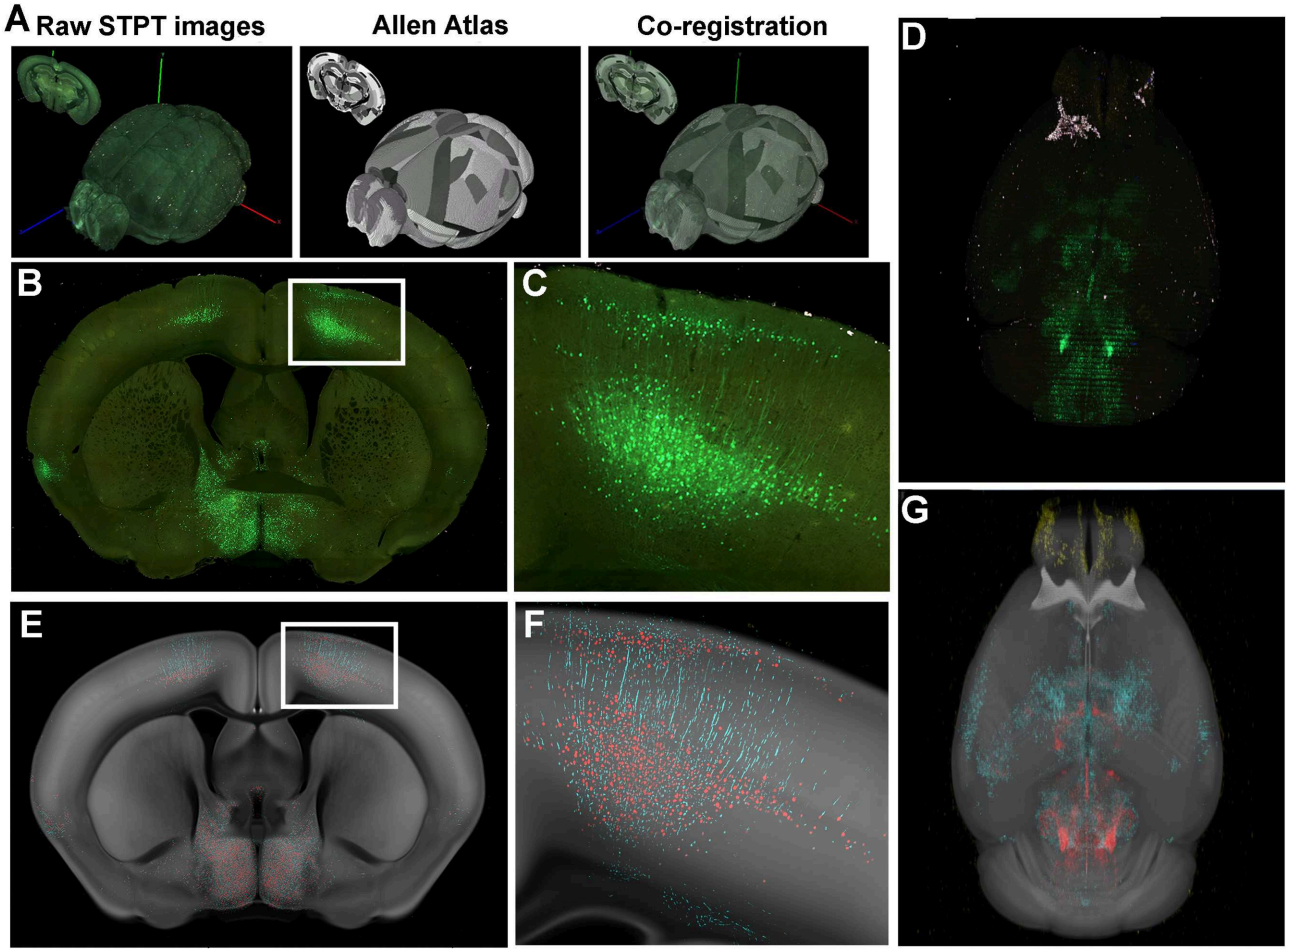

FIGURE 1 | Serial two-photon tomography of the whole mouse brain. **(A)** Overview of serial two-photo tomography (STPT) data acquisition and registration. **(B)** Representative coronal section raw fluorescence image, with **(C)** expansion of areas identified in white box in B showing GFP+ neuronal cell bodies and processes. **(D)** Coronal images are stacked into a 3D representation and co-registered to the Common Coordinate Framework (CCF 3.0; Allen Institute for Brain Science) Atlas. **(E)** Probability map output of the same section shown in **(B)** depicting pixels classified via machine learning (ML) as either GFP+ cell bodies (red) or GFP+ neuronal processes (cyan) overlaid onto the corresponding section from the atlas (CCF 3.0 average template) shown in gray. **(F)** Enlarged image of boxed area in **(E)** showing fine detail and accurate classification of neuronal cell bodies and processes corresponding to the raw fluorescence image shown in **(C)**. **(G)** 3-D rendering of the probability maps corresponding to the raw fluorescence images of the brain shown in D. GFP^+ cell bodies, red, GFP^+ neuronal processes, cyan, atlas images, gray.

TIFF images with the same number of images as physical sections in the STPT image (190). At least three representative sections containing examples of fluorescent signals of interest (e.g., GFP^- expressing neurons or e450-labeled T cells) were selected from each sample. The random forest ML model was trained on these selected sections by assigning labels including as fluorescent cell bodies, tissue autofluorescence, stroke, and other features (e.g., microbubbles surrounding the olfactory bulbs). After completing the initial training, each of the sample images was iteratively updated until visible misclassifications were minimized. Each cohort of brains (PRV injected or T cell injected) was used to train an independent model for classification, and every section from every brain in the cohort was subjected to the same model. Ilastik predictions were exported as an 8-bit "probability map" TIFF for each trained label, with the pixel value of 0 mapping to 0% probability and 255 100% probability of a pixel belonging to the label. The resulting TIFF stacks were warped to the CCF 3.0 using the transformation parameters identified by elastix via transformix. The summed intensity of all voxels lying within CCF 3.0 annotated regions were quantified using custom MATLAB software, producing a matrix of signal intensity for each sample, label, and brain region.

Image Analysis Validation

To assess the performance of the ilastik-based image analysis pipeline, three independent observers (i.e., different than the individual that trained the ilastik model) selected at least 8 random 1-megapixel subregions from at least two brains from each experimental condition (8 brains total, 4 from $CD8^+$ T cell cohort, 4 from PRV −152 cohort) for manual annotation of critical labels (e.g., fluorescent cell bodies, stroke). Each observer utilized Adobe Photoshop tools to create binary masks for each test label, as well as autofluorescence and black background labels. These observer-generated binary masks were considered the reference set, with the ilastik probability maps as the test set. Custom MATLAB software was used to compare each reference image to the corresponding test image while varying the segmentation thresholds in the test image (i.e., to convert the 8-bit range of the probability map to a complementary binary map). From these comparisons the true positive, false negative, false positive, and false negative rates were calculated for each threshold. These values were calculated on a voxel basis to match the values quantified in these studies. For the critical test labels (fluorescent cell bodies and stroke) the ilastik model achieved very low false positive rates even when a segmentation threshold at 5% of the 8-bit range ($CD8^+$ T cell bodies: 0.008 ± 0.001%; PRV GFP^+ cell bodies: 2.0 ± 0.5%; stroke: 0.10 ± 0.03%; $n = 8$ subregions each from 2, 4, and 4 brains, respectively). In control samples for the $CD8^+$ T cell experiments (samples lacking labeled T cells), observers noted rare blue spots in the tissue that roughly resembled the small T cell bodies and annotated them. The false positive rate for T cell-negative samples was even lower than for the labeled T cell samples (0.0006 ± 0.0003%, 8 subregions from 2 brains). True positive rates at these thresholds were not saturated ($CD8^+$ T cell bodies: 57.0 ± 4.8%; PRV GFP^+ cell bodies: 84.6 ± 4.4%; stroke: 48.2 ± 0.5%; 2, 4, and 2 brains, respectively). F1 score (scale 0 to 1 with 1 being best performance), a common measurement of model accuracy, indicated strong performance for PRV GFP^+ cell bodies and adequate performance for $CD8^+$ T cell bodies and stroke voxels ($CD8^+$ T cell bodies: 0.72 ± 0.13; PRV GFP^+ cell bodies 0.90 ± 0.03; stroke 0.73 ± 0.04; $n = 2$, 4, and 2 brains, respectively). The Matthews Correlation Coefficient, an alternative metric (ranging from −1, worse than chance, to 0 for chance, to 1 for optimal), showed similar results to the F1 score ($CD8^+$ T cell bodies: 0.63 ± 0.04; PRV GFP^+ cell bodies: 0.84 ± 0.4; stroke 0.64 ± 0.4, $n = 2$, 4, and 2 brains, respectively).

These validation studies indicate that the ilastik model was conservative (prioritized low false positive rates at the expense of true positives) for the labels quantified in these studies.

In order to further validate the ilastik STPT quantification, we manually counted cell bodies in the primary motor cortex (MOp), primary somatosensory cortex (SSp), and supplemental motor cortex (MOs) in both the right and left hemispheres in STPT sections. We counted cells within a range of 71 coronal slices. The initial slice was identified by the morphology of the hippocampus, size of lateral ventricles, and the presence of the fasiculus retroflexus. The final slice in the range was determined from the size of the olfactory bulb. The images used for manual quantification were identical to those used for automated quantification. We classified a cell as a circular object with GFP signal that was clearly distinguishable from the background. Manual quantification of neuronal processes was not performed.

$CD8^+$ T Cell Isolation, Labeling, and Intravenous Injections

Using magnetic CD8 T cell isolation kits (STEMCELL Cat. 19853), donor CD8 T cells were isolated from the spleens of naïve, adult donor WT mice ($n = 8$). A small aliquot of cells was assessed before and after enrichment by flow cytometry to ensure purity of the isolated CD8 T cells. CD8 T cells were then labeled with a fluorescent proliferation dye according to manufacturer's protocol (e450; eBioscience 65-0842-85) and resuspended in 1XPBS immediately prior to injection. On average, $\sim 3.2 \times 10^6$ $CD8^+$ T cells were intravenous injected into the tail veins of WT recipient mice. Brains were extracted and further post-fixed overnight in 4% PFA at 4°C, transferred to 1X PBS + 0.01% NaN_3 and stored at 4°C until embedding. Peripheral migration of T cells into secondary lymphoid organs (i.e., spleen and cervical lymph nodes) was confirmed using flow cytometry. Briefly, single cell suspensions were generated from secondary lymphoid organs, and 1×10^6 cells were used for the fluorescent antibody staining to specific leukocyte (CD45-APC-Cy7) and T cell (TCRβ-711, CD4-PE/Dazzle 594, CD8-APC) markers for 30 min. at 4°C and subsequently washed and fixed in 1% paraformaldehyde. Flow cytometric data were acquired using a BD LSRFortessa using FACS Diva 6.0 software and FlowJo 9.0 software was used to subset leukocytes according to gating strategy shown in **Supplementary Figure 1**.

Statistics

Statistical differences were analyzed using unpaired parametric two-sample Student's *t*-test, ratio paired student's *t*-test, two-way

repeated measures ANOVA where appropriate and indicated in the text (Graph Pad Prism 6.0). Manual cell counts and ML probability values were correlated using a linear regression analysis (Graph Pad Prism 6.0). Values of $p < 0.05$ were considered significant. All experimenters were blinded to condition, and all animal were randomly assigned to group.

RESULTS

Whole Brain Visualization of Post-stroke Neural Connectivity

Previous studies utilizing traditional and viral retrograde tracers demonstrated robust descending connections from the brain to the skeletal muscle (Kerman et al., 2003, 2006; Lee et al., 2007). Furthermore, many studies demonstrate that stroke induces widespread changes in neuronal connectivity. Much attention has been given to remodeling of the corticospinal and corticorubral tracts (Ishida et al., 2016; Okabe et al., 2017), including increased corticospinal innervation of the stroke-impaired forelimb from the uninjured contralesional motor cortex (Bachmann et al., 2014). One recent study showed that connectivity in the brainstem also undergoes dynamic changes after a photothrombotic (PT) stroke in the primary motor cortex, highlighting the importance of global interrogation of circuitry (Bachmann et al., 2014). Imaging techniques, such as *in vivo* magnetic resonance imaging (MRI), can be used in mice to quantify whole-brain changes in connectivity after stroke (Dijkhuizen et al., 2012; Bauer et al., 2014). However, such techniques do not offer sufficient resolution to visualize cell bodies or axonal processes. Microscopy methods such as STPT can visualize and quantify these fine details, making these techniques vital in developing an understanding of connectivity on a mesoscale.

To demonstrate how STPT can be used to elucidate post-stroke changes in neural connectivity, 8–11-week-old C57/B6 mice received either a PT focal stroke in the right primary motor cortex (MOp) or a sham surgery. Two weeks later, mice received an intramuscular left forelimb injection of pseudorabies virus (PRV-152) carrying GFP, an effective trans-synaptic retrograde tracer that labels motor tracks which project to distal musculature (Kerman et al., 2003) Following STPT processing of the brains, the resultant images were analyzed using the custom-developed automated pipeline (**Figure 1A**). During the process of training the ML-based pixel classification algorithm, the random forest classifier was trained to recognize multiple structures of interest including cell bodies, neuronal processes, and areas of infarction. **Figure 1** shows raw STPT data of GFP^+ cell bodies and processes (**Figures 1B–D**), as well as the probability maps generated from the STPT data for automated identification of cell bodies and processes in the healthy mouse brain (**Figures 1E–G**). We also generated 3-D videos of these data from an uninjured brain, with fly-through and rotational videos of raw STPT data (**Supplementary Videos 1, 2**), as well as fly-through and rotation videos of corresponding probability maps (**Supplementary Videos 3, 4**).

The probability maps of these cortical regions show that neuronal cell bodies and their processes in both the left and right motor and somatosensory cortices (SS) of uninjured animals have been accurately identified by the trained ML algorithm, with more cells in the right cortex compared to the left (**Figures 2A–D**). In addition to the cell bodies and processes of layer 5 neurons, second-order neurons in layer 2 and 3 of the motor cortex and axons passing in the corpus callosum were also visible in labeled data set. The probability maps clearly demonstrate the widespread robust viral labeling, indicating a large number of descending connections to the left forelimb from the predicted motor cortex regions, as well as remote regions in the midbrain and brainstem. In mice that received a stroke, the ML algorithm detected some cells in the contralesional left motor cortex, albeit fewer than observed in uninjured animals (**Figures 2E–H**). ML classified bright autofluorescent signal in the ipsilesional right motor cortex as infarcted tissue (**Figure 2G**). While the ML algorithm did not classify all pixels within the lesion as infarcted tissue, it still offered excellent spatial resolution of most of the lesioned tissue and provided detailed visualization of where the PT stroke was induced in the brain (**Figure 2H**). The 3-D videos of stroke-injured brains clearly identify the PT stroke in both the fly-through and rotational videos of raw STPT data (**Supplementary Videos 5, 6**), as well as fly-through and rotation videos of corresponding probability maps (**Supplementary Videos 7, 8**).

In uninjured mice, nearly all cortical sensory and motor areas were labeled in the right hemisphere. Cortical sensory and motor areas had many GFP^+ cell bodies and processes and therefore, a robust fluorescent signal in these areas in the absence of injury. The highest fluorescent signal was observed in the layer 5 neurons in the right primary motor cortex (MOp5) and in neurons in the primary somatosensory area associated with the lower limb (SSp-ll), an area adjacent to the primary motor cortex (**Figure 2C**). Fewer PRV^+ cells were detected in left MOp5 neurons and SSp-ll neurons in these uninjured animals, suggesting that there was greater innervation of the left forelimb flexor from the right cortical motor regions in the absence of stroke (**Figures 2I,J**). After stroke, we observed that there were fewer GFP^+ MOp5 neurons in the right (i.e., lesioned) motor cortex, decreasing the fluorescent signal in this region and indicating a disruption in the corticospinal tract due to injury. Uninjured animals had significantly higher fluorescent signal in the right MOp (80,536 pixels/mm^3) compared to the left MOp (33,519 pixels/mm^3; $p < 0.001$; **Figure 2I**). After stroke, there was a dramatic decrease in the fluorescence intensity in the right ipsilesional MOp (to 665,2 pixels/mm^3) compared to the right MOp of mice that received a sham surgery ($p < 0.0001$), indicating the expected loss of descending connections from the MOp to the forelimb after ischemic injury.

Previous studies found that contralesional plasticity, as detected by injections of PRV into the forelimb flexor, was associated with improved functional recovery after stroke (Liu et al., 2009). Therefore, we hypothesized that we would observe contralesional plasticity after stroke and predicted that after a focal ischemic injury, descending connections from the left contralesional MOp to the affected forelimb would increase in mice that received a stroke compared to uninjured mice. However, we did not observe any significant differences in the fluorescent signal of neuronal cell bodies compared to our control

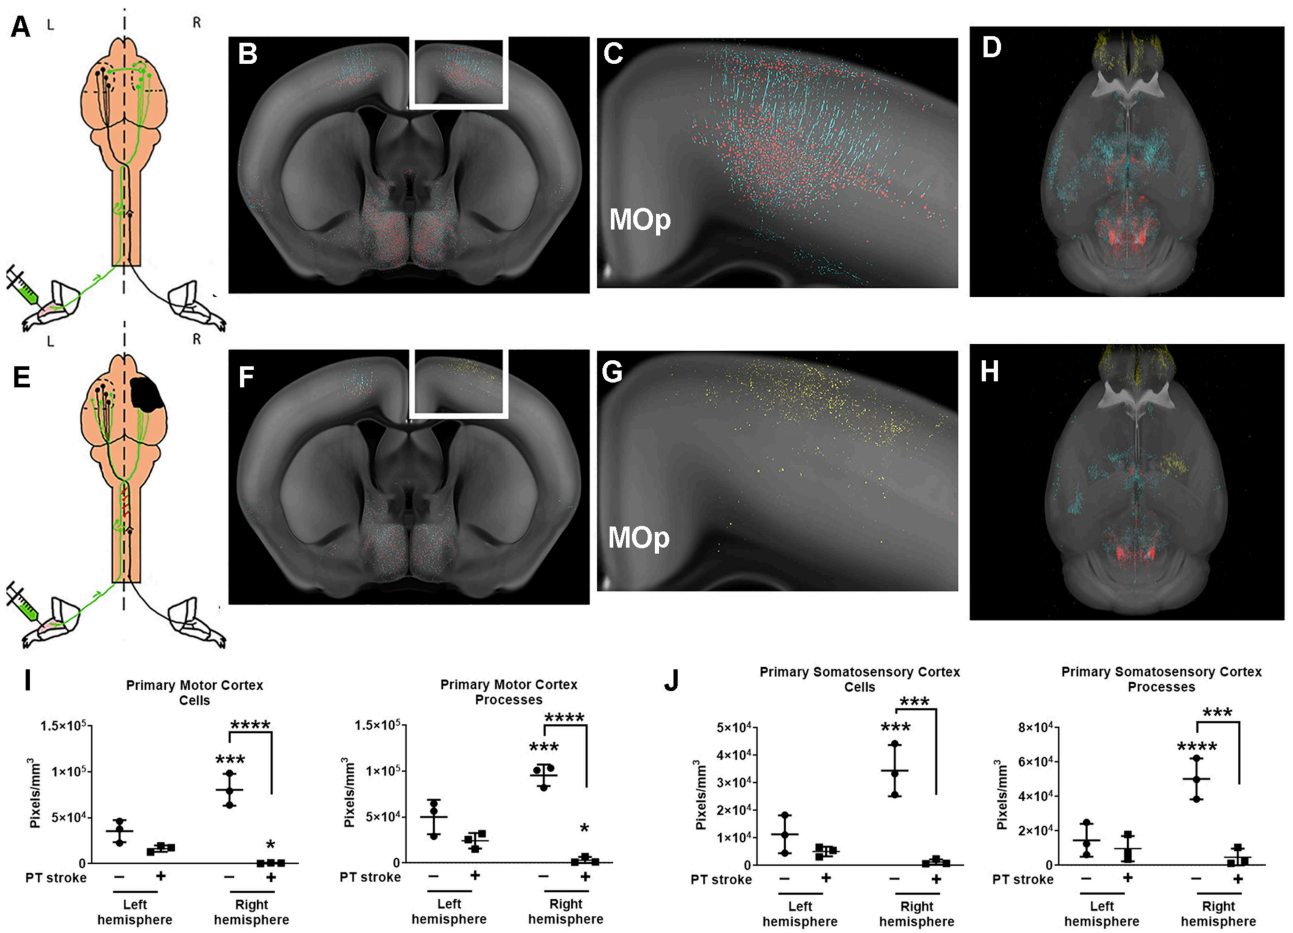

FIGURE 2 | Quantification of changes in forelimb innervation after stroke. **(A)** Schematic of pseudorabies virus (PRV) injection in healthy mice, with **(B)** corresponding coronal section of the probability maps from a representative animal overlaid onto the CCF 3.0 average template (gray) at the level of the primary motor cortex (MOp) **(C)** Enlargement of white boxed area shown in **(B)** depicts pixels classified as cell bodies (red) and neuronal processes (cyan). **(D)** 3-D rendering of the whole brain probability map (images from this animal also shown in **Figure 1**) **(E)** Schematic of PRV injections after stroke (black area, right hemisphere). **(F)** Corresponding coronal section of the probability maps from a representative post-stroke animal overlaid onto the CCF 3.0 average template (gray) at the level of the primary motor cortex. **(G)** Enlargement of white boxed area shown in **(F)** depicts pixels predominantly classified as infarction (yellow) in the right hemisphere. **(H)** 3-D probability map shows area of infarction in the right hemisphere. **(I,J)** Quantification of cell bodies and processes in **(I)** primary motor cortex (MOp) and **(J)** primary somatosensory cortex (SSp) for both left and right hemispheres of uninjured (circles) and post-stroke (square) cohorts. Data shown are pixels/mm^3 for each area. $^*p < 0.05$, $^{***}p < 0.001$, $^{****}p < 0.0001$ vs. left hemisphere unless otherwise indicated by brackets.

cohort ($p = 0.1$). Analysis with two-way ANOVA determined there was a significant effect of both group (stroke vs. no stroke; $p < 0.01$) and hemisphere (right vs. left; $p < 0.01$) on post-stroke neural connectivity in the MOp. Furthermore, there was a significant interaction between group and hemisphere on fluorescence intensity per mm^3 in the MOp ($p < 0.001$).

Because neuroplasticity has also been shown in regions neighboring the ischemic lesion, we quantified changes in fluorescence intensity in the primary somatosensory cortex (SSp) (Bachmann et al., 2014). Similar to the MOp, there was a higher density of fluorescent pixels in the right SSp compared to the left SSp of uninjured mice ($p < 0.001$). Stroke diminished the fluorescent signal in the right SSp ($p < 0.001$). There was no significant difference between the left and right SSp in mice that received a stroke and no difference in fluorescence intensity in the left SSp of injured and uninjured mice.

We also quantified the fluorescent signal in neuronal processes (e.g., axons, dendrites). While the fluorescent signal in virally labeled cell bodies was brighter than that of neuronal processes, as expected, there was still robust labeling of the proximal axons and dendrites in the left and right hemisphere of mice with and without strokes. These data complement the findings observed when quantifying GFP$^+$ cell bodies, showing fluorescent processes in the same regions in which we found cells (i.e., MOp5, SSp-ll). There was unilateral cortical labeling in primary motor and sensory areas, particularly in the MOp5 and SSp-ll, in uninjured mice. Fluorescent processes, predominantly apical dendrites, were identified in both the left (50,099 pixels/mm^3) and right (95,526 pixels/mm^3) hemisphere with significantly more labeling in the right hemisphere (**Figure 2J**; $p < 0.001$). In the stroke cohort, there was sparse labeling of axons in any primary motor or sensory areas, with the

exception of one mouse that showed faint axonal labeling in the left contralesional MOp5 and SSp-II regions (right MOp−3,094 pixels/mm^3). Additionally, there was moderate fluorescent signal in bilateral mid- and hindbrain nuclei in both healthy and injured mice, supporting our findings of robust labeling of neuronal cell bodies in these brain areas.

We also trained our model to identify tissue regions affected by ischemic injury. The PT model produces a small permanent focal lesion in the primary motor cortex. Fluorescent signal corresponding to damaged tissue was identified in the 3 mice that received PT strokes (**Figure 2G**, **Supplementary Videos 7, 8**). All 3 mice that received a stroke exhibited autofluorescent tissue in the MOp, our target region. Damage, albeit to a lesser extent, was also observed in the SSP-ll, a region immediately adjacent to the MOp. The control cohort of mice did not exhibit any fluorescent signal indicative of ischemic tissue in their cortical sensory and motor regions. These data confirm successful induction of stroke in the primary sensory and motor cortices.

In addition to detailed, region-specific visualization of connectivity in the post-stroke brain, our methodology is also able to provide global quantification of alterations in brain architecture after injury. We generated heat maps that visually represent which brain regions contain pixels classified as one of our fluorescent signals of interest, which allowed us to compare probability values between brain regions, between animals, and between the stroke and no stroke cohorts. We selected 52 brain regions to analyze, particularly focusing on regions that were associated with motor or sensory function and/or undergo dynamic changes after stroke (Bachmann et al., 2014). We also selected "control" regions that we predicted would not innervate the forelimb [e.g., hippocampal formation (HPF), olfactory areas (OLF)]. There were high fluorescent signals in many brain regions, albeit with moderate variability between mice. Fluorescence labeling from cell bodies (**Figure 3**) and neuronal processes (**Supplementary Figure 1**) was higher in the mice that did not receive a stroke. The most robust labeling for the cell bodies and neuronal processes was observed in the midbrain and hindbrain, and this labeling was largely bilateral. The brain regions with the most consistently high fluorescent signal appeared to be the medulla, behavioral state related (MY-sat) and the magnocellular reticular nucleus (MARN), a medullary motor-related nuclei, in both the uninjured (left) and injured (right) hemispheres.

Comparison of Automated and Manual Counting

In order to confirm that our ML algorithm had correctly classified pixels as neuronal cell bodies, we manually counted cell bodies in 70 coronal sections in one uninjured mouse (# 439, **Figure 3**). Several cortical regions were quantified: SSp, MOp, and supplemental motor cortex (MOs; **Figure 4A**). Our ML algorithm identified higher fluorescent signal in the right hemisphere of all regions examined, with the highest probability of classification in the MOp5 (**Figure 4B**). Manual counting confirmed that there was a greater number of GFP$^+$ cell bodies in each of these ipsilesional right brain areas (**Figure 4C**). The largest number of cells was located in the right MOp, followed by the SSp, and lastly, the MOs (**Figure 4D**). Similar distributions of cells were observed in the left hemisphere, albeit with fewer cell bodies labeled (**Figure 4E**). There was a significant correlation between the normalized probability values obtained from our ML algorithm and our manual counting ($R^2 = 0.77$; $p < 0.05$; **Figure 4F**). These data support the classification accuracy of the ML algorithm and registration to regions of interest.

Whole Brain Visualization of Post-stroke Neuroinflammation

In addition to neural connectivity, we were also interested in whether STPT and our automated imaged analysis pipeline could quantify immune cell diapedesis after stroke. We focused on the migration patterns of cytotoxic CD8$^+$ T cells within the brain. Early studies confirm migration of CD8$^+$ T cells into the brain (Gelderblom et al., 2009), but with little to no examination of specific brain regions targeted by these cells outside of the area of injury. In order to examine this phenomenon, 13–15-week-old WT mice were given a left transient middle cerebral artery occlusion (tMCAo) and were randomly assigned to experimental groups that would either receive serial intravenous (i.v.) tail injections of either PBS or e450$^+$-labeled CD8$^+$ T cells. We confirmed the presence of viable e450$^+$-labeled cells in the both spleens and cervical lymph nodes of recipient mice (**Supplementary Figure 2**). Flow cytometry confirmed the purity of e450$^+$-labeled cells, as these cells were primarily CD8$^+$ T cells that were present only in the CD8$^+$ T cell recipient group shown both by percentage (**Supplemental Figures 2B,C**) and absolute cell number (**Supplemental Figures 2D,E**), but not the PBS controls.

We trained the ML algorithm to identify e450$^+$ fluorescent cells in representative sections throughout the whole brain, and observed CD8$^+$ T cells within the brain tissue, traveling through blood vessels, and interestingly, along the meninges (**Supplementary Videos 9, 10**). CD8$^+$ T cell diapedesis occurred throughout the brain, including ipsilesional somatosensory cortices (SS; **Figures 5A–C**) and sensory-related midbrain regions (MBsen; **Figures 5D–F**). 3-D renderings of our probability maps and associated videos were generated, demonstrating the bilateral movement of cells throughout the whole brain. After applying the ML algorithm to the entire cohort, a heat map was generated with 41 brain regions that were pre-selected as regions of interest for immune cell diapedesis (**Figure 6**). Similar to the heat maps in the neural connectivity studies (**Figure 3**), these heat maps allow for the comparison of the fluorescence intensity of e450$^+$-labeled CD8$^+$ T cells across multiple brain regions, between groups and animals. As expected, the PBS group showed low fluorescent signal in many of the brain regions, although "background" fluorescence was detected, potentially due to increased autofluorescence in dead or injured ischemic tissue secondary to the tMCAo model. Additionally, some variability was observed in the amount of CD8$^+$ diapedesis between animals of the T cell-recipient group, with high diapedesis into two brain regions in particular, the behavioral state-related midbrain (MBsta) and sensory

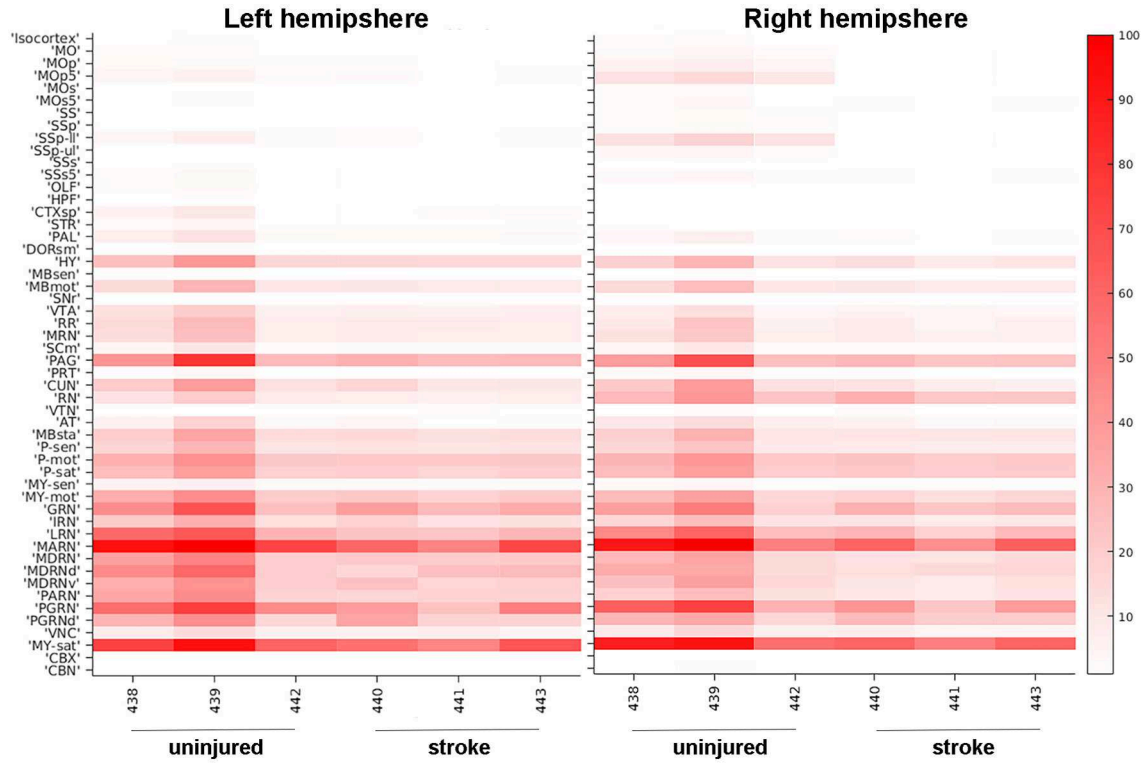

FIGURE 3 | Heat map of neuronal cell body quantification in cortical and other areas. The signal intensities for pixels classified via machine learning as neuronal cell bodies in various cortical areas are shown for uninjured and stroke animals in both left hemisphere (left panel) and right hemisphere (right panel). Each brain area analyzed is listed on the left Y-axis according to the nomenclature used in the CCFv3.0 and individual animals (#, x-axis) are grouped by uninjured and stroke-injured cohorts. The intensity scale is shown on the right Y-axis and corresponds to the number of pixels classified as neuronal cell bodies normalized per region volume (pixels/mm^3). MO, somatomotor areas; MOp, primary motor cortex; MOp5, primary motor cortex, Layer 5; MOs, supplemental motor cortex; MOs5, supplemental motor cortex, Layer 5; SS, somatosensory areas; SSp, primary somatosensory cortex; SSp-ll, primary somatosensory cortex, lower limb; SSp-ul, primary somatosensory cortex, upper limb; SSs, supplemental somatosensory cortex; SSs5, supplemental somatosensory cortex, layer 5; OLF, olfactory areas; HPF, hippocampal formation; CTXsp, cortical subplate; STR, striatum; PAL, pallidum; DORsm, thalamus, sensory motor-related; HY, hypothalamus; MBsen, midbrain, sensory-related; MBmot, midbrain, motor-related; SNr, substantia nigra, reticular part; VTA, ventral tegmental area; RR, midbrain reticular nucleus, retrorubral area; MRN, midbrain reticular nucleus; SCm, superior colliculus, motor-related; PAG, periaqueductal gray; PRT, pretectal nucleus; CUN, cuneiform nucleus; RN, red nucleus; VTN, ventral tegmental nucleus; AT, anterior tegmental area; MBsta, midbrain, behavioral state-related; P-sen, pons, sensory-related; P-mot, pons, motor-related; P-sat, pons, behavioral state-related; MY-sen, medulla, sensory-related; MY-mot, medulla, motor-related; GRN, gigantocellular reticular nucleus; IRN, intermediate reticular nucleus; LRN, lateral reticular nucleus; MARN, magnocellular reticular nucleus; MDRN, medullary reticular nucleus; MDRNd, medullary reticular nucleus, dorsal part; MDRNv, medullary reticular nucleus, ventral part; PARN, parvicellular reticular nucleus; PGRN, paragigantocellular reticular nucleus; PGRNd, paragigantocellular reticular nucleus, dorsal part; VNC, vestibular nuclei; MY-sat, medulla, behavioral state-related; CBX, cerebellar cortex; CBN, cerebellar nuclei.

motor-related thalamus (DORsm). Our ML algorithm was not trained to detect ischemic tissue in these animals.

Overall, CD8$^+$ T cells migrated into many areas of the brain of all animals 4 days after stroke, with greater diapedesis apparent in the left injured hemisphere compared to the right uninjured hemisphere. CD8$^+$ T cells targeted the left ipsilesional SSp and secondary somatosensory cortex (SSs), with significantly more cells detected in the left SSp compared to PBS controls ($p < 0.05$; **Figure 5G**) and more cells in the left SSs ($p < 0.01$; **Figure 5H**). The left ipsilesional MOp was also infiltrated by CD8$^+$ T cells, with more cells in the ipsilesional MOp than the corresponding contralateral MOp ($p < 0.05$; **Figure 5J**). Given the nature of a tMCAo injury, which affects motor and sensory cortices, it is likely these cells were targeting regions damaged by the stroke. In addition to these cortical motor and sensory regions, there was bilateral movement of CD8$^+$ T cells into remote brain regions associated with motor and sensory function, namely the midbrain (**Figures 5D–F,I**) and the pons (**Figures 5K,L**). One region, corpus callosum (cc), exhibited higher contralesional CD8$^+$ T cell diapedesis compared to ipsilesional cc ($p < 0.05$; **Figure 5M**). CD8$^+$ T cells did not significantly infiltrate behavioral-state related regions in either the midbrain or the pons (data not shown) or the hippocampus (**Figure 5N**). Our data demonstrate that 4 days following tMCAo, CD8$^+$ T cells migrate into the brain, targeting both sensory- and motor-related regions of the cortex, midbrain, and pons. In some regions, such as the MBsen and P-sen, this movement is bilateral, with cells detected in both the ipsilesional and contralesional hemisphere relative to PBS controls. In other regions, including the SSp, there is preferential migration into the ipsilesional hemisphere compared to the corresponding contralesional brain regions in CD8$^+$ T cell recipients. Together, these results illustrate how STPT can

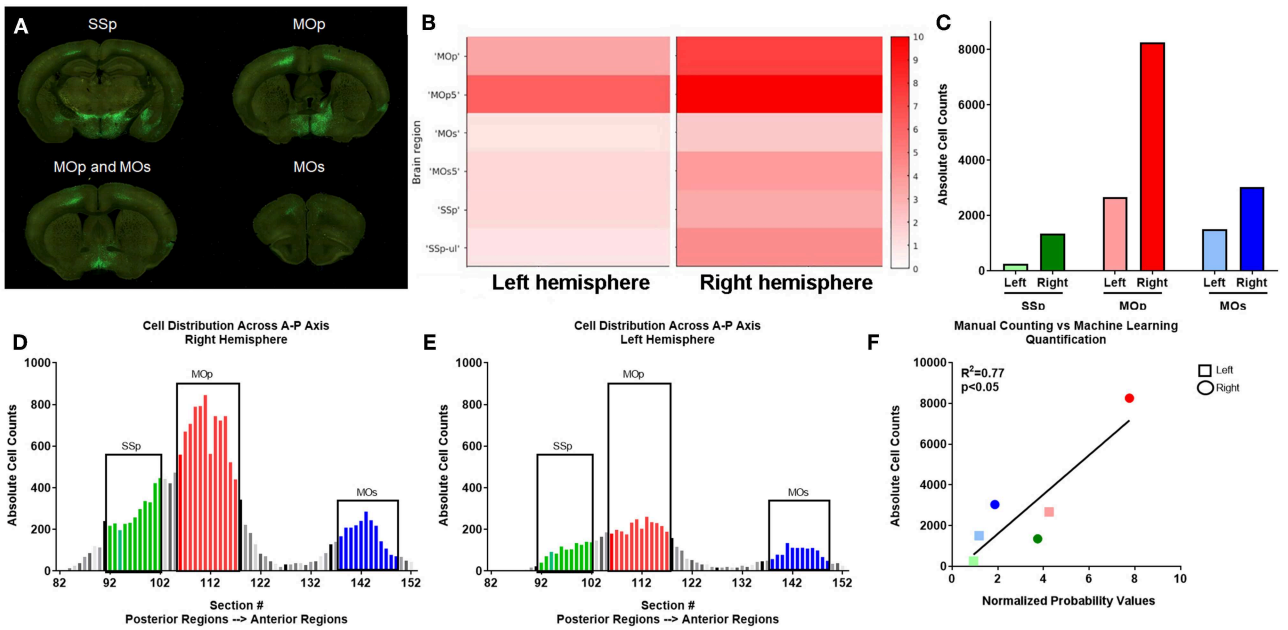

FIGURE 4 | Verification of automated quantification via manual counting. **(A)** PRV labeled neurons are identified by GFP expression in serial two-photon coronal section images, including primary somatosensory (SSp), primary motor (MOp), and supplemental motor (MOs) areas. **(B)** ML identified fluorescent intensity (right y axis in heat map) in the indicated subregions (noted in the left y axis) for left and right hemispheres corresponding to the coronal sections shown in **(A)** for this uninjured mouse. Heat map show visual depiction of the summed probabilities of pixels classified as neuronal cell bodies from the ML data set, with highest intensity shown as red. **(C)** Manual quantification of PRV+ cell bodies in each region. **(D,E)** Manual quantification of PRV+ cell bodies in all coronal sections with PRV+ cell bodies for a representative uninjured brain, shown in a posterior to anterior orientation (left to right on the graph) for SSp (green), MOp (red), and MOs (blue) regions in both the **(D)** right and **(E)** left hemispheres. **(F)** Linear regression analysis of ML data (x axis) and manual counts (y axis) demonstrate a correlation between the two data sets.

be utilized to quantify region-specific diapedesis of immune cells into the ischemic brain.

DISCUSSION

While much research has been performed on post-stroke neuroplasticity and neuroinflammation (Gelderblom et al., 2009; Bachmann et al., 2014), these studies have been limited by conventional imaging methods. STPT, a modern microscopy technique that produces large-scale, 3-D images of intact, uncleared brain tissue, is expanding the capacity to investigate brain-wide circuit mechanisms associated with brain injury, as well as models of neurological and psychiatric disorders. Our work establishes this technique as a reliable method to quantify whole brain neural connectivity and neuroinflammation after stroke to understand region-specific mechanisms of injury and repair. STPT provides many advantages over traditional slide-based methods of mesoscale brain imaging. While automated slide scanning instruments improved our ability to image large numbers of serial sections at high resolution, sectioning and mounting artifacts such as tissue folding and tearing are unavoidable using traditional sectioning methods. These artifacts lead to inaccurate 3-D reconstruction of the whole brain. Additionally, traditional sectioning studies are often limited in scope to discrete brain regions or small numbers of whole brains due to the amount of processing and imaging time needed. STPT, through its use of automated block face imaging and sectioning, overcomes these issues. Optical clearing has also become a popular method to develop 3-D models of neuronal circuits that allows one to acquire volumetric images of the whole brain without physical sectioning (Cai et al., 2019). STPT, however, uses standard perfusion fixed brains and as such avoids a potential pitfall of optical clearing: namely, morphological changes such as increases or decreases in organ size that may distort neuronal circuits in a non-uniform way and reduce the accuracy of brain wide circuit analyses. Despite these advantages, STPT is not without its limitations. One drawback of the method is that it requires tissue to have an inherent fluorescent signal. While this is compatible with viral tracers and fluorescently labeled cells as used in our study, as well as many strains of transgenic mice with expression of fluorescent reporter proteins, it does not allow for staining with traditional primary antibodies, an accessible and commonly used technique in most laboratories. Additionally, STPT is a time-consuming method for whole brain imaging. Data could be more quickly acquired using newer technologies such as high-throughput light tomography (HTLP) (Yang et al., 2018). Future studies should utilize HTLP and other volumetric imaging techniques to confirm our findings regarding changes in axonal connectivity and $CD8^+$ T cell diapedesis after stroke. Another issue to consider when using STPT or any volumetric imaging strategy is the effect of stroke on atlas registration. Missing tissue or swelling around the site of injury could lead to inappropriate designation of anatomical regions. This problem is

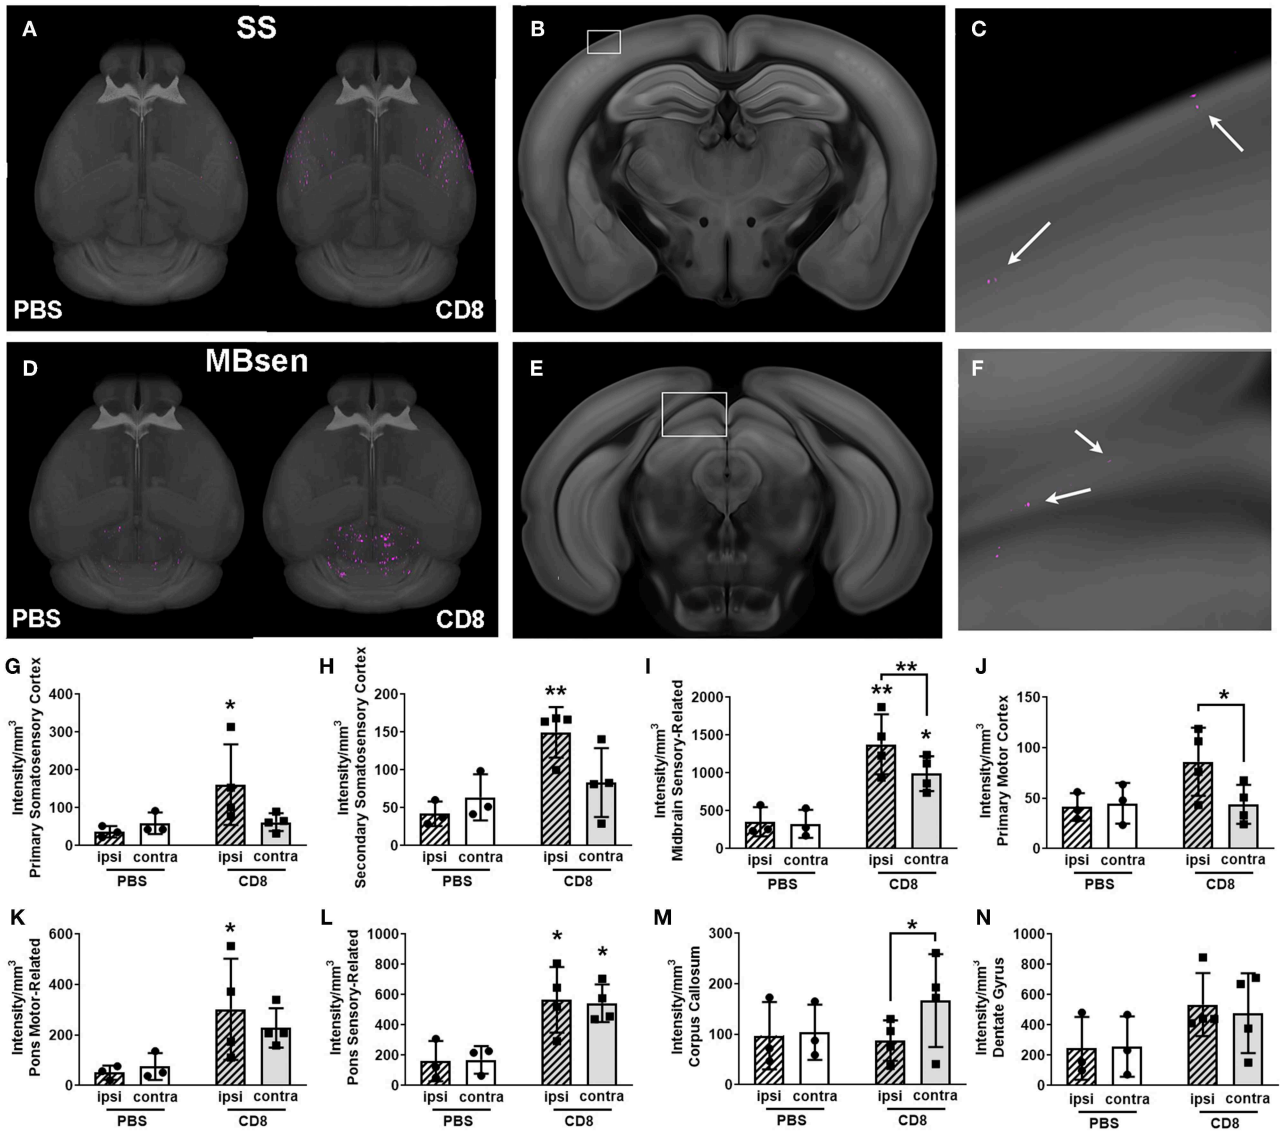

FIGURE 5 | Visualization of quantification of CD8$^+$ T cell diapedesis in the whole brain after stroke. **(A)** Masked 3-D probability map images of somatosensory areas only from a representative CD8$^+$-treated animal (right brain) overlaid onto the CCF 3.0 average template (gray) shows pixels classified as CD8$^+$ T cell (magenta) which have migrated into somatosensory areas (SS). Minimal magenta pixels are present in the PBS-treated brain (left) **(B)** Coronal section with white box highlighting part of the primary somatosensory area from the brain shown in A, with **(C)** enlargement of white boxed area showing several magenta areas classified as CD8$^+$ T cells (white arrows). **(D)** 3-D probability maps from the same brains as in **(A)** but masked to show pixels classified as CD8$^+$ T cells in the midbrain, sensory-related (MBsen) shows high CD8$^+$ T cell diapedesis (magenta) in both hemispheres, though PBS-treated mice (left brain) also have some background level of pixels classified as fluorescently labeled CD8$^+$ T cells. **(E)** Coronal section with white box highlighting MBsen from the brain shown in C, with **(F)** enlargement of white boxed area showing several magenta areas classified as CD8$^+$ T cells (white arrows). **(G–N)** Bar graph shows ipsilesional (hatched bars) and contralesional (plain bars) diapedesis into selected regions in CD8$^+$-treated mice (black squares, right columns) and PBS controls (black circles, left columns). Ipsilesional CD8$^+$ T cell diapedesis also occurs in **(G)** primary somatosensory cortex, **(H)** supplemental somatosensory, **(I)** MBsen, **(J)** primary motor cortex, and **(I)** motor-related pons. **(L)** Sensory-related pons exhibits bilateral diapedesis, while **(M)** the corpus callosum is predominantly contralesional. **(N)** There is no significant CD8$^+$ T cell diapedesis into the dentate gyrus. $^*p < 0.05$, $^{**}p < 0.01$ vs. PBS control unless otherwise indicated by brackets.

not limited to studies of stroke. Indeed, automated quantification of STPT or any type of volumetric images of mouse models of brain injury or neurodegeneration could be similarly impaired by improper tissue warping and atlas registration due to abnormal presentation of the brain tissue.

In this study, we used STPT to examine neural connectivity and neuroinflammation. In order to study of neural connectivity we utilized PRV-152, a viral retrograde tracer. Because PRV is a trans-synaptic virus, this method allows labeling from specific muscles, to spinal interneurons and motor neurons, and ultimately to motor projection neurons in the brainstem and cerebral cortex. However, because it is a trans-synaptic tracer, one downside to this method is that we cannot distinguish between first-, second-, and third-order

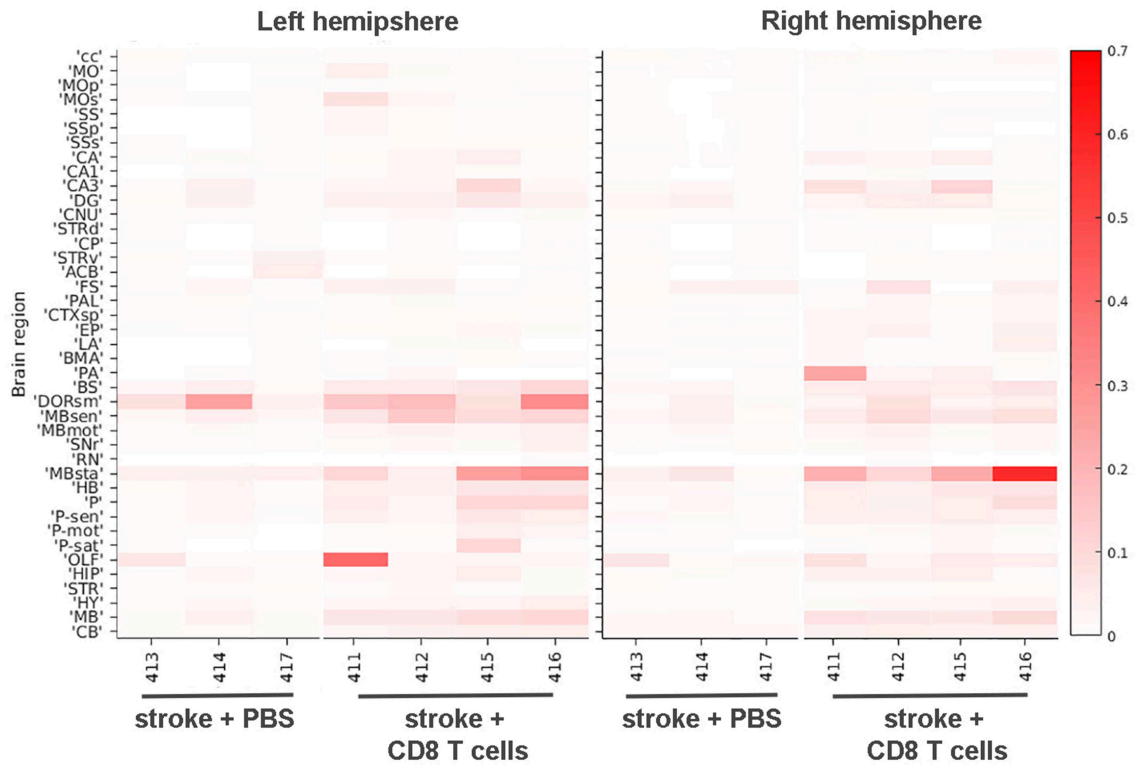

FIGURE 6 | Heat map of CD8$^+$ T cell diapedesis in cortical and other areas. The signal intensities for pixels classified via ML as e450-labeled CD8$^+$ T cells in various cortical and other brain areas are shown for stroke animals either injected with PBS or CD8$^+$ T cells in both left hemisphere (left panel) and right hemisphere (right panel). Each brain area analyzed is listed on the left Y-axis according to the nomenclature used in the CCF 3.0 and individual animals (#, x-axis) are grouped by PBS and T cell injected cohorts. The intensity scale is shown on the right Y-axis and corresponds to the number of pixels classified as CD8$^+$ T cells normalized per region volume (pixels/mm^3). cc, corpus callosum; MO, somatomotor areas; MOp, primary motor cortex; SS, somatosensory areas; SSp, primary somatosensory cortex; SSs, supplemental somatosensory cortex; CA, Ammon's horn, CA1, field CA1; CA3, field CA3; DG, dentate gyrus; CNU, cerebral nuclei; STRd, striatum, dorsal region; CP, caudate putamen; STRv, striatum, ventral region; ACB, nucleus accumbens; FS, fundus of the striatum; PAL, pallidum; CTXsp, cortical subplate; EP, endopiriform nucleus; LA, lateral amygdalar nucleus; BMA, basomedial amygdalar nucleus; PA, posterior amygdalar nucleus; BS, bed nuclei of stria terminalis; DORsm, thalamus, sensory motor-related; MBsen, midbrain, sensory-related; MBmot, midbrain, motor-related; SNr, substantia nigra, reticular part; RN, red nucleus; MBsta, midbrain, behavioral state-related; HB, hindbrain; P, pons; P-sen, pons, sensory-related; P-mot, pons, motor-related; P-sat, pons, behavioral state-related; OLF, olfactory areas; HIP, hippocampal region; STR, striatum, HY, hypothalamus, MB, midbrain, CB, cerebellum.

connections to the forelimb. New viral monosynaptic tracers, such as glycoprotein-deleted rabies virus, and traditional monosynaptic chemical tracers like FastBlue could allow us to look specifically at first-order connections, although this would require direct injections into spinal cord or brain. Furthermore, PRV is a lethal virus, inducing significant cell death and neuronal dysfunction, and ultimately killing the animal (McCarthy et al., 2009). We had a 50% mortality rate in the PT stroke cohort, while all mice that received sham surgeries survived, suggesting a detrimental synergistic effect of ischemic injury and PRV-induced cytotoxicity at 6 days after peripheral intramuscular injection. The newer viral tracers have sought to reduce or eliminate this toxicity with the promising new development of a self-inactivating glycoprotein-deleted rabies virus that allows for life-long labeling of circuits (Ciabatti et al., 2017).

It is well-established that immune cells diapedese into the infarct and penumbral regions after stroke (Xie et al., 2018), but it is less clear where and when immune cells traffic into remote brain regions that support functional recovery. Furthermore, post-stroke diapedesis has never been characterized in 3-D, making this study the first whole-brain quantification of CD8 trafficking from the periphery following stroke. One of the limitations of our study is that CD8 T cells may diapedese from the ventricles and the meninges before they reach their targeted brain tissue after stroke (Benakis et al., 2018; Yanev et al., 2019). Not all of the meningeal lymphatics are removed during sample preparation, and the ventricles are adjacent to several analyzed brain regions. Thus, it is possible that these areas could be warped and registered into the atlas, giving the false positive impression of parenchymal penetration of CD8$^+$ T cells when in actuality, they are traveling through the meningeal lymphatics or ventricles to another location. It may be necessary to visually inspect coronal sections on a case by case basis, particularly if larger immune cell populations are quantified in a similar manner.

Modern techniques such as STPT and other new imaging methods further our understanding of post-stroke pathology and repair. Our data demonstrate that rapid whole brain microscopy

followed by large-scale automated analyses can provide new insight into neural connectivity and neuroinflammation post-stroke in an unbiased, region-specific manner that is difficult, if not impossible, with current conventional techniques. Future studies should use these techniques to further investigate neuroplasticity and neuroinflammation following stroke, as well as other diseases and injuries with global effects on the brain.

DATA AVAILABILITY STATEMENT

All datasets generated for this study are included in the manuscript/**Supplementary Files**. All raw data is immediately available upon request.

ETHICS STATEMENT

The animal study was reviewed and approved by University of Texas Southwestern Medical Center Institutional Animal Care and Use Committee.

AUTHOR CONTRIBUTIONS

MG, KP, and DB designed the neural connectivity experiments. KP, DB, SM, XK, and SG acquired data for neural connectivity experiments. AS and VT designed the neuroinflammation experiments. US isolated $CD8^+$ T cells for neuroinflammation experiments. VT and XK acquired data for neuroinflammation experiment. EP performed all stroke surgeries. AA, JM, and DR acquired all STPT data and conducted pipeline analyses. KP, DB, VT, and AS analyzed final STPT results. All authors edited the manuscript.

FUNDING

This study was funded by grants to AS from NIH/NINDS (NS088555), to AS from the Dana Foundation David Mahoney Neuroimaging Program, to VT from the NIH Intergrative Immunology Training Program (5T32AI005284-40) the Haggerty Center for Brain Injury and Repair, and the Texas Institute for Brain Injury and Repair (TIBIR) (UTSW). SG was supported by the National Center for Advancing Translational Sciences of the National Institutes of Health under award Number KL2TR001103. PRV-152 was generously provided by Dr. Lynn Enquist (Princeton University, Princeton, NJ) through the Center for Neuroanatomy with Neurotropic Viruses (NIH P40 OD010996).

ACKNOWLEDGMENTS

The authors acknowledge the Moody Foundation Flow Cytometry Facility at the Children's Research Institute and the Neuro-Models Facility at UT Southwestern.

Magnetic resonance imaging (MRI) provides a unique tool for *in vivo* visualization and tracking of stem cells in the brain. This is of particular importance when assessing safety of experimental cell treatments in the preclinical or clinical setup. Yet, specific imaging requires an efficient and non-perturbing cellular magnetic labeling which precludes adverse effects of the tag, e.g., the impact of iron-oxide-nanoparticles on the critical differentiation and integration processes of the respective stem cell population investigated. In this study we investigated the effects of very small superparamagnetic iron oxide particle (VSOP) labeling on viability, stemness, and neuronal differentiation potential of primary human adult neural stem cells (haNSCs). Cytoplasmic VSOP incorporation massively reduced the transverse relaxation time T2, an important parameter determining MR contrast. Cells retained cytoplasmic label for at least a month, indicating stable incorporation, a necessity for long-term imaging. Using a clinical 3T MRI, 1×10^3 haNSCs were visualized upon injection in a gel phantom, but detection limit was much lower (5×10^4 cells) in layer phantoms and using an imaging protocol feasible in a clinical scenario. Transcriptional analysis and fluorescence immunocytochemistry did not reveal a detrimental impact of VSOP labeling on important parameters of cellular physiology with cellular viability, stemness and neuronal differentiation potential remaining unaffected. This represents a pivotal prerequisite with respect to clinical application of this method.

Keywords: human adult stem cells, magnetic labeling, MRI, cell tracking, CNS – disorder

INTRODUCTION

Stem cell transplantation represents one of the most promising strategies for the restoration of lost cells or tissue including their functions, or at least for delaying the pathogenic progress in neurodegenerative diseases (Janowski et al., 2015). The question whether adult or embryonic stem cells are best suited for clinical applications remains open (Modo et al., 2002;

Dietrich and Kempermann, 2006), yet adult stem cells show reduced probability of teratoma formation, and thereby represent a promising candidate for clinical translation (Dietrich and Kempermann, 2006; Bellenchi et al., 2013). In humans, adult neural stem cells are present in the subventricular zone and in the subgranular zone of the hippocampal dentate gyrus (Zimmer et al., 1995; Stroh et al., 2005, 2009). These cells can be isolated from patients with intractable temporal lobe epilepsy subjected to neurosurgical intervention (Hoehn et al., 2002). Stem cells tracking and long term monitoring is demanded for thorough development of safe and efficient transplantation protocols and to further our understanding about therapeutic modes of action in both the preclinical and clinical setting.

To date, magnetic resonance imaging (MRI) of magnetically labeled stem cells represents the only clinically applicable imaging method for highly sensitive, non-invasive detection and long-term tracking of transplanted stem cells over extended periods of time (Modo et al., 2002; Stroh et al., 2005, 2009). Citrate-coated very small superparamagnetic iron oxide particles (VSOP) are widely used for pre-transplantation stem cell labeling. These particles are incorporated via endocytosis, aggregate and ultimately get stored in intracytoplasmic vesicles (Zimmer et al., 1995; Stroh et al., 2005). Incorporation of VSOP can be enhanced by lipofection to enhance the percentage of strongly labeled cells (Hoehn et al., 2002). Superparamagnetic iron oxide particles also seem to be biodegradable (Weissleder et al., 1989) and can even be utilized by the cells in iron metabolism pathways (Pouliquen et al., 1991).

However, the incorporation of iron oxide particles may lead to distinct changes in stem cell physiology (Stroh et al., 2004; Guzman et al., 2007; Focke et al., 2008; Neri et al., 2008). Moreover, superparamagnetic iron oxide/poly-L-lysine-labeling of a mouse neural stem cell line was reported to induce changes in expression of genes responsible for iron homeostasis, despite apoptotic pathways were not upregulated in that particular study (Walczak et al., 2006). Further, iron oxide particles have been shown to cause transient oxidative stress, closely linked to the free iron during incubation (Stroh et al., 2004), and most likely due to degradation and release of ferric ions into the acidic endolysosomal compartments (Soenen et al., 2011). Thus, evaluating the safety and impact of VSOP labeling on the differentiation potential of highly sensitive human adult stem cells is an important prerequisite for clinical translation (Gupta et al., 2007). Finally, the intended labeling protocol needs to be tailored to the respective stem cell population to ensure an acceptable balance between labeling intensity/efficacy and safety (Boltze et al., 2015).

Our study investigates describe the long term efficacy of human adult human neural stem cell (haNSC) VSOP labeling and its impact on viability, expansion, and neuronal differentiation potential for the first time. We analyzed both non-differentiated haNSCs as well as mature haNSCs-derived neurons, with murine embryonic stem cells (mESC) serving as cellular controls. We also assessed cell detection limit *in vitro* MRI with different modalities including one being close to a potential clinical application.

RESULTS

Safety of Cell Labeling With VSOP

To assess safety of haNSC preparation, cryopreservation, and labeling (0.5 mM), or to detect any donor-dependent differences, cell viability was tested in the first step. No significant donor-dependent differences in cell viability between cells which underwent the labeling procedure with 0.5 mM (85–89%) and non-labeled control cells (91%, sample pooled from all patients) could be detected 1 day after labeling (**Figure 1A**). All samples could be included in onward experiments according to preset viability criteria (>80%). Next, cell viability of haNSCs and mESCs was compared 8 and 48 h after labeling with 0.5 and 1.5 mM VSOP, respectively (**Figure 1B**). Again, no significant differences in haNSCs viability between non-labeled control cells (95%), as well as 8 (87.5%) and 48 h (94.5%) after labeling became apparent. Viability of mESCs decreased slightly to 89% at 8 h and to 93.5% at 48 h after labeling. No viability differences were observed between 0.5 and 1.5 mM VSOP concentration.

Efficacy of Magnetic Cell Labeling

Incubation of haNSCs with 0.5 mM VSOP alone ("simple") and additional lipofection resulted in a substantial uptake of magnetic label (**Figure 2**). Prussian blue staining revealed a homogenous ferric ion distribution in the cytoplasm, excluding the nuclei (**Figures 2a,b**). Prussian blue signals remained unchanged from day 2 to day 28 post simple incubation (**Figures 2c,d**), indicating a stable vesicular incorporation of VSOP for at least 1 month. This ratio did not differ significantly between day 2 and day 28. No apparent increase in iron-oxide particle uptake was observed upon visual inspection in lipofected cells (**Figures 2e,f**), which was confirmed by counting labeled cells. Overall, 96–100% of haNSCs were labeled. Labeling efficacy could not be improved significantly at any time point by additional lipofection (+L) (**Figure 2g**), so lipofection was omitted in all further experiments.

Proliferation Assays

We next conducted a proliferation assay of labeled and non-labeled haNSCs. Over the course of 8 days, an exponential increase in cell number could be observed, yet, notably, no significant difference could be detected between the proliferation curves on non-labeled and haNSCs incubated with 0.5 and 1.5 mM VSOP (**Figure 2h**).

Magnetic Resonance Properties

Next, the impact of 0.5 and 1.5 mM VSOP-labeling of both stem cell populations on magnetic resonance properties was determined after 8 and 48 h via NMR relaxometry (**Figures 3a,b**). Unlabeled cells had a T2 time of 2110 ms (mESCs) and 1948 ms (haNSCs), revealing no significant difference between both protocols. In contrast, VSOP-labeling with 0.5 mM and 8 h incubation time led to a significant reduction of T2 time to 10% of control values (mESCs: 218 ms, haNSCs: 227 ms, **Figure 3a**, $P < 0.01$). 48 h after incubation, T2 time ranged at 15% of control values (mESCs: 298 ms, haNSCs: 408 ms, **Figure 3b**). Further increasing VSOP concentrations to 1.5 mM resulted in

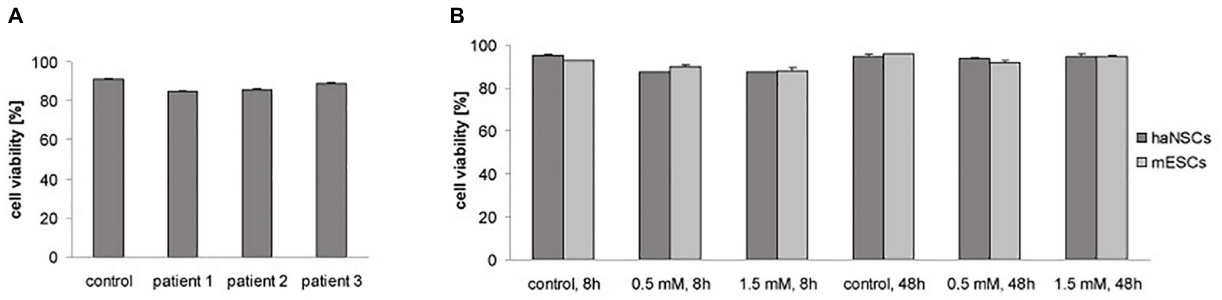

FIGURE 1 | Cell viability of magnetically labeled haNSCs and mESCs (n = 3 with 3 technical replicates each). **(A)** Trypan blue exclusion test showed no significant differences in viability of three different patient samples (labeling with 0.5 mM). **(B)** Trypan blue exclusion test 8 and 48 h after labeling showed no decrease in cell viability due to the labeling procedure.

an additional reduction of average T2 time which, however, was not statistically significant from that after 0.5 mM incubation.

In vitro MR Imaging

To assess clinical applicability of the labeling protocol, gradient echo MR images of gel phantoms with injected cells were acquired (**Figures 3c,g**). On the T2*-weighted images two needle tracks on the gel surface can be delineated as hyperintense signal changes (**Figure 3c**) in injection phantoms. On the left side of the phantom 1×10^3 magnetically labeled haNSCs were injected, whereas 1×10^3 unlabeled control haNSCs where placed on the right side. The T2*-weighted images clearly showed hyperintense signal changes only in the left injection track deposit of 1×10^3 labeled haNSCs (**Figures 3d,e**). Cell detectability was lower in layer phantoms imaged at 3T SWI with a protocol that could be applied on hypothetical patient. Only 5×10^4 labeled cells were detectable with the applied imaging protocol (**Figures 3f,g**).

Characterization of Non-differentiated VSOP Labeled Stem Cells

Cells were magnetically labeled and subsequently analyzed by RT-PCR and Western Blotting (**Figure 4a**). Non-labeled haNSCs and mESCs served as cellular controls. After culturing in the appropriate expansion media, all cells except the HT22 expressed the mRNA for the stemness markers Oct4 and Sox2, and the neural progenitor marker nestin. haNSCs and mESCs loaded with 0.5 mM VSOP (VSOP) or VSOP plus lipofection agent (VSOP + L) revealed the same mRNA expression pattern. No difference between stem cells incubated with (L) and without lipofectin became apparent.

Analysis of haNSCs using fluorescent immunocytochemistry showed that 99% of cells express the intermediate filament protein nestin (**Figure 4b**). 65% co-expressed the nuclear proliferation marker Ki-67 (**Figures 4c,d**). 99% of haNSCs, which underwent the VSOP-labeling procedure and subsequently had a high cytoplasmatic iron loading, expressed nestin while 64% of cells were found positive for Ki-67 (**Figures 4e–g**). Substantial differences between control cells and VSOP labeled haNSCs from all three donors could not be observed (**Figure 4h**). Analysis of nestin and Ki-67 co-expression revealed no impact of VSOP labeling (**Figure 4i**). However, we found a significant effect on relative numbers of cells co-expressing nestin and Ki-67 in the three patients ($P < 0.01$).

Differentiation Potential of VSOP-Labeled Stem Cells

Figure 4j illustrates the analysis of stem cells that were magnetically labeled and subsequently neuronally differentiated over 15 days. Non-labeled, but neuronally differentiated haNSCs and mESCs served as controls. To characterize the transition from neural progenitors to mature neurons, mRNA expression levels of β-tubulin III, doublecortin (DCX), neural cell adhesion molecule 1 (NCAM-1) as well as microtubule associated phosphoprotein 2 (MAP-2) were investigated. RT-PCR analysis indicated neural progenitors and immature neurons in control cell populations as well as in magnetically loaded cell populations. No differences in expression patterns were observed.

DISCUSSION

In this study, we were able to show that labeling of haNSC with iron-oxide-particles, required for a high-resolution MR Imaging, is both safe and efficient. Labeling efficiency using 0.5 mM VSOP was found up to 100% and resulted in stable cell labeling for at least 1 month. Trypan blue exclusion tests at different time points and comparison of different patient samples demonstrated that VSOP-labeling had no effect on overall haNSCs viability. Using clinical 3T MRI, we visualized 1×10^3 labeled cells in an injection phantom, modeling the *in vivo* situation under optimal imaging conditions. Moreover, 3T SWI MRI of layer phantoms with layers containing up to 5×10^4 labeled cells was performed, applying an imaging protocol taking 41:00 min. This is short enough to be applied in a hypothetical clinical scenario, but on the upper limit what could be performed in critically ill patients. The protocol settings were chosen on optimal detectability in VSOP-labeled mesenchymal stem cells (Stroh et al., 2011). The analysis of Oct4 and Sox2 mRNA-expression in addition to the quantitative fluorescence immunocytochemistry analysis of Ki-67 and nestin co-expression as stem cell markers and indicators of proliferation activity showed no impact of VSOP labeling, but

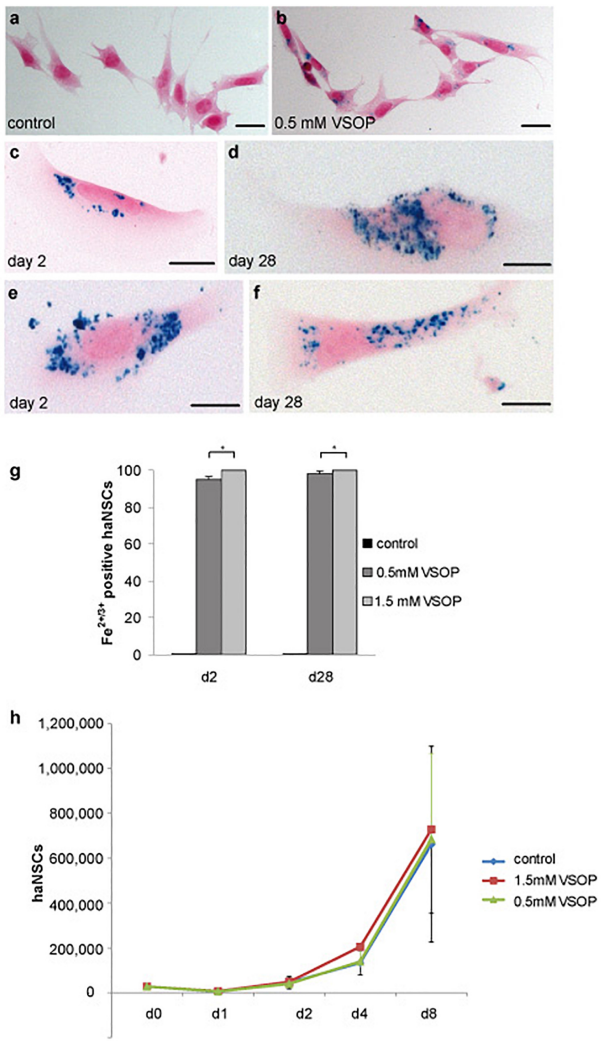

FIGURE 2 | Cytological analysis of magnetically labeled haNSCs (n = 3 with 3 technical replicates each). **(a)** Unlabeled control cells and **(b)** intracytoplasmic VSOP uptake by haNSCs following incubation with 0.5 mM VSOP. **(c–f)** Cells were fixed with 4% phosphate-buffered saline-buffered paraformaldehyde and intracellular iron was visualized using Prussian blue staining on day 2 as shown in **(c,e)** and on day 28 as provided in **(d,f)** after labeling. **(g)** Cell counting revealed that labeling efficacy at any time point could not be enhanced significantly by lipofection. **(h)** Proliferation analysis of VSOP-labeled haNSC (1.5 mM) revealed no statistically significant difference in the proliferation abilities of unlabeled haNSC and haNSCs labeled with 0.5 mM VSOP, respectively. Scale bars in **(a–f)** represent 10 μm. $^*p < 0.01$.

significant differences in haNSC samples from different donors. Furthermore, neuronal differentiation potential and neuronal marker expression were not affected by the labeling procedure.

Prussian blue staining resulted in a homogenous ferric ion distribution in the cytoplasm, but not in the nucleus. This is in line with previous findings from our group, showing a direct relation between VSOP incubation, intracellular iron load as measured by atomic absorption spectroscopy, and T2 time reduction (Stroh et al., 2005). Prussian blue staining was found stable after 48 h and 28 days, indicating a transfer of VSOP onto daughter cells during cytokinesis for proliferating cells. Our data indicate no difference in labeling efficiency and stability between incubation with VSOP and additional lipofection. One explanation of the efficient incorporation with VSOP alone could be the small diameter and the negative surface charge of the citrate coating, already allowing efficient uptake without additional lipofection. Albeit lipofection did not raise a safety concern in our study, off-target effects and immune response caused by transfection reagents have been described (Bauer et al., 2006). Thus, sufficient labeling with VSOP but omitting lipofection may represent a clear advantage for subsequent *in vivo* and clinical applications.

It is known that citrate coating may interact with the extracellular domain of integrins and triggers their activation and subsequently intracellular signaling cascades (Miller et al., 2010). Furthermore, VSOP can induce increased levels of transferrin receptor-1. VSOP incubation can also result in a fast increase and high level of reactive oxygen species (ROS), most likely due to degradation and release of ferric ions into the acidic endolysosomal compartments (Soenen et al., 2011). Although no detrimental influence has been shown in the present study, the overall impact of these potential alterations should be carefully controlled after *in vivo* transplantation. While measures of T2 relaxation times provide an indication of the cellular iron uptake, a direct measure of iron content, as conducted in previous studies of ours using the same iron-oxide particles, yet in different cells, would be desirable (Stroh et al., 2005, 2009). We were not able to conduct these assays due to the scarcity of the cellular material. Also, iron-oxide particles have shown to induce oxidative stress (Stroh et al., 2004), potentially leading to oxidative damage to proteins, lipids and even DNA, also at low concentrations of the label (Novotna et al., 2012). Viability assays, as conducted here, might not be sensitive toward these molecular changes, but again, we were not able to conduct these assays due to the limited availability of the cells.

Potential effects of iron oxide on the neuronal differentiation potential of haNSC and mESC, were analyzed on the gene transcription level. The present data indicates that VSOP-labeled haNSCs and mESCs can be expanded without affecting their potential for both neurogenesis, as represented by the pluripotency markers Sox2 (Suh et al., 2007) and Oct4 (Nichols et al., 1998), or their ability for neuronal differentiation. Magnetic labeling had also no impact on mRNA transcription of nestin and Ki-67 expression even after 14 days in culture. In this study, we used iron-oxide nanoparticles, which are presumably taken up by the cells by endocytosis (Stroh et al., 2004). This means, that in contrast to genetically encoded labels, the concentration of particles in the cells will diminish over time, both due to cell proliferation, and also due to particle degradation. This limits the time window, in which these cells will be detectable by MRI. What is more, we provided data on RNA level on the differentiation potential of these labeled cells, but this does not prove a functional stable differentiation into a given neuronal subtype. For that, additional assays on protein level and ultimately electrophysiological evidence need to be conducted (Stroh et al., 2011).

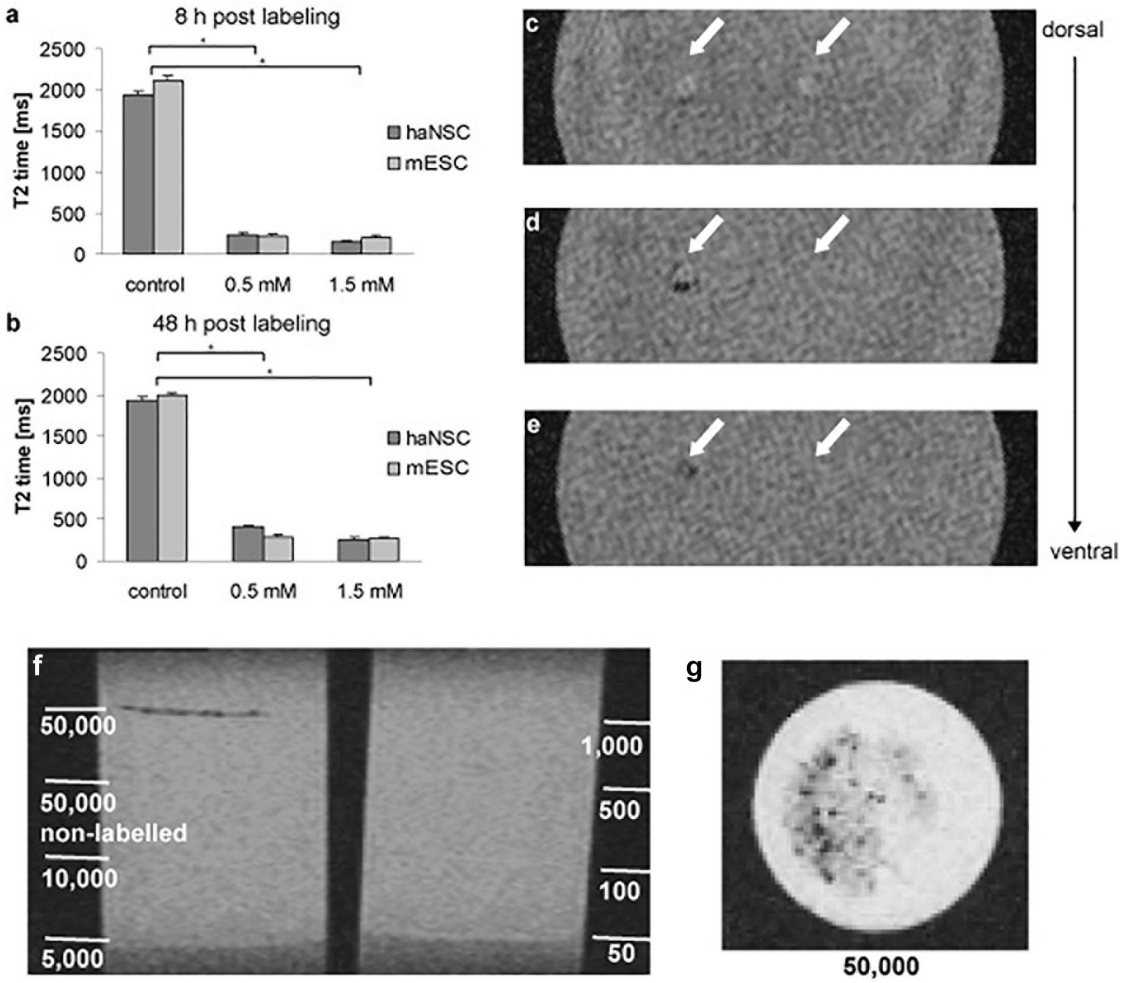

FIGURE 3 | NMR relaxometry and gradient echo MR images of gel phantoms containing haNSCs (n = 3 or more). **(a,b)** Efficiency of VSOP-labeling was determined after 8 **(a)** and 48 h **(b)** using NMR relaxometry. All data were analyzed and presented as mean ± SEM. Differences were considered significant at $P < 0.01$. **(c)** Coronal section at gel surface showing two needle tracks as hyperintense signal change. 1×10^3 VSOP labeled haNSCs were injected on the left side; on the right side 1×10^3 unlabeled control haNSCs were injected. **(d)** Slice 4.5 mm ventral of **(c)**. In the left injection track an area of signal loss can be visualized, due to clusters of magnetically labeled haNSCs. No signal change in the right injection track was observed. **(e)** Slice 5 mm ventral of **(c)**. The left injection track again shows an area of signal loss, no signal change in the right injection track. **(f,g)** layer phantoms investigated in 3T SWI MRI. Only 5×10^4 labeled haNSCs were detectable with an imaging protocol being short enough (41:00 min) to be applicable in a hypothetical clinical scenario. *$p < 0.01$.

1×10^3 VSOP-labeled haNSC were easily identified in a gel phantom, reliably modeling the situation upon stereotactic transplantation *in vivo* (Stroh et al., 2005). This detection range is more than sufficient to monitor cell migration in clinical scenarios where 20 to 300×10^3 or even more cells are transplanted (Kondziolka et al., 2004; Stover et al., 2005). Nevertheless, the detection limit is rather high compared to other studies that repeatedly shown single cell detectability. A direct comparison is difficult though. For instance, some studies employed ultra-high field strengths (11.7T) and imaging protocols optimized for that purpose (Hinds et al., 2003). Others used long imaging times and different cell types such MDA-MB-231BR breast cancer cells or J774 macrophages (Heyn et al., 2006). Both cell types are much larger (up to 25 μm diameter and up to 100 μm in length for MDA-MB-231BR) than neural stem cells and therefore can store much higher amounts of VSOP, while macrophages are particularly efficient in uptaking VSOPs. We also had to apply relatively long scanning times to visualize 1×10^3 labeled cells. Moreover, ultra long-term *in vivo* imaging at 3T may necessitate higher cell concentrations as cell loss or dilution of intracellular iron content due to *in vivo* proliferation may reduce the overall signal obtained. It should be noted though that cell detectability is different in gel phantom and *in vivo* imaging, the latter commonly associated with higher detection limits.

On the other hand, 3T SWI with a short-term protocol optimized for cell detectability was only able to detect 5×10^4 cells in a layer phantom, modeling wide-spread cell distribution as can be observed after systemic transplantation or migration. Apart from the shorter imaging time and the lower number of

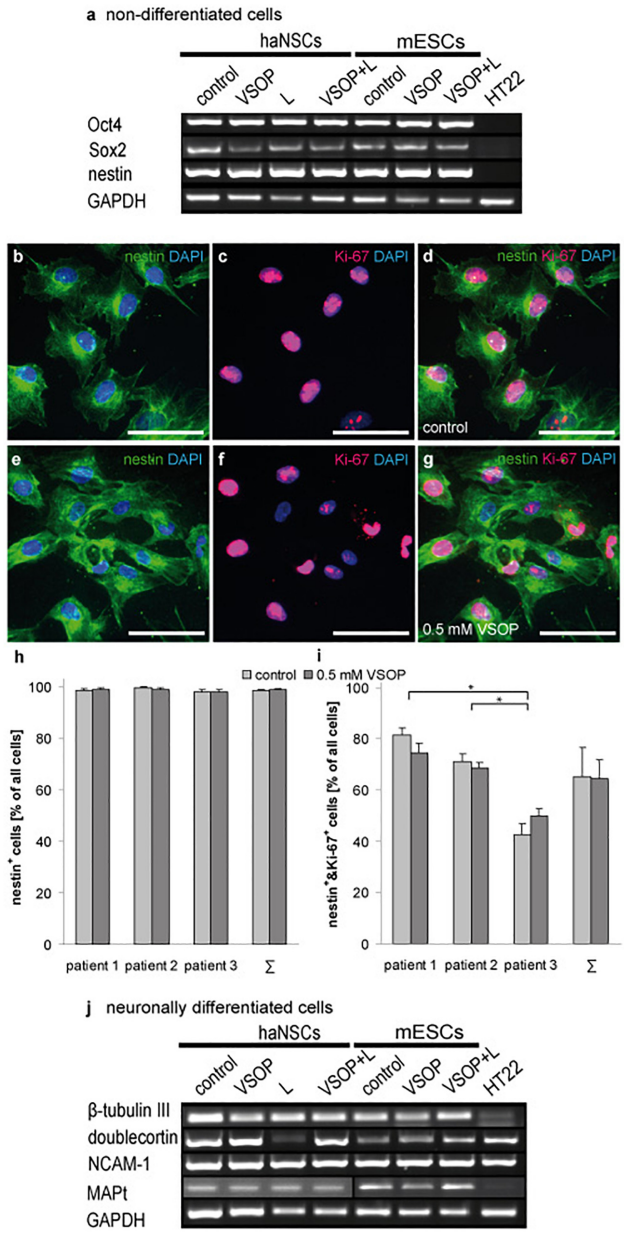

FIGURE 4 | Transcriptional and immunohistochemical analysis of stemness and neuronal differentiation (n = 6 to 10). **(a)** VSOP-labeling and lipofection of non-differentiated stem cells; RT-PCR analysis of pluripotency markers revealed no impact on stemness, and transcribed nestin. 99% of haNSCs expressed the intermediate filament protein nestin, and 65% co-express the nuclear proliferation marker Ki-67. No significant difference between control cells and VSOP labeled haNSCs could be detected. **(b–d)** show unlabeled control cells, and **(e–g)** give the VSOP labeled pendant. **(h)** Nestin expression of haNSCs from three different patients was compared, showing that there is neither a significant difference between patients nor between control cells or labeled cells. **(i)** 65% of haNSCs co-express nestin and Ki-67, but significant differences between the three patients become apparent. **(j)** Subsequent neuronal differentiation (n = 6 to 10) resulted in a neuronal phenotype transcribing β-tubulin III, doublecortin, N-CAM1, and MAP-2. Mature mouse hippocampal cells HT22 served as a negative control for pluripotency markers and as a positive control for mature neuronal markers. Scale bars represent 50 μm. *$p < 0.01$.

averages, the higher detection limit might have two potential reasons. First, layer phantoms represent the cell distribution seen after systemic (intraarteriell or intravenous) cell injection. Systemic cell injection is believed to be more feasible for clinical applications and is therefore used predominantly in ongoing clinical trials (Cui et al., 2019). The density of cells is lower than in injection phantoms that represent the situation after stereotactic cell implantation procedures, being reserved for a targeted approach requiring local cell deposits. Second, the imaging protocol applied for layer phantom imaging was developed for mesenchymal stem cells which are larger than haNSCs and might therefore incorporate more VSOP leading to better detectability. 7T MRI, which is being introduced into clinical imaging, and allowing for detection of small local concentrations of labeled cells while the feature of VSOP to further reduce the longitudinal (T1) and transverse (T2) relaxation time may provide much better cell detectability at high filed strengths in future applications (Klug et al., 2010).

In summary, our study strongly suggests that in the clinical setting, cell tracking using magnetic VSOP labeling represents a safe method, capable of addressing three key issues vital for effective transplantation strategies: location, migration, and viability.

MATERIALS AND METHODS

Ethics Statement

Human adult neural stem cells were obtained from patients with temporal lobe epilepsy submitted to epilepsy surgery. Informed and written consent was given for additional scientific investigations approved by the local ethics committee of the University of Erlangen, in accordance with the Declaration of Helsinki.

Human Adult Neural Stem Cell and Murine Embryonic Stem Cell Cultures

Composition of expansion and differentiation media is given in **Table 1**. After surgical en bloc resection, the dentate gyrus was micro-dissected and dissociated mechanically followed by enzymatic digestion as described previously (Hoehn et al., 2002). Of the obtained cells, haNSC from passage 5 to 11 were cryopreserved, shipped to the primary investigation site and used for all experiments. Cells were plated on poly-L-ornithine (250 μg/mL)-/laminin (15 μg/mL, both Sigma-Aldrich, Munich, Germany)-coated cell culture dishes (Sarstedt, Nuembrecht, Germany) and grown in expansion medium at 37°C and 5% CO_2. Medium was changed every second day. Cells were detached with accutase (PAA, Cölbe, Germany) at 80% confluence, and split. Culturing over at least five passages selected for proliferating cells.

Previously cryopreserved mouse embryonic stem cells (mESCs, CRL-1934, ATCC, Manassas, United States) were cultured in expansion medium (**Table 1**) at 37°C and 5% CO_2 on mouse fibroblasts (CRL-1503, ATCC, Manassas, United States) inactivated by mitomycin C (Sigma-Aldrich). Stem cells were

+2 μg/mL heparin						

separated from the fibroblast layer at 60% confluence by detaching them with accutase, and transferred to gelatin-coated cell culture dishes with daily medium changes. mESCs were detached and transferred every other day. A fibroblast-free mESCs culture was obtained after three passages.

Magnetic Cell Labeling and Viability Assessment

Sterile VSOP (C200, Ferropharm, Teltow, Germany), consisting of a 5nm iron oxide core coated with monomer citrate, resulting in a hydrodynamic diameter of 11 nm and a negative charge were used for labeling at 0.5 and 1.5 mM with or without additional lipofection agent (lipofectin, Invitrogen) for 4 h as described previously (Gupta et al., 2007). These molarities were chosen based on previous findings showing that VSOP labeling causes transient oxidative stress or even irreversible cell damage (Stroh et al., 2004, 2009). Transient oxidative stress is already observed at 1.5 mM, and higher incubation molarities such as 3.0 or 6.0 mM cause more intensive stress or even increase apoptosis and necrosis. In turn, higher VSOP incubation molarities not necessarily shortens T2 relaxation times or increases detectability, particularly in smaller cells (Stroh et al., 2009).

Control specimens were incubated in Opti-MEM I for 4 h instead. First, potential donor-specific viability differences were assessed 20 h after labeling with 0.5 mM VSOP. Only cells samples with >80% viability after labeling were defined acceptable for further investigation. Next, cell viability in relation to incubation molarities was assessed 8 and 48 h after VSOP incubation by the Trypan Blue (Sigma-Aldrich) exclusion test on 10 randomly selected regions per coverslip.

Labeling Efficacy Assessment and haNSC Proliferation Experiments

Uptake of VSOP was evaluated using Prussian blue staining 48 h and 28 days after VSOP labeling by phase contrast microscopy of 10 regions per coverslip. The relative labeling efficacy was displayed as a ratio of Prussian blue positive cells to all cells identified by nuclear counterstaining.

After labeling with 0.5 μM or 1.5 μM VSOP (see above), haNSCs were seeded on 12-well-plates covered with poly-L-ornithine-covered (Sigma-Aldrich) at a density of 7,500 cells/cm^2 (28,500 cells/well) on expansion medium. Unlabeled haNSCs served as controls. Proliferation of haNSCs was monitored over 8 days, and cell culture medium was exchanged every second day. Cell numbers were assessed on days 1, 2, 4, and 8 in three wells for each VSOP concentration and on each day. Experiments were performed with using a total of six haNSC lines derived from three different patients ($n = 3$).

NMR Relaxometry

Further, nuclear magnetic resonance (NMR) relaxometry was performed to determine the T2 time (transverse relaxation time). 9×10^5 cells were suspended in 3 mL PBS and measured in a NMR-Relaxometer Minispec 0.47T/20MHz (Bruker, Ettlingen, Germany). Data analysis was performed using the ORIGIN Pro 8G software (OriginLab Corporation, Northampton, MA,

United States). All samples have been analyzed in three independent experiments.

Clinical MR Imaging at 3 Tesla

Detectability of VSOP labeled haNSCs was assessed by *in vitro* MRI. Two different types of agarose gel phantoms, cell injection and cell layer phantoms, were used. For injection phantoms, 1×10^3 magnetically labeled haNSCs (1.5 μM VSOP) were injected into air bubble-free gel phantoms as described previously (Soenen et al., 2011). Briefly, 1×10^3 magnetically labeled haNSCs were injected on one side of the phantom, and 1×10^3 non-labeled haNSCs on the other.

Injection phantom MRI was performed on a clinical 3 Tesla scanner (Achieva 3T, Philips Medical Systems, Best, Netherlands) under conditions optimized for cell imaging. A 3T solenoid rat coil (RX SN 1116, Philips) with a coil diameter of 55 mm was used. 2D gradient echo sequences were applied, with TE/TR 13.8/50 ms, a flip angle of the excitation pulse of 15°, yielding images that were T2* (effective transverse relaxation time) weighted. Both a coronal as well as a sagittal data set was acquired covering the entire gel phantom. The slice thickness was 0.3 mm, the interslice distance 0.15 mm, with a 20 mm field of view, and a 288 × 288 matrix, resulting in an inplane resolution of 69 μm and a voxel size of $69 \times 69 \times 300\ \mu m^3$.

Layer gel phantoms were produced as described elsewhere (Lobsien et al., 2013). Two phantoms were produced, each containing four layers in which unlabeled or VSOP-labeled haNSCs (1.5 μM) were embedded. Layer phantom 1 contained layers with 5×10, 1×10^2, 5×10^2, and 1×10^3 VSOP-labeled haNSCs, respectively. Layer phantom 2 contained layers with 5×10^3, 1×10^4, and 5×10^4 VSOP-labeled haNSCs, as well as a layer containing 5×10^4 unlabeled haNSCs.

Layer phantom MRI was performed on a clinical 3 Tesla Scanner (Magnetom Trio, Siemens, Erlangen, Germany) equipped with a standard 8ch knee coil. The imaging protocol was not particularly optimized for cellular imaging but rather to reflect a clinical situation. 3D Susepctibility-weighted images (SWI) were obtained with TE/TR 20/60 ms at a flip-angle FA of 15°. A voxel size of $560\ \mu m^3 \times 490\ \mu m^3 \times 250\ \mu m^3$ was achieved. Acquisition time TA was 41:00 min. SWI sequences were processed by vendor-specific software of the MRI scanner (Syngo B15, Siemens, Erlangen, Germany) and analyzed without further post-processing.

RT-PCR Analysis

Cells were harvested before and after magnetic labeling, and neuronal differentiation (see below), respectively. RNA species >200 nt were extracted using Mini RNeasy kit. cDNA synthesis with integrated removal of genomic DNA contamination was performed on 1 μg RNA using QuantiTect Reverse Transkription kit (both Qiagen, Hilden, Germany). PCR was performed on 2 μl of cDNA using Taq-DNA-Polymerase all inclusive kit (Peqlab, Erlangen, Germany). **Table 2** shows the primer sequences used in this experiment. All samples were analyzed in at least three independent experiments. Mature mouse hippocampal cells HT22 were used as a negative control for pluripotency and neural progenitor markers.

TABLE 2 | List of primers.

Gene	Primer forward	Primer reverse
Oct4	5′- CTCCTGAAGCAGA AGAGGATCAC-3′	5′-CTTCTGGCGCCGG TTACAGAACCA-3′
Sox2	5′-TGCAGTACAACT CCATGACCA-3′	5′-GTGCTGGGACATGT GAAGTCG-3′

GAPDH	5′-CAACGAATTTGGC TACAGCA-3′	5′-AGGGGTCTACATG GCAACTG-3′

Fluorescence Immunocytochemistry and Characterization

For characterization of cultured haNSCs and for determining effects of magnetic labeling on stemness, cells were fixed in PBS-buffered paraformaldehyde (4%). Processing, immunocytochemistry and quantitative evaluation were performed as described elsewhere (Heyn et al., 2006). Mouse-anti-Ki67 (Dako, 1:100, proliferation marker), and rabbit-anti-nestin (Millipore, 1:200, neural progenitor cell marker) were used as primary antibodies, and Alexa Fluor 555 or 488 (both Invitrogen, 1:100) served as secondary antibodies. Nuclei were labeled by 4′,6-Diamidino-2-phenylindole dihydrochloride (DAPI, Sigma-Aldrich, 1.1000). For analysis, 10 randomly selected regions per coverslip were counted. Percentage was determined as the number of nestin$^+$, Ki-67$^+$, or Ki-67$^+$/nestin$^+$ cells compared to total cells identified by nuclear DAPI counterstaining.

Neuronal Differentiation of haNSCs and mESC

The possible interference of VSOP-labeling or lipofectin on neuronal differentiation was also assessed. haNSC were differentiated for 15 days in haNSC differentiation medium (**Table 1**), which was changed every second day. Six independent experiments were conducted, containing at least three technical replicates each.

mESCs-differentiation was performed as described elsewhere (Bibel et al., 2004) with some modifications. For embryoid body formation expanded mESCs were transferred into bacterial dishes and LIF was removed. After 6 days cells had aggregated and formed embryoid bodies, which were carefully transferred to gelatine-coated dishes. During the following 2–3 days, the heterogeneous bodies adhered and migrating cells started to form a monolayer. Neural progenitor cells were selected for 3 days and then expanded in neural progenitor expansion medium

(**Table 1**) for 10 days. RT-PCR analysis and Prussian blue staining were performed as described above. Ten independent experiments were conducted.

Statistical Analysis

Statistical analysis was conducted using SPSS (Chicago, IL, United States) software. First, data sets from all conditions were tested for normal distribution using the parameter free one-sample Kolmogorov-Smirnov test. In cases where normal distribution of data was confirmed, the parametric two-tailed Student's *t*-test was employed to compare means. *P*-values <0.01 were considered statistically significant. All data are presented as mean ± standard error of the mean (SEM).

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

Human adult neural stem cells were obtained from patients with temporal lobe epilepsy submitted to epilepsy surgery. Informed and written consent was given for additional scientific investigations approved by the local ethics committee of the University of Erlangen, in accordance with the Declaration of Helsinki.

AUTHOR CONTRIBUTIONS

AS, JK, IB, JS, CZ, and JB: conception and design. AS, JK, RC, AD, WF, and SZ: collection of data. AF and DL: collection of data, and data analysis and interpretation. AS, JK, and JB: data analysis and interpretation, and manuscript writing. All authors have approved the final manuscript.

FUNDING

VSOP were kindly provided by Herbert Pilgrimm, Ferropharm. This work was supported by the Bavarian State Ministry of Sciences, Research and the Arts ("ForNeuroCell").

ACKNOWLEDGMENTS

The authors thank Vasilis Ntziachristos, AF, and Birte Rings for expert technical support.

Thyroid hormones are of fundamental importance for brain development and essential factors to warrant brain functions throughout life. Their actions are mediated by binding to specific intracellular and membranous receptors regulating genomic and non-genomic mechanisms in neurons and populations of glial cells, respectively. Among others, mechanisms include the regulation of neuronal plasticity processes, stimulation of angiogenesis and neurogenesis as well modulating the dynamics of cytoskeletal elements and intracellular transport processes. These mechanisms overlap with those that have been identified to enhance recovery of lost neurological functions during the first weeks and months after ischemic stroke. Stimulation of thyroid hormone signaling in the postischemic brain might be a promising therapeutic strategy to foster endogenous mechanisms of repair. Several studies have pointed to a significant association between thyroid hormones and outcome after stroke. With this review, we will provide an overview on functions of thyroid hormones in the healthy brain and summarize their mechanisms of action in the developing and adult brain. Also, we compile the major thyroid-modulated molecular pathways in the pathophysiology of ischemic stroke that can enhance recovery, highlighting thyroid hormones as a potential target for therapeutic intervention.

Keywords: brain, recovery, stroke, thyroid hormones, 3,5,3′,5′-tetraiodo-L-thyronine (T_4), 3,5,3′-triiodo-L-thyronine (T_3)

INTRODUCTION

Thyroid hormones (TH), 3,5,3′,5′-tetraiodo-L-thyronine (T_4) and 3,5,3′-triiodo-L-thyronine (T_3), are important for brain development in mammals, during embryonic and fetal stages, regulating processes of neuronal proliferation, migration and differentiation, neurite outgrowth, synaptic plasticity, dendritic branching, and myelination (1–5). Also, after birth, TH are crucial for normal brain function throughout the entire life. Specifically for the central nervous system (CNS) the active form T_3 is a key regulator for normal metabolism in humans and rodents (1, 6, 7).

Availability of T_3 to the developing and adult brain is tightly controlled by mechanisms regulating TH secretion, free fraction unbound to thyroxine binding globulins (TBG), transmembrane transporters and the activity of iodothyronine deiodinases (DIO). The pattern of these regulatory processes may vary according to the developmental stage and in the adult brain. T_3 plays an essential role for neurological functions, and minimal disturbances of these mechanisms may have consequences for normal brain development and function (1, 8).

Dependence of the CNS on T_3 at all stages of development prompted us to review the actions of TH and the relevance of these mechanisms for processes of recovery after ischemic stroke. We will begin to provide an overview on TH signaling in the brain during development and throughout adult life. Thereafter, we will focus on molecules involved in TH signaling after stroke. TH actions at specific time points after the insult, that are dependent of carrier proteins, transmembrane transporters, DIO activity, thyroid hormone receptors (TR) and co-factors, may provide information on underlying molecular and cellular mechanisms that enhance functional recovery of lost neurological functions. Moreover, we will discuss which mechanisms of action of TH in the brain may contribute to enhance functional outcome in stroke patients.

THYROID HORMONE TRANSPORT AND AVAILABILITY TO THE HUMAN AND RODENT BRAIN

In the adult, TH originate in the thyroid gland that secretes ∼93% as T_4 and 7% as T_3. Once secreted to plasma, TH binding proteins play an important role to maintain TH homeostasis and distribution into tissues, and <0.1% of TH circulate free in the blood (9, 10). In humans, 65% of TH bind to TBG, 20% to albumin and about 15% to transthyretin (TTR) (11, 12) while in rodents TTR is the main protein carrier in the blood circulation (13, 14). TH also bind to lipoproteins to a less extent (15, 16).

In contrary to processes during brain development, a different fraction of T_3 in the adult brain is provided from free T_3 available in the blood circulation and in the cerebrospinal fluid (CSF) (17, 18). Most of TH provided to the brain crosses the blood brain barrier (BBB) and around 20% the blood cerebrospinal fluid barrier (BCSFB) (19, 20). This passage is mediated by transmembrane transporter proteins with overlapping specificity that were identified in endothelial cells of brain microvessels that constitute the BBB and epithelial cells of the choroid plexus (CP) of humans and rodents. These transporters are also important for brain development, and include monocarboxylate transporter (MCT), organic anion transporting polypeptide (OATP), large neutral aminoacid transporter (LAT) and sodium/taurocholate co-transporting polypeptide (SLC10A1) families (17, 21–31). Among those, MCT8 is of particular importance for T_3 (21, 26, 29), and in mice deficient for this transporter, T_3 uptake is compromised (32). In humans, MCT10 also facilitates uptake and efflux of TH, in particular for T_3 (33). The gene that encodes MCT8 (*Slc16a2*) is also present in membranes of neurons, astrocytes, tanycytes and oligodendrocyte precursor cells and OATP1C1 mRNA has been found in astrocytes (34), mediating intracellular TH transport. In addition, it has been proposed that either T_4 or T_3 or both are captured via gaps at the endfeet of astrocytes covering brain microvessels (35, 36).

In contrast to the rodent, MCT8 deficiency in humans results in low T_3 levels in the brain and high levels in the serum due to TH transport deficiency. Thus, the development of the cerebral cortex is impaired accompanied with severe neurological impairment (37–40). The lack of alternative TH transporters such as OATP1C1 (28) and MCT10 (41) in the adult human brain to compensate the transport of T_3, may contribute to the neurological deficits observed in humans with MCT8 mutations. The activity of DIO2 and DIO3 in the brain is important to balance neuronal intracellular T_3 levels in the adult brain, according to the developmental stage and brain region (42–44). DIO enzymes catalyze and remove specific iodine atoms from iodothyronine molecules. In rodents, ∼50% of T_3 levels localized in the brain relies on local deiodination of T_4 in astrocytes and tanycytes by DIO2 (45). T_3 produced in glial cells is able to promote T_3 driven transcriptional activity in neurons, demonstrated by *in vitro* experiments in co-cultures of H4 human glioma cells expressing DIO2 and neuroblastoma cells (46). Homeostasis of T_3 in the CNS is also controlled by DIO3 activity in neurons, that converts T_4 into 3,3′,5′ reverse triiodo-L-thyronine (rT_3) and inactivates T_3 into 3,3′-diiodo-L-thyronine (T_2) (43, 47, 48).

Other compensatory mechanisms to maintain sufficient T_3 levels in the rodent brain include the reduction of DIO3 activity and consequently T_3 degradation, the increase of DIO2 activity in astrocytes (17, 32, 49) and the increase of *Dio2* expression in interneurons in the cerebral cortex (50).

THYROID HORMONES IN BRAIN DEVELOPMENT

It has been shown that mechanisms of brain development might be re-activated in processes of brain reorganization following stroke (51) involving cascades regulated by TH. Therefore, knowledge of TH actions critical and specific for each step of brain development is instrumental to understand their functions following stroke. Epidemiological and clinical studies in humans clearly show that several conditions that compromise maternal TH availability to the fetus impair brain development and are associated with neurological disorders and structural defects, most of them irreversible. A detailed review about TH transport, metabolism and function in the developing brain was recently published (52).

Despite epidemiological and clinical studies have demonstrated the demand of TH during brain development, animal experimental models are of high relevance to identify molecular mechanisms and detailed morphological changes of their biological function during brain development (53). Processes of neurogenesis, proliferation, migration, and maturation show different temporal profiles between humans and rodents, however, basic mechanisms and pathways that regulate brain development are similar (54, 55) allowing the extrapolation of TH deficiency mediated effects in rodents to abnormal TH signaling in humans. Maternal TH are crucial for early cortical neurogenesis, neuronal migration and maturation, during the first trimester of gestation, when fetal brain development occurs (1, 56–58). Both T_4 and T_3 are detected in the human brain embryo even before fetal thyroid gland maturation (59) that occurs at 11–12th week of gestation and starts to secrete TH at week 16 (60).

Also in the rat, the embryo is exposed to maternal TH after embryonic day 11 (E11), before the start of thyroid gland development at E17 (61–64). Experimental hypothyroxinemia induced in rats during this period (before E18) causes abnormal neurogenesis in the cortex and hippocampus, leading to impairment of synaptic plasticity and cognitive deficits (65–67), processes of high relevance in mechanisms of recovery after stroke.

Most of TH dependent processes during brain development are due to the interaction of T_3 with nuclear receptors and regulation of gene expression (68). Increasing levels of protein and mRNA encoding TR alpha and beta (TRα and TRβ) isoforms in the cerebrum and cerebellum start from the 8th to 10th week and increase over gestational time (69, 70) and in rodents there is expression of nuclear TR protein before thyroid gland functioning (71) suggesting transcriptional activity of TH. Several TH dependent genes expressed in the fetal rat brain and neuronal cultures, such as cytoskeletal proteins, are involved in mechanisms of neuronal migration and maturation, branching in neurons and astrocytes (1, 72–74). In both human and rodent species, mutations at the *TRα* and *TRβ* result in several neurological disorders (75–79).

The expression pattern of TR in the brain changes during CNS development. TRα1 is the predominant isoform with mRNA and protein expression in the entire brain, in rodents from E14 (80, 81) and in humans from 8th week of gestation (82, 83) onwards, importantly the expression decreases during brain development (84). TRβ1 is expressed at later stages of brain development and in contrary to TRα, TRβ1 mRNA levels do not decrease over gestational time (80, 84, 85). These studies indicate that gene transcription mediated by nuclear TR has spatiotemporal expression patterns and, therefore, TH actions are distinct in all stages of brain development.

In an *in vitro* model of differentiating mouse embryonic stem cell line (ES-E14TG2a) T_3 treatment (1 nM) enhanced the number of nestin-positive neuronal progenitors, accelerated differentiation and increased survival of pyramidal neurons (86). T_3 mediated differentiation was associated with the regulation of genes involved in corticogenesis namely *nestin*, empty spiracles homeobox 1 *(Emx1)*, T-box brain gene 1 *(Tbr1)*, Calmodulin kinase 4 *(Camk4),* and RC3/Neurogranin *(Nrgn)* (86). Regulation of gene expression during differentiation seems to be inversely correlated with levels of chicken ovalbumin upstream-transcription factor 1 (COUP-TF1) (86), that is crucial for adequate neuronal development (87).

MECHANISMS OF THYROID HORMONES ACTIONS IN THE ADULT BRAIN

Cellular actions of TH in the adult brain can be mediated by nuclear receptors and transcriptional activity, and also by non-genomic actions (85, 88, 89). Here we will elaborate in relevant TH actions described in the literature, and below we will delineate TH actions that might be involved in neurorepair processes.

Genomic Actions of TH

Actions of T_3 in the brain are mainly dependent on transcription mediated by T_3 binding to the nuclear receptors and formation of regulatory complexes (85, 88–91). In the presence of TH, TR are regulated by corepressors (CoR) and coactivators (CoA), proteins, that repress or activate transcription, respectively (36, 85, 88, 89, 92) (**Figure 1**).

In mammals, there are four isoforms of TR (TRα1, TRα2, TRβ1, and TRβ2) encoded by genes alpha (*Thra*) and beta (*Thrb*), which expression and distribution is different to the developmental brain (93). These isoforms are differently distributed in the tissues, regulate the transcription of different genes and exert different biological actions (94).

TRα1 and TRβ1 are the predominant isoforms in the CNS. TRα1 mRNA and protein accounts to 70–80% of TR expression in the brain (36, 95, 96). Thus, genomic actions of T_3 in the brain are mainly, but not exclusively, dependent of TRα1 signaling (97). The analysis of brains from TRα1—green fluorescent protein (GFP) mice revealed that this receptor is expressed in all NeuN positive neurons, especially in the nucleus (83). TRα1 is expressed in both excitatory glutamatergic and inhibitory GABAergic neurons in several brain regions including the striatum, cerebral cortex, hippocampus and dentate gyrus, hypothalamus and cerebellum (83, 98). This isoform of TR is also found in tanycytes lining the third ventricle and oligodendrocytes in the hypothalamus, but not in the striatum, somatosensory cortex or hippocampus (83, 99). Its presence in astrocytes is not completely clear (100), however may be dependent on the activation status. Although lower concentration of the receptor is found in cultured rat astrocytes (101), it is not expressed in glial fibrillary acidic protein (GFAP) positive astrocytes in the naïve rat and mouse brain (83, 99). TRα1 is absent in Purkinje cells in the cerebellum (83). Levels of TRα2, a non T_3 binding isoform, is also detected in the adult brain in a similar pattern as TRα1 (98).

TRβ1 is expressed in the neocortex, and mainly expressed in the pyramidal cell layers of the hippocampus, granule cells of dentate gyrus and paraventricular hypothalamic nucleus (102). It is also expressed in myelin basic protein positive oligodendrocytes (99). In contrary to TRα1, this isoform is highly expressed in Purkinje neurons (94). The TRβ2 isoform is restricted to the anterior pituitary gland and hypothalamus (102–105). As for TRα isoforms, TRβ1 and TRβ2 were not observed in positive GFAP positive astrocytes in the rat brain (99).

Although TR are mainly localized in the cell nucleus and nuclear membrane, TRα1 and TRβ1 isoforms have also been found in the cytoplasm of neurons and astroglia, and this shuttle may increase the rate of T_3 nuclear import (106). It has been suggested that T_4 may also exert genomic actions in the brain through binding to TRα1, that is more susceptible to T_4 than TRβ1 (36), however we did not find experimental studies supporting this hypothesis. So far, a total of 4,108 genes, of which 734 have been identified as being repeatedly regulated by T_3 in the rodents' brain by microarray analysis (72). In this review, we provide an overview on T_3-modulated genes that might be involved in brain repair mechanisms (**Table 1**). Hence, different

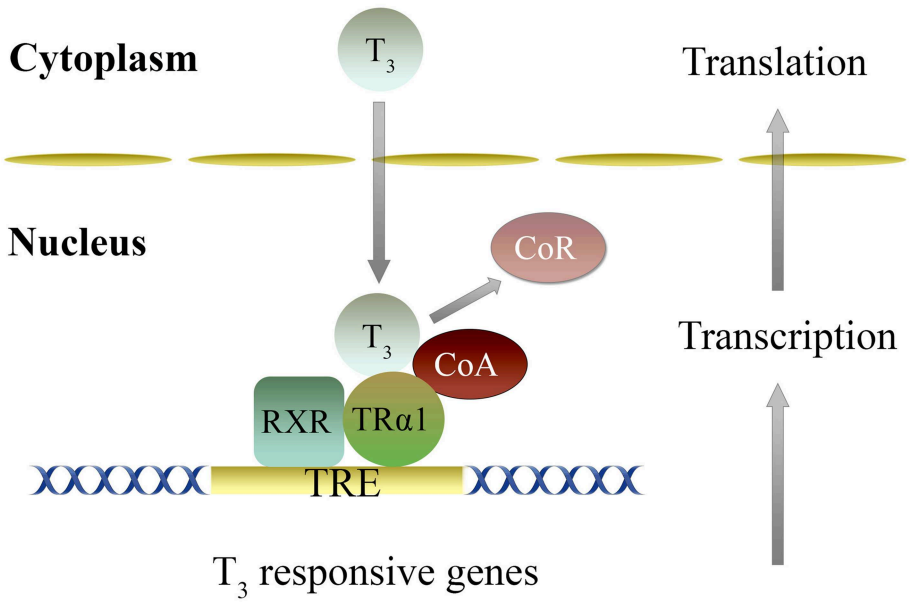

FIGURE 1 | Genomic mechanisms of thyroid hormones action in the brain. Genomic actions of T_3 are dependent on gene transcription mediated by its binding to nuclear TRα and TRβ, and the formation of heterodimer complex with RXR (RXR-TR) that binds to a TRE, located at the regulatory region of T_3 target genes. This activity is regulated by an exchange of CoR for CoA. CoA, Co-activator; CoR, Co-repressor; RXR, Retinoid X receptor; TR, Thyroid hormone receptor; TRE, Thyroid response element; T_3, 3,5,3′-triiodo-L-thyronine.

T_3–dependent transcriptional activities have been observed in different cell types and brain regions.

Non-genomic Actions of TH

TH non-genomic actions that do not require TH binding to nuclear receptors are well-described in the literature (127–130). Actions are immediate and include several interactions of TH with extranuclear receptors, including TRα and TRβ, located in the cytoplasm, cellular membrane, cytoskeleton and mitochondria, modulating several intracellular pathways.

The following points summarize relevant non-genomic actions of TH binding to membranous and cytoplasmic receptors (i–iii), cytoplasmic TH binding proteins affecting ion pumps activity (iv) and the action of TH on the cytoskeleton (v) (**Figure 2**). (i) T_3 complexed to TRβ1 in the cytoplasm interacts with p85α subunit of phosphatidylinositol 3-kinase (PI3K), resulting in phosphorylation and activation of protein kinase (PK) B/Akt signal transduction pathway, rapamycin (mTOR) and phosphorylation of $p70^{S6K}$ (131–136). (ii) T_3 is able to bind to integrin αvβ3 S1 domain in plasma membranes and activates PI3K via Src kinase. T_4 and T_3 interact with integrin αvβ3 S2 domain and activate mitogen-activated protein kinase 1/2 (MAPK 1/2) signaling cascade, through phospholipase C (PLC) and PKC (127, 133, 137–140). Subsequently, it results in an nuclear translocation of TRβ1 (141), estrogen receptor α (142), signal transducing and activator of transcription (STAT) 1α, interferon gamma (IFN-γ) (143) and CoA protein Trip230 (144). In addition, hormone activated MAPK 1/2 phosphorylates TRβ1 at Ser-142, leading to recruitment of CoA proteins (145). (iii) T_4 non-gnomically activates MAPK 1/2 in HeLa and CV-1 cultured cells (146, 147) and phosphorylation of p53 (148) and STAT3 (147). (iv) T_3 modulates Na^+/H^+ exchanger in myoblasts (149); Na-K-ATPase activity in alveolar epithelial cells (150–152), embryonal hepatocytes (153), and synaptosomes (154, 155) through either the PI3K or MAPK pathways (152, 156); the Ca-ATPase activity in erythrocytes (88), the sarcoplasmic reticulum in the heart (157) and in cerebrocortical synaptosomes (158). (v) T_4 and rT_3 stimulate polymerization of actin components of the cytoskeleton neuronal and astrocyte cell cultures, through TH binding to an extranuclear truncated form of TRα1 (TRΔα1) (159–162).

THYROID HORMONES IN THE AGING BRAIN AND ISCHEMIC STROKE

The complex process of aging is associated with changes in TH metabolism and action in all tissues. During aging, the disruption of circadian rhythm leads to a reduction in thyroid stimulating hormone (TSH) secretion (163–165) and circulating TH levels, in particular T_3, in humans (166, 167) and rodents (168). Nevertheless, TH signaling is well-preserved in the aging brain, as demonstrated in mouse models of aging (169).

TABLE 1 | List of genes regulated by thyroid hormones involved in their transport into the brain, mechanisms of tissue repair, and neuronal plasticity following ischemic stroke.

Genes human/rodent	Gene name	Function	Tissue/cultured cells	References
SLC16A2/Slc16a2	MCT8	TH transport	Brain	(107)
DIO2/Dio2	DIO2	TH deiodination		
DIO3/Dio3	DIO3			
Bcl2	Bcl2	Neuronal survival, neurogenesis and neurotrophic factors	Brain cortex	(107–109)
Vegfa	VEGFA			
Sox2	SRY-box2			
Ntf	Neurotrophin			
Nos2	NOS2			
HIF2α	HIF2α		Neuroblastoma cell line	(107)
VEGF	VEGF			
c-JUN	c-Jun			
ENO2	Enolase-2			
Emx1	empty spiracles homeobox 1		mES cell line	(86)
Tbr1	T-box brain gene 1			
Bdnf	Brain derived neurotrophic factor		Hippocampal slices	(110)
Slc12a5	KCC2			
NRGN/Nrgn	Neurogranin	Synaptic plasticity	Hippocampus and forebrain/mES cell line	(86, 111–113)
CAMK4/Camk4	Calmodulin kinase 4		Brain/Neurons/mES cell line	(86, 114–117)
Reln	Reelin		Brain	(118–120)
Srg1	Synaptotagmin-related gene 1		Brain	(121)
Nefh	Neurofilament heavy polypeptide		Neurons	(122)
Nefm	Neurofilament medium polypeptide			(122)
GFAP	GFAP		Astrocytes	(123)
Vim	Vimentin		Mesenchimal cells	(122)
Nes	Nestin		Neurons	(86, 122)
Vegf	VEGF	Angiogenesis	Brain	(124–126)
Angpt2	Angiopoietin-2			

However, hypothyroidism and decreased TH availability to the brain has been considered a risk factor for the development of neurodegenerative diseases (170, 171) and acute ischemic stroke (172, 173). In addition, recent epidemiological studies have associated low levels of T_3 with poor functional outcome after acute ischemic stroke (174–179). Interestingly, lower total T_3 levels is not related with poor functional recovery after ischemic stroke in patients below 65 years of age, suggesting that the association between levels of T_3 and stroke recovery may be clinically important in older patients (180). Non-thyroidal illness syndrome also impairs functional recovery after stroke (181). Besides, stroke patients with thyroid dysfunction (lower levels of TSH and higher levels of free T_4) are associated with poorer clinical outcome (182). Together, studies point toward the need for a systemic assessment of thyroid dysfunction and stroke outcome.

Some reports suggest neuroprotective effects of hypothyroidism prior to brain ischemia in humans (183, 184), as well as experimental studies in rodents (185, 186). In a recent systematic review, stroke patients with subclinical hypothyroidism (higher levels of TSH and normal levels of free T_4 within the reference range) were more prone to suffer a non-fatal stroke and minor adverse events (182). However, we lack mechanistic studies how systemic levels of TH exactly influence processes in the postischemic brain. It is likely that hypothyroid episodes prior to stroke only delayed neuronal death, due to decreased metabolic demand of neurons, decreased glutamate production and delayed oxidative stress (185, 187). There is no evidence from experimental studies that show beneficial effects in hypothyroid animals after stroke. A recent animal study suggested that daily intravenous administrations of rT_3, an inactive form of T_3, prevents ischemic-reperfusion injury in rats subjected to transient MCAO, however authors did not evaluate if rT_3 induced an hypothyroid state (188). Similarly, in rats subjected to permanent middle cerebral artery occlusion (MCAO), TH serum levels are reduced 14 days after injury correlated with increased neurological impairment (189).

On the other hand, hyperthyroidism has been associated with an increased risk for ischemic stroke in humans (190–192). However, the population-based study was performed in patients

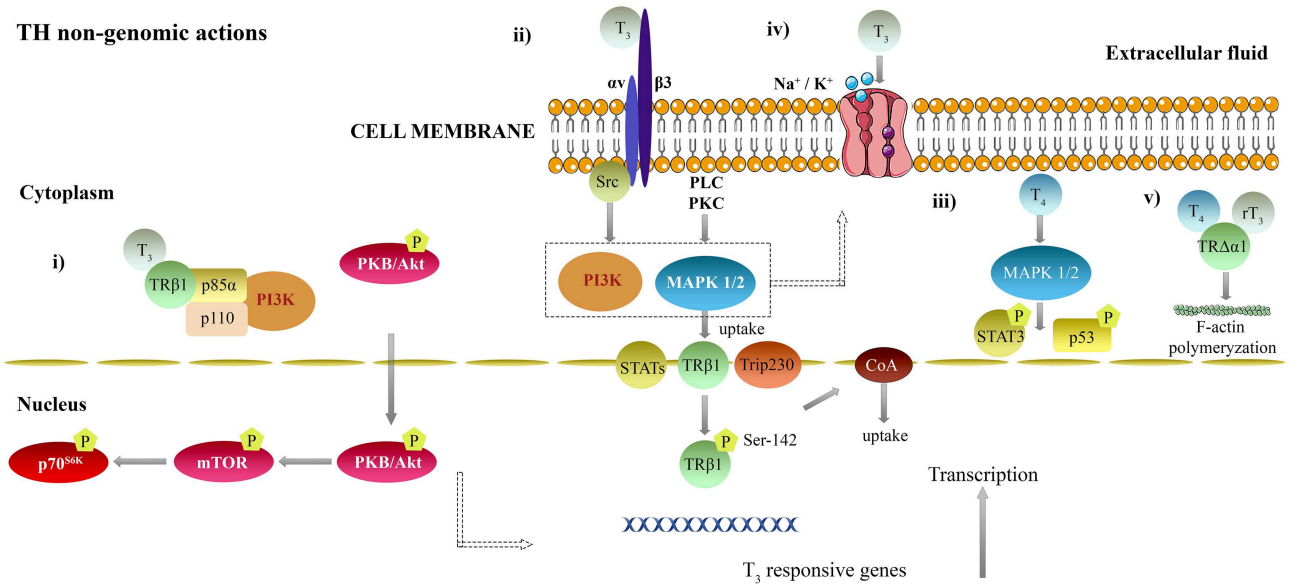

FIGURE 2 | Non-genomic mechanisms of thyroid hormones action in the brain. T_3 can also modulate other genes not containing TRE, by non-genomic actions. **(i)** T_3 complexed to TRβ1 in the cytoplasm interacts with p85α subunit of PI3K, resulting in phosphorylation and activation of PKB/Akt signal transduction pathway, mTOR and phosphorylation of $p70^{S6K}$ (131–136). **(ii)** T_3 is able to bind to integrin αvβ3 S1 domain in plasma membranes and activates PI3K via Src kinase. T_4 and T_3 interact with integrin αvβ3 S2 domain and activate MAPK 1/2 signaling cascade, PLC and PKC (127, 133, 137–140). Subsequently, it results in an nuclear translocation of TRβ1 (141), estrogen receptor α (142), STAT1α, IFN-γ (143) and CoA protein Trip230 (144). In addition, hormone activated MAPK 1/2 phosphorylates TRβ1 at Ser-142, leading to recruitment of CoA proteins (145). **(iii)** T_4 non-gnomically activates MAPK 1/2 in HeLa and CV-1 cultured cells (146, 147) and phosphorylation of p53 (148) and STAT3 (147). **(iv)** T_3 modulates Na^+/H^+ exchanger in myoblasts (149); Na-K-ATPase activity in alveolar epithelial cells (150–152), embryonal hepatocytes (153) and synaptosomes (154, 155) through either the PI3K or MAPK pathways (152, 156) the Ca-ATPase activity in erythrocytes (88), the sarcoplasmic reticulum in the heart (157) and in cerebrocortical synaptosomes (158). **(v)** T_4 and rT_3 stimulate polymerization of actin components of the cytoskeleton neuronal and astrocyte cell cultures, through TH binding to an extranuclear truncated form of TRα1 (TRΔα1) (159–162). IFN-γ, interferon gamma; MAPK 1/2, mitogen-activated protein kinase 1/2; PLC, phospholipase C; PI3K, phosphatidylinositol 3-kinase; PK - protein kinase; mTOR – rapamycin; STAT - signal transducing and activator of transcription; TH, Thyroid hormones; TR, Thyroid hormone receptor; TRE, Thyroid response element; T_4, 3,5,3′,5′-tetraiodo-L-thyronine; T_3, 3,5,3′-triiodo-L-thyronine.

aged 18–44 years. Hence, this study has not been adjusted for other risk factors such as hypertension and atrial fibrillation that may independently contribute for stroke. Larger infarct volumes also have been found in hyperthyroid rats after transient MCAO (193). Hence, hyperthyroid rats (oral administration of TH for 4 weeks) showed profound effects on the cardiovascular system including hypertension and tachyarrhythmia and treatment resulted in a catabolic metabolism (193).

Interestingly, increased mRNA expression of *Dio2* has been found in astrocytes during the first 72 h after transient MCAO (194). Together with modulation of *Thrb* expression, that is reduced in the infarct core and increased in the peri-infarct area, it suggests a local action of T_3 (189). Repeated daily administrations of T_4, before and on days one, two and three after stroke, decrease neuronal damage in the cornu ammonis CA1 pyramidal cells in the hippocampus (195). In an animal model of MCAO, intraperitoneal injection of T_4 (11 μg/kg, 1 h after ischemia and 6 h after reperfusion) reduced cortical and striatal infarct volume 24 h after stroke, with a reduction of GFAP, Iba-1, PKC, and MAPK 1/2 expression (196). Treatment with levothyroxine (25 μg/kg intraperitoneal) 1 h after traumatic brain injury stimulated mRNA expression of genes encoding MCT8, DIO2, and DIO3; genes related with neuronal survival and neurogenesis, namely *Bcl2*, vascular endothelial growth factor A (*Vegfa*), *Sox2,* and neurotrophin (*Ntf*) in the cortex, and of inducible nitrite oxide synthase 2 (*Nos2*) (107).

Moreover, intraperitoneal administration of T_3 at 12 μg/kg 1 h after traumatic brain injury reduced lesion size and inflammation (197). T_3 treatment 25 μg/kg 30 min after transient MCAO also reduced volume of stroke damage in mice through stimulation of fatty acid oxidation by astrocytes (198). A combination therapy of bone marrow stromal cells, daily injections of T_3 200 μg/kg and mild exercise was related to reduce ischemic damage 7 days after transient MCAO in rats (199). Likewise, intraperitoneal administration of thyroxine derivates, 3-iodothyronamine and thyronamine, 50 mg/kg 1 h after MCAO in mice, also reduced infarct volume (200). Neuroprotective action of 3-iodothyronamine administered 2 days before MCAO was associated with hypothermia (200). Although molecular mechanisms have not been evaluated, these studies suggest that non-genomic actions of TH contribute to neuroprotection in the acute phase following stroke. In addition, T_3 treatment prior to brain ischemia (25 μg/kg intravenous) has prevented edema through suppression of aquaporin-4 (AQP4) water channel expression and thereby reducing infarct volume and improving neurological outcome after transient MCAO (109), effects that

were enhanced when T_3 was administrated in nanoparticles at equivalent doses (108). Recently, it has been demonstrated that T_3 modulates AQP4 expression dependent on developmental stage of the CNS. Treatment of mice with T_3 at 1 μg/g increased AQP4 expression in astrocytes in the cerebral cortex until the 60th postnatal day. In contrast, whereas in glioblastoma cell lines stimulation with T_3 (50 nM) treatment was downregulating the expression of AQP4 (201).

Few experimental studies have been performed to identify the mechanisms of TH actions in neuroprotection. Treatment of mouse hippocampal slices lesioned between CA3 and CA1 with T_4 increases levels K-Cl cotransporter (KCC2) mRNA in a brain derived neurotrophic factor (BDNF) dependent manner, that promoted survival and regeneration of damaged neurons in the CA1 region (110). Moreover, it has been demonstrated that treatment with T_3 has a protective effect against glutamate toxicity in cultured astrocytes and neurons (202, 203). This action has been linked to non-genomic actions of TH on Na^+/H^+ exchange activity and glutamate transport (204). Also, T_3 treatment stimulated the expression of *HIF2α*, *VEGF*, *c-JUN,* and Enolase-2 (*ENO2*) in the neuroblastoma in an *in vitro* hypoxia model (107). Although only a few scattered studies have been performed, they indicate an involvement of T_3 in pathways that promote neuronal protection and recovery, through genomic or non-genomic actions.

The expression of TR in the human brain after ischemic stroke have not been studied. Also in experimental models, TR expression has not been investigated, and we found only one experimental study reporting TR expression after permanent MCAO (189). Interestingly, TRα1 expression is increased in microglial cells in the infarct core and in neurons in the peri-infarct area. Astrocytes mildly express nuclear TRα1 and expression of TRβ1 is strongly expressed in the astrocytic scar. If TRα1 and TRβ1 play a crucial role for recovery after brain stroke, in humans and rodents, it remains to be investigated. In fact, TRα1 have been demonstrated to play a crucial role for cardiomyocyte survival after myocardial infarction (205) Therefore, the idea that TRα1 could be a target to promote stroke recovery definitively needs to be further investigated.

MECHANISMS OF THYROID HORMONES THAT MAY ENHANCE MECHANISMS OF RECOVERY AFTER STROKE

Beyond the acute phase after stroke, the brain shows the capacity of spontaneous recovery of lost neurological functions albeit to a limited extent. This process remains slow, however, the intrinsic mechanisms are present and patients may benefit from enhancing those. TH regulate several pathways that are involved in neurorepair, namely regulation of processes of neuronal plasticity, neurogenesis, angiogenesis, and glutamate toxicity. Adjuvant therapies that modulate those processes may improve recovery of function after stroke, in particular when applied in combination with physiotherapy in stroke patients or an enriched environment in rodent models of stroke (206, 207).

Neuronal Plasticity

Neuronal reorganization occurs during the recovery phase of stroke and is initiated by cellular responses to degeneration. Cell death in the infarct core results in synaptic degeneration, instigating regenerative responses among surviving neurons, as the formation of new synaptic connections (208). Neuronal plasticity includes all mechanisms involved in modulation of dendritic and axonal arborization, dendritic spine density and neuronal density that will determine the formation of new synaptic connections and neuronal networks (209, 210).

Neuroplasticity occurs spontaneously during stroke recovery and TH have been identified as a modulator of several genes that may stimulate endogenous neuroplasticity and therefore contributing to facilitate recovery (**Table 1**).

In rodents, T_3 regulates neuron specific RC3/Neurogranin gene (*Nrgn*), that encodes a calmodulin binding protein (112) which binds to calmodulin in the absence of calcium distribution in spines and enhances synaptic plasticity (211). *Nrgn* is highly expressed in dendritic spines in the hippocampus and forebrain and deficiency of *Nrgn* in mice has been reported to induce deficits in spatial learning and anxiety-like tendencies (113). In the human, the homolog gene NRGN is also a direct TH target, during development and in the adult brain (111). TH also regulates *Reelin* (*Reln*) expression during brain development (118). Administration of T_3 increases *Reln* expression in the hippocampus of adult rats (212). Reelin is involved in the migration of multipolar neurons in the developing neocortex (120) and in the adult brain interacts with apoliprotein E receptors and regulates synaptic plasticity and neurogenesis (119).

During brain development, T_3 regulates genes related with the calcium/Calmodulin-activated kinase 4—cAMP responsive element-binding protein 1 (CaMK4/Creb1) signaling pathway, as demonstrated in cultured fetal neurons (213), a mouse embryonic stem cell line (86) and *in vivo* studies (114–117). The CaMK4/Creb1 pathway regulates calcium influx and dendritic growth during development (214), inhibits apoptosis through phosphorylation of Creb and increases anti-apoptotic gene expression. Synaptotagmin-related gene 1 (*Srg1*) is also a TH responsive gene during brain development, that has a putative role as a mediator of synaptic structure and activity (121).

Reorganization of spine cytoskeleton, principally microtubules and actin filaments, can be dynamically modulated and consequently change the pattern of synaptic activity (215). Several studies have shown that TH modulate tubulins (216, 217), microtubule associated proteins (218) and Tau protein (219) in the cytoskeleton during brain development and in the adult brain. TH has also been demonstrated to modulate transcription of genes of intermediate filaments, namely neurofilaments (*Nefh* and *Nefm*), GFAP in mature astrocytes, vimentin in mesenchymal cells and nestin (116, 122). Experiments in cerebral cortex slices suggest that TH activates phosphorylation of cytoskeletal proteins mediated by GABAergic signaling dependent on PKA and PKCaMII activity (220). Studies conducted in cultured glial cells also suggests that TH reorganize the cytoskeleton

through GFAP phosphorylation mediated by RhoA signaling pathway (221).

Actions of TH in the cytoskeleton are particularly important during brain development, to guarantee proper cell migration and to foster neurite outgrowth (160). T_3 also regulates transcription of genes involved in cytoskeleton formation in neurons and astrocytes, during fetal and postnatal brain development (74). Hypothyroidism leads to impaired actin cytoskeleton formation in neurons and astrocytes, affecting neuronal migration and neurite outgrowth. Both rT_3 or T_4 administration can restore polymerization of intracellular filaments F-actin (222, 223) and laminin (223, 224), but this effect was not observed by T_3 administration. Also in neuronal and astrocyte cultures, T_4 and rT_3 stimulate polymerization of the actin cytoskeleton, as already mentioned above (**Figure 2**) (159, 160, 162). As during brain development, basic transcription element-binding protein is upregulated by TH and this protein may play a role in neuronal outgrowth, modulating changes in the cytoskeleton, and cell differentiation (225, 226).

Studies also demonstrate that TH signaling is critical to proper functioning of short term (227) and long term synaptic plasticity (228). Induced hypothyroidism has been related with disruption in synaptic plasticity (229, 230) and long term potentiation in the CA1 neonatal (231, 232) and adult (233) rat hippocampus. Hyperthyroidism has been also related to detrimental effects in dendritic spines. Intraperitoneal injection of T_3 750 μg/kg during 5 consecutive days in adult rats significantly decreased dendritic spine density in CA1 pyramidal cells in the hippocampus (234) and thyroxine induced hyperthyroidism impairs special learning and synaptic plasticity in rats (235).

On the cellular level, TH genomic or non-genomic actions may modulate the activity of ion pumps that are important for normal excitable cell function. Particularly in brain tissues affected by ischemia, directly or indirectly, adapted function of ion pumps is required to avoid intracellular overload of H^+ and Ca^{2+}, preventing cell acidosis and excitotoxicity. T_3 has been shown to decrease the activity of Na, K-ATPase (154, 155) and to stimulate the Na^+/H^+ exchanger (149) and Ca^{2+}/Mg^{2+} ATPase pump activity (158) in cerebrocortical synaptosomes. T_3 increases the transcription of SR Ca^{2+}-ATPase gene (ATP2A2) in the sarcoplasmic reticulum (157). In addition, T_3 has been demonstrated to be benefical in *in vitro* and *in vivo* experimental myocardial ischemia preventing excessive intracellular Ca^{2+} accumulation (236, 237).

Also, T3 contributes to glutamate uptake by astrocytes, protecting neurons from intracellular calcium toxicity and death (203). Neuroprotective effect was attributed to an increased expression of mRNA and protein levels of GLT-1 and GLAST in the astrocytes. It also has been demonstrated that T3 decreases N-methyl-d-aspartate (NMDA)-evoked currents and prevent glutamate-induced neuronal death in hippocampal neurons (202). Together, these actions might be beneficial to prevent cell dysfunction or death of principal neurons during the acute phase after ischemic stroke. Conversely, these mechanisms might be involved to reduce the activity of inhibitory neurons in critical periods of plasticity during the first weeks after stroke. Hence, these actions most likely will dependent on receptor expression profiles in different neuron populations.

The balance between excitation and inhibition is of particular importance for neuronal plasticity processes potentially relevant for recovery. During development, TH increases the level of γ-aminobutyric acid (GABA) in the brain, while the opposite effect is observed in the adult brain. In the developing brain, hypothyroidism impairs the generation of interneurons including reduced proliferation and delayed differentiation of precursor cells in the cerebellum and their migration to the cerebellar cortex (238). These effects could be antagonized by administration of T_3 binding to the TRα1. Likewise, deletion of TRα1 reduced cerebellar GAT-1 expression and Pax-2 precursor cell proliferation (238). TH also affect the release and uptake of GABA from the neuron into the synapse. T_3 stimulates depolarization and release of GABA in synaptosomes from rat cerebral cortex (239). In the adult brain, hypothyroidism is reported to increase glutamic acid decarboxylase (GAD) activity and GABA reuptake, from cerebral cortex homogenates (240, 241) while hyperthyroidism has no effect on GABA uptake (241). In addition, T_3 administration inhibits GABA-induced Cl^- currents, which may affect $GABA_A$ receptors in the cerebral cortex, by non-genomic mechanisms (242).

Adult Neurogenesis

TH signaling is crucial for proper neurogenesis during brain development (1). Several studies have demonstrated that neurogenic events in the adult brain are dependent on TH actions (243–250) and have been reviewed in detail (251, 252). Particularly T_3 is involved in mechanisms of proliferation, survival, differentiation and maturation of neuronal precursors in the adult brain (246, 251). With potential contribution of TH NSPCs from the SVZ may proliferate, migrate and differentiate into neurons, astrocytes or oligodendrocytes in the damaged region and thereby contribute to brain plasticity after ischemic stroke or other brain injury (253, 254). Stem cell therapy and neurogenesis have been explored as a potential therapeutic strategy for neuronal repair after ischemic stroke (255).

Angiogenesis

Therapeutic angiogenesis has been used to enhance brain repair promoting the formation of new blood vessels and restoration of blood flow in the damaged area (256–258). Angiogenic effects of TH have been demonstrated in infarcted tissue of the myocardium (259). Moreover, an increased number of new blood vessels has been found in the brain of hypothyroid rats after administration of 3,5-diiothyroprionic acid (a thyroid hormone analog) or T_4 (260). The proangiogenic effects of TH are apparently mediated by non-genomic actions, through binding to integrin αvβ3 resulting in activation of MAPK 1/2 and STAT3. TH binding to αvβ3 directs transcription of genes that promote angiogenesis, namely fibroblast factors, VEGF and angiopoietin-2 (124–126, 137, 147, 261, 262). To our knowledge, so far no experimental studies have been performed to investigate pro-angiogenic effects of TH after stroke.

TRANSLATION TO CLINICAL STUDIES

Current epidemiological studies in humans and experimental evidence from rodents strongly suggest that TH signaling plays a crucial for stroke recovery. In particular T_3, the active form in the brain, exerts genomic and non-genomic actions that may foster functional outcome after stroke.

Although several epidemiological studies have associated low levels of TH with poor outcome, no clinical trials have been performed to evaluate the recovery promoting effects of TH in stroke patients. At the current stage the first step of translational studies will be to understand exact mechanisms underlying beneficial action of TH after stroke in animal models, in particular T_3. Based on knowledge about mechanisms of action, exact treatment regimens with specific targets can be developed and tested during critical windows of stroke recovery. In this context, the development of cell-specific approaches to target TH signaling in the postischemic brain may result in specific treatments in experimental stroke models, that later, might be translated into clinical studies.

CONCLUSIONS

Several mechanisms in the brain are tightly regulated by TH and T_3 availability to the brain is dependent on factors including (i) maternal TH release before fetus thyroid gland development; (ii) TSH levels and TH release by thyroid gland; (iii) passage of TH through placenta in the fetus; (iv) control of free fraction of TH determined by TH binding proteins; (v) TH transmembrane transport into the cytoplasm; (vi) local activity of iodothyronine deiodinases; (vii) expression and distribution of TR; (viii) and translational activity and non-genomic actions of TH in the brain. Disruption in these mechanisms compromise TH availability and actions in the brain and may result in impairments of neurological functions. There is clinical and preclinical evidence that TH are involved in mechanisms of neuronal plasticity and function of glial cells after ischemic stroke. Further understanding and targeting those might be exploited in future therapies to enhance functional recovery in stroke patients.

AUTHOR CONTRIBUTIONS

DT conceptualized and wrote the review, under supervision of KR. KR, CS, and IG revised the manuscript. All authors approved the final version of the manuscript for submission and publication.

FUNDING

This work was supported by funds from the Health Sciences Research Center (CICS-UBI) through National Funds by FCT—Foundation for Science and Technology (UID/Multi/00709/2019); by a doctoral fellowship (SFRH/BD/104679/2014) from Fundação para a Ciência e Tecnologia; partially supported by Programa Operacional do Centro, Centro 2020 through the funding of the ICON project (Interdisciplinary Challenges on Neurodegeneration; CENTRO-01-0145-FEDER-000013); the Swedish Brain Fund; the Crafoord Foundation, Sveriges Stroke Riksförbundet; the Hans-Gabriel and Alice Wachtmeister Foundation, Sparbanksstiftelsen Färs & Frosta and the Stiftelsen Sven-Olof Jansons livsverk.

Background: Behcet's disease (BD) is multi-systemic vasculitis, which generally is repeated oral and genital ulcerations as well as ocular and skin lesions. Today, the pathogenesis of BD remains mostly unknown. It is also suggested that the disease is probably related to autoinflammatory and autoimmune disorders, and innate immunity damages were perceived as key in its pathologic process. Only 5% of BD patients have neurological involvement, and it usually occurs in 4–6 years after the initial symptoms. Early onset of neurological impairment makes it difficult to diagnose and treat definitely.

Case Presentation: A 38-year-old man was admitted to our hospital with numbness and weakness of the left extremities. Diffusion magnetic resonance imaging (MRI) revealed focal infarction in the posterior limb of the internal capsule. Skin pathology suggested small vessel vasculitis, and high-resolution MRI revealed intracranial arteritis. The patient had a negative skin pathery test and then developed a scar at the venous puncture site at the early stage of disease. Laboratory examination showed that interleukin 8 (IL-8) increased. The patient was treated with an immunosuppressive agent including mycophenolate mofetil, hydroxychloroquine, and colchicine. All symptoms were alleviated after half a year's treatment. There was neither stroke nor recurrence of oral ulcer thereafter.

Conclusion: This case demonstrates that neurological involvement might be an early symptom of BD. IL-8 could act as a novel target for the treatment of BD theoretically and probably play a key role in disease recovery.

Keywords: Behcet's disease, neuro-Behcet's disease, cerebral infarction, cerebral arteritis, IL-8

INTRODUCTION

Behcet's disease (BD) is recognized as a multi-systemic disease characterized by possible inflammatory lesions of any-size vessels (1). Although the etiopathogenesis has not yet been clarified, it is generally believed that immunological factors play an important role (2–4). It is also suggested that the disease is probably related to autoinflammatory and autoimmune disorders, and innate immunity damages were perceived as having a key role in its pathologic process (5–7). The diagnosis is established by clinical criteria only (8). The international criteria for BD (ICBD) allow for earlier recognition, thus leading to earlier and accurate diagnosis and treatment with salutary results (9).

Involvement of central nervous system symptoms is reported in 3.2–49%, mostly about 5%, in BD patients (10, 11), which is known as neuro-Behcet's disease (NBD).Nervous system impairment mostly occurs in 4–6 years after the onset of BD (12). However, some of the patients have neurological symptoms at the same time as or even before the classical BD symptoms, which may lead to diagnostic confusion and may result in there being more BD patients than actually reported (13).

In this kind of patient, the pathological feature is various types of arteriovenous vasculitis, which mainly affects small vessels in multiple systems. It appears as focal or multiple brain parenchymal damage in the central nervous system (14, 15). Artery involvement is rare compared with venous involvement, manifesting as arterial stenosis and aneurysm formation, which often lead to arterial infarction or intracranial and/or subarachnoid hemorrhage (16–18).

CASE PRESENTATION

A 38-year-old man was admitted to our hospital with numbness and weakness of the left extremities. Diffusion-weighted imaging (DWI) revealed focal infarction in the posterior limb of the internal capsule, and cranial and cervical magnetic resonance angiography was normal (**Figure 1**).

The patient had recurrent multiple and painful oral ulcers after 2 months; meanwhile, he suffered pain in both knees and the left shoulder joint. The physical examination revealed that the old and new *acneiform folliculitis* were alternated on the face and back and behind the ears (**Figure 2**); also, a scar was shown at the venous puncture site (**Figure 3**). The patient had no other risk factors for cerebral atherosclerotic disease and is also not a smoker. Blood routine, serologic etiology test (including syphilis, AIDS, and other pathogens), lipid profile, plasma glucose, plasma and urine homocysteine levels (indicating the possibility of a genetic predisposition to thrombosis), proteins C and S deficiency, antithrombin III deficiency, activated protein C resistance, antiphospholipid antibody (hypercoagulability markers), anticardiolipin immunoglobulin G (IgG) and immunoglobulin M (IgM), antineutrophilic cytoplasmic antibody, C-reactive protein (CRP), erythrocyte sedimentation rate, and rheumatoid factor were performed, and all of them were within normal range. Transesophageal echocardiography, contrasted transthoracic echocardiography, and 24-h dynamic electrocardiogram were normal. Interleukin 8 (IL-8) was increased to 252 pg/ml (normal value: <62 pg/ml), but IL-6, tumor necrosis factors (TNF), and other cytokines were maintained at normal levels. No cardiogenic embolism, cardiac structure and rhythm abnormalities were found.

High-resolution magnetic resonance imaging (HRMRI) of the brain suggested that some blood vessel walls were slightly thickened, including the terminal portion of the left internal carotid artery, V4 segment of the bilateral vertebral artery, P2 segment of the right posterior cerebral artery (**Figure 4**), the terminal portion of M1 segment of the right middle cerebral artery (MCA), M2 and M3 segments of bilateral MCA, and A2 segment of the bilateral anterior cerebral artery. The enhancement scanning showed a double-track-like change and a narrowed vascular lumen, which suggested multiple intracranial arteritis. Hip magnetic resonance imaging (MRI) showed a long and flaky T1-weighted and T2 high fat-suppression signal on the lateral of the left femoral head, which suggested degenerative changes. Pathological biopsy of the skin lesion showed that some regions were infiltrated by extensively perivascular inflammatory cells, suggesting small vessel vasculitis (**Figure 5**). Genetic testing also was performed to analyze hereditary cerebrovascular disease elements (detected by Golden Field Medical, Inc., using analysis of missense mutations and alternative splicing; this lab has gotten the accreditation of the College of American Pathologists), and the result *did not* show pathogenic variation. Based on the above testing results and related to a history of genital ulcers of the patient, this case was diagnosed as BD under the direction of diagnostic criteria. The patient could not use azathioprine (AZP) to thiopurine S-methyltransferase (TPMT) mutation, and this could be checked by gene detection, which indicated that there was TPMT*3C (A719G) in this patient. Meanwhile, the patient refused to use cyclophosphamide after acquainting with its side effects (nephrotoxicity etc.) and its cumulative toxicity with long-term use (19).

Therefore, the patient was treated with mycophenolate mofetil dispersible tablets (Seccopin), hydroxychloroquine tablets (Flush), and colchicine tablets. After half a year's treatment, the patient's skin rash gradually was alleviated, and the symptoms of oral ulcer and nervous system damage did not recur.

DISCUSSION AND CONCLUSIONS

Our patient fulfilled the diagnostic criteria of ICBD; he had recurrent oral ulcers (2 points), skin lesions (1 point), central nervous system lesions (1 point), vascular symptoms (1 point), and a positive pathergy test (1 point).

The patient initially consulted for acute cerebral infarction. This patient did not show risk factors for cerebral atherosclerotic disease other than smoking and also had no abnormalities in the gene test of hereditary cerebrovascular disease and other common causes, for example, hypercoagulability. According to his medical history, laboratory tests, and examination results, vasculitis caused by syphilitic vasculitis, rheumatoid arthritis, systemic lupus erythematosus, and Sjogren's syndrome can be excluded. The high-resolution MRI (HRMRI) of the brain showed intimal thickening in the wall of the intracranial and cervical arteries, which suggested arteritis. However, carotid

dissection or Moyamoya symptoms *were not* shown. The new internal capsule lesion seen on MRI was consistent with the occlusion regions resulting from arteritis of the MCA deep perforator branches. In conclusion, the patient was diagnosed with BD.

Vasculitis is the central pathological process of BD. In this case, skin pathology was a representation of vasculitis, and it was verified by HRMRI as cerebral arteritis. Venipuncture is an inflammatory lesion of the skin, and it is similar to spontaneous skin lesions seen in the disease. Our patient had a negative skin pathery test, which developed a scar at the venous puncture site for the intravenous fluid infusion at the early stage of disease, but we have not observed the whole process of scar formation. The investigation results revealed that the presence of a positive reaction was irrelevant to the clinical manifestations of the disease (20, 21). However, the pathery reaction (PR) was reported to be significantly associated with vascular involvement (22). Chang et al. described that the intravenous Pathergy test seemed to be superior to the skin Pathergy test on specificity, sensitivity, and positive rate. Pathergy test reactions usually occur during active periods of BD as well (23). Although no peripheral vascular pathological examination was performed, the case was tested by negative classic PR, and the results suggested that the scar formation at the venipuncture site was caused by peripheral venous vasculitis.

Different immunologic abnormalities in the etiopathogenesis of BD have been reported. Increased Th1-associated cytokines such as IL-12, interferon-γ (IFN-γ), and tumor necrosis factor-α (TNF-α), as well as IL-2, IL-8, and IL-6, have been documented in BD patients (24). Many studies have reported that increased serum IL-8 plays an important role in BD (25–31). One recent report even implied that serum IL-8 could be a more credible marker of disease activity than CRP or erythrocyte sedimentation rate (ESR) (32). Durmazlar et al. found that IL-8 is positively correlated with the activity of BD and also closely related with the BD activity index and numbers of disease clinical manifestations. IL-8, known as neutrophil activating factor, is substantially produced by granulocytes, T cells, macrophages, and endothelial cells. A small amount of IL-8 can also be induced in keratinocytes, fibroblasts, chondrocytes, and hepatocytes (31, 33, 34). It strongly attracts and activates leukocytes. It has been supposed to establish a prominent connection between immune system activation and endothelial alterations involved in the conversion of mononuclear to granulocytic infiltration and causes raised adhesion of peripheral blood leukocytes to endothelial cells in BD. It has been found that the significant increase of IL-8 is associated with different clinical manifestations

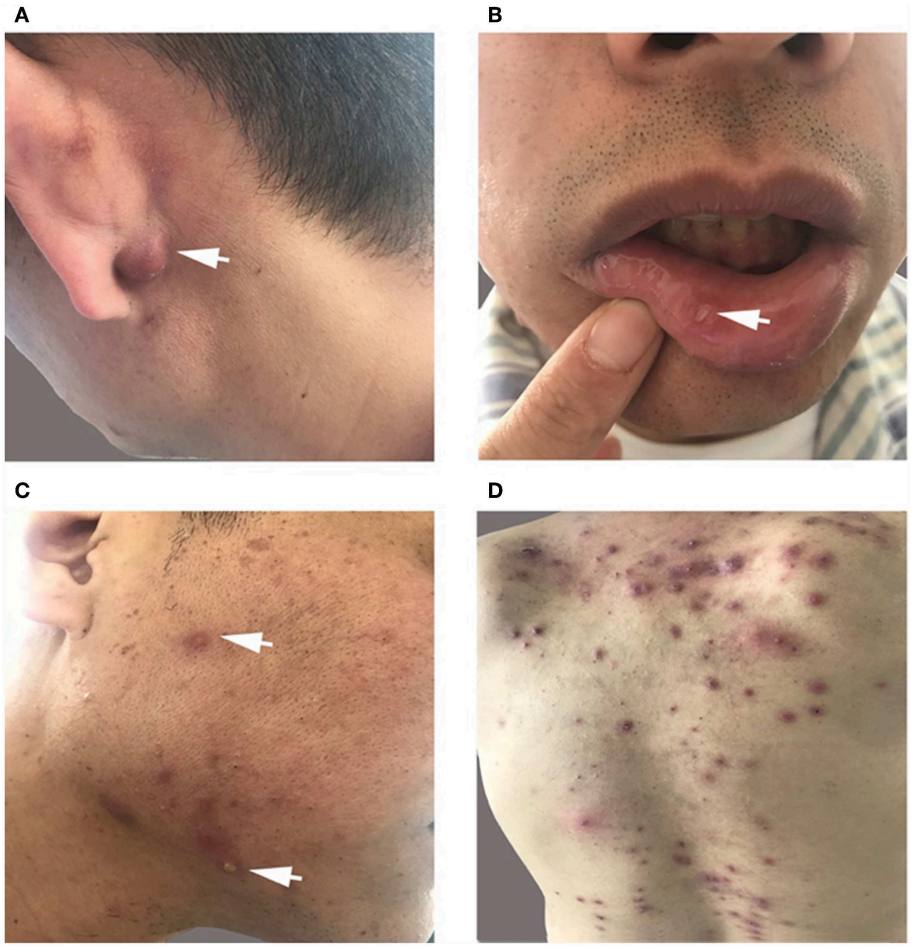

FIGURE 2 | (A,C,D) Old and new acneiform folliculitis behind the ears **(A)** and on the face **(C)** and back **(D)**. **(B)** Recurrent multiple and painful oral ulcers.

in BD, such as skin lesions, oral lesions, and ocular manifestations in one study (31). Moreover, compared with the active patient group without vascular involvement, the levels of IL-8 in patients with vascular involvement were markedly increased. On the basis of the patients' pathology and imaging, active BD patients with vascular involvement were found to possess pretty enhanced IL-8 in serum levels, which supported that endothelial cells may be partly responsible for secretion of IL-8 in the active phase of BD (35), since an IL-8 increase of fourfold in the active phase may represent endothelial injury in any part of the body. HRMRI results suggested central nervous system vasculitis. It is considered to be largely associated with a high IL-8 level, resulting in vascular endothelial destruction.

BD *is not* generally received as a cerebral vasculitis introducer compared with other systemic diseases known to lead to vasculitis. Only 1–5% arterial involvement is seen throughout the course of BD. The pattern of cerebral infarction and cerebral vasculitis represents a specific and uncommon form of neuro-Behcet's manifestation, and only two cases have been reported so far (10, 36). In one case, neurological deficits were considered to be infarction in the deep perforating branch of MCA, but it did not show specific change in brain imaging. The other case was an autopsy study, and it showed clearly that the infarction area was consistent with the occlusion regions resulting from arteritis of the MCA branches (37). Vascular involvement is a fatal complication for BD patients, so early diagnosis is very important.

Fortunately, for this case, the above conditions could be excluded according to the result that there was extensive cerebral artery intimal thickening from HRMRI. So we could clearly diagnose this case as BD with cerebral arterial infarction caused by cerebral arteritis, which led to early nervous system symptoms. In addition, we found that plasma IL-8 level was significantly elevated at the early stage of this case, while ESR, CRP, and other indicators have no obvious abnormalities. IL-6 is a key cytokine involved in NBD, especially since this inflammatory marker has been found to be increased also in the cerebrospinal fluid of patients with BD. However, IL-6 was not changed in the patient's plasma, which suggested that IL-8 is a dominant factor in the BD process.

AZP is the preferred treatment for BD. It commonly causes myelosuppression, presenting as megaloblastic anemia, leukopenia, severe hair loss, macrocytosis, pancytopenia, and thrombocytopenia (38–40). Leukopenia and severe hair loss are

strongly associated with mutations in TPMT and NUDT15, which are widespread in the Asian population (41). Gene detection indicated that there was TPMT*3C (A719G) in this patient, so we did not choose AZP to treat patients. Mycophenolate mofetil is used in organ transplantation, multiple sclerosis, Crohn's disease and other immune-related diseases. Borhani Haghighi and Safari divide the anti-NBD armamentarium into first-line, second-line, and experimental drugs. Mycophenolate mofetil is classified as a second-line drug (42). The International Neuro-Behcet's Advisory Group has developed a consensus on NBD, which refers to mycophenolate mofetil as an alternative drug for NBD (43). Colchicine is used for the treatment of gout (44), as well as specific inflammatory conditions such as familial Mediterranean fever (FMF) (45), recurrent pericarditis (46) and BD (47). It seems to inhibit neutrophil chemotaxis and reduce plasma levels of cytokine, thereby reducing the occurrence and the duration of mucocutaneous (oral ulcers, erythema nodosum, genital) and articular manifestations of the disease (47). Hydroxychloroquine is proven to have a relatively benign toxicity profile and a low incidence of infections as an immunosuppressive agent (48, 49). A large cohort study has reported the successful empiric use of hydroxychloroquine to treat BD (50).

Considering the choice of patients and the drugs, the inflammatory activity was controlled followed by treatment with mycophenolate mofetil dispersible tablets (Seccopin), hydroxychloroquine tablets (Flush), and colchicine tablets. The clinical symptoms were ameliorated, such as suppressing oral

immunity, preventing relapses in skin lesions and progressive neurological disease, as well as settling the systemic disease. However, it is unclear whether long-term immunosuppression might also work well in central nervous system (CNS) vasculitis. That is to say, the risk of recurrent cerebral infarcts remains to be elucidated in the future. Therefore, seeking new medicine targets becomes an urgent issue. IL-8, a major chemoattractant and activator of neutrophils, could act as a novel target for the treatment of BD theoretically and perhaps prove to be the key to recovery.

DATA AVAILABILITY STATEMENT

Publicly available datasets were analyzed in this study. This data can be found here: hospital ID: 000444000, Shandong Povincial Qianfoshan Hospital.

ETHICS STATEMENT

The studies involving human participants were reviewed and approved by the ethics committee of Qianfoshan Hospital. The patients/participants provided their written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

There is currently no treatment for restoring lost neurological function after stroke. A growing number of studies have highlighted the potential of stem cells. However, the mechanisms underlying their beneficial effect have yet to be explored in sufficient detail. In this study, we transplanted human induced pluripotent stem cell-derived neural precursors (iPSC-NPs) in rat temporary middle cerebral artery occlusion (MCAO) model. Using magnetic resonance imaging (MRI) and magnetic resonance spectroscopy (MRS) we monitored the effect of cells and assessed lesion volume and metabolite changes in the brain. We monitored concentration changes of myo-inositol (Ins), Taurine (Tau), Glycerophosphocholine+Phosphocholine (GPC+PCh), N-acetyl-aspartate+N-acetyl-aspartyl-glutamate (NAA+NAAG), Creatine+Phosphocreatine (Cr+PCr), and Glutamate+Glutamine (Glu+Gln) in the brains of control and iPSC-NP-transplanted rats. Based on initial lesion size, animals were divided into small lesion and big lesion groups. In the small lesion control group (SCL), lesion size after 4 months was three times smaller than initial measurements. In the small lesion iPSC-NP-treated group, lesion volume decreased after 1 month and then increased after 4 months. Although animals with small lesions significantly improved their motor skills after iPSC-NP transplantation, animals with big lesions showed no improvement. However, our MRI data demonstrate that in the big lesion iPSC-NP-treated (BTL) group, lesion size increased only up until 1 month after MCAO induction and then decreased. In contrast, in the big lesion control group, lesion size increased throughout the whole experiment. Significantly higher concentrations of Ins, Tau, GPC+PCh, NAA+NAAG, Cr+PCr, and Glu+Gln were found in in contralateral hemisphere in BTL animals 4 months after cell injection. Lesion volume decreased at this time point. Spectroscopic results of metabolite concentrations in lesion correlated with volumetric measurements of lesion,

with the highest negative correlation observed for NAA+NAAG. Altogether, our results suggest that iPSC-NP transplantation decreases lesion volume and regulates metabolite concentrations within the normal range expected in healthy tissue. Further research into the ability of iPSC-NPs to differentiate into tissue-specific neurons and its effect on the long-term restoration of lesioned tissue is necessary.

Keywords: iPSC-NPs, stroke, magnetic resonance, metabolic changes, IMR, MRS

INTRODUCTION

Stroke is a neurodegenerative disorder and the leading cause of disability in adult humans. One in six people worldwide will have at least one stroke in their lifetime (1). There is currently no treatment for restoring lost neurological function after stroke. A growing number of studies have highlighted the potential of stem cell transplantation and more differentiated neural cell transplantation as intriguing therapeutic approaches to post-stroke reparation. Cells from different sources (fetal cortical- and striatal-derived neural precursors, subventricular zone precursors, neuroepithelial stem cells, bone marrow stromal cells, hESC-derived neural precursors, etc.) have been tested for their ability to reconstruct the forebrain and improve function after transplantation in animals with stroke (2–5). As an autologous, multifunctional cell therapy for stroke, induced pluripotent stem cell-derived neural precursors (iPSC-NPs) have significant potential. Several studies have demonstrated the beneficial effect of iPSC-NPs in ischemia treatment using animal models (6–9). It has been shown that transplantation of human iPSC-derived cells is a safe and efficient approach to promoting recovery after stroke, supplying the injured brain with new neurons for replacement (6). In one rat model study, pluripotent stem cells were shown to differentiate into more specific cortical neuronal progenitors, in turn differentiating into functional neurons, and improving neurological outcomes after intracortical implantation (10). Grafted human iPSCs-NPs have been shown to survive, differentiate into neurons and ameliorate functional deficits in stroke-injured neonatal (11), and aged brains (7). Their strong therapeutic potential has also been demonstrated in large animal models (9). However, the mechanisms of iPSC-NPs in stroke treatment have yet to be investigated in sufficient detail.

Magnetic resonance imaging and spectroscopy (MRI/MRS) are powerful non-invasive diagnostic tools used to provide anatomical and biochemical information. MRI is an optimal imaging modality for ischemic lesion visualization. MRS is a technique used in preclinical and clinical studies to obtain metabolic information of the brain parenchyma under experimental conditions. Although MRS cannot directly localize the area of transplanted cells, it can provide information on the metabolic processes of the brain following cell transplantation. The most frequently assessed metabolites in proton magnetic resonance spectroscopy (^{1}H-MRS) are lactate, which accumulates as the end product of anaerobic glycolysis, and N-acetyl-aspartate (NAA), which is considered a predominantly neuronal marker (12, 13). Thus, reduction of NAA is often acknowledged as an indicator of neuron loss (14). However, alternative explanations, such as the metabolic degradation and redistribution of NAA, warrant further analysis (15).

In this study, we transplanted human induced pluripotent stem cell (IMR90)-derived neural precursors in a rat temporary middle cerebral artery occlusion (MCAO) model. As previously demonstrated in our laboratory, grafted cells successfully survive and provide trophic support to host brain tissue, leading to the recovery of sensorimotor, and motor functions (16). It should be noted, however, that these effects were mainly demonstrated in animals with small lesions, while animals with big lesions showed no improvement.

The aim of this study was to determine metabolic changes by ^{1}H-MRS in the striatal tissue region of the rat brain within 4 months after focal brain ischemia. We studied the effect of transplanted iPSC-NPs on metabolite concentrations at measured time points (1 month and 4 months) by comparing changes in ischemic lesion size. The results presented here may help to elucidate the biochemical changes that occur during early stages of ischemic stroke, distinguish at-risk individuals, benefit early diagnosis, and improve our understanding of the dynamic pathogenesis of early cerebral ischemia (17).

MATERIALS AND METHODS

Animals and Study Groups

All animal experiments were performed in accordance with EU Directive 2010/63/EU on the protection of animals used for scientific purposes, and approved by the ethics committees of the Institute of Experimental Medicine, the Czech Academy of Sciences, and the Institute for Clinical and Experimental Medicine.

The study group consisted of 35 ten-week-old female Sprague-Dawley rats, including healthy controls ($n = 3$). Body weight ranged from 280 to 350 g to minimize differences in body size. All animals were pre-trained in the tape removal test for 3–4 days and tested for both behavioral tests the day before MCAO. Six days after MCAO, rats were randomly divided into control ($n = 12$) and transplanted groups ($n = 20$) and the last group began to receive the immunosuppression. Cells were transplanted 7 days after induction of the lesion. First MRI was performed 7 days after transplantation. According to its results, two existing groups were divided as follows: small control lesions without transplantation (SCL; $n = 6$), small lesions treated with iPSC-NPs (STL; $n = 10$), big control lesions without transplantation (BCL; $n = 6$), and big lesions treated with iPSC-NPs (BTL; $n = 10$). All these animals underwent MRI/MRS and behavioral tests according to the timeline shown in **Figure 1**, and immunohistochemical

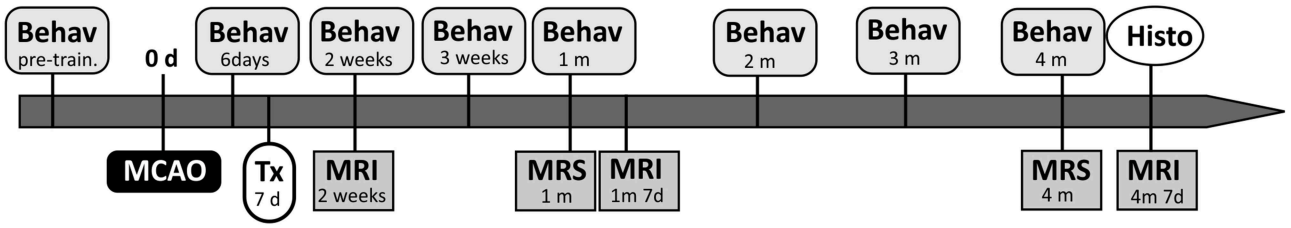

FIGURE 1 | Schematic timeline of the experiments. The day when MCAO have been performed was taken as day 0. Animals were transplanted (Tx) with iPSC-NPs 7 days after lesion and were followed by magnetic resonance imaging (MRI), magnetic resonance spectroscopy (MRS), behavioral tests (Behav) over 4 months. Histological data (Histo) were acquired in the end of the experiment. D, days; m, months.

analysis was used at the end of the study of brain tissue. However, MRS data of several rats were excluded from the statistical analysis in accordance with the rules, which are described in the MRS section below.

Human Induced Pluripotent Stem Cell-Derived Neural Precursors

The human iPSC line was derived from female fetal lung fibroblasts (IMR90 line, ATCC, USA) transduced with a lentivirus-mediated combination of OCT4, SOX2, NANOG, and LIN28 human cDNA [see (18)]. Clone selection, validation of the iPSC line and derivation of neuronal precursors are described in detail in Polentes et al. (16). Human induced pluripotent stem cell-derived neural precursors (iPSC-NPs) were routinely cultured in tissue culture flasks coated with poly-L-ornithine (0.002% in distilled water) and laminin (10 μg/ml in DMEM:F12), both obtained from Sigma (St. Louis, MO). Growth media comprising DMEM:F12 and neurobasal medium (1:1), B27 supplement (1:50), N2 supplement (1:100) (GIBCO, Life Technologies, Grand Island, NY), L-glutamine (2 mM) (Sigma), penicillin and streptomycin (50 U/ml) (GIBCO), FGF (10 ng/ml), EGF (10 ng/ml), and BDNF (20 ng/ml) (PeproTech, London, UK) were changed 3 times per week. Prior to implantation, the neural precursors were pre-differentiated in the same medium (omitting FGF and EGF) for 7 days.

Antibodies and Immunocytochemistry

Pre-differentiated iPSC-NPs plated on poly-L-ornithine and laminin-coated chamber slides were washed in PBS and fixed with 4% paraformaldehyde in PBS for 15 min. Fixed cells were washed twice with PBS before staining. To identify neural precursors and differentiated neurons, antibodies directed against βIII-tubulin (1:100), Olig2 (1:400), nestin (1:200), chondroitin sulfate proteoglycan (NG2, 1:400), NF70 (1:200) (all Sigma-Aldrich), and Ki-67 (1:50) (Abcam) were used. To visualize primary antibodies, goat anti-mouse IgG conjugated with Alexa-Fluor 488 (1:400) and goat anti-rabbit IgG conjugated with Alexa-Fluor 594 (1:400) (Molecular Probes, Eugene, OR) were used. To visualize cell nuclei, DAPI was used. Confocal images were taken with the Zeiss LSM 5 Duo confocal microscope (Carl Zeiss AG). The index of the mitotic activity of the cells was evaluated as the ratio of Ki-67 positive cells to the total number of cells in the 10 randomly selected fields of view.

Middle Cerebral Artery Occlusion Model and Cell Transplantation

Animals were anesthetised with 2.5% isoflurane (Forane®, Abbott Laboratories, Queenborough, UK). Transient focal cerebral ischemia was induced by intraluminal right middle cerebral artery occlusion (MCAO) using a nylon thread (0.08 mm diameter) and terminal cylinder of silicon (3 mm length, 0.24 mm diameter) for 90 min. Animals were then re-anesthetised for reperfusion and divided into control ($n = 12$) and transplanted ($n = 20$) groups. Based on volumetry results obtained by MRI, groups were further categorized according to lesion size.

Cell-treated animals were transplanted 7 days after ischemia induction. The control group was left untreated. Using an aseptic technique, a small hole was drilled into the skull above the lesion (0.5 mm anterior to the bregma, 3 mm lateral to the midline). Next, using a Hamilton syringe with its tip placed 4.5–5 mm deep from the cortical surface, 3 μl of a cell suspension (100 000 cells/μl) was slowly injected over a 5-min period into the lesion. Triple drug immunosuppression was used to prevent graft rejection. Sandimmun (10 mg/kg; intraperitoneal) (Novartis, East Hanover, NJ), Imuran (4 mg/kg; intraperitoneal) (Aspen Pharma Trading Ltd., Dublin, Ireland), and Solu-Medrol (2 mg/kg; intramuscular) (Pfizer Inc., New York, NY) were administered throughout the experiment (for 1 or 4 months). Immunosuppression administration started 1 day before cell transplantation and then was applied each second day (or three times per week).

Behavioral Testing

The adhesive tape removal test (sensorimotor integration) was performed on iPSC-NP-transplanted animals and controls. A sticky colored paper dot (12 mm in diameter) was placed over the rat's left paw and fingers, and the time taken to remove the dot was measured. Rats were pre-trained for 3–4 days before MCAO and tested 3 times per week until the end of the experiment.

Apomorphine-induced rotation (motor dysfunction, pharmacological) was performed on all groups and quantified for 30 min after an intra-peritoneal injection of 1 mg/kg apomorphine in saline. Deficits were quantified using a formula modified from Arvidsson et al. (19): Score = IspiCyl+(2xIpsiHslf)-ContrCyl-(2xContrHslf) with IpsiCyl: rotation ipsilateral to the lesion around the central cylinder; IpsiHslf: rotation ipsilateral on itself; ContrCyl: rotation

contralateral to the lesion around the central cylinder; ContrHslf: rotation contralateral on itself.

Magnetic Resonance

MRI measurements were performed using a 4.7 T Bruker equipped with a custom-made surface coil. Rats were anesthetised by passive inhalation of 1.5–2.5% isoflurane in air. Breathing was monitored during the measurements. For imaging, a T_2-weighted turbo spin-echo sequence (Rapid Acquisition with Relaxation Enhancement—RARE) was used. Sequence parameters were as follows: repetition time TR = 3,000 ms, effective echo time TE = 36.0 ms, turbo factor = 8, number of acquisitions AC = 8, field of view FOV = 3.5 cm, matrix 256 × 256, slice thickness 0.85 mm, number of slices = 29 (covering whole brain), voxel resolution 0.0159 μl, acquisition time 9 min 36 s. Imaging was performed 7 days, 1 and 4 months following iPSC-NP transplantation in treated groups. For the control groups the same time span was used for the unification, even if no transplantation procedure was carried out. Acquired images were used for anatomy reference and localization of spectra.

Following the imaging protocol, magnetic resonance spectroscopy was performed 1 and 4 months after MCAO. ^{1}H-MR spectra were obtained from the striatal tissue of both hemispheres in all groups. They were then measured by the single-voxel PRESS MRS sequence with water suppression using the variable pulse power and optimized relaxation delays (VAPOR) technique according to the following parameters: TR = 2,500 ms, TE = 13.2 ms, AC = 512, acquisition time 21 min 30 s. The volume of interest was FOV = 4 × 4 × 4 mm^3 (0.064 ml) for each hemisphere. Shimming for correction of magnetic in homogeneities was performed using an automated mapshim procedure. To get as robust data as possible, we had strict rules for data used in following imaging and spectroscopic analyses. Animal data were excluded if (1) there was movement artifacts due to breathing problems; (2) the half-width of water signal was 14 Hz or higher; (3) Cramér-Rao lower bounds (CRLB) was 25% and higher. To assess metabolic profiles of striatal tissue in both hemispheres, spectra were evaluated using the LC Model v 6.1 (20) to obtain metabolite concentrations. This software takes unsuppressed water as a reference. No corrections of calculated metabolite concentration for relaxation times were performed.

Concentrations of the following brain metabolites were used for analysis: Ins—a glial-specific marker (21) connected with cell metabolism and signaling pathways (22), it is also an osmolyte and essential requirement for cell growth (23); Tau—an osmoregulator and neuroprotectant with antioxidative properties that stabilizes the membrane, regulates cytoplasmic calcium levels, and reduces proinflammation (24, 25); GPC+PCh—are associated with membrane breakdown, myelinization/demyelinization or inflammation in brain diseases and were released in the brain with calcium overload (26); NAA+NAAG—markers of neuronal viability (27); Cr+PCr—PCr acts as a reservoir for the generation of ATP (23), this pair is also involved in antioxidative mechanisms and cellular bioenergetics (28); Glu+Gln—glutamate is the brain's major neurotransmitter and during ischemia acts as an important mediator of neuronal degeneration (29), also Glu+Gln pair decreased signals reflect glutamate-glutamine cycle dysfunction, while increased levels are connected with higher neurotoxicity and cell death in stroke (25, 30). Some metabolite values are presented together, as overlapping peaks from some of the spectra results made them difficult to distinguish.

Volumetry and Experimental Groups

Images obtained by MRI were used for lesion volumetry analysis. Lesion volume was assessed by manually marking MR images using ImageJ software (version 1.46r, National Institutes of Health, USA) (31). According to initial lesion size measurements (14 days after MCAO and 7 days after iPSC-NP transplantation), animals were divided into two groups in both control and treated groups, with the dividing threshold at 0.027 ml (small lesion <0.027 ml <big lesion). Groups were divided into small control lesions without transplanted cells (SCL; $n = 5$), small lesions treated with transplanted cells (STL; $n = 3$), big control lesions without transplanted cells (BCL; $n = 6$), and big lesions treated with transplanted cells (BTL; $n = 10$). To make results more precise, lesion size was calculated as the mean value of the axial and coronal areas segmented in MR images.

Histological Analysis

To analyse the fate of grafted iPSC-NPs, rats were sacrificed 4 months after transplantation. For the control groups the same time span was used for the unification, even if no transplantation procedure was carried out. The anesthetised animals were perfused with 4% paraformaldehyde in PBS (pH 7.4). Fixed brains were dissected and immersed in PBS with 30% sucrose. Frozen coronal sections (40 μm) were cut through the areas of interest. To identify human neural precursors transplanted into the rat brain, antibodies directed against human mitochondria (MTC02, 1:125) (Abcam) and against human nuclei (HuNu 1:40) (Chemicon, Temecula, CA) were used. For volumetric measurements, six sections were selected at 1-mm intervals along the craniocaudal axis, and whole images of the brain were taken with an Axioskop 2 plus microscope (Carl Zeiss AG, Oberkochen, Germany) and analyzed by ImageJ software (31). To follow the fate of the transplanted iPSC-NPs, antibodies directed against MAP2 (1:500), DARPP32 (1:500), Ki67 (1:50) (all Abcam), NeuN (1:100), TH (1:1,000) (Millipore, Billerica, MA), and GFAP (1:200) (Sigma-Aldrich) were used. To visualize primary antibody reactivity, the following appropriate secondary antibodies were used: goat anti-mouse IgG conjugated with Alexa-Fluor 488 (1:400) and goat anti-rabbit IgG conjugated with Alexa-Fluor 594 (1:400) (Molecular Probes, Eugene, OR). To visualize cell nuclei, DAPI was used. Confocal images were taken with the Zeiss LSM 5 Duo confocal microscope (Carl Zeiss AG). The index of the cell mitotic activity was calculated as the ratio of Ki-67-positive cells to the total number of surviving cells positive for HuNu. Cells were counted in the samples from 4 animals using at least 10 randomly selected fields of view for each animal. The total volume of the transplanted cell mass was estimated as described in Romanyuk et al. (32).

Statistical Analysis

Statistical analysis was performed using GraphPad Prism 7 software. The following parameters were evaluated using non-parametric Wilcoxon matched paired test: metabolite concentration measurements of lesion and contralateral hemispheres at 1 and 4 months and comparisons of volumetry results at all-time points. To compare control and treated groups the non-parametric Kruskal-Wallis multiple comparison test with Dunn's multiple comparisons were used. Non-parametric Spearman correlation was estimated between lesion volume and metabolite concentrations from both time points and both hemispheres separately. For correlation and volume changes the Bonferroni correction was applied. Statistical analysis of RT-qPCR data was performed based on $\Delta\Delta$Ct values using GraphPad Prism software (GraphPad Prism 5, La Jolla, CA, USA). For all analyses $p \leq 0.05$ was considered significant.

RESULTS

Human Induced Pluripotent Stem Cell-Derived Neural Precursors Before and After Transplantation

In order to prepare iPSC-NPs for transplantation, cells were pre-differentiated over 7 days in a regular culture medium omitting FGF and EGF. According to immunocytochemical staining, the majority of pre-differentiated neural precursors were positive for nestin, βIII-tubulin, NG2, NF-68, and Olig2. Only 23.8 + 3.2% were positive for Ki67 (**Figure 2**). These data confirm their neural phenotypes prior to transplantation. For more detailed antigens and gene expression characteristics of pre-differentiated iPSC (IMR90)-NPs, see Romanyuk et al. (32).

Human iPSC-NPs in the ischemic rat brain were evaluated for survival and differentiation into neuronal and glial phenotypes 4 months after transplantation. The engrafted cells were identified by immunohistochemical staining for the human-specific markers HuNu and MTC02 (**Figure 3**). The severe necrotic processes occurring in big lesions complicated the quantitative estimation of the number of surviving grafted cells. Graphical information on transplant survival is presented in **Supplementary Figure 1**. Histological analysis of the survival, proliferation and differentiation of transplanted cells was performed in all transplanted animals where the graft survived ($n = 12$). Two of them are not presented in **Supplementary Figure 1**, because the graft survival was very poor. The total volume of the transplanted cell mass was 1.16 ± 0.12 mm^3 for animals with big lesion and 0.70 ± 0.09 mm^3 for animals with small lesion. Some grafted cells differentiated into more mature and tissue-specific neurons, such as NeuN-, MAP2- and DARPP32-positive cells (**Figures 3E–G**). A small portion of transplanted cells were positive for GFAP

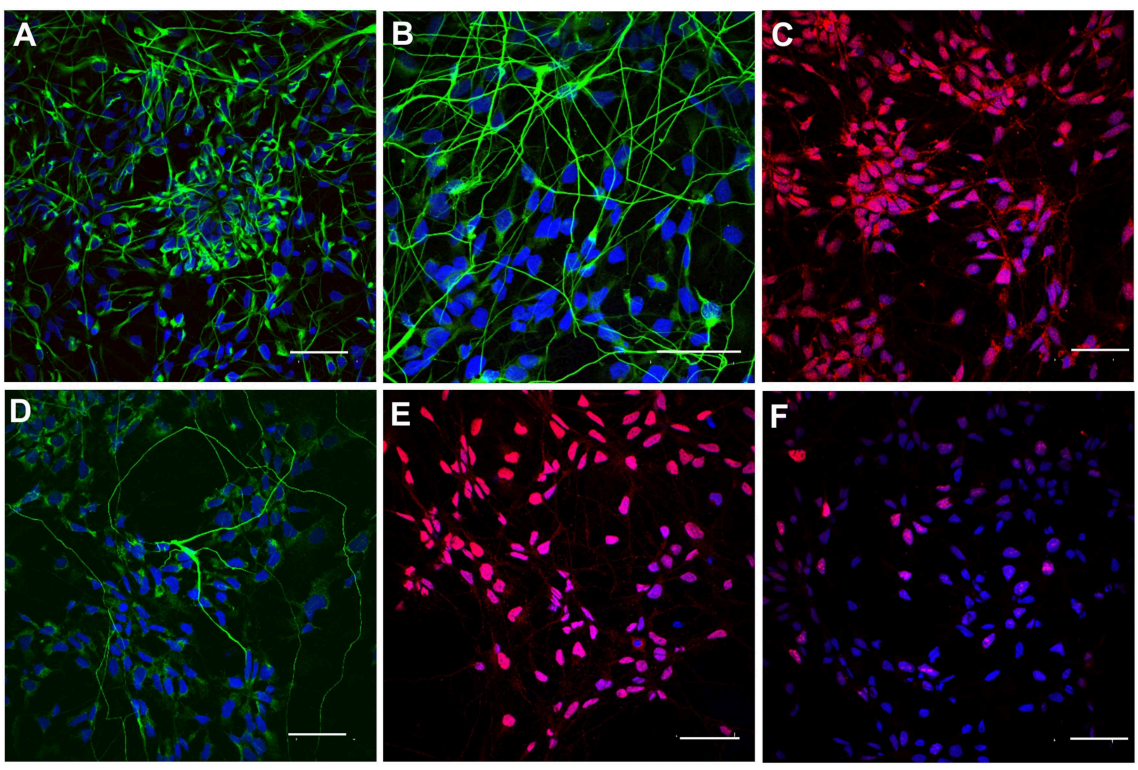

FIGURE 2 | Immunocytochemical staining of pre-differentiated iPSC-NPs prior to transplantation. **(A)** Nestin, **(B)** βIII-tubulin, **(C)** NG2, **(D)** NF-68, **(E)** Olig2, **(F)** Ki67; magnification −20 μm.

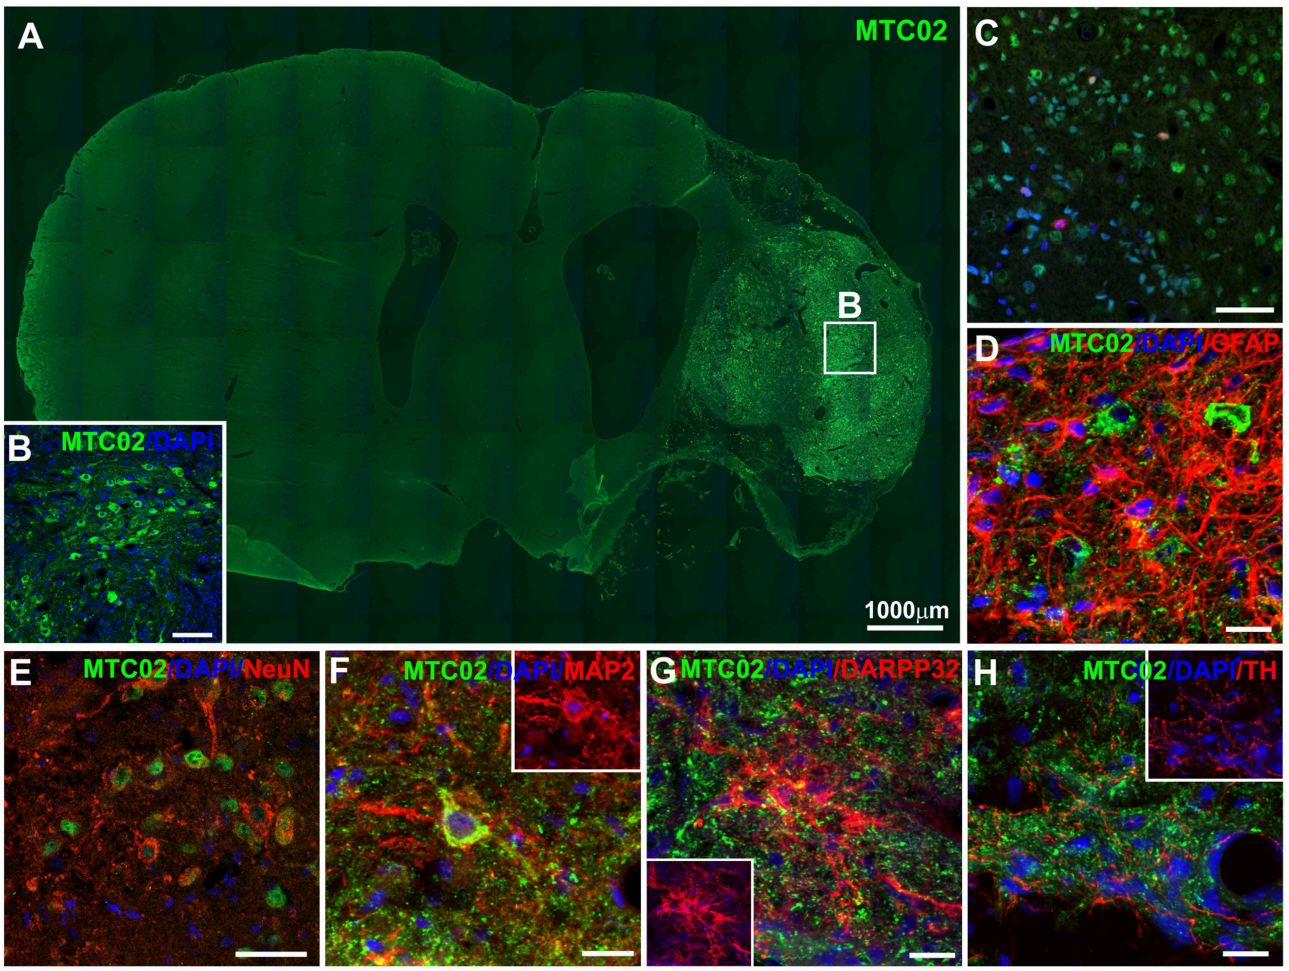

FIGURE 3 | Immunohistochemical staining of ischemic rat brain tissue 4 months after iPSC-NP transplantation. Grafted neural precursors survived and migrated toward the lesion area **(A,B)**, differentiated into NeuN- **(E)**, MAP2- **(F)**, and DARPP32- **(G)** positive cells, actively integrated into the lesioned host tissue **(D,H)** and decreased their Ki67 index **(C)** to 3.2–0.8%.

(**Figure 3D**), while transplants infiltrated by host cells were positive for GFAP or thyroxine hydroxylase (**Figures 3G,H**). Quantification of mitotic activity with Ki-67 immunoreactivity identified 2.53 ± 0.54% dividing cells, which was similar to the index shown previously for these cells (16, 32). Histological analysis of transplanted iPSC-NPs in animals with small lesions is presented on **Supplementary Figure 2**. No tumor formation was observed throughout the whole experiment. The survival of iPSC-NPs grafted in the rat brain was estimated from serial cross sections.

Behavioral Testing

To evaluate functional improvement after iPSC-NP transplantation in animals with big ischemic lesions, behavioral tests—the tape removal test and apomorphine test—were performed starting from the fifth day after lesions appeared (2 days before transplantation). Grafted animals showed almost no significant improvement compared to control animals with big lesions. Whereas, in animals with small lesions transplantation of iPSC-NP rescued functional impairment (**Figure 4**).

Magnetic Resonance Imaging and Volumetry

Images obtained by MRI confirmed the effect of MCAO on brain tissue. Ischemic lesions were localized and assessed for both size and changes caused by iPSC transplantation at different time points. MR images were used in volumetric lesion measurements and for MRS localization.

Focal brain ischemia volume measurements were performed at three time points: 7 days, 1 month, and 4 months after cells transplantation in the treated animals and at the same time points for the control groups. Lesion volume changes were observed at all-time points and in all groups. In the BCL group, lesion sizes increased and, especially between 1 and 4 months, signal became more homogenous. In the BTL group, lesion sizes increased at first (between 7 days and 1 month) but then decreased between 1 and 4 months. In the SCL group,

lesions decreased throughout the experiment, reaching a value three times smaller than initial sizes after 4 months. In the STL group, lesion sizes decreased at first (between 7 days and 1 month) to a value three times smaller than initial sizes but then increased after 4 months. The volumetry results are summarized in **Table 1**. MR images representative for average results obtained from all time points in presented groups are contained in **Figure 5**.

Magnetic Resonance Spectroscopy

^{1}H-MR spectroscopy (^{1}H-MRS) was employed to determine metabolic changes in the striatal tissue region of the rat brain over 4 months after focal brain ischemia. CRLB was usually around 10% in our study. Unfortunately, sometimes there was problem with shimming. It resulted in wide Full Width Half Maximum (FWHM) of the water signal. Linewidths of <0.1 ppm are considered essential for ^{1}H-MRS *in vivo*; for 4.7T it is 20 Hz (33). We excluded data if FWHM > 14 Hz); usually FWHM was around 10 Hz in our study. The spectroscopy results are summarized in **Tables 2A,B**, with typical spectra given in **Figure 6**.

MRS results from big lesion groups 1 and 4 months after MCAO revealed significant ($p < 0.05$) or at the limit of statistical significance ($p = 0.0625$) differences in metabolite concentrations [IU] between ipsi- and contralateral hemispheres. Significant differences were observed in MRS measurement 4 months post-MCAO in BTL group (**Figure 7**) in the following metabolites: Tau ($p = 0.0039$), NAA+NAAG ($p = 0.0039$), Cr+PCr ($p = 0.0039$), Glu+Gln ($p = 0.0039$). These changes are thought to occur due to the extent of ischemic injury. In the same group metabolite changes (Tau, GPC+PCh, NAA+NAAG, Cr+PCr, Glu+Gln) were observed to be on the limit of

statistical significance ($p = 0.0625$) 1 month after occlusion was performed. Also in the BCL group results on the limit of statistical significance ($p = 0.0625$) were observed. Four out of six measured metabolite concentrations differed between ipsilesional and contralateral brain tissue in this group: Tau (4 months), NAA+NAAG (4 months), Cr+PCr (1 month and 4 months), and Glu+Gln (1 month and 4 months). In all four groups, metabolite concentrations were lower on the lesion side. The metabolite concentrations did not differ significantly between healthy animals and contralateral hemisphere in SCL group with MCAO and without iPSC transplantation. The absolute concentration of selected metabolites obtained from healthy animals were: Ins = 6.4 ± 0.9 IU, Tau = 8.0 ± 0.1 IU, GPC+PCh = 1.9 ± 0.3 IU, NAA+NAAG = 11.4 ± 2.4 IU, Cr+PCr = 9.8 ± 1.4 IU, Glu+Gln = 19.2 ± 4.9 IU (**Supplementary Figure 3**).

Metabolite concentrations changes between 1 and 4 months after MCAO were calculated using Wilcoxon matched paired test. In the BTL group significant results were observed on the contralateral side for Ins ($p = 0.0156$), Tau ($p = 0.0156$), GPC+PCh ($p = 0.0156$), NAA+NAAG ($p = 0.0313$), Cr+PCr ($p = 0.0156$), Glu+Gln ($p = 0.0156$) (**Figure 8**).

Spectroscopic results from all groups were compared, separately for both time points and both hemispheres using the Kruskal-Wallis multiple comparison tests with Dunn's multiple comparison test (**Tables 2A,B**). After 1 month, groups were observed to be significantly heterogeneous in results from all measured metabolites and in both hemispheres. The highest significant heterogeneity was obtained from NAA+NAAG ($p < 0.0001$) 1 month after MCAO on the lesion side. From this time point also between-groups significant differences were found. On the lesion side almost all metabolites (Tau, NAA+NAAG, Cr+PCr, Glu+Gln) concentrations were observed to differ between SCL vs. BTL groups using Dunn's multiple comparisons test. On the contralateral side this difference was found for all metabolites. Four months after lesion, results from ipsilateral hemisphere of MCAO groups were significantly inhomogeneous in NAA+NAAG and Cr+PCr, while no inhomogeneity was found on the contralateral hemisphere at this time point. There were no significant differences found between the control and treated groups with the same lesion sizes. Although the mean metabolite concentrations between BCL and BTL groups from the lesion side were all higher in the BCL animals after 1 month and then in the BTL after 4 months. The same regularity was observed for the contralateral side. In small lesions the mean metabolite concentration was higher in SCL for all metabolites in both hemispheres after 1 month. After 4 months all concentrations were higher in SCL only on the contralateral side and NAA+NAAG, Cr+PCr, Glu+Gln on the lesion side. The rest of the metabolites (Ins, Tau, GPC+PCh) were found to have higher mean concentration in STL group.

Correlation Between Lesion Size Changes and Metabolic Profiles in the Ischemic Rat Brain

The aim of this part of the experiment was to determine a possible correlation between volume changes and metabolic profiles in lesioned and contralateral areas over a 4-months period after occlusion and cell injection. These changes at different time points were compared using non-parametric Spearman correlation test. Spectroscopic results from lesion side correlated with volumetric measurements with the highest correlation observed in both time points for NAA+NAAG (1 month: $r = -0.83$, $p = 0.0002$; 4 months: $r = -0.87$, $p = 0.000002$) (**Figure 9**). Other metabolites on the lesion side significantly correlating with lesion volume were Ins (4 months: $r = -0.61$, $p = 0.0067$), Tau (1 month: $r = -0.72$, $p = 0.003$), GPC+PCh (1 month: $r = -0.71$, $p = 0.003$), Cr+PCr (1 month: $r = -0.75$, $p = 0.001$; 4 months: $r = -0.76$, $p = 0.0003$), and Glu+Gln (1 month: $r = -0.77$, $p = 0.0007$; 4 months: $r = -0.74$, $p = 0.0005$). No correlation was found between spectroscopic results from contralateral side and lesion volume.

DISCUSSION

A large number of iPSC-differentiated derivatives have already been obtained and successfully used in experimental models of different disorders (34–37), including different stroke models (6, 8, 9). The data in this study may be valuable in elucidating the action mechanisms of neural precursors derived from human iPSCs in stroke models. Using a rat MCAO model, we previously demonstrated that iPSC-NPs (IMR90) successfully alleviate stroke-induced dysfunction. Transplanted neural precursors reversed stroke-induced sensorimotor and motor deficits and also dramatically protected the host substantia nigra from atrophy (16). However, these effects applied only to rats with small lesions, whereas animals with big lesions demonstrated no functional improvement. In this current study, we confirm the promising use of human iPSC-NPs for post-ischemic tissue repair in animals with big lesions. Our histology analysis reveals that transplanted cells survived and migrated toward the lesion area during the 4 month-period after transplantation. They then integrated into the striatal tissue and underwent further differentiation into more mature and tissue-specific neurons. No tumor formation was observed throughout the entire experiment.

Potential recovery and/or other changes were also quantified by volumetric measurements and metabolic changes. The biggest changes in lesion volume means per group were in the small lesion groups. In the SCL group, the volume of ischemic brain lesions decreased throughout the experiment (7 days, 1 month, 4 months), becoming almost invisible on MR images (0.004 ± 0.003 ml) 4 months after MCAO. This effect may be connected with spontaneous recovery of less extensively damaged brain tissue not subjected to invasive transplantation. In STL subjects

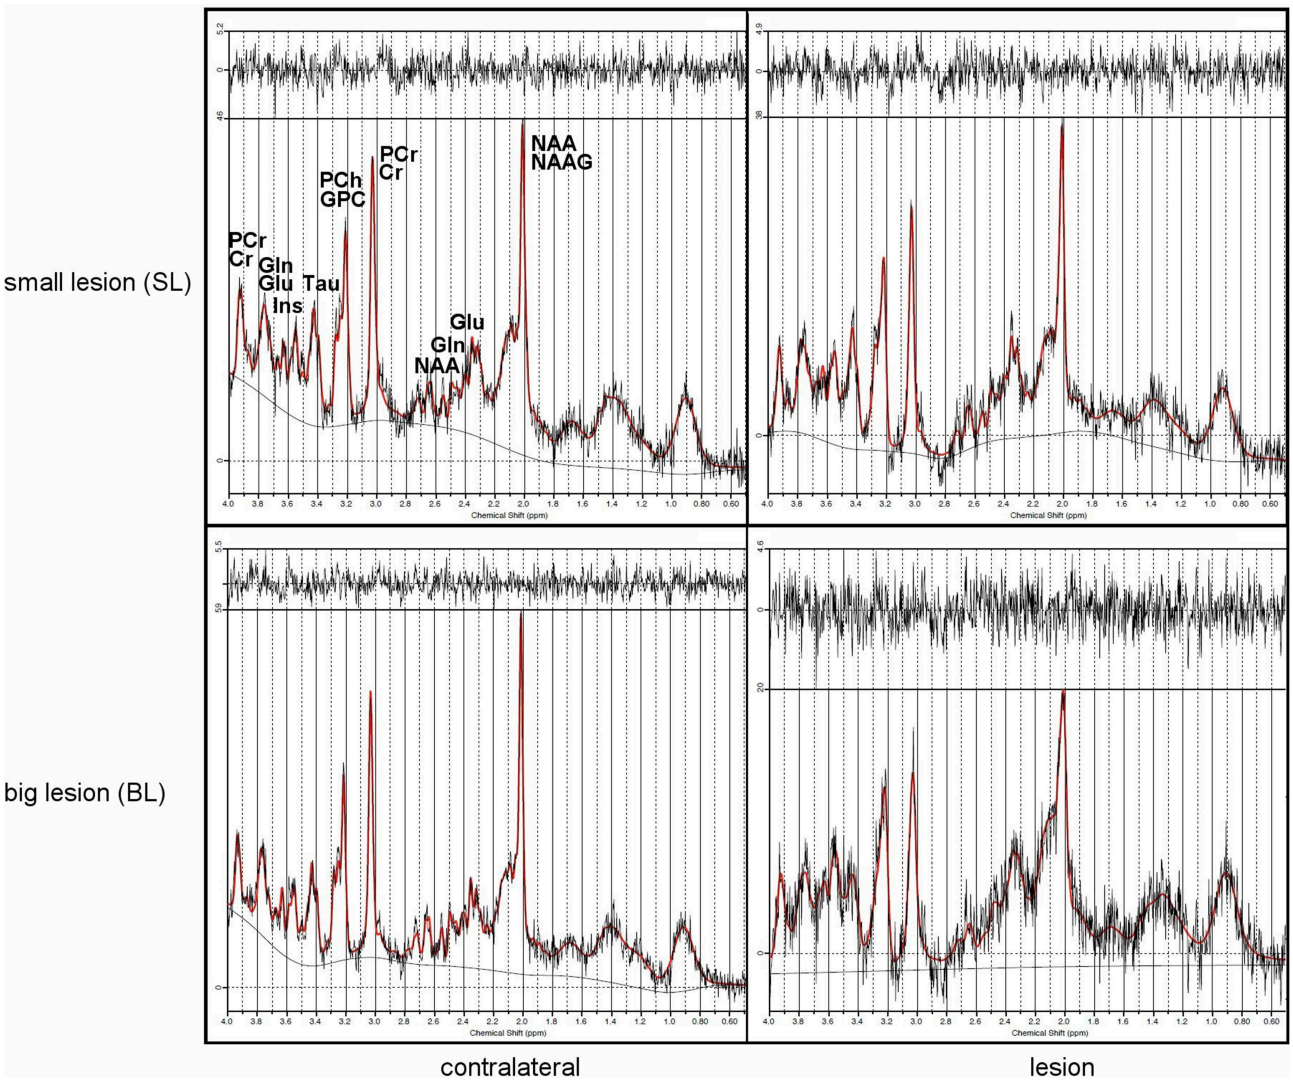

FIGURE 6 | Typical MRS rat brain spectra showing lesions (right) and contralateral sides (left) from small (top) and big (bottom) lesions with signal intensities scaled to the highest signal in the spectrum.

that did undergo the transplantation procedure, lesion volume also decreased during the first part of the experiment (between 7 days and 1 month: 0.006 ± 0.009−0.002 ± 0.0008) but then increased (between 1 and 4 months: 0.002 ± 0.0008–0.011 ± 0.007). The reason for this difference may be a secondary effect of brain tissue damage arising from cell transplantation and/or inflammation. In the big lesion groups, lesion volume changes were more variable. In BCL animals, lesion sizes increased, with signals becoming more stable between 1 and 4 months (0.125 ± 0.07–0.145 ± 0.09), which may have been caused by a greater range of tissue damage or anoxic depolarization (38). In the BTL group, lesion sizes increased at the beginning but then decreased, with the restoration of the brain cells functions perhaps attributable to cell grafts integrating into the tissue at this time point. Our hypothesis to explain the initial lesion size increase followed by a decrease is that the necrotic processes are slowing down in time and grafted cells need time to incorporate to the lesioned tissue, maybe more time points would standardize these results. All of these results suggest that, in the case of big lesions, spontaneous recovery and compensation of ischemic damage in the brain is limited.

Spectroscopy is a non-invasive method used to precisely determine biochemical changes in damaged tissue. In addition to lesion volume alterations, we also observed changes in metabolite concentrations in our animal model. As with volumetry analysis, results were again more variable in the case of big lesions. The first round of statistical analysis involved obtaining data on metabolite concentrations from the ipsilesional and contralateral hemispheres as a control for themselves. In the BTL group, a significant difference ($p < 0.01$) in Tau, NAA+NAAG, Cr+PCr, Glu+Gln concentrations were observed 4 months after MCAO, with higher values on the contralateral side. According to the

literature, taurine has the ability to maintain neuronal calcium homeostasis and prevent neuronal cell death due to necrosis or apoptosis (24). Taurine may also be used in ischemic stroke, during which intracellular free calcium increases. Levels of taurine are understood to increase in patients after stroke (25, 39). An increase in glutamate concentration is considered toxic, as it binds to ionotropic N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. This in turn promotes a major influx of calcium, which triggers phospholipases and proteases that degrade essential membranes and proteins (40). Tissue necrosis may have been suppressed with the neuroprotective influence from Tau, NAA+NAAG and Cr+PCr. Confirming these findings in our study, we observed a decrease in lesion volume co-occurring with higher metabolite concentrations after 4 months in both hemispheres. Previous studies have identified lower concentrations of the neuronal marker NAA (27) in lesions (41) and the ability of Cr to protect the brain from neurotoxicity (28). All mentioned metabolites had also higher (on the limit of statistical significance) concentrations on the contralateral side 1 month after MCAO. Here additional might be the functional improvement induced by GPC, already mentioned in models of ischemic damage (42).

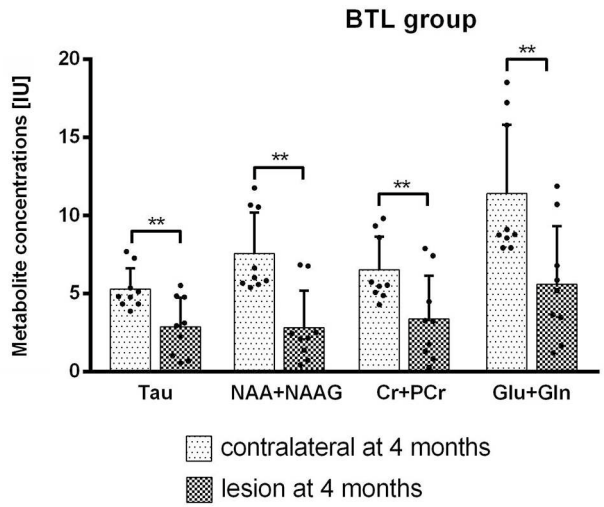

FIGURE 7 | Metabolite concentrations from both hemispheres were compared using Wilcoxon matched paired test. BTL group at 4 months after MCAO. Significant results ($p = 0.0039$) were observed for Tau, NAA+NAAG, Cr+PCr, and Glu+Gln concentrations [IU].

In the BCL group results which reflect the direction of changes (1 month: Cr+PCr, Glu+Gln; 4 months: Tau, NAA+NAAG, Cr+PCr, Glu+Gln) were found, all with concentrations higher on the contralateral side. In all four groups in our study, metabolite concentrations were lower on the lesion side.

In the second round of statistical analysis, differences occurring over time on both contralateral and lesion sides were measured. In BLT group metabolites concentrations changed—this time on the contralateral side, with significant results in all metabolites. In our study, the contralateral side probably compensated for the decrease in lesion metabolites concentration and may have influenced the decrease in lesion volume, as we observed in BTL and SCL groups. Here we can point out also trend of results observed in the BTL group, with Cr+PCr concentrations higher on the lesion side 4 months after MCAO compared to the initial

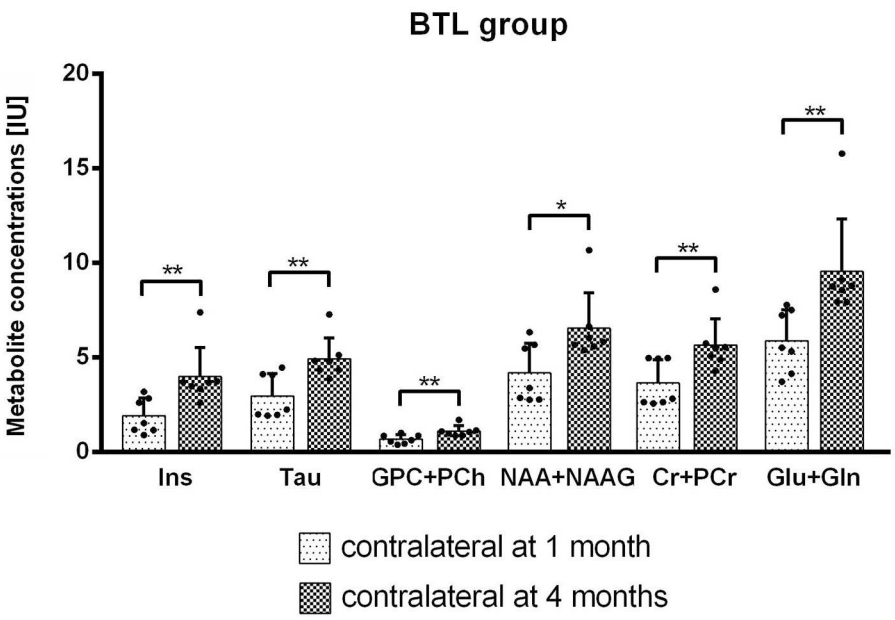

FIGURE 8 | Metabolite concentrations [IU] for the contralateral hemisphere in time were compared using Wilcoxon matched paired test. BTL group from between 1 and 4 months after MCAO on the contralateral side. Significant results were observed for Ins ($p = 0.0156$), Tau ($p = 0.0156$), GPC+PCh ($p = 0.0156$), NAA+NAAG ($p = 0.0313$), Cr+PCr ($p = 0.0156$), Glu+Gln ($p = 0.0156$) concentrations [IU].

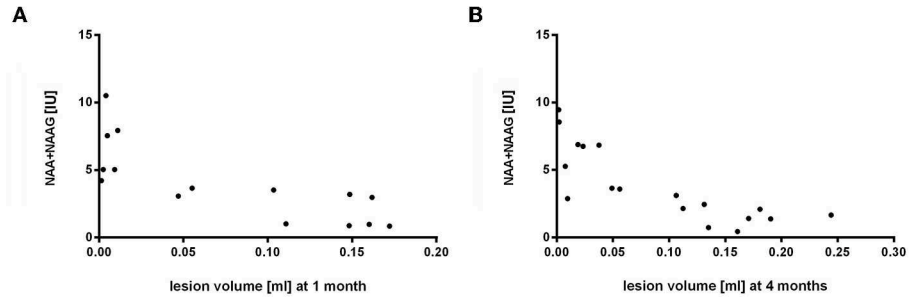

FIGURE 9 | Correlation of volumetry to spectroscopy results from the lesion side 1 and 4 months after MCAO. Lesion volume [ml] and NAA+NAAG concentrations [IU] were compared by Spearman correlation (1 month: $r = -0.83$, $p = 0.0002$; 4 months: $r = -0.87$, $p = 0.000002$).

measurement. This may have influenced the recovery of brain tissue, as lesion volume also decreased during this time. The functions of creatine and phosphocreatine in improving cerebrovascular function and reducing lesion have been previously reported (43).

Based on group comparisons, the biggest differences in metabolites were found 1 month following transplantation. However, no significant results in metabolite concentrations between same lesion size groups was obtained, in the BTL group all metabolite concentrations from both hemispheres were lower than those in the BCL group after 1 month and all higher after 4 months. In the STL group, the same trend was observed on the lesion side for Ins, Tau and GPC+PCh.

The glutamate concentrations are higher on the contralateral side possibly because there is no tissue necrosis in this hemisphere after 1 and 4 months and as there is healthier neural tissue, we can observe higher glutamate levels. If the measurement would be performed in shorter period after the MCAO procedure was carried out, there would be probably more glutamate measured on the lesion side, as the changes in the tissue structure were not so drastic. Our results show that bigger mean differences between hemispheres in glutamate concentrations were observed in big lesions (**Table 2B**), what could support our hypothesis.

The lower metabolite concentrations in treated animals we observed were probably due to the inherent fluctuation of transplanted cells and the injections, an invasive procedure that can lead to biochemical changes. In all animals, in which lesion volume decreased at the onset of ischemic damage, the protective function of the penumbra could be observed (44). Its possible influence highlights the importance of introducing additional measurements during early stages of lesion development.

Based on our literature search, our data are not in contradiction with published MRS results (45). However, it should be mentioned that published MRS data are usually obtained from MR scanners with higher magnetic field (45), which affect significantly relaxation times, or from different species (46). Therefore, concentration of metabolites can be slightly different.

The findings of this study have to be seen in light of some limitations. The first is the absence of sham operated group of animals and group of animals transplanted with vehicle. Our interpretation of the above results is possibly limited by the small group sizes and the time discrepancy between measurements of MRS (taken 1 and 4 months after MCAO) and MRI (initially taken 14 days after MCAO). Even the smallest changes in time can have a crucial influence on stroke, a factor that may reflect our results. It is necessary to mention that metabolite concentrations were assessed by LCModel without T1, T2 correction factor. TR = 2,500 ms was chosen as a compromise between accuracy and scan time (to minimize passing of animal during scanning). If we look at the relaxation times of metabolites [for example (47) or (48)], we can roughly estimate that real absolute metabolite concentration would be about 20% higher. Higher effect has T1 relaxation time, attenuation of MRS signal due to T2 is not high because T2 relaxation times of metabolites are much higher than used TE (13 ms) (47, 48). Due to the technical reasons, we were not able to quantify the numbers of surviving and differentiated grafted iPSC-NP cells.

CONCLUSION

We confirm the beneficial effect of induced pluripotent stem cell-derived neural precursors on post-ischemic tissue repair in animals with small lesions (demonstrated previously) as well as in those with big lesions. We suggest that iPSC-NP transplantation leads to a decrease in lesion volume and helps to regulate metabolite concentrations within the normal range expected in healthy nervous tissue. These results may add to the current store of knowledge on the biochemical processes occurring during early stages of ischemic stroke. Studying the correlation of lesion volume changes with spectroscopic changes over time may improve our understanding of how metabolite concentrations change after occlusion and how they are linked to lesion volume, leading to better predictions of stroke outcomes. This may in turn benefit early diagnosis and elucidate the dynamic pathogenesis of early cerebral ischemia. The decrease in lesion volume we observed in animals with big lesions indicates that iPSC-NP transplantation may indeed be a safe tool for cell transplantation therapy in stroke and a promising tool for restoring neurological function. However, how the differentiation of iPSC-NPs into tissue-specific neurons leads to the long-term restoration of lesioned tissue precisely needs to be researched in more details.

As most of the major changes occur at stroke onset, particular attention should be given to the metabolite and morphologic changes that occur during early stages of stroke.

Methods

RNA Extraction and Quantitative PCR Analysis of Gene Expression

Brain tissue was dissected from animals of two different groups: control animals with big lesions that underwent the MCAO procedure only ($n = 4$) and animals with big lesions grafted with iPSC-NPs ($n = 4$) sacrificed 4 months after transplantation. Total RNA was extracted from rat brain tissue (frozen sections) using the High Pure RNA Paraffin Kit (Roche, Penzberg, Germany) according to the manufacturer's instructions. Reverse transcription was performed using the T100™ Thermal Cycler (Bio-Rad, Hercules, CA, USA) and the Transcriptor Universal cDNA Master (Roche, Penzberg, Germany).

Expressions of the rat (Rattus norvegicus) target genes Bdnf, Ngf, Vegf, Fgf8, Dcx, Syp, Ppp1r1b, Drd1, Drd2, Gap43, and Actb were determined by quantitative real-time reverse transcription polymerase chain reaction (qPCR) using StepOnePlus™ (Life Technologies, Carlsbad, CA, USA), the FastStart Universal Probe Master (Roche, Penzberg, Germany) and TaqMan Gene Expression Assays (4331182) [Rn02531967_s1/Bdnf/, Rn01533872_m1/Ngf/, Rn01511601_m1/Vegfa/, Rn00590996_m1/Fgf8/, Rn00670390_m1/Dcx/, Rn01528256_m1/Syp/, Rn01452984_m1/Ppp1r1b/, Rn03062203_s1/Drd1/, Rn00561126_m1/Drd2/, Rn01474579_m1/Gap43/, Rn00667869_m1/Actb/]. The final reaction volume amounted to 10 μL containing 25 ng of extracted RNA. The following thermal profile was used: a single cycle to prevent carryover contamination for 2 min at 50°C and 10 min at 95°C for DNA polymerase activation, followed by 40 cycles of denaturation at 95°C for 15 s and annealing and extension at 60°C for 1 min. The results were analyzed using integrated StepOnePlus® software (Life Technologies, Carlsbad, CA, USA). Each data set was normalized with an appropriate TaqMan endogenous control selected by NormFinder. Actb [Rn00667869_m1] was chosen as the housekeeping gene. Finally, data were recalculated to relative quantities and transformed to a $\log_2$ scale.

Results

To evaluate the effect of transplanted iPSC-NPs on endogenous regenerative processes, we examined the gene expression of several neurotrophic factors and the neurospecific genes Bdnf, Ngf, Vegfa, Fgf8, Dcx, Syp, Ppp1r1b, Drd1, Drd2, and Gap43 separately in the right (lesioned) and left hemispheres of control and transplanted animals 4 months after cell grafting using qPCR. This analysis was performed only for

animals with big lesions; similar results for animals with small lesions are presented in Polentes et al. (16). We found no significant differences in the expression of listed genes in transplanted animals vs. control animals with big lesions (**Supplementary Figure 4**).

Supplementary Figure 1 | Graft survival and localization in rat ischemic brains with small and big lesions showing immunohistochemical staining with MTC02, a marker of human mitochondria; magnification −1 mm.

Supplementary Figure 2 | Immunohistochemical staining of ischemic rat brain tissue with small lesion size 4 months after iPSC-NP transplantation. Grafted human neural precursors were identified by the staining for MTC02 **(A,B)**. They differentiated into NeuN- **(E)**, MAP2- **(F)** and DARPP32- **(D)** positive cells, actively integrated into the lesioned host tissue **(C,G)**.

Supplementary Figure 3 | Metabolite concentrations [IU] ± std for healthy animals.

Supplementary Figure 4 | Effect of transplanted iPSC-NPs on rat gene expression 4 months after MCAO.

Diabetes leads to an elevated risk of stroke and worse functional outcome compared to the general population. We investigate whether L-4F, an economical ApoA-I mimetic peptide, reduces neurovascular and white-matter damage in db/db type-2 diabetic (T2DM) stroke mice. L-4F (16 mg/kg, subcutaneously administered initially 2 h after stroke and subsequently daily for 4 days) reduced hemorrhagic transformation, decreased infarct-volume and mortality, and treated mice exhibited increased cerebral arteriole diameter and smooth muscle cell number, decreased blood-brain barrier leakage and white-matter damage in the ischemic brain as well as improved neurological functional outcome after stroke compared with vehicle-control T2DM mice ($p < 0.05$, $n = 11$/group). Moreover, administration of L-4F mitigated macrophage infiltration, and reduced the level of proinflammatory mediators tumor necrosis factor alpha (TNFα), high-mobility group box-1 (HMGB-1)/advanced glycation end-product receptor (RAGE) and plasminogen activator inhibitor-1 (PAI-1) in the ischemic brain in T2DM mice ($p < 0.05$, $n = 6$/group). *In vitro*, L-4F treatment did not increase capillary-like tube formation in mouse-brain endothelial cells, but increased primary artery explant cell migration derived from C57BL/6-aorta 1 day after middle cerebral artery occlusion (MCAo), and enhanced neurite-outgrowth after 2 h of oxygen-glucose deprivation and axonal-outgrowth in primary cortical neurons derived from the C57BL/6-embryos subjected to high-glucose condition. This study suggests that early treatment with L-4F provides a potential strategy to reduce neuroinflammation and vascular and white-matter damage in the T2DM stroke population.

Keywords: diabetes, stroke, blood–brain barrier (BBB), white matter (WM), inflammation

INTRODUCTION

Diabetes mellitus (DM) is a major risk factor for ischemic and hemorrhagic stroke. Stroke patients with DM exhibit a worse neurovascular prognosis and white-matter (WM) lesion and neurological function than non-DM stroke patients. Therefore, development of therapeutic approaches for the DM-stroke population are urgently needed.

Type-2 diabetes (T2DM) constitutes 90% of the DM population. DM patients have low levels of blood high-density lipoprotein (HDL) (Maron, 2000; Sharrett et al., 2001; Gotto and Brinton, 2004; Bonora, 2006) and impairment of HDL function such as the antioxidative capacity of HDL

(Bonora, 2006; Kontush and Chapman, 2006; Anan et al., 2010; Kruit et al., 2010; Mulder et al., 2011; Scheffer et al., 2011; Dullaart et al., 2012). Improved HDL functionality may contribute to maintenance of pancreas beta-cell function in subjects with well-controlled T2DM (Dullaart et al., 2012). Impairment of HDL anti-oxidative function in T2DM contributes to enhanced formation of oxidative stress products, such as advanced glycation end products (AGEs) (Mulder et al., 2011; Scheffer et al., 2011). Dysfunction of HDL also promotes inflammatory effects (Kruit et al., 2010) and increases proinflammatory factor activation, such as tumor necrosis factor alpha (TNFα) (Igarashi et al., 2008; Nayak et al., 2010; Gomez-Banoy et al., 2016), high-mobility group box 1 (HMGB1) and AGE receptor (RAGE) (Williams and Nadler, 2007; Ye et al., 2011), and plasminogen activator inhibitor-1 (PAI-1) (Scarabin et al., 1998; Bonora, 2006; Williams and Nadler, 2007; Al-Hamodi et al., 2011; Ye et al., 2011; Costa and Soares, 2013; Gorska-Ciebiada et al., 2016), which can exacerbate vascular and WM damage after stroke in T2DM. Therefore, improving HDL function through modification of its lipid and/or protein content maybe a therapeutic target for the treatment of stroke in T2DM.

In human, the circulating blood contains only about 40% of the total amount of HDL, with most of HDL particles present in human interstitial fluids including the arterial intimal fluid (Miller et al., 2013). The HDL particles in plasma contain either a single copy or multiple copies of apolipoprotein A-I (ApoA-I). ApoA-I has been shown to possess several atheroprotective functions, including inhibition of inflammation. However, ApoA-I is a selective target for oxidation by myeloperoxidase, which results in impaired HDL function (Imaizumi et al., 2011). 4F is an economical 18 amino acid peptide mimetic the tertiary structure of ApoA-I. There are two 4F species, D-4F (right hand) and L-4F (left hand). When administered subcutaneously, D-4F and L-4F are equally efficacious, D-4F is orally efficacious but L-4F is digested by gut proteases (Navab et al., 2009). Both of them have remarkable anti-inflammatory properties based on their ability to preferentially bind proinflammatory oxidized lipids and decrease serum oxidized low-density lipoprotein (LDL) level (Van Lenten et al., 2008; Liu et al., 2014; Yao et al., 2015), improve HDL function (Ou et al., 2005; Van Lenten et al., 2008; Yu et al., 2008; Navab et al., 2009; Nandedkar et al., 2011; Qin et al., 2012), and increase cholesterol efflux (Navab et al., 2004; Sherman et al., 2010). Our previous studies show that D-4F treatment of wild-type mice subjected to stroke reduces vascular and WM damage as well as improves recovery of neurological function 14 days after stroke (Cui et al., 2016). Rats with type-1 diabetes and subjected to stroke receiving orally administered D-4F initiated at 2 h after stroke, and subsequently at 24 and 48 h after stroke exhibit significantly decreased neuroinflammation (Ning et al., 2017). However, to our knowledge, there are no studies investigating whether L-4F has a therapeutic effect on stroke-induced vascular and WM damage in T2DM mice. In this study, we therefore investigated the hypothesis that anti-inflammation may play an important role in L-4F treatment of stroke induced neuroprotection and reduction of WM damage in a clinically relevant stroke model using db/db T2DM mice.

MATERIALS AND METHODS

Animal Stroke Model and Experimental Groups

The number of animals for the *in vivo* study was calculated *a priori* by power analysis. For blood biochemistry, lesion volume, and histochemical/immunohisto-staining measurement, 11 mice per group survival stroke animals were targeted to achieve a power of 0.83 at a significance level of < 0.05, assuming 25% difference in mean, a 20% standard deviation at the 95% confidence level. For Western-blot (WB) and real time-quantitative PCR (RT-qPCR) assays, 6 stroke mice per group were needed. To meet these experimental targets, a total of 90 adult male T2DM mice (BKS.Cg-$m + / + Lepr^{db}$/J, db/db mice, 3 month old, Jackson Laboratory, Wilmington, MA, United States) were used. For middle cerebral artery occlusion (MCAo) surgery, animals were anesthetized with 2% isoflorane in a jar for pre-anesthetic, and spontaneously respired with 1.5% isoflurane in 2:1 N_2O:O_2 mixture using a facemask connected and regulated with a modified FLUOTEC 3 Vaporizer (Fraser Harlake). Rectal temperature was maintained at 37°C throughout the surgical procedure using a feedback regulated water heating system. Transient right MCAo was induced for 1 h by advancing a 6-0 surgical nylon suture (8.0–9.0 mm), determined by the animal weight, with its tip rounded by heating near a flame, to block the origin of the MCA, using a method of intraluminal vascular occlusion modified in our laboratory (Liu et al., 2007). One hour after MCAo, reperfusion was performed by withdrawal of the suture. Two hours after suture withdrawal mice were randomly separated into three groups by drawing different colored balls:

(1) Sham-control group: mice were subjected to the same procedures as the MCAo without insertion of filament ($n = 4$ mice).
(2) MCAo group: mice were subcutaneously administered saline daily for 4 days ($n = 52$ mice).
(3) L-4F treatment group: mice were administered L-4F (BioMatik, Cambridge, ON, Canada) 16 mg/kg ($n = 34$ mice) and subsequently daily for 4 days. All survival animals were sacrificed 4 days after MCAo.

Functional Tests

To evaluate neurological functional deficits and recovery after stroke, all animals were evaluated on the modified neurological severity score (mNSS, the total score is 12) and left foot-fault test before MCAo (as the baseline) and at 1, 3, and 4 days after MCAo, as previously described (Chen et al., 2001; Shehadah et al., 2014). Functional analyses were performed by an investigator blinded to the experimental groups.

Blood Biochemistry Measurement

To test blood biochemistry, the animals were fasted overnight and blood was collected from tail vein before MCAo as the baseline and prior to sacrifice. Blood levels of glucose were measured using glucose test strips in a glucose analyzer (Accu-Chek Compact System; Roche Diagnostics, Basel, Switzerland), and the levels of HDL, total-cholesterol (T-CH) and triglyceride were tested using

CardioChek P●A analyzer (Polymer Technology System, Inc., Indianapolis, IN, United States), following the manufacturer's instructions. Each sample was tested in triplicate and the data are presented as mg/dl values.

Cerebral Hemorrhagic Transformation, Lesion Volume, and Survival Rate Measurement

All brains were fixed by transcardial-perfusion with saline, followed by perfusion and immersion in 4% paraformaldehyde and were then embedded in paraffin. Using a mouse brain matrix (Activational Systems Inc., Warren, MI, United States), the cerebral tissues were cut into seven equally spaced (1 mm) coronal blocks, and a series of adjacent 6 μm thick sections were cut from each block. Seven coronal sections of tissue were processed and stained with hematoxylin and eosin (HE). For calculation of brain hemorrhage volume, the percentage areas of petechial and gross hemorrhage were measured in each histological section and summed. For lesion volume measurement, the indirect lesion area was calculated, in which the intact area of the ipsilateral hemisphere was subtracted from the area of the contralateral hemisphere. Lesion volume is presented as a volume percentage of the lesion compared with the contralateral hemisphere (Swanson et al., 1990). For evaluation of mortality, all animals were counted daily. The total number of dead animals in each group was counted within the 4 days after MCAo. The survival rate is presented as a percentage of the total number of stroke animals in each group.

Histochemical and Immuno-Staining

For histochemical/immunostaining, a standard paraffin block was obtained from the center of the lesion (bregma −1 to +1 mm). A series of 6-μm thick sections were cut from the block. Every 10^{th} coronal section for a total of five sections was used. Histochemical-staining for Bielshowsky silver (BS, an axon marker) and Luxol fast blue (LFB, a myelin marker), or histoimmino-staining for antibodies against albumin (BBB leakage marker, 1:500; Abcam), von Willebrand Factor (vWF, a vessel marker, 1:400; Dako), α-smooth muscle actin (αSMA, a smooth muscle cell-SMC marker, 1:800, Dako), SMI31 (a marker of phosphorylated-neurofilament, 1:1000, Covance), platelet-derived growth factor receptor alpha (PDGFRα, a marker of oligodendrocyte progenitor cells-OPCs, 1:100, Chemicon), and HMGB1 (1:800, Abcam) were performed. For immunostaining measurement, five sections with each section containing 8 fields of view within the cortex and striatum from the ischemic boundary zone (IBZ), defined as the area surrounding the lesion, which morphologically differs from the surrounding normal tissue, were digitized using a 40X objective (Olympus BX40) using a 3-CCD color video camera (Sony DXC-970MD) interfaced with an MCID computer imaging analysis system (Imaging Research, St. Catharines, ON, Canada).

BBB Leakage Measurement

Cerebral infiltration of albuminuria, which is associated with DM, has been flagged as a predictor for cerebrovascular events (Anan et al., 2008) and as an index of BBB permeability (Wallin et al., 2000). In this study, to test whether L-4F treatment enhances BBB-integrity after stroke in T2DM mice, the albumin density in the ischemic brain was measured. The positive area of albumin in the ischemic border area is presented.

Vascular Density, Perimeter/Diameter, and Cell Number Measurement

vWF-immunoreactivity was employed to identify vascular vessels, and αSMA was used as a marker of arterioles (Ho et al., 2006). The density and perimeter of vWF-coated vessels, and the number and diameter of αSMA-positive arterioles (have only one to two layers of SMCs, diameter 10–20 μm) were analyzed in the IBZ. The diameter is presented as the average of a total 10 largest arteries in the IBZ.

WM Density and OPC Number Measurement

For measurement of WM-density, the BS, LFB, or SMI31 -positive area in the WM bundles of striatum and the total number of PDGFRα^{+}-OPCs in the IBZ of the striatum were measured in each referenced coronal section using the MCID computer imaging analysis system.

Real-Time RT-PCR Assay

Tissues from the ischemic area of the ipsilateral hemisphere from both vehicle-control and L-4F-treatment T2DM mice were isolated 4 days after MCAo. Total RNA was isolated using a standard protocol. Quantitative PCR was performed on an ABI 7000 PCR instrument (Applied Biosystems, Foster City, CA, United States) using three-stage program parameters provided by the manufacturer. Each sample was tested in triplicate, and analysis of relative gene expression data using the $2^{-\Delta\Delta CT}$ method. The following primers for RT-PCR were designed using Primer Express software (ABI). TNFα: Fwd: TACTCCCAGGTTCTCTTCAAGG, Rev: GAGGTTGACTTTCTCCTGGTA; PAI-1: Fwd: GTCTTTCCG ACCAAGAGCAG.

Rev: ATCACTTGGCCCATGAAGAG; GAPDH: Fwd: AGA ACA TCA TCC CTG CAT CC, Rev: CAC ATT GGG GGT AGG AAC AC.

Western Blot (WB) Assay

Equal amounts of brain-tissue lysate from the ischemic area of the ipsilateral hemisphere were subjected to WB analysis. Specific proteins were visualized using a SuperSignal West Pico chemiluminescence kit (Pierce). The following primary antibodies were used: anti-RAGE (1:1000, rat, R&D MAB1179), anti-HMGB1 (1:1000, rabbit, Abcam ab18256), anti-TNFα (1: 1000, Abcam ab9755), anti-PAI-1 (1:500, rabbit, Santa Cruz sc-8979), anti-ED1 (CD68, 1:800, Bio-rad, MCA341, a single chain glycoprotein of 90–110 kDa, is the widely used pan-macrophage marker), and anti-β-actin (1:2000; Santa Cruz sc-1616) for 16 h at 4°C. The membranes were washed with blocking buffer without milk, and then incubated with horseradish peroxidase-conjugated secondary antibody in blocking buffer.

Mouse Brain Cerebral Endothelial Cell (bEnd.3) Culture and Capillary-Like Tube Formation Assay

The bEnd.3 cell line (ATCC, cat# CRL02299) was used. Briefly, 0.1 ml growth factor reduced Matrigel (Becton Dickinson) was added per well of a 96 well plate, and cells (2×10^4 cells) were seeded in Matrigel and cultured with serum free DMEM medium. The cells were divided into four groups (n = 6 wells/group), and treated with: (1) normal-glucose (12.5 mM glucose) as control; (2) high-glucose (HG, 37.5 mM glucose); (3) HG + L-4F (50 ng/ml); (4) HG + L-4F (100 ng/ml). Cells were incubated for 5 h and the capillary tube formation measurement was performed. For quantitative measurements of capillary tube formation, Matrigel wells were digitized under a 4X objective (Olympus BX40). Tracks of cells organized into networks of cellular cords (tubes) were counted and averaged in randomly selected three microscopic fields, and the total tube length of capillary tube formation was measured using a video camera (Sony DXC-970MD) interfaced with the MCID image analysis system.

Primary Artery Cell Migration Measurement

To investigate whether L-4F treatment promotes arterial cell migration in hyperglyceridemia, a primary artery explant culture model was employed (Cui et al., 2011). The aorta was surgically removed from adult C57BL/6 wild-type mice (6–8 weeks, purchased from Jaxson Lab) 24 h after MCAo. The artery explant was cut to 1 mm^3 and placed in Matrigel and cultured with DMEM medium containing 2% B27. The artery explants were divided into four groups as follows: (1) normal glucose (12.5 mM) as a control; (2) HG (37.5 mM glucose); (3) HG + L-4F (50 ng/ml); (4) HG + L-4F (100 ng/ml). Arterial explant cultures were allowed to grow for 5 days before being photographed and the 10 longest distances of outgrowth were measured under a microscope at 4X magnification, processed with the MCID and averaged. n = 6/group.

Primary Cortical Neuron (PCN) Culture and Neurite/Axonal Outgrowth Measurements

The PCNs derived from E15 C57BL/6 embryos were employed, as previously described (Cui et al., 2016). Briefly, embryos were removed, and the cerebral cortex was dissected out, stripped of meninges, and dissociated by a combination of Ca^{2+}- and Mg^{2+}-free Hanks balance salt solution (HBSS) containing 0.125% trypsin digestion and mechanical trituration. The dissociated cell suspensions were seeded into poly-L-lysine precoated plates in a density of 10^5 cells/cm^2. The cells were grown in Dulbecco's Modified Eagle Medium (DMEM, Invitrogen, Carlsbad, CA, United States) supplemented with 5% fetal bovine serum (FBS, GIBCO, Grand Island, NY, United States) at 37°C with 5% CO_2. After 24 h, the cell cultures were switched to incubate with serum-free neurobasal medium (Invitrogen) with 2% B27 supplement (GIBCO), 0.5 mM L-glutamine, and 1% antibiotic-antimycotic media.

To test whether L-4F dose-dependently increases neurite-outgrowth in hyperglycemia after ischemia, the PCN cultures were subjected to 2 h of oxygen and glucose deprivation (OGD) on day-*in vitro* 4 (DIV4) followed by 24 h of reperfusion. The DIV5 OGD-PCNs were randomly divided into (n = 6 wells/group): (1) normal glucose control; (2) HG; (3) + L-4F 50 ng/ml; (4) + L-4F 100 ng/ml for 24 h. The PCN cultures were then stained with TUJ1 (a phenotypic marker of neural cells, 1:1000, Covance) with Cy3 and photographed using a 10 × objective fluorescent microscope (Zeiss). The average length of the 20 longest neurites in each well was calculated (Cui et al., 2016).

For testing whether L-4F increases axonal-outgrowth in HG condition, the axonal-outgrowth was measured using a microfluidic axonal growth model (Standard Neuron Device; catalog No SND450, Xona Microfluidics) (Cui et al., 2016). On DIV4, the PCN cultures were divided into four groups (n = 6 well/group): (1) normal glucose control; (2) HG; (3) + L-4F 50 ng/ml; (4) + L-4F 100 ng/ml. All axon-cultures were allowed to grow for an additional 48 h and were subjected to TUJ-1 immunostaining, and the axonal-outgrowth was measured on DIV6. The average length of the 10 longest axons in each well was calculated.

Statistical Analysis

One-way ANOVA followed by Tukey *Post Hoc* Test were used for analysis of the differences among the three or four groups of sham, MCAo and L-4F treatment *in vivo* or *in vitro* experiments. $p < 0.05$ was set as a significant difference, and all data are presented as mean ± Standard Error (SE).

RESULTS

L-4F-Treatment Deceases Hemorrhage/Lesion Volume and Mortality Rate, and Improves Functional Outcome After Stroke in T2DM Mice

There were no significant differences in the levels of blood glucose, HDL, T-CH, and triglyceride among animals of sham-control (n = 4) and MCAo groups treated with or without L-4F (n = 11/group) 4 days after MCAo, respectively (**Figures 1A,B**). However, L-4F treatment of MCAo mice significantly decreased hemorrhage volume (**Figure 1C**, n = 11/group), and reduced lesion volume (**Figure 1D**, n = 11/group) and mortality rate (**Figure 1E**, n = 52 in MCAo-control group, n = 34 in L-4F treatment group) compared to the MCAo-control group ($p < 0.05$).

Stroke induced significant functional deficits as indicated by significantly increased mNSS and left foot-fault at 1, 3, and 4 days in T2DM mice in the MCAo-control group (n = 11) compared with non-stroke T2DM mice in the sham-control group (n = 4, $p < 0.05$). L-4F treatment significantly improved neurological functional outcome 4 days after MCAo in T2DM-stroke mice

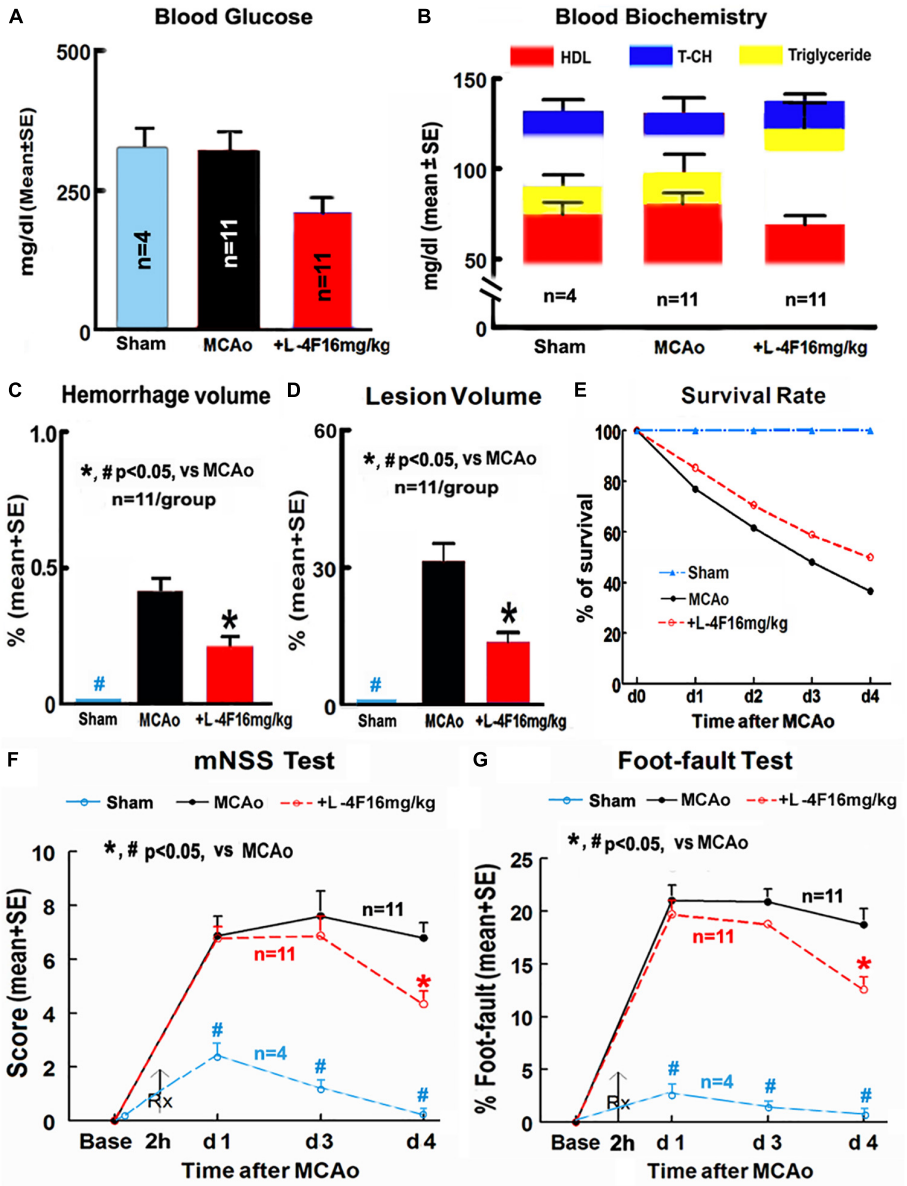

FIGURE 1 | L-4F treatment did not change blood biochemistry, but decreases hemorrhage/lesion volumes in the ischemic brain and reduces mortality, and improves functional outcome in T2DM mice 4 days after MCAo. **(A)** Blood levels of glucose; **(B)** blood level of HDL, T-CH, and triglyceride; **(C)** hemorrhage volume; **(D)** lesion volumes; **(E)** survival rate; **(F,G)** functional outcome.

(**Figures 1F,G**, $p < 0.05$, $n = 11$/group). These data indicate that L-4F significantly decreases cerebral hemorrhagic transformation and reduces lesion volume and mortality as well as improves neurological functional outcome, independently of blood HDL and glucose level.

L-4F Treatment Reduces Vascular Damage in the Ischemic Brain in T2DM Mice

There was no albumin infiltration in the non-stroke brains ($n = 4$). However, albumin infiltration was observed in the ischemic core area in the T2DM-stroke brains, and the albumin density was significantly decreased in the L-4F treatment group compared with MCAo-control group (**Figure 2A**, $p < 0.05$, $n = 11$/group). These data indicate that the integrity of the BBB was compromised in the ischemic brain in T2DM stroke mice, and early L-4F treatment protects BBB integrity in the ischemic brain after stroke in T2DM mice. These data (i.e., BBB disruption as measured using albumin) are consistent with our previous study that D-4F enhances BBB-integrity as detected by Evans blue (EB) dye infiltration detection in the ischemic brain in C57BL/6 wild type mice after stroke (Cui et al., 2016).

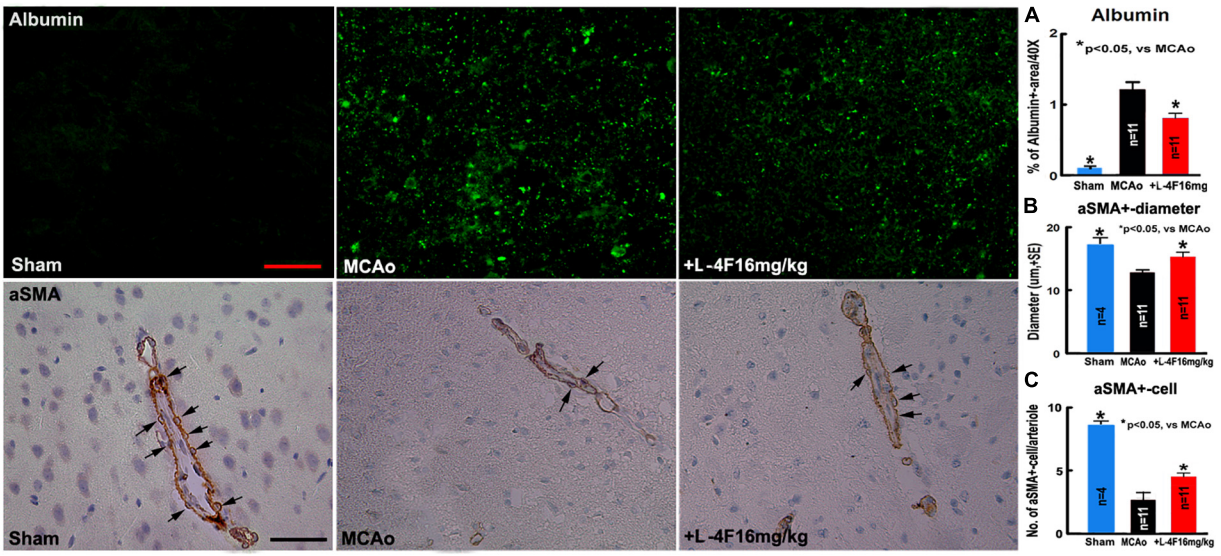

FIGURE 2 | L-4F treatment decreases BBB-leakage, increases SMC number and arteriolar diameter in the ischemic brain in T2DM mice 4 days after MCAo; **(A)** albumin-immunostaining and quantitative data; **(B)** αSMA-immunostaining and quantitative data. **(C)** Numbers of αSMA^+-cells in the arteriolar walls. Scale bar = 25 μm; n = 4 in sham-control group, n = 11 in MCAo-control and L-4F treatment group.

Using vascular density, diameter and perimeter to indicate vascular structure changes, we found that there is no difference in the density/perimeter of vWF^+-vessels among the sham-control, MCAo-control and L-4F treatment groups, and no differences in the density of αSMA^+-arterioles between sham-control and MCAo-control groups. However, both the diameter of αSMA^+-arterioles and the number of αSMA^+-SMCs were significantly decreased in the MCAo-control group (n = 11) compared with sham-control group (n = 4), and the diameter of αSMA^+-arterioles (**Figure 2B**) and the number of αSMA^+-SMCs (**Figure 2C**) in the IBZ significantly increased in the L-4F treatment group compared with MCAo-control group ($p < 0.05$, n = 11/group). These data indicate that vascular structure was damaged in ischemic brain in T2DM stroke mice, and early L-4F treatment has a vascular protective effect on the ischemic brain after stroke in T2DM mice.

L-4F Treatment Decreases WM-Damage and OPC Loss in the Ischemic Brain in T2DM Mice

To investigate whether L-4F reduces WM-damage and OPC loss after stroke, we measured the densities of BS^+ (axon marker, **Figure 3A**), $\alpha SMI31^+$ (phosphorylated-neurofilament marker, **Figure 3B**), LFB^+ (myelin marker, **Figure 3C**) and the number of PDGFR(+-OPCs (**Figure 3D**) in the IBZ of striatum in the ischemic ipsilateral hemisphere, respectively. Compared with sham-control mice (n = 4), the MCAo-control mice (n = 11) exhibited a significant decrease in the densities of axons, phosphorylated-neurofilament, myelin and the number of OPCs 4 days after MCAo ($p < 0.05$). However, L-4F treatment significantly increased the densities of axons, phosphorylated-neurofilaments, myelin and the number of OPCs 4 days after MCAo compared with MCAo-control group ($p < 0.05$, n = 11/group). These data indicate that L-4F treatment decreases WM damage and OPC loss after stroke in T2DM mice.

L-4F Treatment Reduces Macrophage Infiltration and Decreases RAGE/HMGB1 and PAI-1 Expression in the Ischemic Brain After Stroke in T2DM Mice

To investigate the mechanism underlying L-4F treatment-induced neuroprotection in T2DM, the macrophage infiltration was measured by ED1 protein level, and the protein and mRNA levels of HMGB1, RAGE, TNFα, and PAI-1 were measured by using immunostaining, WB or RT-PCR assay, respectively. The data show that L-4F treatment significantly decreases HMGB1 protein levels measured by immunostaining (**Figures 4A–D**, n = 11/group) and reduces RAGE/ED/HMGB1 level measured by WB (**Figures 4E,F**, n = 6/group). Moreover, L-4F treatment significantly decreases TNFα and PAI-1 protein and mRNA level (**Figures 4G–I**) in the ischemic ipsilateral brain compared to MCAo-control group ($p < 0.05$, n = 6/group).

L-4F Treatment Does Not Change Capillary-Like Tube Formation, but Increases Artery Explant Cell Migration Under HG Condition

To confirm the *in vivo* findings, *in vitro* capillary-like tube formation assay for angiogenesis and primary artery explant cell migration for artery function test were employed. L-4F treatment at concentrations of 50 or 100 ng/ml did not increase capillary tube formation under HG conditions compared to non-treatment control (**Figure 5A**). However, L-4F treatment

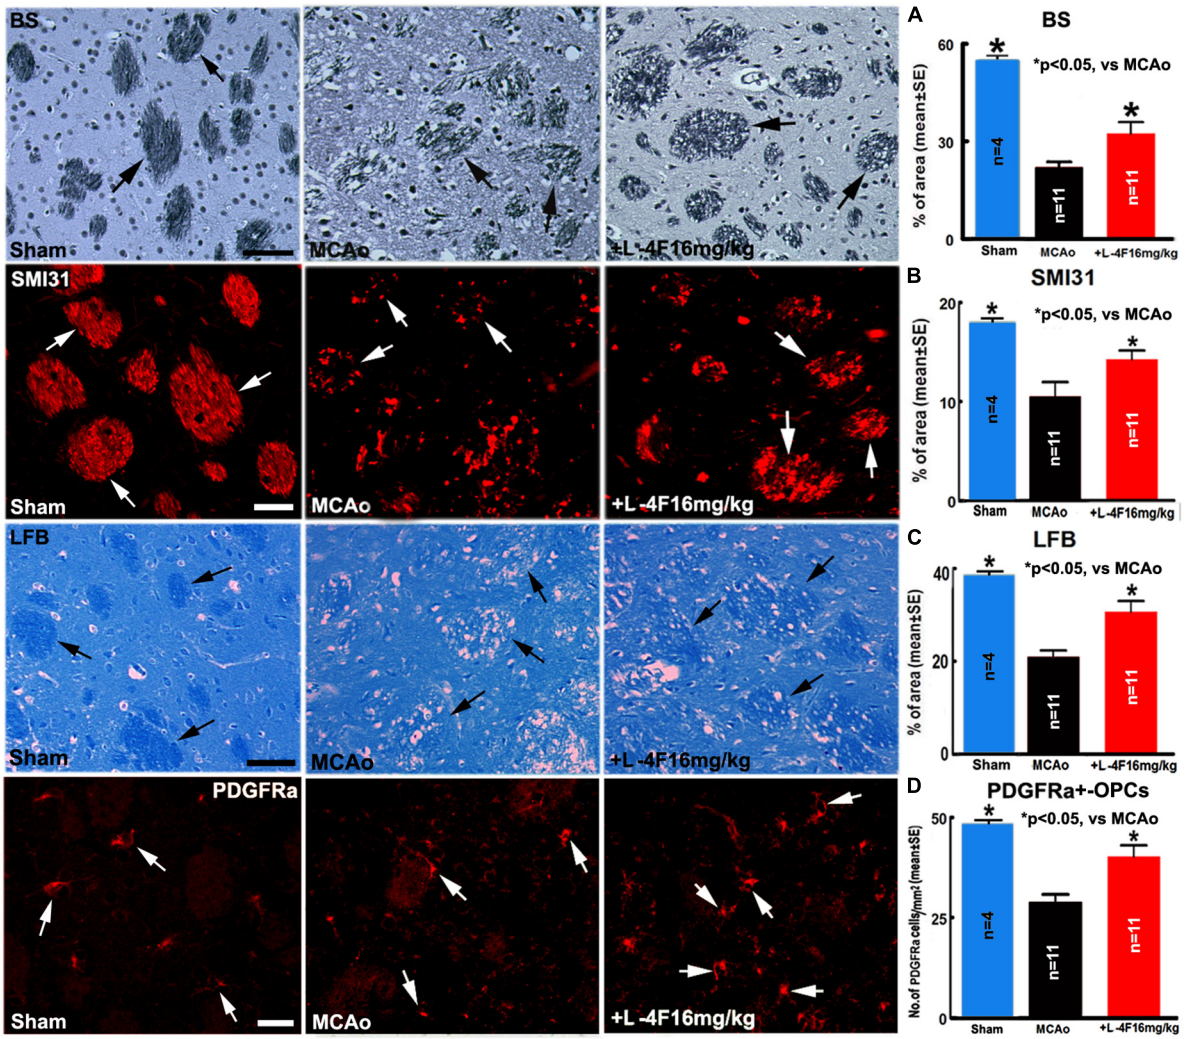

FIGURE 3 | L-4F treatment increases WM density and OPC numbers in the ischemic brain in T2DM mice 4 days after stroke. **(A)** BS^{+} -axon and quantitative data; **(B)** SMI31^{+} -neurofilament and quantitative data; **(C)** LFB^{+} -myelin and quantitative data; **(D)** PDGFRα^{+} -OPCs and quantitative data. Scale bar in **(A,C)** = 40 μm; in **(B,D)** = 20 μm. *$p < 0.05$, $n = 4$ in sham-control group, $n = 11$ in MCAo-control and L-4F treatment group.

significantly increases artery explant cell migration at both 50 and 100 ng/ml concentration in HG media (**Figure 5B**, $p < 0.05$, $n = 6$/group) compared to non-treatment control, respectively. These data suggest that L-4F does not change angiogenesis, but increases arterial function in HG condition.

L-4F Treatment Increases Neurite/Axonal Outgrowth in HG Condition

To confirm the *in vivo* findings that L-4F treatment protects WM damage, we measured the neurite and axonal outgrowth under HG conditions. To mimic *in vivo* ischemia, the PCNs were subjected to 2 h of OGD. The data show that HG decreases PCN neurite outgrowth, but L-4F treatment (both 50 and 100 ng/ml) significantly increases PCN neurite outgrowth after ischemia (**Figure 6A**). In addition, L-4F (50 and 100 ng/ml) also increases and axonal outgrowth in HG condition compared with non-treatment control group (**Figure 6B**, $p < 0.05$, $n = 6$ wells/group).

DISCUSSION

T2DM confers increased micro- and macro- vascular complications and amplifies of morbidity and mortality after ischemic stroke (Basu et al., 2005; Madonna and De Caterina, 2011). Compared to non-DM stroke patients, T2DM stroke patients have chronic states of oxidative stress and inflammation, which accompany long-term endothelial dysfunction and impaired vasodilation, and increased vasogenic edema, BBB damage, and secondary hemorrhage transformation (Capes et al., 2001; Kruger et al., 2005; Ergul et al., 2007; Peterson et al., 2007; Ding et al., 2015). WM-damage is an important prognostic factor for the development of functional deficits after

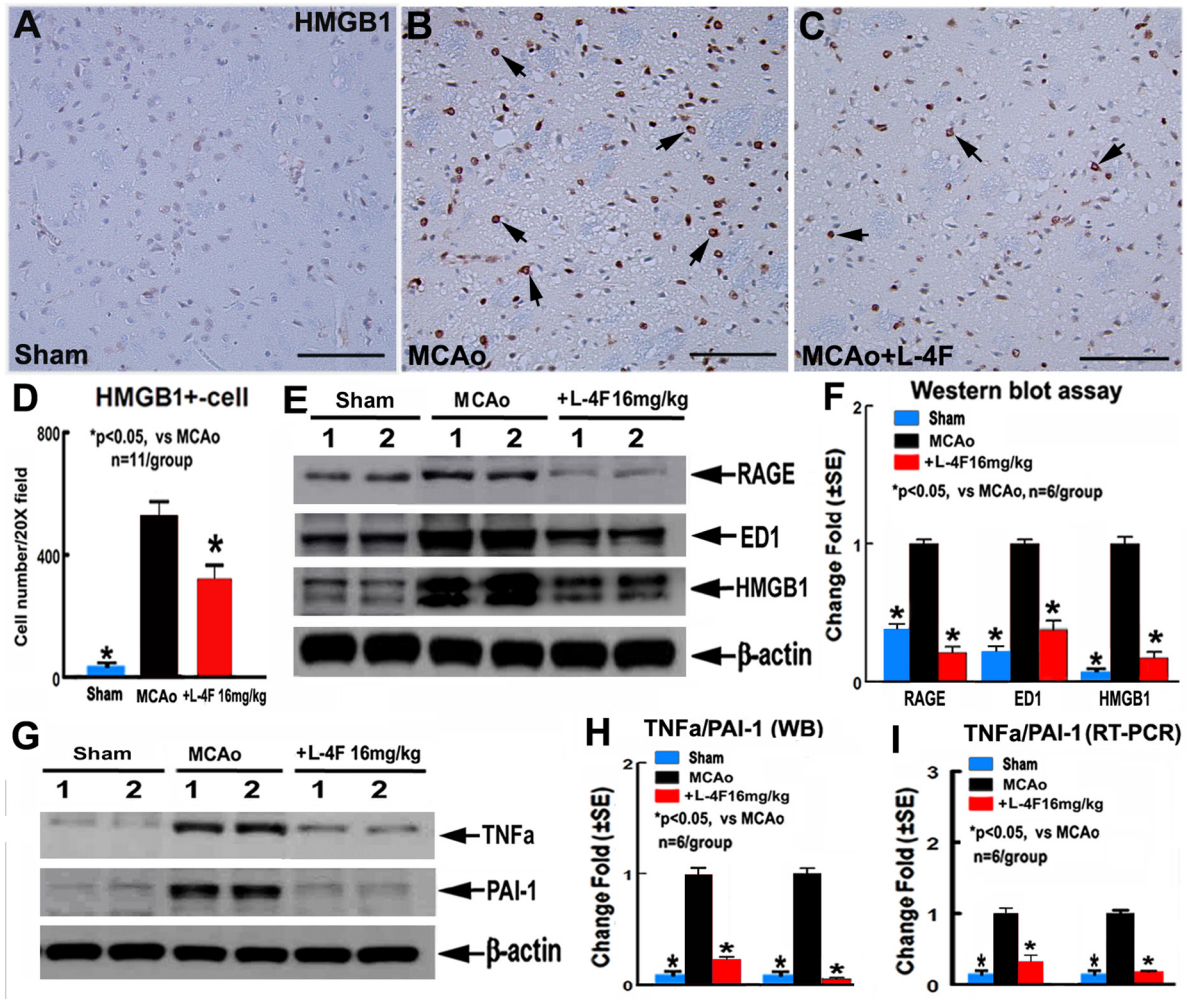

FIGURE 4 | L-4F treatment decreases RAGE/ED1/HMGB-1, and PAI-1 in the ischemic brain in T2DM mice 4 days after MCAo. **(A–D)** HMGB-1 immunostaining and quantitative data; **(E,F)** RAGE/ED1/HMGB-1 WB assay and quantitative data; **(G,H)** TNFα/PAI-1 WB assay and quantitative data; **(I)** TNFα/PAI-1 RT-PCR data. stroke (Anan et al., 2008), BBB and WM damage which are associated with enlarged infarct volume and worse functional outcome after stroke is found in both the experimental T2DM rodents and T2DM patients (Mooradian et al., 2005; Ennis and Keep, 2007; Anan et al., 2010). D-4F increases arterial concentrations of hemeoxygenase-1 and superoxide dismutase, decreases superoxide levels and endothelial cell fragmentation, and restores arterial vasoreactivity to normal in DM animal models (Ou et al., 2003, 2005; Kruger et al., 2005; Sherman et al., 2010). In a mouse model of systemic sclerosis, D-4F functioned to improve vasodilation and angiogenic potential, while reducing myocardial inflammation and oxidative stress (Sherman et al., 2010). In addition, L-4F dramatically improves impaired vasodilation in LDL receptor knockout (Ldlr−/−) mice, via decreased oxidative damage to endothelium (Ou et al., 2003). In our previous study, using a dose-dependent effect on MCAo model in wild type mice, an elevated concentration of D-4F (32 mg/kg) did not provide increased benefit on neurovascular and WM remodeling compared to treatment with a reduced concentration (16 mg/kg) (Cui et al., 2016). D-4F and L-4F have similar anti-inflammatory properties (Van Lenten et al., 2008; Liu et al., 2014; Yao et al., 2015). Therefore, in the present study, the dose of 16 mg/kg L-4F, the same as the optimal dose of D-4F identified from our previous study was used. db/db mice are gene knockout mice which mimic features of human T2DM and have been widely used to investigate diabetic stroke (Vannucci et al., 2001; Kumari et al., 2010; Chen et al., 2011; Cui et al., 2011; Kumari et al., 2011; Sims-Robinson et al., 2012). The db/db stroke mice exhibit increased neurovascular and WM damage and hemorrhagic/mortality rate compared with non-DM stroke mice (Chen et al., 2011; Cui et al., 2011; Ye et al., 2011). In the current study, db/db mice were employed as the T2DM model. We found that L-4F treatment initiated from 2 h post-stroke onset significantly decreased animal mortality rate and hemorrhage/infarct volume, decreased BBB leakage and WM damage, as well as increased vascular SMC

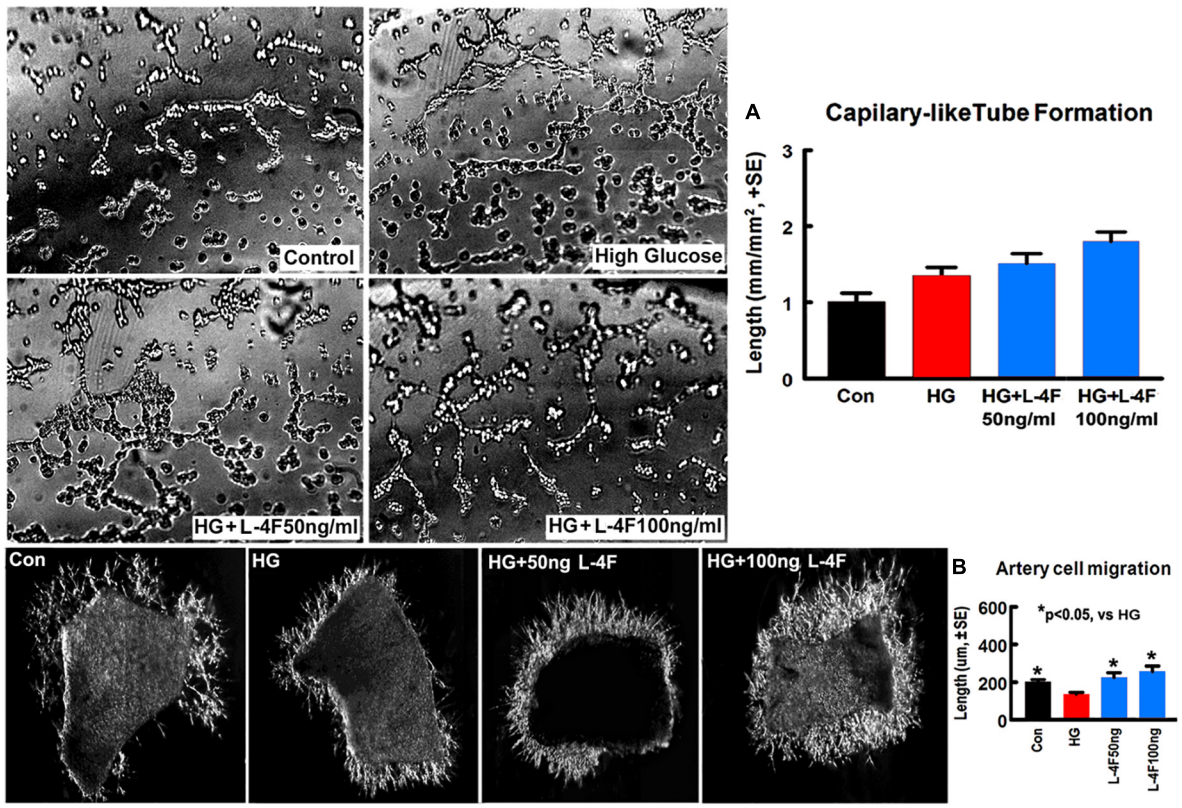

FIGURE 5 | L-4F treatment does not change capillary-like tube formation, but increases artery cell migration in normal and HG condition. **(A)** *In vitro* capillary-like tube formation and quantitative data; **(B)** primary cultured artery cell migration and quantitative data in normal and high glucose condition. $*p < 0.05$, $n = 6$ well/group.

and OPC numbers and enlarged arteriolar diameter in the ischemic brain 4 days after stroke. *In vitro* study shows that L-4F treatment did not change angiogenesis of mouse cerebral endothelial cells, but increased artery explant cell migration and neurite/axon outgrowth under HG condition. These data suggest that improving vascular integrity and retaining vasodilation as well as protecting WM damage, but not necessarily angiogenesis may play important role in L-4F induced neuroprotective effects.

In the brain of both T2DM patients and animal models, the extensive vascular and WM damage are highly associated with and are a consequence of inflammation (Golay et al., 1987; Williams and Nadler, 2007; Anan et al., 2010; Doll et al., 2015). Under normal physiology, RAGE is expressed at low levels, but it is highly upregulated in T2DM under chronic inflammation states because of the accumulation of various RAGE ligands such as AGEs and HMGB1. Blocking RAGE signaling in cell and animal models has revealed that targeting RAGE impairs inflammation and progression of DM vascular complications (Hudson and Lippman, 2018). M1-phage macrophages ($ED1^+$) constitute about 70% of infiltrating cells and exert a major inflammatory function in the brain lesions (Tran et al., 1998). HMGB1 is mainly released from activated immune cells, such as the peripherally infiltrating immune cells (e.g., macrophage/monocytes) in the ischemic brain (Wang et al., 2010; Qin and Crews, 2012; Crews and Vetreno, 2014). HMGB-1 functions also as a proinflammatory factor, promotes cell toxicity and cell death, regulates clot-promoting properties which propagate further inflammation and coagulation (Semeraro et al., 2012), and contributes to the initiation and progression of stroke (Hu et al., 2016). In the present study, L-4F treatment significantly reduced macrophage infiltration and HMGB1/RAGE level. These data suggest that L-4F treatment suppresses neuroinflammation in the ischemic brain, which may contribute to L-4F induced neuroprotective effects in T2DM stroke mice.

High stroke risk in T2DM patients is often related to their accelerated endothelial dysfunction which is accompanied by an array of abnormalities, including altered endothelial-dependent vasodilation, and an imbalance between local pro- and anticlotting factors (Scarabin et al., 1998; Bonora, 2006; Al-Hamodi et al., 2011; Costa and Soares, 2013; Gorska-Ciebiada et al., 2016). The AGE/RAGE signaling pathway not only promotes inflammation such as TNFα and cell death, but also increases endothelial activation biomarker PAI-1 expression in cultured endothelial cells (He et al., 2003; Gregorio et al., 2018). Moreover, TNFα also exerted a stimulatory effect on PAI-1 protein release and increased PAI-1 mRNA levels in T2DM (Birgel et al., 2000; de Carvalho et al., 2006). Recombinant

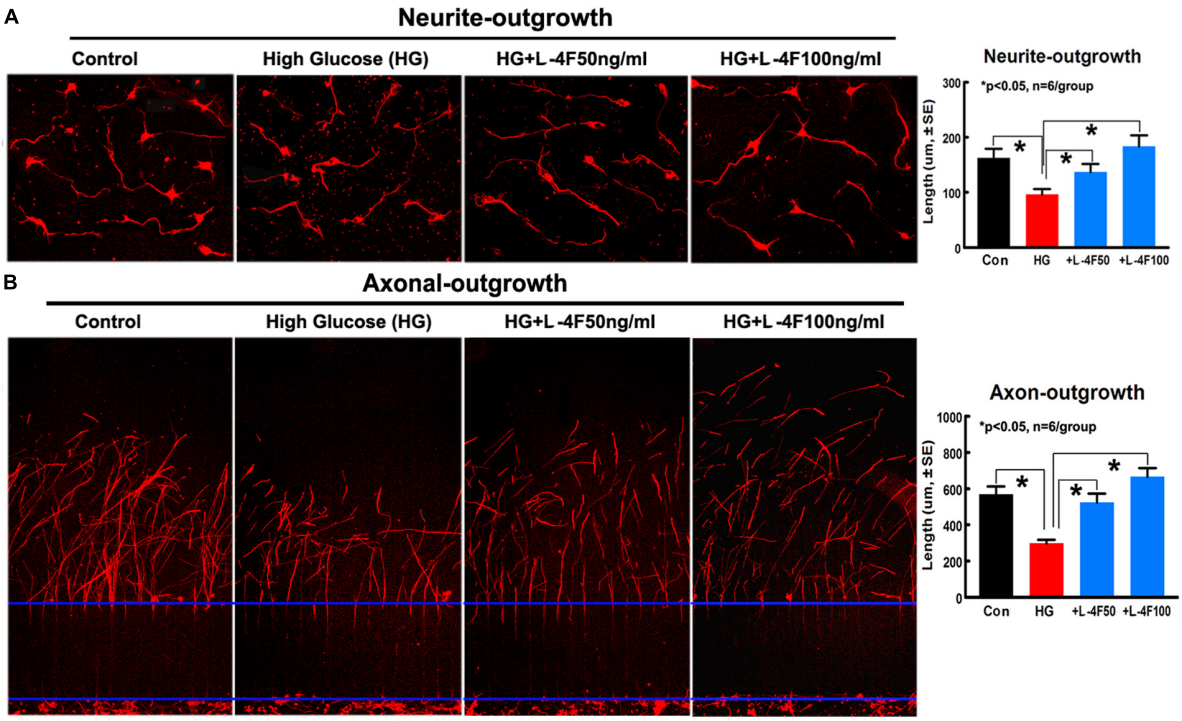

FIGURE 6 | L-4F treatment increases neurite and axonal outgrowth under HG condition. **(A)** *In vitro* neurite outgrowth and quantitative data. **(B)** Axonal-outgrowth and quantitative data. *$p < 0.05$, $n = 6$ well/group.

human HMGB1 increases the secretion of PAI-1 and tissue plasminogen activator (tPA) in cultured human endothelial cells, and elicits proinflammatory responses of endothelial cells and may contribute to alterations in endothelial cell function in human inflammation (Fiuza et al., 2003). HMGB-1 can bind to both tPA and plasminogen, and enhance tPA-dependent fibrinolytic activity, while PAI-1 is a key negative regulator of fibrinolysis through inhibition of plasminogen and tPA (Scarabin et al., 1998; Bonora, 2006; Al-Hamodi et al., 2011; Costa and Soares, 2013; Gorska-Ciebiada et al., 2016). Moreover, PAI-1 exerts various cellular effects independently of fibrinolysis, such as insulin resistance, metabolic abnormalities and endothelial dysfunction as well as pro-inflammatory effects (Cheng and Daskalakis, 2015; Kaji, 2016). PAI-1 is significantly increased in DM subjects compared with non-DM subjects with or without cardiovascular disease (Scarabin et al., 1998; Bonora, 2006; Al-Hamodi et al., 2011; Costa and Soares, 2013; Gorska-Ciebiada et al., 2016). In the present study, L-4F treatment significantly decreases TNFα and PAI-1 expression in the ischemic brain which may partially contribute to L-4F treatment-induced vascular and WM protection in T2DM stroke mice.

Plasma levels of HDL and glucose are highly associated with WM lesions in T2DM patients not receiving insulin treatment (Anan et al., 2010). Moreover, severe vascular and WM damage and neurological functional deficits in diabetic stroke populations are highly associated with dysfunction of HDL in the plasma (Anan et al., 2010; Kruit et al., 2010). Using ApoE-null (ApoE-/-) mice, administration of L-4F (20 mg/kg body weight, once daily subcutaneously) increases HDL level and ApoA-I concentration at 72 h post initial dosing (Chen et al., 2009). However in our study, T2DM mice subjected to stroke and treated with L-4F for 4 days did not exhibit significant changes in blood HDL cholesterol, triglyceride and glucose levels. Our data are consistent with others that D-4F or L-4F have no effect on blood T-CH or HDL concentrations (Navab et al., 2004, 2006, 2009; Kruger et al., 2005; Ou et al., 2005; Bloedon et al., 2008; Van Lenten et al., 2008; Yu et al., 2008; Morgantini et al., 2010; Sherman et al., 2010; Nandedkar et al., 2011). Other studies show that D-4F or L-4F reduces proinflammatory HDL levels and changes HDL function, increases cholesterol efflux, reduces lipoprotein oxidation and improves arterial vasoreactivity in T2DM patients, and in DM mice and rats (Navab et al., 2004, 2006, 2009; Kruger et al., 2005; Ou et al., 2005; Bloedon et al., 2008; Van Lenten et al., 2008; Yu et al., 2008; Morgantini et al., 2010; Sherman et al., 2010; Nandedkar et al., 2011). In addition, high levels of blood PAI-1 are associated with decreased functional HDL in T2DM patients (Bonora, 2006; Al-Hamodi et al., 2011; Gorska-Ciebiada et al., 2016). HDL can also regulate inflammatory responses in various types of cells that have been activated by proinflammatory stimuli in the arterial wall cells including endothelial cells and vascular SMCs (Mineo and Shaul, 2013). Therefore, we speculate that L-4F treatment may improve HDL function and decrease neuroinflammation, and thereby lessens vascular and WM damage after stroke in db/db T2DM mice.

CONCLUSION

This study demonstrates that L-4F, an economical ApoA-I mimetic peptide, reduces neurovascular and WM damage via reducing proinflmammatory factors RAGE/HMGB-1 and TNFα/PAI-1 in the ischemic brain in db/db T2DM stroke mice. These provide a proof-of-concept that treatment with L-4F is a potential strategy to reduce neuroinflammation in the T2DM stroke population.

DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this manuscript will be made available by the authors, without undue reservation, to any qualified researcher.

ETHICS STATEMENT

Our animal use protocols were approved by the Guide for the Institute of Animal Care and Use Committee of the Henry Ford health System and in accordance with the standards of the Institutional Animal Care and Use Committee, National Institutes of Health. Adult male db/db mice (3 month old) were used.

AUTHOR CONTRIBUTIONS

XC, JC, and MC conceived and designed the study. XW, RL, AZ, JL-W, and XC acquisition of data and statistical analysis. XW and XC drafted the manuscript. JC and MC critical revision of the manuscript for intellectual content.

FUNDING

This study was supported by National Institute of Neurological Disorders and Stroke Grants R01NS097747 (JC).

ACKNOWLEDGMENTS

We thank Qinge Lu and Sutapa Santra for technical assistance, and Yisheng Cui for performing behavioral functional tests.

Despite its extensive use in clinical studies, the molecular mechanisms underlying the effects of transcranial direct current stimulation (tDCS) remain to be elucidated. We previously described subacute effects of tDCS on immune- and stem cells in the rat brain. To investigate the more immediate effects of tDCS regulating those cellular responses, we treated rats with a single session of either anodal or cathodal tDCS, and analyzed the gene expression by microarray; sham-stimulated rats served as control. Anodal tDCS increased expression of several genes coding for the major histocompatibility complex I (MHC I), while cathodal tDCS increased the expression of the immunoregulatory protein osteopontin (OPN). We confirmed the effects of gene upregulation by immunohistochemistry at the protein level. Thus, our data show a novel mechanism for the actions of tDCS on immune- and inflammatory processes, providing a target for future therapeutic studies.

Keywords: direct transcranial current stimulation, gene expression, microarray, MHC-I, osteopontin, transcriptome

INTRODUCTION

Transcranial direct current stimulation (tDCS) has been applied in experimental and clinical settings for more than 20 years and may facilitate rehabilitation after stroke as suggested by clinical data (Hummel et al., 2005; Sparing et al., 2009). Moreover, tDCS is used as experimental therapy for various neurological and psychiatrical diseases, e.g., multiple sclerosis, Parkinson's, depression, dementia, evaluated by Lefaucheur et al. (2017). TDCS leads to changes of the cortical excitability in animals and humans (Bindman et al., 1962; Nitsche and Paulus, 2000), promoting changes in long-term potentiation and synaptic plasticity via NMDA-receptors

Abbreviations: DAVID, database for annotation visualization and integrated discovery 6.8; FDR, false discovery rate; Iba1, ionized calcium binding adaptor molecule 1; MHC I, major histocompatibility complex class I; OPN, osteopontin; tDCS, transcranial direct current stimulation; SVZ, subventricular zone.

(Bolin et al., 2002; Nitsche et al., 2003; Fritsch et al., 2010; Monte-Silva et al., 2013; Kronberg et al., 2017). As tDCS can be applied either using anodal or a cathodal current polarity, anodal tDCS increases cortical excitability while cathodal tDCS results in its decrease (Fritsch et al., 2010; Stagg and Nitsche, 2011; Lafon et al., 2017).

Intriguingly, tDCS evokes various cellular effects on neural stem cells, neurons, astrocytes, oligodendrocytes, and microglia exceeding its primary neurophysiological actions: In the healthy rat brain, tDCS increases proliferation and migration of endogenous neural stem cells and activates microglia as the brain-resident immune cells (Rueger et al., 2012a; Keuters et al., 2015). Both anodal and cathodal tDCS induce neurogenesis, both in healthy animals (Braun et al., 2016) as well as after experimental stroke (Braun et al., 2016; Pikhovych et al., 2016). Cathodal tDCS recruits oligodendrocyte precursors toward an ischemic lesion while supporting polarization of microglia toward a pro-inflammatory M1-phenotype (Braun et al., 2016). Depending on the current density, tDCS downregulates inflammatory mediators (Peruzzotti-Jametti et al., 2013) and the constitutive expression of ionized calcium binding adaptor molecule 1 (Iba1) by activated microglia (Spezia Adachi et al., 2012; Peruzzotti-Jametti et al., 2013; Pikhovych et al., 2016). These data suggest that – depending on current density and polarity – tDCS possesses distinct immunomodulatory effects and supports stem cell-mediated regeneration in the brain. Further knowledge of the patterns of action of the different polarities is still warranted. Cellular effects of tDCS occur from acute effects within hours to subacute and longterm effects within days and weeks after stimulation (Rueger et al., 2012b; Spezia Adachi et al., 2012; Peruzzotti-Jametti et al., 2013; Braun et al., 2016; Pikhovych et al., 2016). It is yet unknown how they are regulated and altered over time. Expression changes on the transcriptome can be expected after a few hours after a stimulus, therefore we chose to investigate the acute tDCS-induced transcriptome in an unbiased microarray approach 6 h after tDCS.

MATERIALS AND METHODS

Animals and Surgery

All animal procedures followed the German Laws for Animal Protection and were approved by the local animal care committee as well as local governmental authorities (Landesamt für Natur, Umwelt und Verbraucherschutz North Rhine-Westphalia, LANUV). To exclude putative influences of hormonal changes on the findings, only male rats were used.

Spontaneously breathing 10–11 weeks old male Wistar rats weighing 260–310 g were anesthetized with 5% isoflurane and maintained with 2.5% isoflurane in 65%/35% nitrous oxide/oxygen. Throughout surgical procedures, body temperature was maintained at 37.0°C with a thermostatically controlled heating pad.

Transcranial Direct Current Stimulation

Twenty-four rats were subjected to a single tDCS session as described previously by our group (Rueger et al., 2012a; Braun et al., 2016). In brief, an epicranial electrode holder made of plastic (self-manufactured) with a defined contact area of 3.5 mm^2 was mounted onto the intact skull over the right hemisphere using non-toxic glass ionomer luting cement (Ketac Cem Plus, 3M-ESPE, Germany) at bregma AP + 2.0 mm, ML + 2.0 mm, and left in place for the entire experiment. The skin around the electrode holder was closed with sutures after the placement. The holder was left in place for the entire experiment. Animals were randomized to receive tDCS with either anodal (n = 8) or cathodal (n = 8) polarity; the control group received a sham-stimulation (n = 8) (**Table 1**).

For transcranial direct current stimulation, an argentic electrode was placed in the electrode holder, and 0.9% sodium chloride was added to buffer electrochemical changes. The counter electrode, a 1.5 cm × 2 cm silver-coated sensor electrode (#DENIS01526; Spes Medica, Genova, Italy), was placed on the rat's ventral thorax.

Transcranial direct current stimulation was applied continuously for 15 min at 500 μA using a constant current stimulator (CX-6650, Schneider-Electronics, Germany) under isoflurane anesthesia, resulting in a charge density of 128 kC/m2. Charge density was calculated as charge (A × s) per area, according to Liebetanz et al., 2009. For sham stimulation, rats were treated equally to the tDCS group with isoflurane anesthesia for 15 min, but were not connected to the current stimulator during this time. tDCS was performed under anesthesia to avoid dislocation of the cable.

After tDCS, animals were allowed to recover in their home cages with access to food and water *ad libitum*.

RNA-Extraction

Six hours after tDCS, four rats of each stimulation group were deeply anesthetized and decapitated. The brains were rapidly removed and the sensorimotor cortices of each hemisphere were isolated. 20mg cortical tissue of each hemisphere was crushed and stabilized overnight in PurifyLater Tissue Stabilizer (BioEcho, Dormagen, Germany). On the next day, the total RNA was isolated using the GenUP^{TM} Total RNA Kit (Biotechrabbit, Henningsdorf, Germany) according to the manufacturer's guidelines. RNA quantification was carried out using a NanoDrop-1000 spectrophotometer (Peqlab, Erlangen, Germany), and RNA quality was monitored by agarose gel separation and with the Agilent 2100 Bioanalyzer (Agilent, Böblingen, Germany). All extracted RNA samples were

TABLE 1 | Overview of the experimental groups.

	Microarray	Immunohistochemistry
Sham	n = 4	n = 4
Anodal	n = 4	n = 4
Cathodal	n = 4	n = 4

found to be of good quality. RNA integrity numbers (RINs) ranged from 9.8 to 10.

DNA Microarray Hybridization

DNA microarray experiments were performed according to the manufacturer's manual and as previously described (Unverricht-Yeboah et al., 2018). Of the total RNA, 400 ng was transcribed into cDNA with an oligo-dT primer, followed by transcription into cRNA labeled with cyanine 3-CTP (Quick-Amp Labeling Kit, One-color, Agilent, Santa Clara, CA, United States). cRNA purification was performed with the RNeasy Mini Kit (Qiagen). cRNA yield and the dye incorporation were measured with the NanoDrop-1000 spectrophotometer. Labeled cRNA samples were hybridized for 17 h to 44 k Whole Rat Genome DNA microarrays (G2519F, Agilent) using a hybridization oven (Agilent). After hybridization and washing, DNA microarrays were scanned with the Microarray Scanner (G2505 B, Agilent) as recommended by Agilent.

Data Analysis

Images of the scanned microarrays were processed with the Agilent Feature Extraction software. Gene expression data were processed, normalized, and analyzed using the GeneSpring GX software (Agilent) and Excel (Microsoft Corperation, Redmond, WA, United States). By data filtering, non-uniform outliers were excluded, as well as signals that were not significantly above the background intensity in at least 25% of the samples. To indicate the significantly regulated genes, the *p*-values were adjusted using the method of Benjamini and Hochberg to calculate the false discovery rate (FDR). Genes with non-FDR adjusted *p*-values were considered for the filtering process to increase the number of potential candidate genes. The criteria for candidate genes were: a significant expression change (>2.0 fold), a FDR $\leq$ 0.16 after filtering, and a *p*-value $<$ 0.05 (**Table 2**). Protein expression of selected candidate genes was analyzed by immunohistochemistry.

Functional Analysis of Significantly Regulated Genes

The significantly expressed genes after anodal and cathodal tDCS were functionally categorized using the Database for Annotation Visualization and Integrated Discovery 6.8 (DAVID) (Huang et al., 2009). To assign the significantly altered genes to affected biological processes and pathways, we used the gene ontology analysis feature.

TABLE 2 | Numbers of significantly regulated genes after tDCS with a fold change > 2.

Groups	Significantly regulated genes (fold change > 2.0, $p < 0.05$, FDR $\leq$ 0.16)
Cathodal ipsilateral vs. Sham	20
Anodal ipsilateral vs. Sham	14
Cathodal contralateral vs. Sham	0
Anodal contralateral vs. Sham	0
Cathodal ipsilateral vs. Cathodal contralateral	1
Anodal ipsilateral vs. Anodal contralateral	0

Immunohistochemistry

Six hours after tDCS, four rats of each stimulation group were deeply anesthetized with isoflurane and decapitated. Brains were rapidly removed, frozen in isopentane, and stored at −80°C before further processing. Serial coronal brain sections of 10 μm were cut throughout each brain at 500 μm intervals. For immunohistochemistry, primary antibodies included: MHC Class I Antibody (Ox18) (1:500 cat# NB120-6405, Novus Biological, Littleton, CO, United States) and anti-Osteopontin-Antibody (1:500 cat# ab8448, Abcam, Cambridge, United Kingdom), Iba1 Antibody (1:1000 cat# 019-19741WAKO, Osaka, Japan), and NeuN Antibody (1:200, cat# MAB377 Merck, Kenilworth, NJ, United States). For visualization of the MHC I-antibody, the ABC-Elite kit (Vector Laboratories, United States) with diaminobenzidine (Sigma, Germany) as the final reaction product was used. For visualization of the other antibodies, fluorescent-labeled secondary antibodies were used (1:500, cat#A11001 Alexa-Fluor–488 and cat#A11036 Alexa-Fluor–568, Invitrogen, Thermo Fisher Scientific, Waltham, MA, United States). Sections were counterstained with Hoechst to label all nuclei (Hoechst 33,342, Thermo Fisher Scientific, Massachusetts, United States).

Representative pictures were taken with an inverted fluorescence phase-contrast microscope (Keyence BZ-9000E, Keyence, Osaka, Japan).

To determine the amount of MHC Class I-positive cells, the size of the subventricular zone (SVZ) was quantified for each animal by measuring the area in μm^2 covered by MHC Class I-positive cells with a predefined length at 100 μm multiplied with the width in μm of the area covered with MHC + cells [as previously described by our group for doublecortin stainings (Klein et al., 2014)], and calculated as the mean of three coronal sections at 500 μm intervals of each animal.

To determine the number of OPN-positive, NeuN-positive, and Iba1-positive cells in the cortex, three coronal sections at 500 μm intervals were stained with the respective antibody. Using a Keyence microscope with a 40× objective, images of representative fields of view (measuring 746 μm × 557 μm) of the sensorimotor cortex of the ipsilateral, stimulated hemisphere were taken of each section. The numbers of positive cells of each antibody staining were counted manually and calculated as the mean of three coronal sections.

Immunohistochemical quantifications of MHC Class I and OPN positive cells were performed by a blinded evaluator (MS).

Descriptive statistics were performed with Graph Pad Prism (GraphPad Software Inc.). For comparison of multiple groups, One Way Analysis of Variance (ANOVA) and Tukey's *post hoc* tests were performed with the same software. Statistical significance was set at the <5% level ($p < 0.05$).

RESULTS

Gene Expression Changes Following Different tDCS Polarities

Six hours after cathodal ipsilateral tDCS (compared to sham stimulation), 20 genes were significantly up- or downregulated (10 genes up-, 10 genes downregulated, cmp. **Supplementary Table S1A**). After anodal ipsilateral tDCS (compared to sham stimulation), 14 genes were significantly up- or downregulated (9 genes up-, 5 genes downregulated, cmp. **Supplementary Table S1B**). Of all the other groups, comparing ipsilaterally stimulated to contralaterally stimulated hemispheres, or contralaterally stimulated hemispheres to sham stimulation, only cathodal ipsilateral tDCS compared to cathodal contralateral stimulation resulted in a significant difference of one gene that was downregulated (**Supplementary Table S1C**).

The effects of tDCS were lateralized in comparison to sham but not in comparison to the unstimulated hemisphere. Given the small size of a rat brain, tDCS stimulation was not assumed to be restricted to one hemisphere. Therefore, tDCS effects will also reflect in the unstimulated hemisphere, albeit to a lower extent, which explains the lack of significant changes between the unstimulated hemisphere and sham. Thus, the "unstimulated" hemisphere cannot function as control. We therefore used sham control animals, specifically from the same hemisphere that was stimulated in the tDCS group.

Biological Processes and Pathways Affected by Different tDCS Polarities

We functionally categorized the upregulated genes, using DAVID (Huang et al., 2009), to examine biological processes and pathways affected by the different tDCS polarities (**Supplementary Figure S1**). Six hours after anodal tDCS, the categories "antigen presentation via MHC I" and "immune response" were significantly upregulated, both consisting of the same 5 different genes coding for RT1 Class (MHC I), thus strongly suggesting an upregulation of MHC I coding genes after anodal tDCS (**Supplementary Figure S1A**).

After cathodal tDCS, the categories "osteoblast differentiation," "positive regulation of angiogenesis," "cellular response to mechanical stimuli," "ossification," and "response to activity" were significantly upregulated (**Supplementary Figure S1B**). For the downregulated genes in cathodal and anodal tDCS no functional categories could be detected.

Identification of Candidate Genes for Immunomodulation

To confirm the effects of upregulated genes seen in the microarray analysis by immunohistochemistry, we selected candidate genes for each stimulation polarity. Given the strong effects of tDCS on neuroinflammation found in earlier studies of our group (Rueger et al., 2012a; Braun et al., 2016; Pikhovych et al., 2016), we focused on genes coding for immunomodulating processes. After anodal tDCS, we identified a cluster of 5 upregulated genes coding for RT1 Class as part of the MHC I complex (RT1-CE2, RT1-CE15, RT1-CE16, Rt1.aa, and RT1-EC2) that we singled out as candidate genes. We performed immunohistochemical stainings for MHC I on brain slices from animals that had been identically treated as the microarray group. Quantification showed more MHC I + cells in the ipsilateral subventricular zone (SVZ) of animals treated with anodal tDCS compared to controls by trend (anodal tDCS 7533,75 ± 881,41 MHC I + cells/μm^2 vs. sham stimulation 6758,33 ± 675,57 MHC I + cells/μm^2). Results are displayed as mean ± SEM (**Figure 1**).

Intriguingly, cathodal tDCS led to upregulation of Spp1 encoding for the phosphoprotein osteopontin (OPN), possessing pleiotropic immunoregulatory properties after cerebral ischemia as well as beneficial effects on endogenous neural stem cells (Rabenstein et al., 2015, 2016; Ladwig et al., 2017). To validate the involvement of OPN, we performed immunohistochemical stainings in animals that had been identically treated as the microarray group. Quantification showed more OPN + cells in ipsilateral the cortex of animals treated with cathodal tDCS compared to sham-treated controls by trend (cathodal tDCS 54.89 ± 1.29% OPN + cells vs. sham stimulation 51.02 ± 2.16% OPN + cells/total cell count). Results are displayed as mean ± SEM (**Figure 2A**). Co-staining OPN with either NeuN for neurons or Iba1 for microglia revealed that OPN was almost exclusively expressed by neurons (**Figures 2B,C**).

Other Genes of Interest

In cathodal tDCS, the Slitrk6 inhibitor of neurite outgrowth was significantly downregulated (Aruga and Mikoshiba, 2003). While bone morphogenic protein 6 (bmp-6), a secreted extracellular matrix (ECM)-associated component with important functions in development, was upregulated, its antagonist Sostdc1 was downregulated (Brazil et al., 2015). Sostdc 1 was also significantly downregulated after anodal tCDS, but without upregulation of bone morphogenic protein.

Both cathodal and anodal tDCS upregulated Wisp2 (Ohkawa et al., 2011) that leads to the facilation of neurite formation. Wisp2 is part of the Wnt signaling pathway involved in neural stem cell development (Bengoa-Vergniory and Kypta, 2015).

Together, both in cathodal and anodal tDCS, neurite growth and stem cell development were enhanced, while extracellular developmental processes were enhanced after cathodal tDCS only.

DISCUSSION

A single session of tDCS led to significant changes in gene expression after 6 h, which were accompanied by concordant changes at the protein level as detected immunohistochemically. The rationale behind this short interval after tDCS was to observe the acute of effects tDCS within the first hours.

Changes in protein upregulation were not statistically significant, most likely since their expression maximum occurred at later time points (Jansen and Pfaffelhuber, 2015). Moreover, increased protein synthesis may not necessarily lead to an

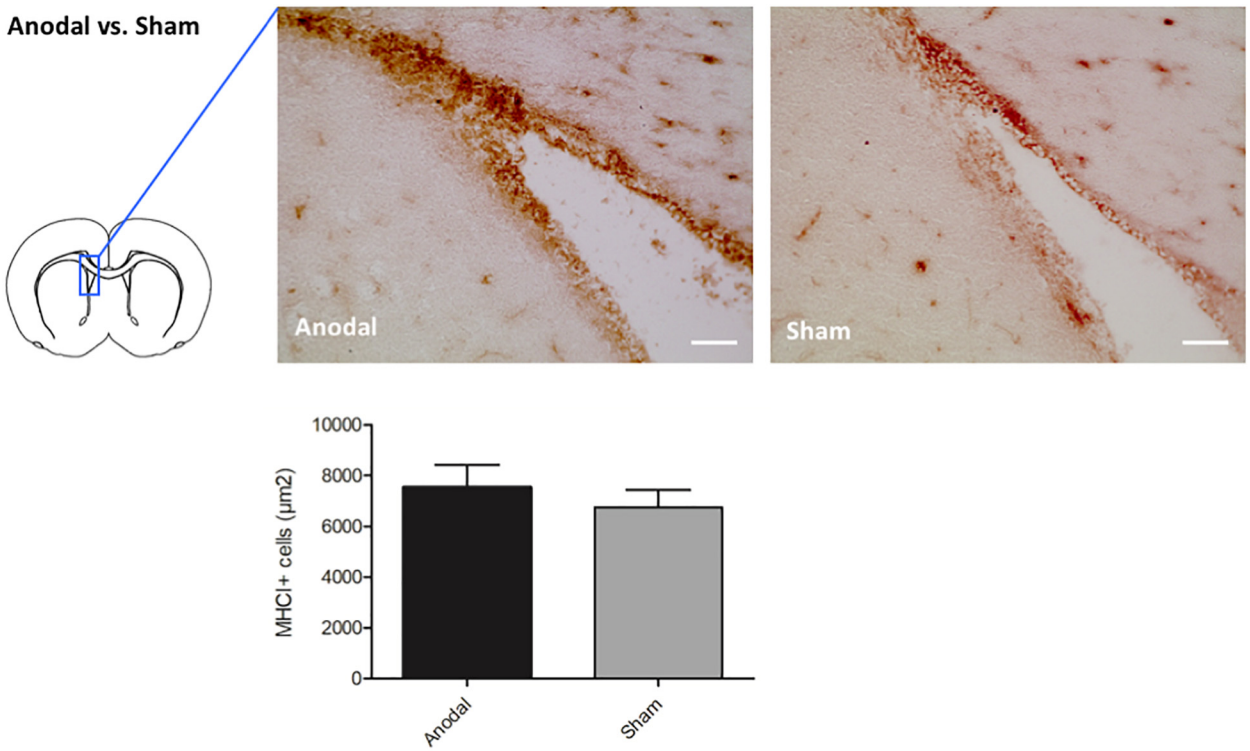

FIGURE 1 | Effects of anodal tDCS on protein expression. Representative immunohistochemical images of Ox18 + cells in the SVZ ipsilateral to anodal tDCS or sham stimulation. Staining for Ox18 (MHC I) in the ipsilateral SVZ revealed more Ox18 + cells in animals treated by anodal tDCS (left panel) compared to sham stimulation (right panel) by trend (scale bars = 100 μm). Results are displayed as mean ± SEM.

increased number of positive cells, but to an increased amount of gene product per cell. Further studies are warranted to address the issue of induced protein expression.

After anodal tDCS, five genes involved in MHC I expression were upregulated. In the healthy brain, MHC-I is expressed at the synapses of neurons (Shatz, 2009; Needleman et al., 2010). It is generally associated with negative regulation of neural plasticity (Datwani et al., 2009; Shatz, 2009; Elmer and McAllister, 2012); on the other hand, decreased MHC I signaling impairs axonal repair (Thams et al., 2008). After brain damage such as stroke, MHC-I is upregulated, and MHC-I presenting cells are recognized by cytotoxic T-cells, supporting neuroinflammation (Schroeter et al., 1994; Piehl and Lidman, 2001). Interestingly, MHC-I is upregulated after kainate-induced seizure and downregulated after activity-blockage (Corriveau et al., 1998). Thus, upregulation of genes coding for MHC-I by anodal tDCS – potentially inducing cortical excitability – is in line with previous reports linking altered neuronal activity directly to MHC I expression (Neumann et al., 1995, 1997). Data suggest that the increase in neuroinflammation seen after tDCS (Rueger et al., 2012a; Braun et al., 2016; Pikhovych et al., 2016) may result from an upregulation of MHC-I that tags neurons to surveillance of microglia, the immunocompetent cells of the CNS. Together, anodal tDCS may act by upregulating MHC I expression through an increase in cortical excitability, leading to an augmented neuroinflammatory response.

Cathodal tDCS led to an upregulation of OPN as an endogenous phosphoglycoprotein with essential roles in tissue homeostasis, wound healing, immune regulation, and stress responses (Denhardt et al., 2001; Brown, 2012). OPN acts as a negative feedback regulator for the synthesis of nitric oxide (Hwang et al., 1994; Rollo et al., 1996), suggesting key immunoregulatory functions. OPN increases survival, proliferation, migration, and neuronal differentiation of endogenous neural stem cells in culture, and enhances proliferation and migration of neuronal precursors *in vivo* after cerebral ischemia (Rabenstein et al., 2015). Additionally, OPN seems to polarize microglia to a neuroprotective subtype in an inflammation setting (Rabenstein et al., 2016). Thus, upregulating OPN by cathodal tDCS may provide an easily accessible non-pharmacological approach to enhance OPN synthesis in order to harness its beneficial effects, e.g., after a stroke. In conclusion, we speculate that cathodal tDCS leads to a multitude of regulatory neuroinflammatory and neuroplastic effects through upregulation of OPN.

As yet, only Holmes et al. conducted an RNA-sequencing study after tDCS (Holmes et al., 2016). They analyzed gene expression only minutes after a single session of anodal tDCS using three different currents (250, 500, and 2,000 μA),

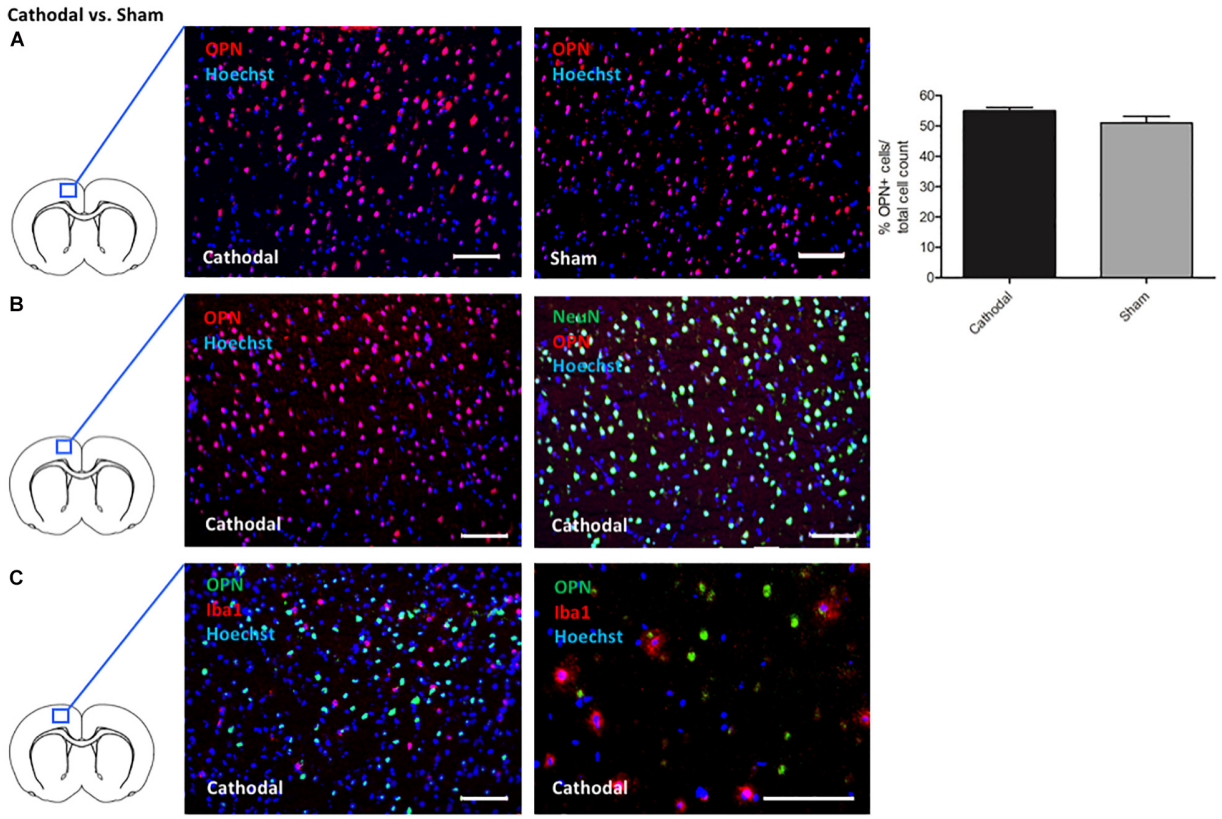

FIGURE 2 | Effects of cathodal tDCS on protein expression. **(A)** Representative immunohistochemical images of OPN + cells (red) in the cortex ipsilateral to cathodal tDCS or sham stimulation, co-stained with a nuclear marker (Hoechst; blue). Staining for OPN revealed more OPN + cells in the cortex of animals treated by cathodal tDCS (left panel) compared to sham stimulation (right panel) by trend (right panel; scale bars = 100 μm). Results are displayed as mean ± SEM. **(B)** Representative immunohistochemical images of OPN + cells co-stained with NeuN (green) in the cortex ipsilateral to cathodal tDCS. All images were co-stained with a cell nucleus marker/DNA dye (Hoechst; blue). OPN + cells almost exclusively co-expressed NeuN (left panel and right panel represent the same picture with and without NeuN fluorescence signal, scale bars = 100 μm). **(C)** Representative immunohistochemical images of OPN + cells (green) co-stained with Iba1 (red) in the cortex ipsilateral to cathodal tDCS. All images were co-stained with a cell nucleus marker/DNA dye (Hoechst; blue). OPN + cells did not express Iba1 (left panel and right panel represent different magnifications, scale bars = 100 μm).

equivalent to charge densities of 132, 264, and 1,057 kC/m^2), while our study was performed 6 h after tDCS of either anodal or cathodal polarity at 128 kC/m^2. For each charge density, Holmes et al. found about 1000 genes differentially up- and downregulated, especially from inflammatory, antidepressant-related, and receptor signaling pathways. In contrast to our study, they chose a fold change of 1.2 with adjusted p-value < 0.1 as the cut-off for significantly regulated genes, while we used a more conservative approach with only >2-fold changes, explaining the larger number of differentially regulated genes in their study. At 132 kC/m^2, similar to the charge density in our study, cellular response to stress- and B-cell activation-clusters, and only at 1,057 kC/m^2 – far above the published lesion threshold (Liebetanz et al., 2009; Rueger et al., 2012a) - a favorable adjustment of immune system regulation clusters was found.

As previously suggested by Liebetanz et al. (2009), another recent study found that subtle lesions can possibly occur even below the current intensity used in our study (Jackson et al., 2017). While this certainly needs to be kept in mind for future studies, we here did not detect any tissue lesions by immunohistochemistry using the current stimulation parameters.

Further studies are warranted to establish the effects of tDCS on gene expression not only in relation to timing but also to charge density and polarity, as well as in awake stimulated animals.

CONCLUSION

Anodal tDCS enhanced expression of several genes coding for MHC-I, affecting inflammation and synaptic plasticity, while cathodal tDCS increased expression of the gene encoding for the immunoregulatory protein OPN linking tDCS treatment to beneficial effects on regeneration after stroke or cerebral hemorrhage (Yan et al., 2009; Wu et al., 2011; Rabenstein et al., 2015; Ladwig et al., 2017; Rogall et al., 2018). Overall, specific modulation of neuroinflammatory processes by non-invasive brain stimulation constitutes a promising therapeutic option with immediate translational relevance.

Neumann S, Boothman-Burrell L, Gowing EK, Jacobsen TA, Ahring PK, Young SL, Sandager-Nielsen K and Clarkson AN (2019) The Delta-Subunit Selective $GABA_A$ Receptor Modulator, DS2, Improves Stroke Recovery via an Anti-inflammatory Mechanism. Front. Neurosci. 13:1133. doi: 10.3389/fnins.2019.01133

Inflammatory processes are known to contribute to tissue damage in the central nervous system (CNS) across a broad range of neurological conditions, including stroke. Gamma amino butyric acid (GABA), the main inhibitory neurotransmitter in the CNS, has been implicated in modulating peripheral immune responses by acting on $GABA_A$ receptors on antigen-presenting cells and lymphocytes. Here, we investigated the effects and mechanism of action of the delta-selective compound, DS2, to improve stroke recovery and modulate inflammation. We report a decrease in nuclear factor (NF)-κB activation in innate immune cells over a concentration range *in vitro*. Following a photochemically induced motor cortex stroke, treatment with DS2 at 0.1 mg/kg from 1 h post-stroke significantly decreased circulating tumor necrosis factor (TNF)-α, interleukin (IL)-17, and IL-6 levels, reduced infarct size and improved motor function in mice. Free brain concentrations of DS2 were found to be lower than needed for robust modulation of central $GABA_A$ receptors and were not affected by the presence and absence of elacridar, an inhibitor of both P-glycoprotein and breast cancer resistance protein (BCRP). Finally, as DS2 appears to dampen peripheral immune activation and only shows limited brain exposure, we assessed the role of DS2 to promote functional recovery after stroke when administered from 3-days after the stroke. Treatment with DS2 from 3-days post-stroke improved motor function on the grid-walking, but not on the cylinder task. These data highlight the need to further develop subunit-selective compounds to better understand change in GABA receptor signaling pathways both centrally and peripherally. Importantly, we show that GABA compounds such as DS2 that only shows limited brain exposure can still afford significant protection and promote functional recovery most likely via modulation of peripheral immune cells and could be given as an adjunct treatment.

Keywords: stroke, inflammation, GABA, immune response, neuroinflammation, functional recovery, neuroimmunology

INTRODUCTION

Stroke is the leading cause of lasting disability, with patients experiencing varied levels of functional recovery, and with more than 50% of survivors being discharged into care (Dobkin, 2008; Go et al., 2014). Changes in neuronal excitability, loss of gamma amino butyric acid (GABA) inhibition, enhanced glutamatergic signaling, and changes in neuronal connections and plasticity all contribute to impairment after stroke (Wittenberg and Schaechter, 2009; Clarkson et al., 2010, 2011, 2015, 2019; Carmichael, 2012; Krakauer et al., 2012). In addition, it is well documented that the full expansion of the infarction and ongoing impairment in the weeks to months following a stroke is underpinned by inflammation and the infiltration of peripheral immune cells that cross the blood–brain-barrier (BBB) (Gelderblom et al., 2009, 2015; Doyle et al., 2015). To date, drug therapies have attempted to minimize the extent of cell death, however, all drug therapies that have been trialled have failed to translate into the clinic. Therefore, new drug therapies need to be developed in order to support the recovery of stroke patients.

Changes in inflammatory processes is a hallmark for many pathologies including obesity, diabetes and stroke. Although acute inflammation is beneficial for the repairing and healing process, chronic inflammation contributes to tissue damage. Immune cells play a critical role in contributing to brain damage initiated by ischemic stroke. As a consequence of stroke, immune cells migrate to the brain in response to danger signals (damage-associated molecular patterns, DAMPs), in an effort to repair the damage (Brait et al., 2010; Gelderblom et al., 2015). However, these cells can also promote further inflammation and damage. In addition, the injured brain has an immune-suppressive effect that promotes life-threating infections, which threaten the survival of stroke patients (Liesz et al., 2015).

Traditionally considered a disease refined to the brain, it is becoming increasingly clear that the immune system heavily impacts the pathology of stroke. Local microglia, endothelial cells, neurons, and astrocytes recognize danger signals released from dying cells, which in turn stimulate the production of pro-inflammatory cytokines that attract circulating immune cells to migrate to the central nervous system (Offner et al., 2006; Gelderblom et al., 2009). Together, local and infiltrating cells, contribute to further neural cell death by producing pro-inflammatory cytokines, reactive oxygen species and by activating matrix metalloproteinases (Amantea et al., 2015). In particular, microglia have been shown to be chronically activated even when the initial DAMPs have been cleared (Huh et al., 2003; McGeer et al., 2003). This results in prolonged neuroinflammation that is associated with delayed recovery in stroke patients (Liguz-Lecznar and Kossut, 2013), and impaired memory, sensory learning and plasticity (Greifzu et al., 2011; Doyle et al., 2015).

Gamma amino butyric acid, known for its role as inhibitory neurotransmitter in the CNS, has a similar inhibiting effect on immune cells thereby creating a link between the CNS and the peripheral inflammatory response (Reyes-Garcia et al., 2007). Both, innate and adaptive immune cells express functional GABA receptors and possess enzymes to synthesize and catabolize GABA (Wheeler et al., 2011; Fuks et al., 2012). This includes microglia, macrophages, dendritic cells and T-cells. GABA signals through $GABA_A$ and $GABA_B$ receptors, both of which are expressed on immune cells (Kuhn et al., 2004; Wheeler et al., 2011; Fuks et al., 2012). The composition of the five subunits that make up $GABA_A$ receptors likely varies for the various immune cells, which in turn will account for differences in potency and efficacy of drug treatments targeting GABA receptors and GABA itself (Fuks et al., 2012). GABA is known to act on $GABA_A$ receptors in both millimolar and nanomolar to micromolar concentrations depending on the location (synaptic versus extrasynaptic) and functional composition of the receptors (Mody, 2001; Semyanov et al., 2003; Glykys and Mody, 2007). Of importance, submicromolar GABA concentrations have not only been found around neurons in the brain, but have also been detected in blood and hormone-producing cells in the intestine (Petty et al., 1999; Braun et al., 2004; Wendt et al., 2004). In addition to being exposed to chronic low levels of GABA, these peripheral tissues and receptors are likely to also be modulated following treatment with various GABA modulators. With the development of subunit specific GABA modulators, we may be able to find and develop compounds that could selectively regulate the function of peripheral immune cells.

Extrasynaptic $GABA_A$ receptors, which are located outside the synapse typically contain either the δ- or α5-subunit and are highly sensitive to low GABA concentrations (Mody, 2001). Recent evidence has shown that modulation of extrasynaptic $GABA_A$ receptors plays an important role in minimizing the extent of damage when given early (within hours) to increase tonic GABA currents after a stroke. In addition, this modulation can also facilitate an improvement in motor function when treatment is initiated at a delay (days) to dampen tonic GABA currents after the initial insult (Clarkson et al., 2010, 2019). As little is known about the role of δ-containing $GABA_A$ receptor after stroke, we were interested in testing the therapeutic effects of the δ-subunit-selective $GABA_A$ receptor modulator DS2 (4-chloro-N-[2-(2-thienyl)imidazo[1,2-a]pyridin-3-yl]benzamide). DS2 positively modulates δ-containing $GABA_A$ receptors (Wafford et al., 2009), however, DS2 has not been investigated in a clinical disease model. Therefore, we aimed to assess the potential of DS2 to improve stroke recovery and to modulate inflammatory responses in innate immune cells. Herein, we show that positive allosteric modulation of δ-containing $GABA_A$ receptors with DS2 affords significant protection and improves motor function in a mouse model of stroke. Investigation into a potential mechanism of action revealed that DS2 reduces the activation of NF-κB in LPS-stimulated macrophages and reduces the expression of activation markers on bone marrow-derived dendritic cells (BMDCs). Interestingly, we show that DS2 only has limited brain exposure, indicating that DS2-mediated effects *in vivo* are most likely attributed to modulation of peripheral immune cells.

MATERIALS AND METHODS

Materials

Lipopolysaccharides from *Escherichia coli* 055:B5 (LPS) were ordered from Sigma-Aldrich (St. Louis, MO, United States); Dulbecco's Modified Eagle Medium (DMEM), 2-Mercaptoethanol, Penicillin/Streptomycin, and Roswell Park Memorial Institute Medium (RPMI) were ordered from Life Technologies (Auckland, New Zealand); foetal calf serum (FCS) was purchased from Moregate Biotech (Hamilton, New Zealand), DS2 from Tocris Bioscience (Bristol, United Kingdom), Zeocin™ from Invitrogen (Auckland, New Zealand) and Quantiblue™ from InvivoGen (CA, United States). The LIVE/DEAD® Fixable Near-IR Dead Cell Stain was purchased from Thermo Fisher Scientific (MA, United States); Granulocyte-macrophage colony-stimulating factor (GM-CSF) and flow antibodies MHCII FITC, CD80 PE, CD86 PE-Cy7, CD11c BV421, and CD40 APC came from BioLegend (Auckland, New Zealand). The reagents for real-time PCR (qPCR) were purchased from the following suppliers: RNeasy® Plus Mini kit from Qiagen (Austin, TX, United States), DNA-free™ kit from Life Technologies Corporation (Carlsbad, CA, United States), SensiFAST cDNA Synthesis Kit and SYBR Green kit from Bioline (London, United Kingdom) and primers ordered from Integrated DNA Technologies (Singapore).

Cell Culture of RAWblue™ Macrophage Cells

RAWblue™ macrophages were cultured in DMEM supplemented with heat-inactivated FCS (10%) and 200 μg/mL Zeocin™ (antibiotic selection) as previously described (Clarkson et al., 2019). For experiments, 5×10^4 RAWblue macrophages were added to a 96-well plate (flat-bottom) in the absence of Zeocin, and left untreated for 16 h. Increasing concentrations of DS2 (10^{-6} to 10^{-3} M) were added for 30 min before LPS (2.5 ng/mL) was added. The supernatant was collected after 6 h and the levels of the secreted embryonic alkaline phosphatase (SEAP) determined using the Quantiblue™ assay. For this, 80 μL of the Quantiblue solution and 30 μL of the cell culture supernatant were combined, left at 37°C for 3 h and the absorbance read at 620 nm. Three independent experiments were performed in triplicate each.

Generation and Stimulation of Bone Marrow-Derived Dendritic Cells

Bone marrow-derived dendritic cells were generated from bone marrow cells obtained from C57Bl/6J mice as described previously (Scheicher et al., 1992). Briefly, bone marrow cells were isolated from the hind legs of mice and processed into single cell suspensions. Bone marrow cells were re-suspended in IMDM supplemented with 5% FCS, 20 ng/mL GM-CSF, 1% streptomycin/penicillin and 0.1% 2-mercapto ethanol, plated at a density of 5×10^5 cells/mL and maintained at 37°C for 6 days. Half of the media was refreshed on days 3 and 5 of the culture. On day 6, BMDCs were seeded to a 96 well plate at 2×10^5 cells/mL and either pre-incubated with DS2 (10^{-8} to 10^{-4} M) for 30 min or left untreated before stimulation with LPS (100 ng/mL). BMDCs were harvested and stained with antibodies against cell surface markers: CD11c BV421, MHCII FITC, CD80 PE, CD86 PE-Cy7, and CD40 APC after unspecific binding was blocked by using the CD16/32 antibody. Dead cells were excluded by gating on LIVE/DEAD® Fixable Near-IR-negative cells. Fluorescence minus one controls for each fluorophore were used to distinguish positive from background staining.

Quantitative Polymerase Chain Reaction (qPCR)

RAWblue macrophages were grown to approximately 80% confluency in 6-well plates and detached using a cell scraper. Cells were spun down to remove residual cDMEM and total RNA was extracted using the RNeasy® Plus Mini kit as previously described (Clarkson et al., 2019). Total RNA was incubated with DNase using the DNA-free™ kit before reverse transcription into cDNA was performed on a ThermoCycler using the SensiFAST cDNA Synthesis Kit (25°C for 10 min, 42°C for 15 min, and 85°C for 5 min). All kits were used according to the manufacturer's instructions and the cDNA was stored at −20°C until further processing. qPCR samples were prepared by mixing the SYBR green master mix with RNAfree water and primers in a 96-well plate. All primers are listed in **Table 1**. qPCR was performed on a Roche LightCycler® (30 s at 95°C, 40 cycles of 5 min at 95°C, 15 s at 60°C and 10 s at 72°C) and the LightCycler 480® software was used to determine *Ct* values. A dissociation curve analysis was performed and the differences in *Ct* values was calculated using the following equation: $2^{(\text{Ctreference} - \text{CTtarget})}$ (Schmittgen et al., 2000). *Ct* values were normalized against the house keeping gene SDHA. Dissociation curve analysis was performed for all samples (60 s at 95°C, 30 s at 55°C, and 30 s at 95°C).

Photothrombosis Model of Focal Ischemia

The University of Otago Animal Ethics Committee approved all animal experiments. Focal stroke was induced in the left hemisphere in either adult (2–3 month old, for protection studies) or aged (22 month old, for recovery studies) male C57BL/6J mice weighing 25–27 g (2–3 month old) or 32–40 g (22 month old) using the photothrombosis method (Clarkson et al., 2010, 2019). Briefly, mice were anesthetized and placed in a stereotactic apparatus, a midline incision was performed to expose the skull, which was subsequently cleared of connective tissue and dried. The cold light source (KL1500 LCD, Zeiss) was attached to a 40× objective to give a 2 mm diameter illumination and was positioned 1.5 mm lateral from Bregma. Rose Bengal solution (0.2 mL, Sigma; 10 g/L in normal saline, i.p.) was administered and the brain illuminated through the intact skull for 15 min after a 5 min lag period. The color temperature intensity used for all experiments to induce a stroke was 3300 K. Mice had unrestricted access to water and food and were housed under a 12-h light/dark cycle.

Drug Administration

DS2 (0.01, 0.1, 1 or 4 mg/kg in DMSO) or vehicle (DMSO) was injected i.p., 1 h after stroke. A second dose was given 24 h

later by an independent experimenter not involved in any other experiments in order to randomize the animals and minimize bias. For recovery studies, DS2 (10 mM) was loaded into ALZET 1002 mini-pumps and implanted subcutaneously from 3-days post-stroke. Mini-pumps were replaced after 2 week with new pumps to allow for continuous treatment for 28-days after stroke. The treatment groups were assigned randomly post-stroke.

Behavioral Assessment

The baseline performance of animals was established 1 week prior to surgery, both, on the grid-walking and cylinder tasks. One week after stroke induction, animals were tested for motor function at the end of their dark cycle. For recovery studies, behavioral assessments were performed on weeks 1, 2, 4, and 6 post-stroke. Observers, blinded to the treatment group, scored the behaviors as previously described (Clarkson et al., 2010, 2019).

Stroke Volume

Animals were anesthetized seven or 42 days post-stroke, and subsequently transcardially perfused with 4% paraformaldehyde, brains extracted and processed histologically. Cresyl violet staining was used to quantify stroke volumes as reported previously (Clarkson et al., 2010, 2011, 2019; Overman et al., 2012).

Assessment of Circulating Pro-inflammatory Cytokine Levels

Three days post-stroke, blood samples were collected into EDTA treated tubes and centrifuged at 1000 × *g* for 10 min, 4°C. Plasma was collected and then stored at −80°C until required for analysis. A multiplex bead assay was performed using the Luminex 100^{TM} analyzer (Luminex Corporation, Austin, TX, United States). Cytokines IL-1β, TNF-α, IL-6, and IL-17 were analyzed with a BioPlex mouse cytokine assay kit (Bio-Rad Laboratories Inc., New Zealand), according to the manufacturer's instructions. For each cytokine, a minimum of 100 events were collected. Cytokine concentrations were automatically calculated

from median fluorescence intensities (MFI), based on standard curve data (detectable range of 2–32,000 pg/ml) using Bio-Plex Manager™ software.

Brain Accumulation of DS2 in Combination With Elacridar

Male black 6 mice (C57/BL/6Ntac, Taconic, Denmark) received i.v. administration of either elacridar (5 mg/kg, 1 mg/ml, in a dose volume of 5 ml/kg, dissolved in dimethyl acetamide/PEG400/30%/(2-hydroxypropyl)-beta-cyclodextrin (HPbCD) (10/40/50)) or vehicle. Thirty minutes later, DS2 [10 mg/kg, 1 mg/ml, in a dose volume of 10 ml/kg, dissolved in 5% dimethylsulfoxide (DMSO) + 30% HPbCD in demineralized water] was administered to mice orally. Animals were sacrificed and blood and brains were isolated at either 0.5 or 1 h post DS2 administration. DS2 concentrations in, plasma and brain tissue homogenates were determined using liquid chromatography-tandem mass spectrometry assay.

Statistical Analysis

All data are expressed as mean ± SD. One-way analysis of variances (ANOVA) and Newman–Keuls' multiple pair-wise comparisons for *post hoc* comparisons were applied for histological, biochemical DS2 brain/plasma levels and behavioral assessments post-stroke. For behavioral assessments in the recovery study, a two-way ANOVA following Tukey's multiple pairwise comparisons performed. Five mice were used per treatment group for histological and seven mice per group for behavioral assessments. $P < 0.05$ was considered significant. Samples sizes were based on prior publications (Clarkson et al., 2010, 2013, 2019). To detect differences in infarct size in vehicle and DS2-treated mice, an $n = 3$ mice/group is sufficient for achieving a power of 80%, when using the following parameters: $\alpha = 0.05$ (type 1 error rate); $\beta = 0.2$ (type 2 error rate); q1 = 0.5 (proportion of mice in vehicle group); q2 = 0.5 (proportion of mice in DS2 treated group); E = 2.94 (effect size, magnitude of difference); and S = 1.26 (Standard deviation).

RESULTS

DS2 Is Neuroprotective and Improves Functional Recovery After Focal Ischemia

It has previously been shown that reduction of extrasynaptic GABAergic signaling from 3 days after stroke improves functional recovery (Clarkson et al., 2010). In contrast, treatment with the flavonoid, 2'MeO6MF, which was shown to stimulate an increase in extrasynaptic GABA signaling, early after stroke affords significant neuroprotection (Clarkson et al., 2019). To further investigate the role of delta-containing $GABA_A$ receptors as a potential target for stroke, we tested the delta-selective compound, DS2, for its ability to afford neuroprotection after stroke. The protective effects of DS2 were investigated in a focal photothrombosis model of stroke. The reperfusion component is minimal in this model and it is in general more difficult to protect against cell death. Mice were injected i.p. with DS2 (0.01-4 mg/kg) or vehicle 1 and 24 h post-stroke. Body temperature was stable (data not shown) and mice did not show signs of sedation. The stroke volume was assessed 7-days post-stroke and demonstrated that treatment with DS2 resulted in a decrease in infarct volume [$F(4,20) = 6.912$; $P < 0.0012$: vehicle, 2.28 ± 0.26 mm^3 versus DS2 (0.01 mg/kg), 1.78 ± 0.58 mm^3, $P > 0.05$; DS2 (0.1 mg/kg), 0.77 ± 0.27 mm^3, $P < 0.01$, DS2 (1 mg/kg), 2.01 ± 0.62 mm^3, $P > 0.05$, and DS2 (4 mg/kg) 1.96 ± 0.62 mm^3, $P > 0.05$: $n = 5$/group; **Figures 1A,B**].

Next mice were tested for grid-walking (forelimb function) and cylinder (forelimb asymmetry) tasks. Consistent with what we have previously reported, mice had increased numbers of foot-faults on the grid-walking test ($n = 5$ per group; **Figure 1C**) and an increase in spontaneous forelimb asymmetry in the cylinder task ($n = 5$ per group; **Figure 1D**) was detected 7-days post-stroke (Clarkson et al., 2010, 2013, 2019). Treatment with DS2 decreased the number of foot-faults on the grid-walking task ($F(4,20) = 4.06$, $P = 0.0144$) and an improved forelimb asymmetry in the cylinder task ($F(4,20) = 5.858$, $P = 0.0027$). *Post hoc* analysis revealed that only treatment with 0.1 mg/kg DS2 significantly improved motor function on either the grid-walking ($P = 0.0094$) or cylinder ($P = 0.0022$) tasks, compared to vehicle-treated controls.

DS2 Modulates Inflammatory Pathways

Inflammation is crucially involved in contributing to modulation and progression of tissue damage induced by the stroke. Inflammation contributes to the induction of apoptotic processes (Downes and Crack, 2010), and stimulates tonic GABA signaling (Wang et al., 2012), which hinders regaining function after stroke (Clarkson et al., 2010). To confirm that innate immune cells express GABA receptor subunits, necessary for responding directly to DS2, qPCR was performed on unstimulated RAWblue macrophages for the following $GABA_A$ receptor subunits (α1, α2, α3, α4, α5, α6, β1, β2, β3, δ, ε, γ1, γ2, γ3, ρ1, ρ2, ρ3, π, θ), GABAB receptor subunits (GABAB1, GABAB2) and GABA transporters (GAT1, GAT3, BGT1, NKCC1, NKCC2, KCC1, KCC2, KCC3, KCC4) involved in GABA signaling. The relative mRNA levels were investigated by qPCR using the specific primers listed in **Table 1**. We detected several $GABA_A$ receptor subunits, with β_1, α_5, α_6, and δ showing the highest relative expression (**Figure 2A**). mRNA levels for the subunits β_2, π, and ρ_2 were lower in comparison but higher than the levels of the low-expressing subunits β_3, ε, γ_{1-2}, and ρ_3. In addition, high levels of transcripts for the betaine/GABA receptor (BGT1), the K^+-Cl^- co-transporters KCC3 and KCC4 and the Na^+ K^+ Cl^- co-transporter NKCC1 were found in RAWblue macrophages (**Figure 2B**). The mRNA levels of GABA receptor subunits and transporters were not significantly changed upon stimulation with LPS for either 6 or 24 h (data not shown).

Next, we assessed the efficacy of DS2 to decrease NF-kB activity, a common measure of inflammation. RAWblue macrophages, stimulated with LPS (2.5 ng/mL), showed a marked increase in NF-kB activity ($P < 0.001$; **Figure 2C**),

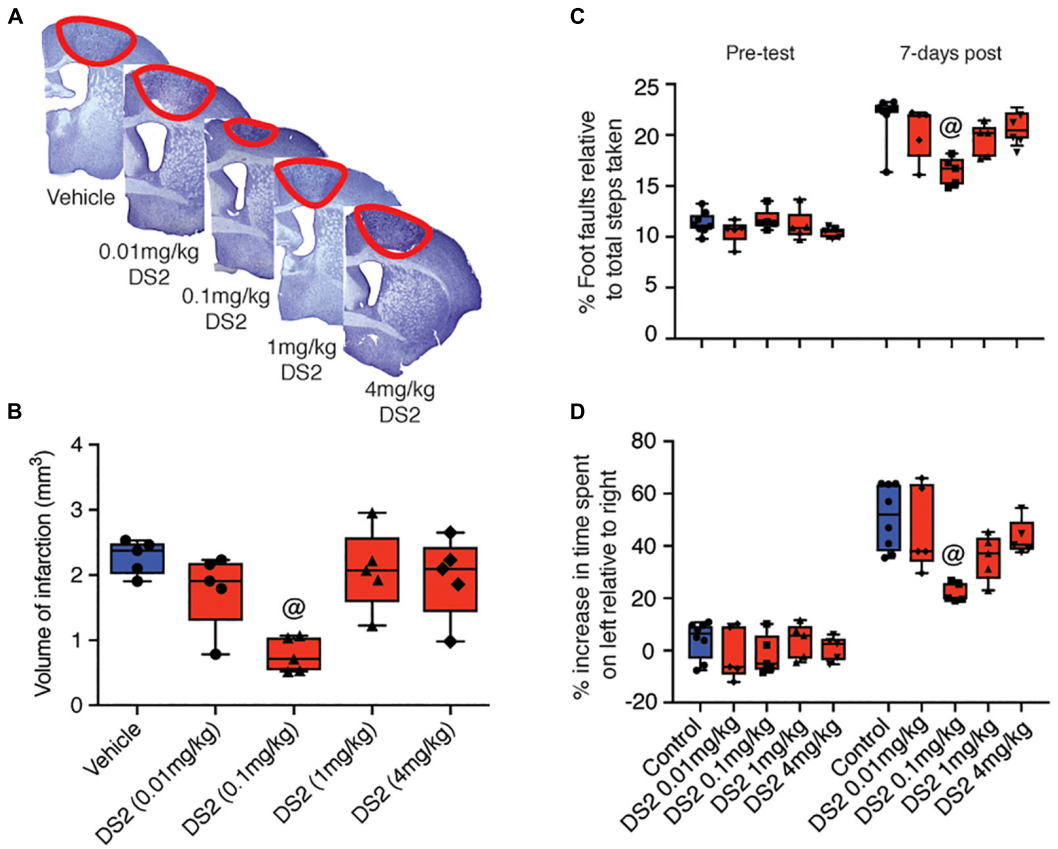

FIGURE 1 | Treatment with DS2 reduces infarct volume and improves functional outcomes post-stroke. Mice were subjected to focal stroke and injected intraperitoneally with either DS2 (0.01, 0.1, 1 or 4 mg/kg) or vehicle 1 and 24 h after the surgery. The brains were collected 7 days later, stained with cresyl violet and the stroke volume was calculated. **(A)** Representative cresyl violet-stained sections of animals treated with vehicle or three different concentrations of DS2. **(B)** Mice injected with 0.1 mg/kg DS2 had significantly smaller strokes than untreated animals. Baseline motor function was established by grid-walking and cylinder test 1 week prior stroke surgery. Mice treated with either vehicle or DS2 (0.01 0.1, 1, and 4 mg/kg) at 1 and 24 h post-stroke induction were assessed in the **(C)** grid-walking (foot-faults) and **(D)** cylinder task (forelimb asymmetry). Data are expressed as mean ± SD for n = 5-7 per group. $^{@}P < 0.01$ compared with vehicle control.

which did not change upon addition of the vehicle (2.5% DMSO). LPS-stimulated macrophages, pre-incubated with DS2 (10^{-3} to 10^{-4} M) showed a significant decrease in NF-kB activity ($P < 0.001$; **Figure 2C**) with levels being similar to unstimulated macrophages.

To confirm the anti-inflammatory effect of DS2, observed in the immortalized RAWblue macrophage cell line, we next tested DS2 using LPS-stimulated primary innate immune cells. For this experiment we generated BMDCs from bone marrow precursor cells by adding GM-CSF to the culture medium. Resulting $CD11c^{+}$ $MHCII^{+}$ BMDCs have previously been shown to closely resemble migratory DCs found *in vivo* (Helft et al., 2015), which makes them an interesting population to study in the stroke context. BMDCs were pre-incubated with varying concentrations of DS2 before LPS was added for 24 h. BMDCs were harvested and the expression of CD40, CD80, and CD86 determined by flow cytometry. BMDCs pre-incubated with the highest dose of DS2 (10^{-4} M) demonstrated a significant decrease in CD40, CD80 ($P < 0.01$) but not CD86 expression when stimulated with LPS (**Figures 2D–F**). Treatment with DS2 did not affect the viability of RAWblue macrophages and BMDCs (data not shown). This data further confirms that DS2 is having a positive effect to dampen the immune response.

DS2 Dampens Stroke-Induced Cytokine Production *in vivo*

Next, we investigated the effects of DS2 on inflammation post-stroke *in vivo*. As reported previously, we show that cerebral ischemia significantly increases peripheral cytokine levels of IL-1β (sham control versus stroke + vehicle: 109.91 ± 20.08 pg/mL versus 209.24 ± 54.05 pg/mL; $P < 0.01$, **Figure 3A**), TNF-α (sham control versus stroke + vehicle: 594.02 ± 97.44 pg/mL versus 960.98 ± 125.63 pg/mL; $P < 0.001$, **Figure 3B**), IL-6 (sham control: 185.33 ± 20.17 pg/mL versus stroke + vehicle: 299.50 ± 41.52 pg/mL; $P < 0.001$, **Figure 3C**), and IL-17 (sham control: 2145.31 ± 124.27 pg/mL, versus stroke + vehicle: 2934.50 ± 204.76 pg/mL; $P < 0.05$, **Figure 3D**). Treatment with DS2 significantly decreased circulating IL-6 (0.1 mg/kg,

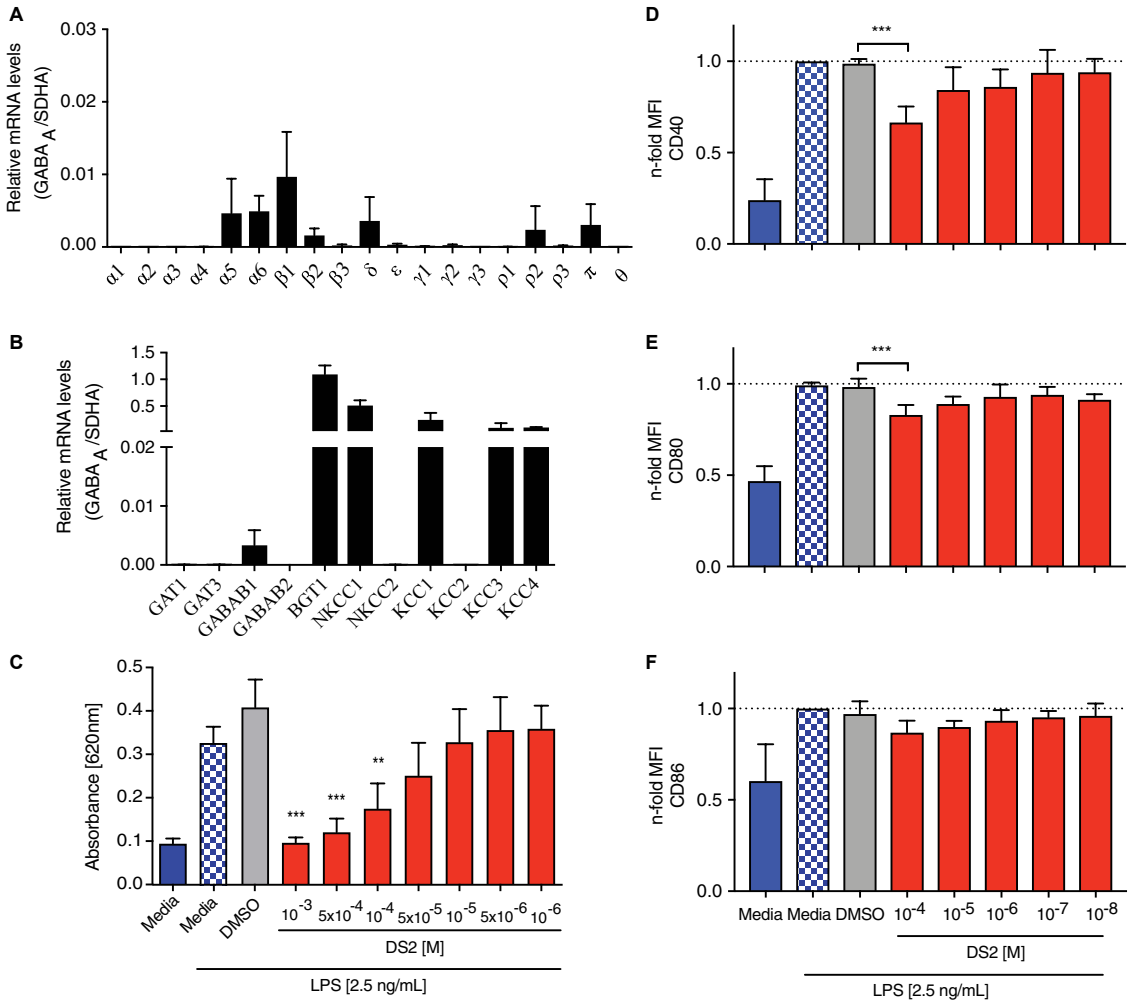

FIGURE 2 | DS2 dampens activation of innate immune cells after an inflammatory stimulus. **(A,B)** Expression of GABA receptor subunits by RAWblue macrophages was analyzed by qPCR. Relative mRNA levels of **(A)** GABA receptor subunits and **(B)** transporters involved in GABA signaling on unstimulated RAWblue macrophages in relation to the reference gene succinate dehydrogenase complex subunit A (SDHA) are shown. **(C)** RAWblue macrophages (5×10^4 cells/well) were either pre-treated with DS2 (10^{-3} to 10^{-6} M) or DMSO (2.5%) for 30 min or left un-treated before stimulation with LPS (2.5 ng/mL) for 6 h. Cell supernatants were collected and the extent of NF-κB activation was determined by quantifying the reporter protein SEAP with the Quantiblue™ assay. **(D–F)** BMDCs were incubated with decreasing concentrations of DS2 (10^{-4} to 10^{-8} M) for 30 min prior to the addition of LPS (100 ng/mL) to the cultures. BMDCs were harvested 24 h later and expression of cell surface markers CD40, CD80 and CD86 on live, $CD11c^+$ $MHCII^+$ BMDCs was determined by flow cytometry. MFI shown as n-fold increase over LPS-treated cells. Results are the mean ± SD of three independent experiments with three replicates each. $^{***}P < 0.001$ and $^{**}P < 0.01$.

$P < 0.01$; 1 and 4 mg/kg, $P < 0.05$), IL-17 and TNF-α levels ($P < 0.05$ and $P < 0.001$, respectively following treatment) at 3-days post-stroke. Treatment however, with DS2 did not have any effect on IL-1β levels with levels remaining similar to stroke + vehicle controls. These data suggest that DS2 can dampen an NF-kB-mediated pro-inflammatory response that is most likely occurring via δ-containing $GABA_A$ receptors located on immune cells.

DS2 Shows Limited Brain Exposure Following Systemic Administration

To correlate our *in vitro* data with our *in vivo* data, we assessed the ability of DS2 to cross the mouse BBB. We found that injection of a single dose of DS2 (i.p.,10 mg/kg), resulted in robust plasma, but only marginal brain exposure at either 0.5 or 1 h following dosing (**Table 2**). The free fraction of DS2 in brain tissue is very low (1.2% unbound, Saniona, unpublished data), corresponding to 54 and 64 nM free at 0.5 and 1 h following dosing respectively, which does not cover the ED50 for potentiating the effect of GABA at the α4β3δ receptors in L(tk-) cells (Wafford et al., 2009). As DS2 was speculated to act as a P-glycoprotein substrate, which could block the entry of DS2 into the brain, we next assessed if co-administration of DS2 with elacridar, an inhibitor of both p-glycoprotein and breast cancer resistance protein (BCRP) (Cutler et al., 2006), would increase brain DS2 levels. Assessment of both brain and plasma DS2 levels in the presence of elacridar revealed similar levels at both 0.5 and

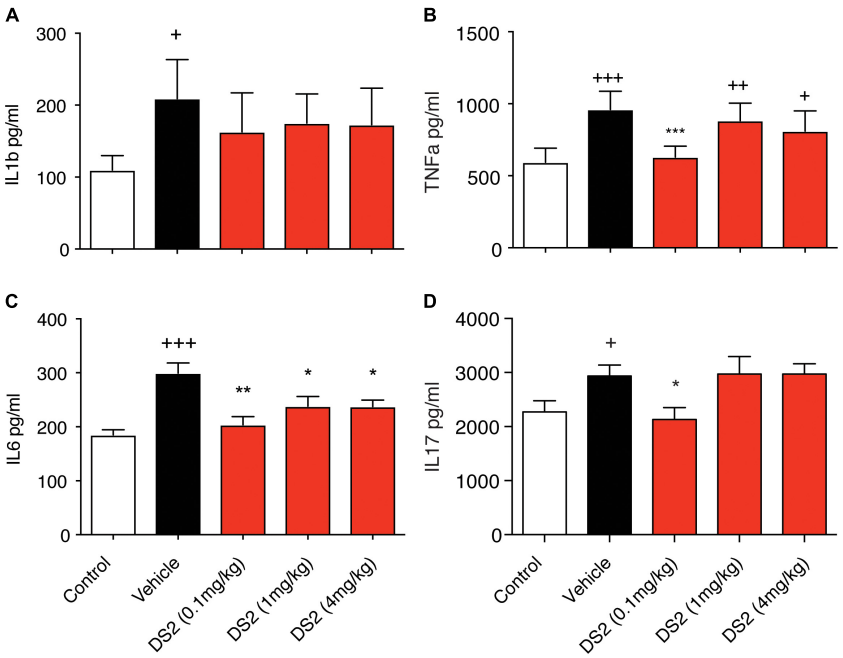

FIGURE 3 | DS2 decreases pro-inflammatory cytokine production post-stroke. Mice were injected i.p. with vehicle or DS2 (0.1, 1 or 4 mg/kg) 1 and 24 h after induction of stroke and peripheral blood collected from the tail vein of mice 3-days post-stroke. Sera were analyzed for **(A)** IL-β, **(B)** TNF-α, **(C)** IL-6, and **(D)** IL-17 concentrations using a BioPlex kit. Data are expressed as mean ± SD for $n = 5$ per group. $^{***}P < 0.001$, $^{**}P < 0.01$, $^{*}P < 0.05$ compared to vehicle. $^{+++}P < 0.001$, $^{++}P < 0.01$, $^{+}P < 0.05$ compared to sham control.

TABLE 2 | Brain and plasma concentrations following DS2 administration and co-treatment with or without elacridar.

		Without ng/ml (μM)	With ng/ml (μM)	Without ng/ml (μM)	With ng/ml (μM)			Without	With
DS2	0.5 h	12,205	12,262	1587	1696	1.0	1.1	0.13	0.14
		(34.5)	(34.7)	(4.5)	(4.8)				
	1 h	15,231	13,928	1874	1957	0.9	1.0	0.12	0.13
		(43.2)	(39.5)	(5.3)	(5.5)				

Data is expressed as both ng/ml and (μM) concentrations.

1 h following DS2 dosing as levels reported without elacridar, indicating that brain penetrance by DS2 is not restricted by active efflux by p-glycoprotein or BCRP (**Table 2**). These results suggest that DS2, in the dose tested, does not lead to sufficient free brain concentrations needed to activate the α4β3δ receptors indicating that the protective effects of DS2 most likely occur via modulation of the peripheral immune response or some as yet unknown mechanism. We also acknowledge that the BBB is leaky after stroke and more so in animals relative to humans, which could lead to mildly higher brain concentrations. However, in a recent study using a GABA modulator, we did not observe this (Clarkson et al., 2019).

DS2 Improves Functional Recovery When Administered at a Delay

Finally, as DS2 appears to dampen peripheral immune activation and only showed limited brain exposure, we assessed the role of DS2 to promote functional recovery after focal stroke to the motor cortex when administered at a delay of 3 days. DS2 was administered continuously from 3 to 28-days post-stroke, a critical period for neuroplasticity in rodents post-stroke (Corbett et al., 2017). This is also a period where we have previously reported that starting treatment with GABA modulators can aid in improving functional recovery without affecting stroke volume (Clarkson et al., 2010; Lie et al., 2017). Throughout the 42 day observation period, we detected marked forelimb motor deficits in the grid-walking and cylinder tasks in mice treated with vehicle only. Vehicle-treated mice showed limited spontaneous recovery (**Figures 4A,B**).

Chronic delayed treatment with DS2 improved motor performance of the affected forelimb on days 7, 14, and 28 post-stroke on the grid-walking task (**Figure 4A**). However, upon discontinuation of treatment, the DS2 treated animals showed a decrease in the recovery, such that no difference was observed in grid-walking performance at 42-days post-stroke compared with

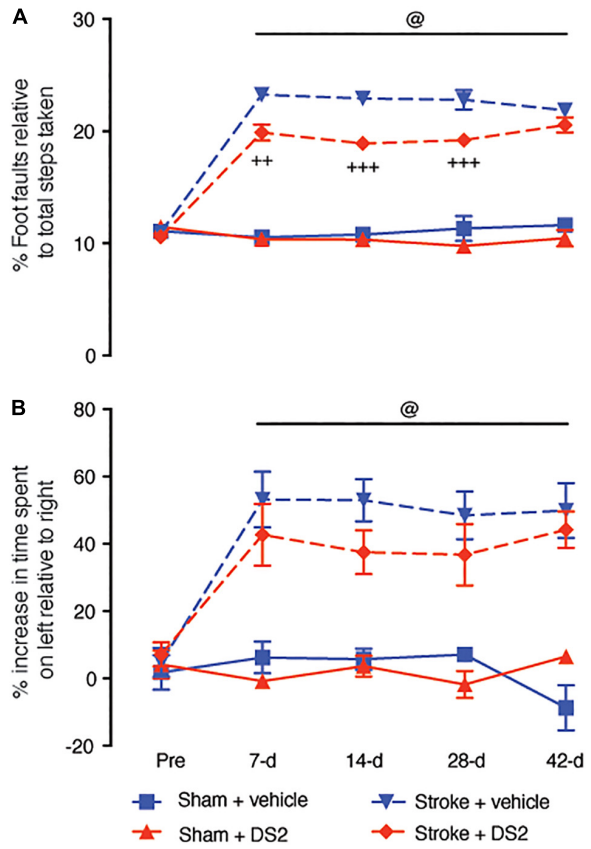

FIGURE 4 | Delayed administration of DS2 from day-3 post-stroke improves functional outcomes when continuously administered. Mice were subjected to focal stroke or sham surgery and DS2 (10 mM, red) or vehicle (blue) were loaded into ALZET 1002 mini-pumps and implanted subcutaneously from 3-days post-stroke. Mini-pumps were replaced after 2 week with new pumps to allow for continuous treatment for 28-days after stroke. Mice were assessed for functional deficits using the **(A)** grid-walking (foot-faults) and **(B)** cylinder task (forelimb asymmetry). Data are expressed as mean ± SD for $n = 7$ per group. $^{+++}P < 0.001$, $^{++}P < 0.01$ compared to stroke vehicle control. $^{@}P < 0.001$ compared to sham controls.

the vehicle-treated controls recovering from the stroke. Analysis of cylinder task performance showed no significant improvement in the presence of DS2 compared to vehicle treated controls (**Figure 4B**). However, it should be noted that some animals did show an improvement.

Delayed DS2 treatment did not induce any obvious signs of seizures or seizure-like behaviors in any of the mice throughout the 42 days. In addition, delayed treatment had no effect on infarct volumes (data not shown).

DISCUSSION

It is currently not fully understood how GABAergic compounds promote neuroprotection after stroke. $GABA_A$ receptor subtype-selective agonists, such as DS2 provide an opportunity to investigate the mechanism of action more thoroughly. Receptor subtype-selective compounds are more likely to have an effect and have therefore been investigated clinically for treating diseases, such as schizophrenia, Downs syndrome and autism (Rudolph and Knoflach, 2011; Rudolph and Mohler, 2014). Furthermore, using subtype selective GABAergic compounds will allow us to increase our understanding of GABA signaling post-stroke. In addition to the positive allosteric $GABA_A$ modulator described here, we have previously reported that negative modulation of $GABA_A$ receptors can improve stroke recovery when administered three days post-stroke (Clarkson et al., 2010). Within this timeframe, the infarct is fully developed and pharmaceutical treatments aimed to improve cortical excitability do not necessarily change the infarct size (Clarkson et al., 2010, 2011). These findings have led to pharmaceuticals companies developing compounds that aim to normalize extrasynaptic $GABA_A$ inhibition, and assess these for stroke in human Phase II clinical trials (ClinicalTrials.gov ID: Hoffman La-Roche – NCT02928393; Servier RESTORE BRAIN Study – NCT02877615).

Activation of $GABA_A$ receptors can mediate both synaptic and extrasynaptic inhibitory currents depending on the receptor composition (Sieghart, 1995). α5- or δ-subunits are crucial components of extrasynaptic $GABA_A$ receptors in the hippocampus, cortex and thalamus (Glykys and Mody, 2007; Olsen and Sieghart, 2009). Antagonism of α5- or δ-subunits facilitates pyramidal neuron signaling to afferent inputs (Drasbek and Jensen, 2006; Glykys and Mody, 2007), and enhances neuronal network excitability (Walker and Semyanov, 2008). Since extrasynaptic $GABA_A$ receptors play an important role in shaping neuronal excitability, modulation of α5- or δ-subunits early could offer a viable treatment for reducing the glutamate-mediated hyperexcitability, which we have recently reported following treatment with the flavonoid, 2'MeO6MF (Clarkson et al., 2019). As flavonoids can have multiple modes of action it is good to assess the mechanistic function of δ-subunit-mediated protection using other δ-subunits modulators, such as DS2 (Wafford et al., 2009) or AA29504 (Vardya et al., 2012).

Prior studies have shown that DS2 binds to and modulates δ-subunit containing extrasynaptic $GABA_A$ receptors in neuronal cell culture systems (Wafford et al., 2009; Jensen et al., 2013; Lee et al., 2016). DS2 enhances the maximum GABA response at α4/6βxδ $GABA_A$ receptors while only a minimal response is observed at α4/6βxγ2 $GABA_A$ receptors, clearly indicating a δ-subunit preference of DS2. While the potency of DS2 is influenced by which α-subunit is present in the receptor complex (α4/6βxδ > α1βxδ >> γ2-GABAA receptors), the type of β-subunit does not affect the potency as much (Wafford et al., 2009; Ahring et al., 2016). Our findings suggest that the effects of DS2 on macrophages are most likely mediated via binding to α6β1/2δ $GABA_A$ receptors. Previously, α6βδ-subunit containing $GABA_A$ receptors have been identified in cerebellar granule cells (Nusser et al., 1998) whereas α4βδ receptors were found in hippocampal interneurons (Barnard et al., 1998).

Our study is one of the first to assess the biological efficacy of DS2 *in vivo*, and in doing so confirm the observation by Jensen et al. (2013) that DS2 has a limited ability to cross the BBB. In the studies by Jensen and colleagues, treatment with DS2, even at doses 10-fold higher than what we used in

the current study, DS2 failed to show any biological response when assessed for gross behavior, psychosis and pain. While the brain concentration we report of 1587 ng/ml (4.5 μM) following a single 10 mg/kg i.p. dose appears modest, the free fraction is only 1.2% of this and therefore, equates to a 45 nM dose equivalent to an ED1-ED5 for potentiating the effect of GABA at the α4β3δ receptors. In our studies, we observed a significant reduction of stroke infarct size and an improvement of functional outcomes after administration of two doses of 0.1 mg/kg DS2. According to our pharmacokinetic studies it can be expected that this dose would result in a total and free plasma concentration of 345 and 4.1 nM, respectively. The total and free DS2 brain concentration are estimated to be 45 and 0.54 nM after a dose of 0.1 mg/kg DS2. Such low brain concentrations are unlikely to elicit a biological effect. It still remains to be determined whether these low concentrations of DS2 can exert a local effect on extrasynaptic $GABA_A$ receptors. The lack of efficacy of DS2 at higher doses could be due to a couple of reasons: (1) potentially desensitization of the delta subunit at these slightly higher doses, which means DS2 may switch from having an agonist effect to having an antagonist effect, but most likely (2) the biphasic dose response is due to hormesis (Calabrese et al., 2017). The term hormesis, which means "to excite," was first described when researchers found some fungi from Red Cedar trees displayed a stimulatory effect at low-doses whilst having an inhibitory effect at high-dose for cell metabolism and survival (Calabrese et al., 2017). Such hormetic dose-responses have been reported previous for stroke, but mainly in a neuroprotective/preconditioning setting (Bradley et al., 2014). In addition, similar hormetic responses have also been extensively reported for cancer and inflammatory conditions (Calabrese, 2005). The mechanisms that underpin hormetic responses is poorly understood, but it is known that changes in intracellular signaling pathways are also altered and it could be an intrinsic cellular response that ensures neuronal activity does not get too out of balance. This is clearly an area that requires much needed work, especially when it comes to drug receptor interactions and pharmacokinetic responses.

In this study, we demonstrate that DS2 can act by dampening immune cell activation and inflammation, offering this as a novel mechanism of action for DS2. Innate and adaptive immune cells produce functional $GABA_A$ receptors (Fuks et al., 2012) where binding of GABA has been demonstrated to reduce inflammation (Reyes-Garcia et al., 2007). Mechanistically this has been linked to a GABA-mediated decrease in IL-1β, IL-6, and IL-12 production following LPS-stimulation of innate immune cells, including peritoneal macrophages (Reyes-Garcia et al., 2007; Bhat et al., 2010). Here we add to these observations by showing that the δ-subunit preferring $GABA_A$ agonist, DS2, reduced LPS-induced NF-kB activation in a murine macrophage cell line and decreased expression of co-stimulatory molecules in primary BMDCs. The influx of DCs into the brain increases dramatically post-stroke and is associated with elevated expression of co-stimulatory molecules MHCII, CD40, and CD80 (Gelderblom et al., 2009; Posel et al., 2014). The induction of these co-stimulatory molecules occurs following exposure to DAMPs that are derived from dying and necrotic cells in the post-ischemic hemisphere (Offner et al., 2006; Gelderblom et al., 2009; Felger et al., 2010). Mature DCs are able to present antigens on MHC molecules to T-cells (signal 1) and provide co-stimulation through CD40, CD80, and CD86 expression (signal 2) and cytokine secretion (signal 3). The initiation of an adaptive immune response has been linked to development of autoimmunity and worse outcomes in stroke patients (Becker et al., 2011). Reduced expression of the co-stimulatory markers seen after treatment of BMDCs with DS2 may therefore translate into decreased ability of DCs to stimulate autoimmune responses in the post-ischemic brain. Since administration of the δ-subunit-selective compound, DS2, led to a decreased inflammatory response in murine macrophages and BMDCs, it is tempting to speculate that the δ-subunit is a crucial component for elucidating anti-inflammatory responses through $GABA_A$ receptors. This is supported by studies showing good expression levels of the δ-subunit in a range of murine and human innate immune cells, such as peritoneal macrophages (Reyes-Garcia et al., 2007), human peripheral blood mononuclear cells (Alam et al., 2006), monocytes and immortalized monocytic cell lines (Wheeler et al., 2011).

Interestingly, expression of $GABA_A$ receptors and in particular the δ-subunit has also been found in resting, activated and encephalitogenic T-cells (Tian et al., 2004; Bjurstom et al., 2008). Even though it remains to be determined if DS2 has a direct effect on T-cells it is likely that DS2 modulates T-cells indirectly. Bhat et al. (2010) have previously demonstrated a direct effect of GABAergic agents on innate immune cells, which did not affect cytokine production or proliferation of T-cells directly. However, cytokines secreted by innate immune cells altered the function of T-cell, which was associated with delayed onset and reduced severity in an animal model of multiple sclerosis. This links a reduced activity of innate immune cells with downstream T-cell responses, known to have a major impact on neurological diseases (Brait et al., 2012; Anderson et al., 2014).

The production of pro-inflammatory cytokines and expression of activation markers on innate immune cells has been previously observed to impact the priming of naïve T-cells and drives the polarization of T-cells toward a distinct effector function (Martin-Fontecha et al., 2003; Joffre et al., 2009). In particular, polarization of γδ T-cells and αβ T-cells toward IL-17-producing subsets has been shown to negatively impact stroke recovery (Shichita et al., 2009). T-cells, producing IL-17 have been found in increased numbers in the blood of patients early after stroke onset and has also been observed in post-mortem brain tissue of stroke patients (Kostulas et al., 1999; Gelderblom et al., 2012). IL-17 also contributes to disruption of BBB tight junctions and neutrophil recruitment into the brain, resulting in further tissue damage (Kebir et al., 2007; Wang et al., 2009; Gelderblom et al., 2012). We report here that systemic administration of DS2 decreases blood cytokine levels of, IL-6, TNF-α, and IL-17, three days post-stroke, which suggests that DS2-mediated suppression of innate immune cell activation could be associated with reduced numbers of Il-17 producing cells infiltrating the brain. It should be noted however, that not all cytokines are suppressed, as IL-1β is still elevated indicating

that part of the innate immune system is most likely still active, the extent of which requires further investigation.

In addition to influencing immune cell phenotypes, inflammatory cytokines, such as TNF-α are able control the extent of immune cell entry into the CNS at the choroid plexus epithelium (Kunis et al., 2013). Here, TNF-α and interferon-γ synergistically promote the expression of trafficking molecules that promote the entry of leukocytes into the CNS under conditions of inflammation. Based on our data, it is possible to assume that the dampened systemic TNF-α levels following treatment with DS2, may inhibit the trafficking of immune cells through the choroid plexus and into the CNS. The reduction in systemic cytokine levels may also be interesting in the context of the recent discovery that innate immune cells originate from the skull bone marrow and migrate to the brain after ischemic injury (Herisson et al., 2018). The skull bone marrow can be reached by the systemic blood supply, containing drugs, such as DS2 and thus potentially impact the trafficking of leukocytes via modulation of cytokine and chemokine expression.

We show here that administration of DS2 attenuates peripheral cytokine levels, associated with inflammation. Recent work demonstrated that pro-inflammatory cytokines, such IL-1β affect the surface expression of $GABA_A$ receptor subunits, such as α_5, which impaired memory (Wang et al., 2012). We observed using DS2 that this also applies to δ-containing $GABA_A$ receptors. Increased cytokine levels could drive a delayed increase in extrasynaptic GABA signaling post-stroke (Clarkson et al., 2010). The relationship between blood cytokine levels and changes in extrasynaptic GABA currents has been reported, however, the mechanisms linking the two remain poorly understood. This could be happening in part via Phosphatidylinositol 3-Kinase/Akt signaling (Serantes et al., 2006). A change in cytokine production would most likely be mediated by the compound acting on immune cells directly and reducing the secretion of cytokines and not via alterations in GABA signaling. In support of this, we report that, DS2 show only limited brain exposure, and most likely dampens NF-kB activity in immune leading to reduced release of cytokines. This in turn could prevent the infiltration of immune cell and release of cytokines in the brain to alter GABA inhibitory currents. Increasing extrasynaptic GABA signaling does not trigger inflammatory processes, however, increased blood cytokine levels can elevate extrasynaptic GABA signaling. For this reason, compounds reducing cytokine production can be used within a day of stroke onset to reduce tissue damage. In addition, as the immune cell/inflammatory cascade is elevated across a protracted time window, starting treatment from day 3 post-stroke also modestly improve functional recovery. Interestingly, DS2 failed to dampen all pro-inflammatory cytokines, so the elevated IL-1β levels still present could possibly have an effect tonic inhibitory currents and still impair some recovery from happening.

In summary, we show here that increasing $GABA_A$ signaling early provides protection, improves motor function and reduces peripheral cytokine levels associated with inflammation. In addition, delaying treatment until 3-days post-stroke resulted in a modest effect to improve functional recovery. In summary, our results identify $GABA_A$ receptors containing the δ subunit as a novel target for stroke therapy and suggest peripheral inflammation as an important factor in driving cell death and impairing recovery post-stroke. However, it should be noted that dosing at these sites does appear to illicit a hormetic dose-response and the mechanisms that underpin this are yet to be ascertained.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

AUTHOR CONTRIBUTIONS

SN, LB-B, EG, TJ, and AC acquired and analyzed the data, and critically revised the manuscript. SN, PA, KS-N, SY, and AC designed the experiments, analyzed the data, and prepared and edited the manuscript. All authors reviewed and approved the final version of the manuscript and have also agreed to be accountable for the content of the work.

FUNDING

This work was supported by a Health Research Council and Royal Society of New Zealand Project grants (AC). This publication was drafted during a New Zealand Lottery Health Postdoctoral Fellowship (SN).

ACKNOWLEDGMENTS

We thank Dr. Zabeen Lateef for technical advice on growing the RAW Blue cells and Professor Vernon Ward for providing these cells.

Various studies performed in cultured cells and in *in vivo* models of neuronal damage showed that cannabinoids exert a neuroprotective effect. The increase in cannabinoids and cannabinoid like substances after stroke has been postulated to limit the content of neuronal injury. As well-accepted, inflammation, and neuronal damage are coupled processes and microglial cells as the main intrinsic immunological effector within the brain play a central role in their regulation. Treatment with the endocannabinoid, 2-arachidonoylglycerol (2-AG) or the endocannabinoid-like substance, palmitoylethanolamide (PEA) affected microglial cells and led to a decrease in the number of damaged neurons after excitotoxical lesion in organotypic hippocampal slice cultures (OHSC). 2-AG activated abnormal cannabidiol (abn-CBD) receptor, PEA was shown to mediate neuroprotection via peroxisome proliferator-activated receptor (PPAR)α. Despite the known neuroprotective and anti-inflammatory properties, the potential synergistic effect, namely possible entourage effect after treatment with the combination of these two protective cannabinoids has not been examined yet. After excitotoxical lesion OHSC were treated with PEA, 2-AG or a combination of both and the number of damaged neurons was evaluated. To investigate the role of microglial cells in PEA and 2-AG mediated protection, primary microglial cell cultures were treated with lipopolysaccharide (LPS) and 2-AG, PEA or a combination of those. Thereafter, we measured NO production, ramification index, proliferation and PPARα distribution in microglial cells. While PEA or 2-AG alone were neuroprotective, their co-application vanished the protective effect. This behavior was independent of microglial cells. Furthermore, PEA and 2-AG had contrary effects on ramification index and on NO production. No significant changes were observed in the proliferation rate of microglial cells after treatment. The expression of PPARα was not changed upon stimulation with PEA or 2-AG, but the distribution was significantly altered. 2-AG and

PEA mediated neuroprotection was abolished when co-applied. Both cannabinoids exert contrary effects on morphology and function of microglial cells. Co-application of both cannabinoids with different targets did not lead to a positive additive effect as expected, presumably due to the contrary polarization of microglial cells.

Keywords: 2-arachidonoylglycerol, palmitoylethanolamide, peroxisome proliferator-activated receptor, neuroprotection, microglial cells

INTRODUCTION

Traumatic brain injury affects a high number of young adults and their hospitalization is still a significant public challenge (Meaney et al., 2014). During neuronal damage a complex series of mechanisms becomes activated (Dirnagl et al., 2003; Kunz et al., 2010). Energy failure leads to calcium overload, depolarization of neurons and release of neurotransmitters with consecutive excitotoxicity, induced through overstimulation from excitatory receptors like NMDA receptor. This cascade is followed by activation of proteolytic enzymes and release of reactive oxygen species, damaging mitochondria, followed by apoptosis and neuronal death (Bruce et al., 1995; Kunz et al., 2010). Injured neuronal tissue releases pro-inflammatory cytokines leading to migration of inflammatory cells to the damaged site and inflammation (Jassam et al., 2017). Microglial cells play a crucial role during this process of secondary neuronal damage since they are the immunocompetent cells of the central nervous system (Kettenmann et al., 2011).

Cannabinoids positively affect cellular and molecular processes during ischemic, excitotoxical, or traumatic brain injury and were shown to be protective in different models mostly via microglial cells. All kind, plant-derived (isolated from *Cannabis sativa*), endo- (animal-derived) and synthetic cannabinoids were shown to affect neuronal damage (Kreutz et al., 2007, 2009; Mechoulam and Shohami, 2007; Koch et al., 2011a,b; Grabiec et al., 2012; Fernández-Ruiz et al., 2015; Guida et al., 2017; Belardo et al., 2019; Impellizzeri et al., 2019). Using the model of excitotoxically lesioned OHSC the number of damaged neurons was significantly reduced after treatment with endocannabinoids, like *N*-arachidonoyl dopamine, 2-arachidonoylglycerol (2-AG) or PEA associated with altered microglial cell number but not the phytocannabinoid, Δ-9-tetrahydrocannabinol (Kreutz et al., 2007; Koch et al., 2011a; Grabiec et al., 2012).

2-AG was shown to induce protection after neuronal lesion and to reduce the amount of tumor necrosis factor α released from LPS activated microglial cells (Facchinetti et al., 2003). Both, PEA and 2-AG are produced in the central nervous system and upregulated after neuronal damage (Kondo et al., 1998; Panikashvili et al., 2001; Franklin et al., 2003) and were shown to exhibit neuroprotection in several *in vivo* and *in vitro* models (Koch et al., 2011a; Beggiato et al., 2018; Herrera et al., 2018). Anti-inflammatory effects of PEA were associated with PPARα activation (LoVerme et al., 2005; Koch et al., 2011a; Citraro et al., 2013), and induction of PPARα expression was related in parallel to protective effects (Genovese et al., 2008; Koch et al., 2011a). A recent study demonstrated the presence of PPARα in different brain regions on neurons, astrocytes and microglial cells (Warden et al., 2016). Effects of 2-AG were abolished by O-1918 and cannabidiol (CBD), both antagonists of the abn-CBD sensitive receptor (abn-CBDR) (Kreutz et al., 2009). Evidence for functional abn-CBDR in the brain was pharmacologically found on microglial cells (Franklin and Stella, 2003; Walter et al., 2003; Kreutz et al., 2009). Consequently, 2-AG mediated protection depends on the presence of microglial cells as confirmed by microglial cells depletion (Kohl et al., 2003; Kreutz et al., 2009).

2-AG mediated protective properties were demonstrated in a variety of animal models of degenerative neurological disorders including multiple sclerosis, Parkinson's disease, and Alzheimer's disease (Scotter et al., 2010; Pertwee, 2014; Mounsey et al., 2015) and *in vitro* in astrocytes exposed to oxygen-glucose deprivation (Wang et al., 2015, 2018). 2-AG is the most abundant endocannabinoid in the brain and known to bind and activate CB_1 and CB_2 receptors. The treatment with exogenous 2-AG attenuated neuronal damage *in vivo* partly via CB_1 and mimicked the effects reported after aplication of synthetic CB_2 agonists. Some effects were absent in $CB_1^{-/-}$ mice (Mechoulam and Shohami, 2007; Magid et al., 2019). Furthermore, Carrier et al. (2004) observed that 2-AG affected microglial cells via CB_2. However, in rat OHSC and after NMDA damage effects of 2-AG were not blocked by CB_1 or CB_2 antagonists but inhibited by abnormal cannabidiol sensitive receptor (abn-CBDR) antagonists. These results make an involvement of CB_1 or CB_2 in 2-AG mediated neuroprotection unlikely (Kreutz et al., 2009). Application of PEA improved neuronal survival *in vitro* in primary mouse cortical astrocyte-neuron co-cultures (Beggiato et al., 2018) and in cortical neurons after hypoxia (Portavella et al., 2018). PEA possessed further beneficial properties in animal models of degenerative neurological disorders including vascular dementia (Siracusa et al., 2017). PEA and anandamide, if administrated together reduced the pain response 100-fold more potently than both substances alone and induced stronger vascular effects (Calignano et al., 1998; Ho et al., 2008). Such a co-application of two active cannabinoids increased their efficacy via the so called entourage effect, which is an endogenous cannabinoid molecular regulation route (Ben-Shabat et al., 1998). Ben-Shabat et al. (1998) demonstrated for the first time, that two inactive compounds, namely 2-linoleoylglycerol and 2-palmitoylglycerol potentiate the binding of 2-AG to the CB_1 and thereby its effects. Additionally, 2-linoleoylglycerol significantly inhibited the inactivation of 2-AG. Similarly, PEA was reported to prevent the inactivation of anandamide (Jonsson et al., 2001;

Abbreviations: 2-AG, 2-arachidonoylglycerol; abn-CBD, abnormal cannabidiol; abn-CBDR, abn-CBD-sensitive receptor; CB, cannabinoid receptor; CBD, cannabidiol; div, day *in vitro*; iNOS, inducible nitric oxide synthase; LPS, lipopolysaccharide; NMDA, *N*-methyl-D -aspartate, NO, nitric oxide; OHSC, organotypic hippocampal slice cultures; PEA, palmitoylethanolamide; PPAR, peroxisome proliferator-activated receptor.

Ho et al., 2008) indicating possible entourage effect. Microglial cells, the main immune cell of the central nervous system, has a ramified morphology and is stationary, surveying its surrounding if in an undamaged and non-inflammatory state (Smith et al., 2012). In pathologies, like neuropathic pain CB_2 expression increased in parallel to appearance of activated microglial cells. CB_2 ligands significantly alleviated the pain indicating that microglial cells are a main target of cannabinoids (Zhang et al., 2003; Luongo et al., 2010). During neuronal damage microglial cells become amoeboid, migrate to the lesion site, proliferate and can be affected by cannabinoids, as for example PEA potentiates microglial cell motility (Franklin et al., 2003; Vinet et al., 2012). Microglial cells mediate neuroprotection, but can also contribute to the damage, e.g., by upregulation of iNOS, an enzyme producing toxic amounts of NO from L-arginine (Garry et al., 2015). 2-AG was shown to induce the iNOS expression and NO production (Lipina and Hundal, 2017) and to stimulate NO release in invertebrate immune cells via CB_1 (Stefano et al., 2000). Contrary, NO donors were found to be neuroprotective (Kakizawa et al., 2007). Little is known about the influence of endocannabinoids on arginase, which inhibits the production of NO as a competing regulatory enzyme in the arginase-NO-synthase regulatory system in microglial cells. In peripheral immune cells Δ-9-tetrahydrocannabinol and AM1241, an CB_2 agonist induced arginase 1 expression (Hegde et al., 2010; Ma et al., 2015).

Earlier studies consistently reported about increased levels of endocannabinoids, such as PEA or 2-AG after neuronal injury. A question is raised why the secondary neuronal damage can't be prevented despite the high presence of neuroprotective substances. Since both endocannabinoids 2-AG and PEA if applied exogenously were shown to be neuroprotective via abn-CBDR or PPARα respectively, we asked whether the neuroprotective potential of both is additive. To assess a potential entourage effect between 2-AG and PEA on neuroprotective properties OHSC were excitotoxically lesioned and treated with PEA, 2-AG or combination of both. As mentioned, PEA and 2-AG target microglial cells. Therefore, their effects on function and morphology of primary microglial cells were investigated in untreated or LPS stimulated cultures. Ramification index, NO production, proliferation index, and temporal PPARα distribution were determined overtime.

MATERIALS AND METHODS

All experiments involving animal material were performed in accordance with the directive 2010/63/EU of the European Parliament and the Council of the European Union (22.09.2010) and approved by local authorities of the State of Saxony-Anhalt (permission number: I11M18, date: 01.12.2012) protecting animals and regulating tissue collection used for scientific purposes.

Materials

2-Arachidonylglycerol (2-AG, 10 nM, stock solved in DMSO; Tocris, Minneapolis, MN, United States, cat No. 1298), Clodronate (100 μg/ml, stock solved in Aqua; Bayer Vital GmbH GB; PZN: 04299668), Palmitoylethanolamide (PEA, 10 nM, stock solved in DMSO, Tocris, cat No. 0879), LPS (10 ng/ml, stock solved in Aqua; Sigma-Aldrich, cat No. L8274) and NMDA (50 μM, stock solved in Aqua bidest., Sigma-Aldrich, cat No. M3262) were used and applied to the culture medium according to treatment protocol.

Cell Culture

Primary microglia astrocyte co-cultures were prepared from 1 day old Wistar rats and cultured, as described earlier (Kohl et al., 2003; Grabiec et al., 2012). Briefly brains were treated with 0.5 mg/mL DNAse (Worthington, Bedford, MA, United States) and 4 mg/mL trypsin (Merck Millipore, Billerica, MA, United States) solved in Hank's balanced salts solution (Invitrogen, Carlsbad, CA, United States). Cells were cultured in DMEM (Invitrogen, cat No. 41965-062) with 10% FBS (Invitrogen, cat No. 10500-062) and 1 ml streptomycin/penicillin (Invitrogen). After 10 days microglial cells were isolated from astrocytic monolayer and seeded into well plates.

For immunocytochemical analysis 50,000 cells were placed on glass cover slips coated with poly-L-lysin and allowed to attach for 3 h. Cannabinoids were applied for 48 h to determine the microglial cells morphology. Bromodeoxyuridine (BrdU) (0.01 mM, Sigma-Aldrich) was added to the culture medium 16 h before the fixation to assess proliferation. Intracellular distribution of PPARα was analyzed 1, 6, and 24 h after treatment. The cells were fixed with 4% paraformaldehyde (Sigma-Aldrich, Munich, Germany) for 10 min and stored in 0.02M PBS at 4°C for further analysis.

For NO measurement supernatant of 50,000 cells treated for 72 h with cannabinoids was collected and stored at −80°C until further analysis.

Organotypic Hippocampal Slice Cultures (OHSC)

Organotypic hippocampal slice cultures were prepared from 7 to 9 day old Wistar rats as reported earlier (Grabiec et al., 2012, 2017; Hagemann et al., 2013; Hohmann et al., 2017, 2019) and kept at 35°C in a fully humidified atmosphere with 5% (v/v) CO_2. Culture medium was changed every other day. After 6 days *in vitro* experiments were started. All slices despite the control groups were treated with NMDA (50 μM) for 4 h. OHSC were treated with PEA (10 nM) or 2-AG (10 nM) or their combination for 72 h. The NMDA treated set of excitotoxically damaged OHSC was supplemented with 2-AG, PEA or combination of both or left untreated to asses an effect on neuronal damage in region of dentate gyrus.

To investigate the role of microglial cells OHSC were incubated with 100 μg/ml clodronate from 1 to 6 day *in vitro* (div). Clodronic acid, a bisphosphonate, affects only cells of the monocytic lineage and leads to apoptosis of microglia and macrophages (Kohl et al., 2003) (**Figures 1**, **2A**).

All slice cultures were treated with propidium iodide (PI; Merck Millipore, cat No. 537059) 2 h prior to fixation to visualize

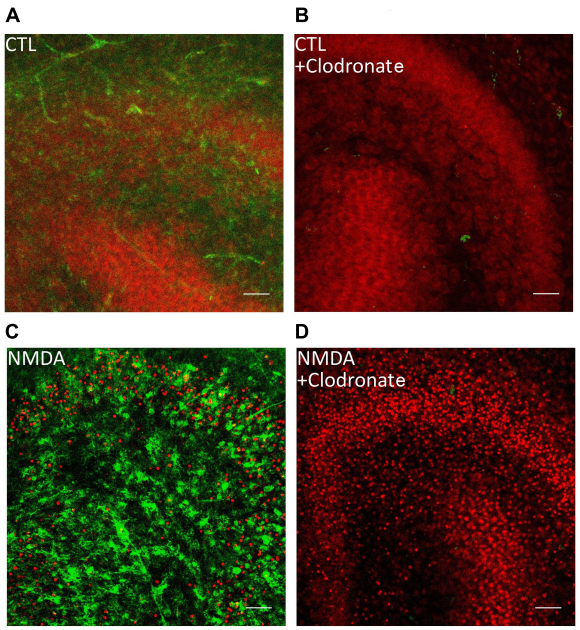

FIGURE 1 | Clodronate depletes microglial cells from OHSC. **(A)** PI labeled control OHSC with dentate gyrus and CA3. No PI positive nuclei (red) and ramified IB_4 (green) labeled microglial cells are visible. **(B)** Application of clodronate to CTL slices removed IB_4 positive microglial cells without damaging the neurons. **(C)** Treatment with NMDA led to massive increase in PI positive cells and IB_4 positive microglia. **(D)** Depletion of microglial cells led to exacerbation of neuronal damage after NMDA treatment in OHSC. Scale bar = 50 μm.

degenerated neurons (Ebrahimi et al., 2010; Grabiec et al., 2012, 2017; Hezel et al., 2012).

Immuno-, Lectinhistochemistry and Staining

All antibodies and lectins and conditions used are listed in **Table 1**. For labeling of incorporated BrdU fixed microglial cells were incubated with 2 mol/l HCl for 1 h, washed three times with PBS/Triton and pre-incubated with normal horse serum (Gibco BRL, Life Technologies, Eggenstein, Germany, cat No. 31874, dilution 1:20) in PBS/Triton. Afterward anti-BrdU antibody (**Table 1**) was applied for 1 h, followed by incubation with Alexa 488 conjugated goat anti-mouse antibody for 1 h. Cells were washed three times with PBS/Triton and incubated with 4′,6-diamidino-2-phenylindole (DAPI, Sigma-Aldrich, Munich, Germany, cat No. D9542).

Organotypic hippocampal slice cultures were stained with Alexa 488 conjugated IB_4 (Molecular Probes). All fluorescence stained slides were washed with PBS/Triton and Aqua dest. before covering with mounting medium (DAKO, Agilent Technologies, Inc., Santa Clara, CA, United States).

For measurement of ramification index biotin labeled IB_4 was used. To measure the PPARα distribution, an anti-PPARα antibody was applied as characterized before (Koch et al., 2011a). After washing with PBS, biotinylated goat anti-rabbit antibody

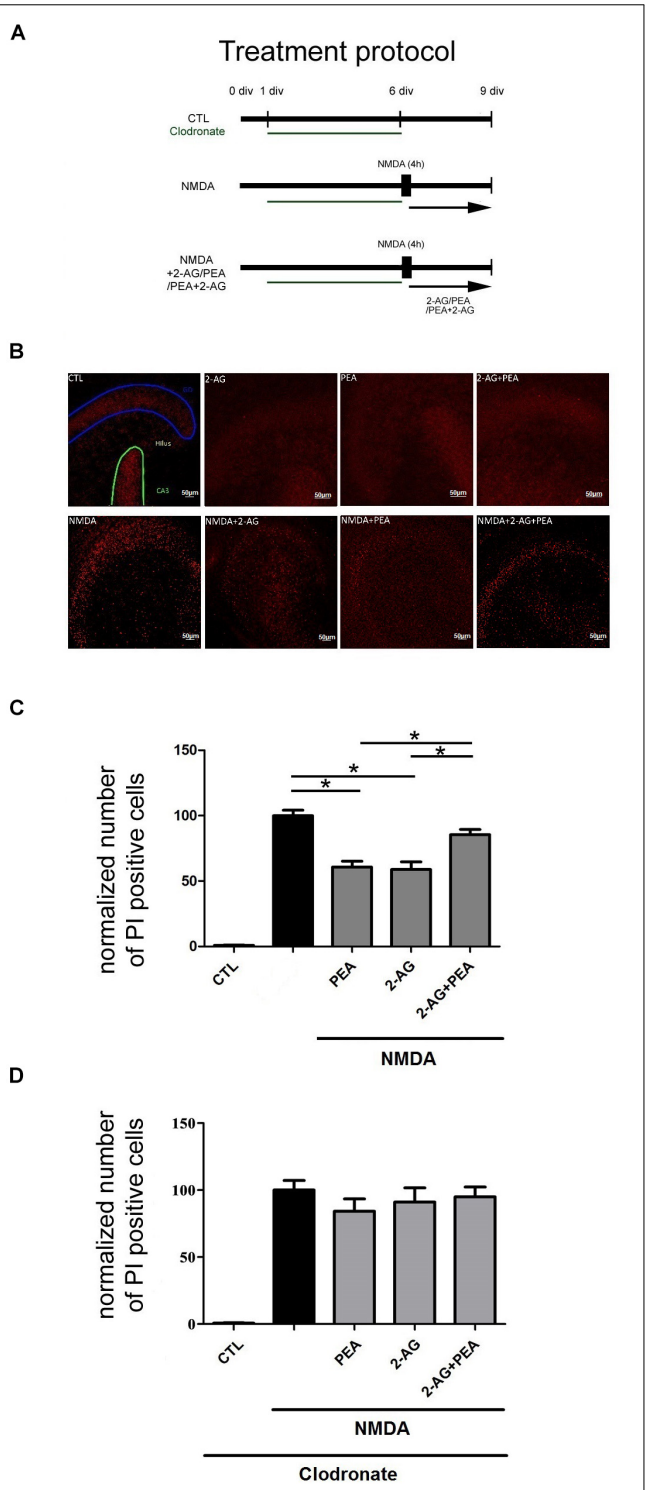

FIGURE 2 | Effects of 2-AG and PEA in excitotoxically damaged OHSC. 2-AG and PEA did not further decrease the number of PI positive degenerated neurons in comparison to OHSC treated with 2-AG or PEA alone.
(A) Treatment protocol. Control OHSC (CTL), were kept in culture medium and served as negative controls. The NMDA treated group function as positive control (NMDA). For microglial cells depleted groups clodronate (green) was applied from 1 div until 6 div. Cannabinoids were added alone on day 6 *in vitro*

(Continued)

FIGURE 2 | Continued
(div) to OHSC or following 4 h incubation with NMDA (NMDA+2-AG/PEA/PEA+2-AG). The fixation was performed on 9 div. **(B)** Representative images of the dentate gyrus in OHSC stained with PI (in red). After NMDA damage a massive increase in the number of damaged neurons occurred in comparison to control group (CTL), PEA, and 2-AG significantly reduced the neurodegeneration, but combination of both did not significantly reduce the number of PI positive nuclei. Dentate gyrus (GD) is highlighted in blue, Cornu ammonis (CA) 3 in green. Scale bar = 50 μm. **(C)** Quantitative analysis of PI positive nuclei in treated groups. The number of PI positive neurons increased significantly after treatment with NMDA (n_{NMDA} = 42) in comparison to control group (n_{CTL} = 42). 2-AG, PEA alone or combination of both had no effect on viability of OHSC (n_{PEA} = 12, n_{2-AG} = 12, $n_{2-AG+PEA}$ = 10). Treatment with PEA ($n_{NMDA+PEA}$ = 23) or 2-AG ($n_{NMDA+2-AG}$ = 20) of excitotoxically damaged OHSC reduced significantly the number of PI positive cells. The combination of 2-AG and PEA after NMDA damage induced no significant protective effect ($n_{NMDA+2-AG+PEA}$ = 34). **(D)** Treatment of microglia depleted OHSC with NMDA induced a massive neuronal damage (n_{CTL} = 15, n_{NMDA} = 18). The application of PEA, 2-AG or combination of both to clodronate treated NMDA damaged OHSC had no significant effect on the number of PI positive cells ($n_{CLO+NMDA+2-AG}$ = 12, $n_{CLO+NMDA+PEA}$ = 12, $n_{CLO+NMDA+2-AG+PEA}$ = 14). Statistics was performed using a One-Way ANOVA with Bonferroni *post hoc* analysis and significance was chosen for $p < 0.05$. The asterisk denotes significant results regarding the respective measurement indicated with the bar. The values are served as a mean with standard error of the mean.

was applied for 1 h. The following subsequent steps were the same as for IB_4 staining: the cells were washed tree times with PBS and incubated with ExtrAvidin-Peroxidase for 1 h. After washing with PBS and Tris buffer, the slides were stained with 3,3′-Diaminobenzidine (DAB) (Sigma-Aldrich, cat No. D8001) and covered with Entallan (Merck Millipore, Darmstadt, Germany, cat No. 107960).

Microscopy and Analysis

For analysis of proliferation index, ramification index and PPARα staining five areas per cover slip were recorded with Leica DMi8 (Wetzlar, Germany) or Axioplan (Zeiss, Oberkochen, Germany) microscopes.

Proliferation index was represented as the ratio of BrdU positive cells to all DAPI positive cells. The BrdU positive cells were counted using image J v1.46r (National Institutes of Health, Laboratory for Optical and Computational Instrumentation, University of Wisconsin, Madison, WI, United States).

To evaluate the ramification of microglial cells, the surface of microglia was stained with IB_4 and the outlining of the cell was divided by the smallest convex hull around the cell. Values close to 1 correspond to strongly amoeboid cells while lower numbers represent ramified cells. The analysis was performed automatically using a self-written MatLab script (The MathWorks, Natick, MA, United States).

Next, the translocation of PPARα from the cytoplasm to the nucleus or vice versa was assessed after treatment with cannabinoids. PPARα staining was performed and manually evaluated by counting cells that showed a nuclear or/and cytoplasmic staining or were free of PPARα labeling. Results are presented as proportion of cells with a specific expression pattern relative to the total number of cells. For the calculation of the standard error of the mean in these experiments we used bootstrapping to calculate empirical standard deviations. Therefore all measurements were used and resampled 10,000 times. Afterward, the proportion of nuclear, cytoplasmic, nuclear+cytoplasmic location or no expression was calculated for each resampling and an empirical standard deviation and standard error of the mean was calculated.

The imaging of the fixed OHSC was performed using a confocal laser scanning microscope (LSM 510 Meta, Zeiss) with an excitation wavelength of 488 nm for IB_4 and 543 nm for PI. Emission was detected using a band-pass filter with $\Delta\lambda$ = 510–550 nm (IB_4) and $\Delta\lambda$ = 610–720 nm (PI). The dentate gyrus was visualized with a 20x objective, as a z-stack with a step width of 2 μm (Grabiec et al., 2012). The number of PI positive death cells in the obtained image stacks was analyzed using the maximal intensity projection and quantified using a self-written Matlab script.

Nitrite Assay

A standard solution was prepared by solving sodium nitrite in medium up to concentrations of 100, 50, 25, 12.5, 6.25, 3.125, and 1.5625 μM. The measured values were used for calculation of a standard curve. 50 μl of the standard solutions or 50 μl of the collected samples were analyzed in duplicate. After applying 50 μl of Griess reagent (Sigma-Aldrich) the extinction was measured after 15 min at 540 nm in a microplate reader (SynergyTM Mx, BioTek Instruments, Winooski, VT, United States). The nitrite concentrations for the samples were interpolated from the standard curves.

Statistical Analysis

Statistics was performed using the one-way ANOVA with Bonferroni post-test and significance was chosen for $p < 0.05$. All *p*-values refer to the respective controls of the same parameter of the same cell line or to the treatment with agonist for the respective receptor. All groups were normalized to the positive

control. Statistics for cellular PPARα was performed using a Chi Square test and significance was chosen for $p < 0.05$. The values are served as a mean with standard error of the mean. The asterisk denotes significant results regarding the respective measurement indicated with the bar.

RESULTS

2-AG and PEA Do Not Further Decrease the Number of PI Positive Degenerated Neurons

The application of NMDA led to an increase in the number of PI positive cells in OHSC (100.0 ± 4.24%) in comparison to control group (0.86 ± 0.28%, **Figures 2B,C**).

Treatment of NMDA lesioned OHSC with PEA (60.64 ± 4.52%) or 2-AG (58.78 ± 5.94%) induced a significant reduction of neuronal damage. Combination of 2-AG and PEA (85.46 ± 3.92%) in excitotoxically damaged OHSC did not decrease the number of dead cells in a significant manner (**Figures 2B,C**). Notably the values were not significantly different when compared to NMDA group, but significantly higher when compared to NMDA+2-AG or NMDA+ PEA groups.

Depletion of Microglial Cells Leads to Loss of Neuroprotection

The application of NMDA to microglia depleted OHSC (**Figure 1**) led to a significant increase in the number of PI positive cells (100.0 ± 7.12%) in comparison to control group (0.74 ± 0.17%, **Figure 2D**). The depletion of microglial cells was controlled through IB_4 staining (**Figure 1**).

Neither the application of PEA (84.19 ± 9.29%) nor 2-AG (91.04 ± 10.68%) to NMDA damaged microglia depleted OHSC induced a significant neuroprotective effect. Also, the combination of 2-AG and PEA (94.93 ± 7.42%) to excitotoxically damaged microglia depleted OHSC showed any significant effect on the number of dead neurons (**Figure 2D**).

Effects of 2-AG and PEA Treatment on Ramification Index

Application of PEA (0.72 ± 0.01) or 2-AG (0.75 ± 0.02) had no impact on ramification index in comparison to control group (0.73 ± 0.01). Treatment with LPS (0.89 ± 0.01) led to a more amoeboid morphology of cells. Co-application of LPS and PEA reduced the ramification index significantly (0.76 ± 0.03) making cells more ramified. Incubation with 2-AG did not change the ramification index (0.84 ± 0.01) in comparison to LPS. However, PEA and 2-AG application together with LPS induced significant reduction in ramification index (0.76 ± 0.02) (**Figures 3A,C**).

Effects of 2-AG and PEA on Nitrite Concentration

Application of PEA (0.19 ± 0.1%), 2-AG (0.14 ± 0.06%), or PEA+2-AG (0.76 ± 0.30%) did not change the nitrite concentration in comparison to control group (0.48 ± 0.22%). Treatment with LPS (100.0 ± 2.24%) led to an increased concentration of nitrite. Whereas co-application of LPS and PEA reduced the nitrite concentration significantly (81.06 ± 4.6%), incubation with 2-AG increased the nitrite concentration (128.2 ± 5.52%) in comparison to LPS. The same increase was detected for application of 2-AG+ PEA+ LPS (134.5 ± 7.11%) (**Figure 3E**).

Effect of 2-AG and PEA on Proliferation of Primary Microglial Cells

After incubation with LPS (0.07 ± 0.01), PEA (0.13 ± 0.04), or 2-AG (0.12 ± 0.05) no significant changes in proliferation were detected in comparison to control group (0.097 ± 0.02). The results for PEA+2-AG (0.07 ± 0.02); LPS+PEA (0.07 ± 0.019); LPS+2-AG (0.09 ± 0.05); and LPS+PEA+2-AG (0.07 ± 0.03) were not significantly altered after treatment (**Figures 3B,D**). The overall test showed no significant differences between the groups.

PPARα Distribution and Cellular Localization After Incubation With 2-AG and PEA

The evaluation of the localization of the PPARα receptor was significantly altered for treated groups overtime (1, 6, 24 h) (**Figures 4A–E**). The positive staining was localized in the cytoplasm and in the nucleus. The subcellular location was scored in 483 (1 h), 362 (6 h), and 337 (24 h) cells by light microscopy and presented as percentage. Each independent experiment was repeated at least three times (n = 3). The number of cells expressing nuclear as compared to cytoplasmic PPARα was significantly different between groups. Treatment with PEA; 2-AG; and LPS induced a significant shift in PPARα distribution after 1 and 6 h from nuclear to cytoplasmic and from cytoplasmic to nuclear localization. PEA and LPS changed significantly the localization of the receptor after 24 h (**Figures 4A–C**). The distribution was significantly different between 2-AG (Nucleus, N: 36%, Cytoplasm, C:21%, Both, B:33%, No signal, None:10%) and 2-AG co-applied with PEA (N:50%, C:4%, B:43%, None:4%) after 1 h, between PEA (N:49%, C:11%, B:38%, None:2%) and 2-AG+PEA (N:22%, C:11%, B:51%, None:16%) after 6 h and between PEA (N:51%, C:3%, B:36%, None:10%) or 2-AG (N:11%, C:7%, B:83%, None:0%) and 2-AG+PEA (N:29%, C:2%, B:66%, None:2%) after 24 h. PEA ($N_{1\ h}$:51%, $C_{1\ h}$:5%, $B_{1\ h}$:17%, $None_{1\ h}$:27%; $N_{6\ h}$:61%, $C_{6\ h}$:7%, $B_{6\ h}$:18%, $None_{6\ h}$:14%), 2-AG ($N_{1\ h}$:67%, $C_{1\ h}$:3%, $B_{1\ h}$:29%, $None_{1\ h}$:1%; $N_{6\ h}$:30%, $C_{6\ h}$:11%, $B_{6\ h}$:34%, $None_{6\ h}$:26%) and PEA+2-AG ($N_{1\ h}$:54%, $C_{1\ h}$:14%, $B_{1\ h}$:20%, $None_{1\ h}$:12%; $N_{6\ h}$:21%, $C_{6\ h}$:21%, $B_{6\ h}$:35%, $NS_{6\ h}$:23%) changed significantly the localization of PPARα after 1 and 6 h in combination with LPS (vs. LPS; $N_{1\ h}$:25%, $C_{1\ h}$:15%, $B_{1\ h}$:53%, $None_{1\ h}$:7%; $N_{6\ h}$:67%, $C_{6\ h}$:10%, $B_{6\ h}$:20%, $None_{6\ h}$:3%). No effect could be observed for LPS+PEA (N: 22%, C: 3%, B: 69%, None: 6%) in comparison to LPS (N: 28%, C: 2%, B: 56%, None: 14%) after 24 h, but 2-AG (N: 27%, C: 2%, B: 69%, None: 2%) and 2-AG+PEA (N: 20%, C: 0%, B: 80%, None: 0%) if co-applied

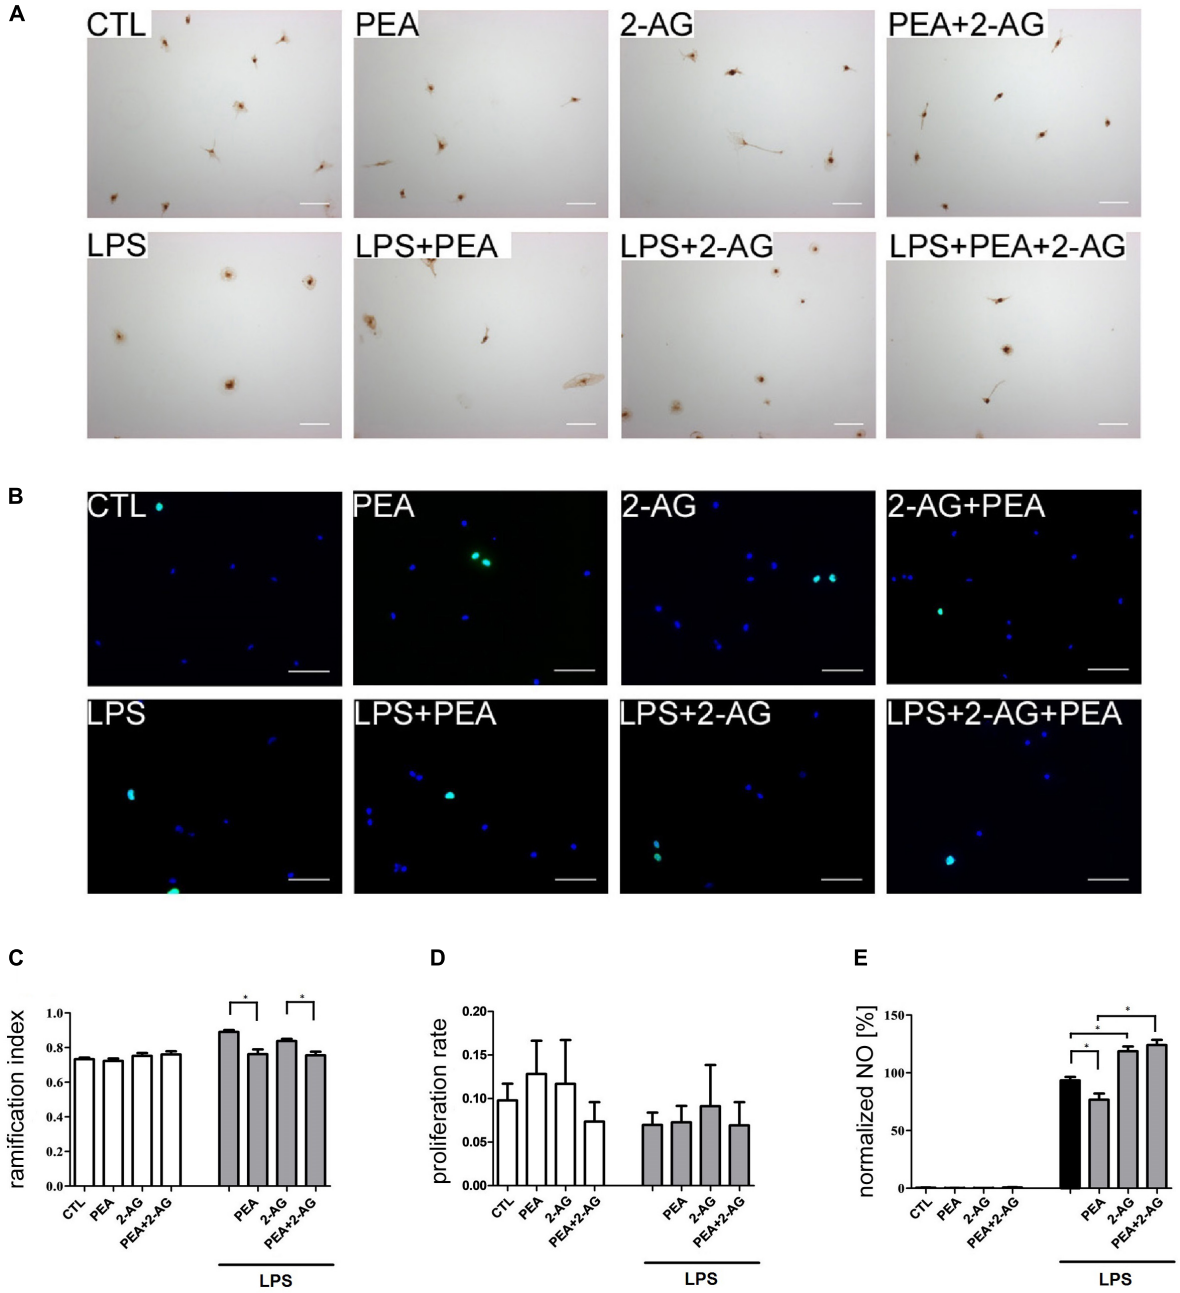

FIGURE 3 | Effect of 2-AG and PEA on ramification index, proliferation index and nitrite concentration of primary rat microglia. Representative pictures of stained microglia for **(A)** ramification index (IB_4) and **(B)** proliferation rate (BrdU in green, DAPI in blue). Scale bar = 50 μm. **(C)** Effects of 2-AG and PEA on ramification index. Application of LPS (n_{LPS} = 22) led to an increase in the ramification index in comparison to control group (CTL; n_{CTL} = 22). Whereas PEA co-applied with LPS ($n_{LPS+PEA}$ = 23) reduced the ramification index significantly, 2-AG ($n_{LPS+2-AG}$ = 23) had no effect. 2-AG, PEA, or combination of both applied alone (n_{PEA} = 19, n_{2-AG} = 22, $n_{2-AG+PEA}$ = 22) had no effect on ramification index. The combination of LPS, 2-AG and PEA ($n_{LPS+2-AG+PEA}$ = 22) led to decrease in the ramification index in comparison to the groups treated with LPS and 2-AG. **(D)** No effect of 2-AG and PEA with/or without LPS on proliferation of primary microglia cells could be observed (n_{CTL} = 12, n_{LPS} = 12, n_{PEA} = 11, n_{2-AG} = 11, $n_{2-AG+PEA}$ = 12, $n_{LPS+PEA}$ = 12, $n_{LPS+2-AG}$ = 11, $n_{LPS+2-AG+PEA}$ = 12). **(E)** Effects of 2-AG and PEA on nitrite concentration after 72 h. PEA, 2-AG, or PEA combined with 2-AG had no effect on the nitrite concentration in primary microglia (n_{CTL} = 18, n_{PEA} = 18, n_{2-AG} = 18, $n_{2-AG+PEA}$ = 18). After administration of LPS, nitrite concentration increased significantly. PEA co-applied with LPS ($n_{LPS+PEA}$ = 18) decreased the NO production in comparison to LPS (n_{LPS} = 18). 2-AG+LPS ($n_{LPS+2-AG}$ = 18) and also 2-AG+PEA+LPS ($n_{LPS+2-AG+PEA}$ = 18) treated microglia produced significantly more NO in comparison to LPS. Statistics was performed using a one-way ANOVA test with Bonferroni correction and significance was chosen for $p < 0.05$. The asterisk denotes significant results regarding the respective measurement indicated with the bar. The values are served as a mean with standard error of the mean.

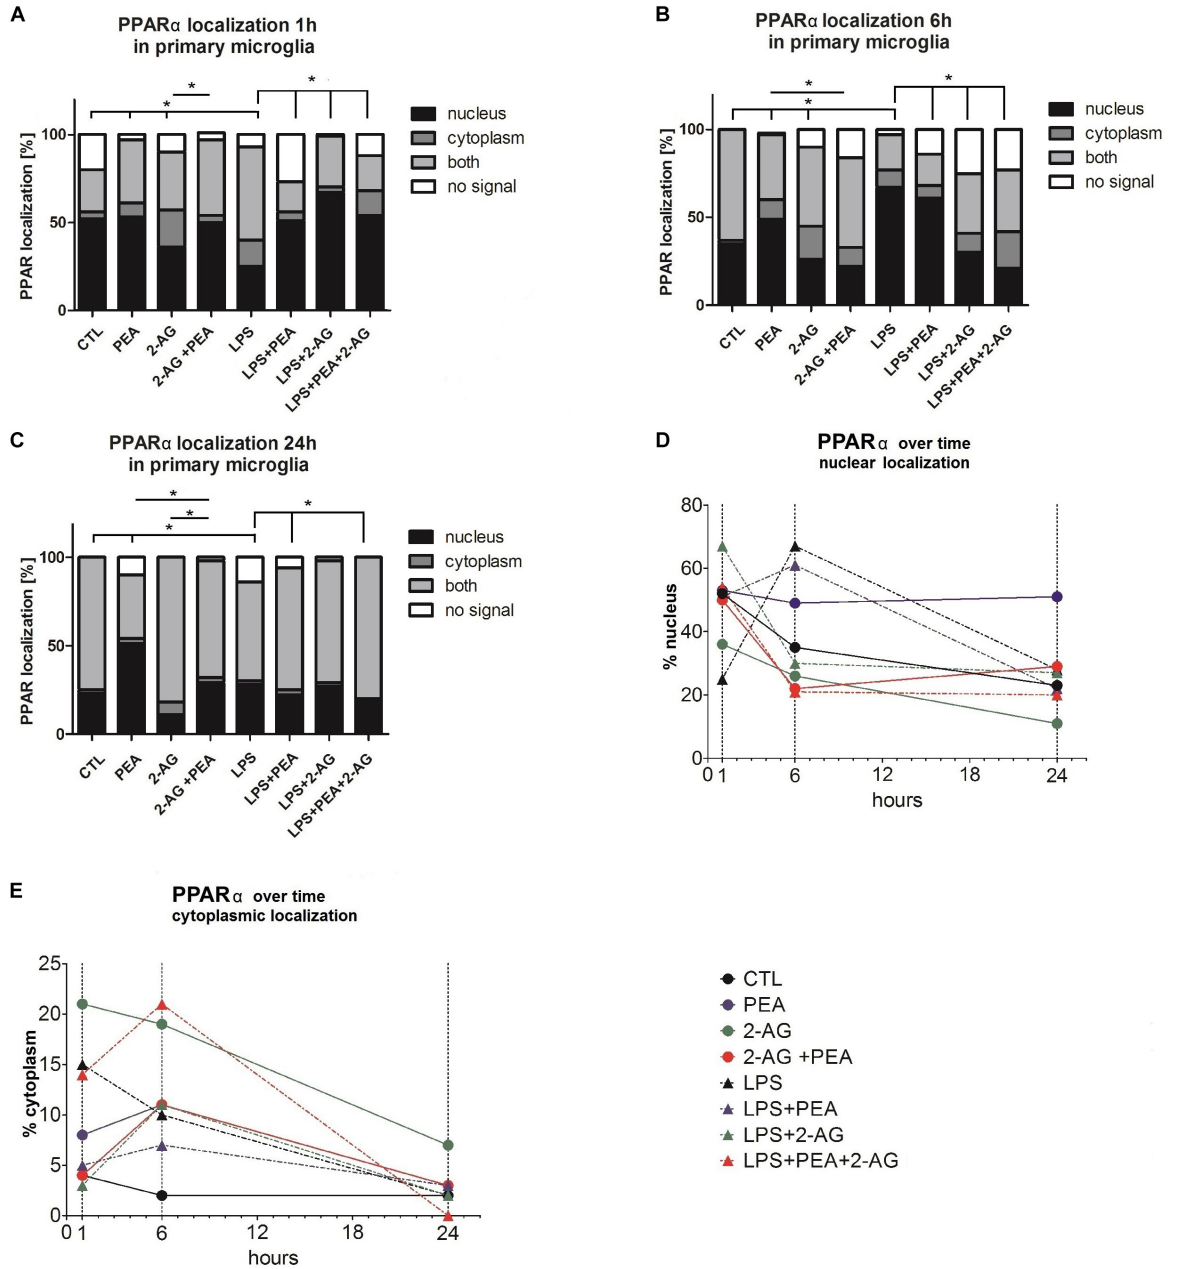

FIGURE 4 | PPARα subcellular distribution and cellular localization after incubation with 2-AG and PEA in primary microglial cells. The localization of PPARα was analyzed over time by the use of staining **(A–C)** 1, 6, and 24 h after treatment, **(D)** nuclear, **(E)** cytoplasmic localization (1, 6, and 24 h after treatment). The number of cells which did not or expressed PPARα in the nucleus or/and cytoplasm was counted. In graphs **(A–E)** the subcellular location was scored in 483 (1 h), 362 (6 h), and 337 (24 h) cells by light microscopy and presented as percentage. Each independent experiment was repeated at least three times. The same data are displayed in two different ways to point out the differences in the distribution **(A–C)** between the time points for cytoplasmic and nuclear localization **(D,E)**. Statistics was performed using a Chi Square test and significance was chosen for $p < 0.05$. The asterisk denotes significant results regarding the respective measurement indicated with the bar. The values are served as a mean with standard error of the mean.

with LPS altered significantly the distribution (**Figures 4A–C** and **Table 2**).

Lipopolysaccharide alone induced a shift to nuclear localization after 6 h, whereas LPS+PEA+2-AG after 6 h led to more cytoplasmic expression, similar to 2-AG and PEA alone (**Figures 4D,E**).

DISCUSSION

Reduction of neuronal damage in injured patients is a main contributor to sustain quality of life, for this reason its improvement and new approaches are needed. Evidence has accumulated that endocannabinoids can be beneficial for

Rounded mean values (two positions) and SEM.

treatment of patients with brain injury (Fernandez-Ruiz et al., 2010). Cannabinoids, as shown before have different targets and are potential therapeutics, but first it is necessary to better understand the molecular and cellular mechanisms of cannabinoid action.

The Protective Effects of 2-AG and PEA Are Abolished, When Both Are Applied Together

In this study, we focused on excitotoxicity, a main factor of neuronal damage as described before (Kunz et al., 2010; Lau and Tymianski, 2010). To investigate the intrinsic responses and to exclude interfering influences such as blood flow and infiltrating peripheral immune cells the well-established model of excitotoxic lesioned OHSC was chosen. Both, PEA and 2-AG were shown to be protective with microglia participation in NMDA lesioned OHSC before. In our previous studies we extensively examined the involvement of cannabinoid receptors in PEA and 2-AG mediated actions. Whereas PEA and the synthetic PPARα agonist Wy-14,643 protected dentate gyrus granule cells, treatment with the PPARα antagonist GW6471 blocked PEA-mediated neuroprotection. Selective activation or inhibition of PPARγ displayed no positive effect (Koch et al., 2011a). Interestingly, 2-AG induced neuroprotection was inhibited by cannabidiol (CBD) and O-1918 and mimicked by abn-CBD indicating the involvement of abn-CBDR. The 2-AG effects were not blocked by the specific CB_2 receptor antagonist (AM630). Depletion of microglial cells abolished the neuroprotection mediated by 2-AG or abn-CBD raising the hypothesis that the neuroprotective effects of 2-AG were abn-CBDR and microglia dependent (Kreutz et al., 2007, 2009). The abn-CBDR is a pharmacologically characterized non-CB_1/non-CB_2 receptor and has been first described on endothelial cells of rat mesenteric blood vessels (Járai et al., 1999; Pertwee et al., 2010), and has not been identified yet. PEA, 2-AG or their analogs were also protective in other models like moderate traumatic injury and reduced neuroinflammation (Panikashvili et al., 2001; Genovese et al., 2008; D'Agostino et al., 2012; Esposito et al., 2012; Mounsey et al., 2015; Guida et al., 2017; Belardo et al., 2019; Impellizzeri et al., 2019). In PPARα$^{-/-}$ mice PEA induced neuroprotection after spinal cord trauma was abolished, however involvement of further PPARs was suggested (Paterniti et al., 2013). The application of PEA was found to trigger the synthesis of 2-AG in human and canine plasma and enhance its effects on transient receptor potential cation channel subfamily V member 1 (TRPV1) in HEK-293 cells (Petrosino et al., 2016). In striatum PEA triggered the synthesis of 2-AG via GPR55 (Musella et al., 2017). These effects were referred to an entourage effect, which might be mediated through TRPV1 activation or inhibition of fatty acid amide hydrolase, with PEA as its substrate or activation of GPR55 (Jonsson et al., 2001; Smart et al., 2002). A further possible explanation is an allosteric modulation, which could explain that 2-AG and PEA abolished their neuroprotective properties in the OHSC model and reduced ramification index at PEA level. While TRPV1 was not found in OHSC, GPR55

was expressed in slices and was associated with neuroprotection (Grabiec et al., 2012; Kallendrusch et al., 2013). Consequently, GPR55 might be involved in the PEA mediated actions observed here. Furthermore, PEA was also shown to enhance the CB_2 expression via PPARα activation in macrophages (Guida et al., 2017). Increased number of CB_2 next to abn-CBDR can be activated by 2-AG and induce further effects. PEA at cellular level reduced ramification index, making cells more ramified whereas 2-AG had no impact on morphology of microglial cells. The decrease in neuroprotection mediated by co-treatment with both cannabinoids might be attributable to their effects on cellular level, especially on microglial cells, the conductor of the neuroprotective properties of 2-AG and PEA. An entourage effect with PEA as enhancer of the anti-inflammatory and anti-nociceptive activity of other endogenous compounds by potentiating their affinity for a receptor or by inhibiting their metabolic degradation (Skaper and Facci, 2014) is missing in OHSC in the context of neuroprotection.

Effects of PEA and 2-AG Are Microglia Dependent

Neuroprotective capabilities of microglial cells include synaptic stripping, induction of neurogenesis, phagocytosis, and maintenance of central nervous system homeostasis (Chen and Trapp, 2016). On the other hand microglial cells are also able to suppress neuroinflammation, protect nerve tissue by producing anti-inflammatory and tissue-repairing cytokines and factors (Colton, 2009). Microglial cells can contribute to neuronal damage via inflammation and release of cytotoxic substances as described earlier and are associated with neurodegenerative diseases, cognitive dysfunction in aging and dementia, epilepsy, and other conditions leading to brain inflammation and neuronal lesion (Ekdahl et al., 2003; Smith et al., 2012; Chhor et al., 2013). Cannabinoids were shown to interact with microglial cells in further pathological states and to change the morphology, activation and number of the cells (Zhang et al., 2003; Luongo et al., 2010; Guida et al., 2017).

After microglia depletion in OHSC with the bisphosphonate clodronate PEA and 2-AG lost their neuroprotective effects supporting the hypothesis that 2-AG, PEA exert their neuroprotective effects via microglial cells. PEA was shown before to induce migration and increase of motility of BV2 microglial cell line (Franklin et al., 2003; Guida et al., 2017). Notably, microglial cells produce both 2-AG and PEA (Muccioli et al., 2007; Muccioli and Stella, 2009) and their levels were found to be increased after focal cerebral ischemia (Franklin et al., 2003).

PEA and 2-AG Mediate Opposite Effects on Nitric Oxide Synthesis in Primary Microglial Cells

Endocannabinoids, which are in part produced by microglia, affect the ability of microglia cells to proliferate, phagocytize, and produce NO (Stella, 2009). NO production occurs enzymatically via a conversion of L-arginine to L-citrulline by NO synthase, competing with arginase for L-arginine as a substrate. iNOS is not expressed in healthy brain tissue under physiological conditions but its expression can be induced in astrocytes and microglial cells through trauma. iNOS induction starts several hours before NO is generated and involves transcription of mRNA and novel protein synthesis. iNOS is mainly expressed under inflammatory conditions and after transient ischemic periods and is known as an antimicrobial defense mechanism of the immune system (Vincent et al., 1998). The increase in NO driven by iNOS might be neurotoxic as it forms reactive nitrogen oxide species like peroxynitrite (Garry et al., 2015). It was reported that 2-AG alone stimulates the release of NO from human immune and vascular tissues and from invertebrate immune cells via CB_1 activation (Stefano et al., 2000). Contrary, in our study 2-AG or PEA applied alone had no effect on NO production by microglial cells after 72 h. However, LPS in combination with 2-AG increased NO concentration, although 2-AG was protective after NMDA damage. PEA was able to reduce NO production by microglial cells after LPS treatment. In accordance to this study PEA significantly inhibited the NO release induced by LPS in murine macrophage cell line RAW264.7, which was not sensitive to pertussis toxin treatment, indicating a G-protein independent mode of action (Ross et al., 2000). Pre-treatment of LPS-stimulated primary mouse microglial cells with PPARα agonists also resulted in inhibition of NO production (Xu et al., 2005). In similarity to PEA in murine macrophage cell line RAW264.7, WIN55,212, a neuroprotective cannabinoid decreased NO level when applied together with LPS via CB_2 receptor (Ross et al., 2000; Koch et al., 2011b). Furthermore, PEA reduced iNOS expression in spinal cord 6 h after paw edema induction (D'Agostino et al., 2007). The results presented in our study are in accordance with previous investigations and strengthen the hypothesis that PEA mediates neuroprotection via microglial cells. The neuroprotective effects observed here in the OHSC model underline the intrinsic positive effects of cannabinoids as influences through alterations in cerebral blood flow and infiltration of peripheral cells are missing (Grabiec et al., 2017), making the inhibition of NO produced by microglial cells one possible explanation for neuroprotection. In agreement with our work and previous studies LPS induces NO production mainly in microglial cells in models of excitotoxicity or during transient ischemic periods (Nakamura et al., 1999; Genovese et al., 2008; Yao et al., 2017). Further endocannabinoids were shown to decrease iNOS activity in rat microglial cells, e.g., CP55940 exerted a dose-dependent inhibition of interferon gamma /LPS-inducible NO production (Cabral et al., 2001) Little is known about the influence of endocannabinoids on arginase, in peripheral immune cells and in microglial N9 cells Δ-9- tetrahydrocannabinol and CB_2 agonist induced arginase 1 expression, what reduce NO production (Hegde et al., 2010; Ma et al., 2015).

Through combination treatment of both PEA and 2-AG, NO production was significantly elevated and neuroprotective properties were diminished. It leads to the hypothesis that PEA may be neuroprotective through reduction of NO present after brain injury. On the other hand, 2-AG significantly elevated NO production while still exerting neuroprotective effects similar

to NO donors (Kakizawa et al., 2007), 2-AG acts probably via another targets and mechanisms.

Changes in Morphology and Phenotypes of Primary Microglial Cells After Treatment

In vivo, *ex vivo,* and *in vitro* a broad spectrum of differentiation stages of microglial cells has been observed (Dubbelaar et al., 2018). Under physiological conditions microglial cells are ramified and constantly scanning their surroundings (Nimmerjahn et al., 2005). Upon damage or inflammation, they become amoeboid, move to the site of neuronal lesion and remove cell debris. However, this morphological change of microglia upon a shift in activation state does not seem to be uniform, but it can be best mimicked by administration of LPS. The morphology ranges from amoeboid-like shapes during inflammation to highly ramified ones and includes many intermediate forms that are often associated with the activation status of microglial cells (Zhou et al., 2017; Dubbelaar et al., 2018). According to the phenotype microglial cells were often described as anti-inflammatory or neuroprotective or proinflammatory and neurotoxic. However, there is no binary system of phenotypes for microglia and they may possess multiple context dependent properties at the same time (Ransohoff, 2016; Dubbelaar et al., 2018).

In synopsis with NO reduction, the administration of PEA to LPS stimulated microglial cells induced a more ramified morphology; these anti-inflammatory properties of PEA may mediate its neuroprotective effects. 2-AG did not alter the LPS induced amoeboid state of microglial cells but increased the NO concentration, indicating that the neuroprotective properties of 2-AG are mediated through other microglial cell dependent mechanisms than those involving NO. However, *in vivo* and in acute experimental autoimmune encephalomyelitis 2-AG increased the ramification of microglia (Lourbopoulos et al., 2011). In excitotoxically lesioned OHSC 2-AG reduced the number of microglial cells (Kreutz et al., 2007). It is plausible that the absence of changes is model dependent or that 2-AG influenced other properties of microglia, which were not examined in this study, like phagocytosis, motility, and alterations in extracellular signaling.

The combination of 2-AG and PEA induced a ramification of microglial cells in comparison to 2-AG and abolished PEA mediated NO concentration decrease. This may indicate that the anti-inflammatory properties of PEA are lost if co-incubated with 2-AG, since decrease in the number of damaged neurons in OHSC was missing and therefore neuroprotection. 2-AG and PEA exert contrary effects on microglial cells and it is plausible, that co-application of both led to their abolishment. Expected entourage effect is missing in case of this model and those substances.

It will be necessary to verify how 2-AG exerts neuroprotection at a cellular level and whether this process is microglia dependent only, since 2-AG was found protective in isolated neuronal cultures (Zhang and Chen, 2008). Interestingly, proliferation of pure microglial cell cultures was not affected in this study, whereas the number of microglial cells was significantly decreased in dentate gyrus in OHSC after excitotoxical damage and treatment with PEA or 2-AG, this effect was mimicked by PPARα agonists and blocked by its antagonists (Kreutz et al., 2007; Koch et al., 2011a). Since microglial cells in culture proliferate very slowly without astrocytes, it seems plausible that the effects observed in OHSC might be the result of PEA actions on astrocytes, microglia, possibly neurons in the network and/or their cross-talk, since all cell types express the PPARα receptor (Xu et al., 2006; Warden et al., 2016).

PPARα Expression and Localization Changed After Incubation With Cannabinoids

Peroxisome proliferator-activated receptors predominantly are localized in the nucleus, theirs activity is modulated via phosphorylation and PPARα undergoes ligand-dependent nucleo-cytoplasmic shuttling (Burns and Vanden Heuvel, 2007; Umemoto and Fujiki, 2012). The amount of PPARα was shown to increase in microglial cells in nucleus after 6 h and to decrease after 24 h after PEA treatment. PPARs are ligand-activated transcription factors, and their biological role is coupled to the function of their target genes. In immunocytochemical staining a translocation of PPARα into the nucleus was seen. Neuroprotective effects of PEA are known to be mediated by PPARα. On the one hand, the nuclear localization of the receptor induces specific PEA related effects; its shift into the cytoplasm reduces the amount of available receptor in the nucleus. On the other hand the cytoplasmic localization of PPARα may favor the binding of other ligands and mediate different actions (Guida et al., 2017). The lower levels of PPARα in nuclei of microglial cells after simultaneous treatment with 2-AG and PEA with or without LPS might be a possible explanation for the missing neuroprotection in OHSC. It also indicates an interference between 2-AG and PEA signaling pathways with a more dominant role of 2-AG and inhibitory actions on PPARs translocation into the nucleus. Specific activation of central PPARα controls inflammation in the spinal cord as well as in the periphery (D'Agostino et al., 2007), when the amount of receptor decreased no effect could be induced. Additionally, fatty acid oxygenase metabolism products of 2-AG were able to activate PPARα receptor in human undifferentiated epidermal keratinocytes and stimulation of PPARα and its downstream target genes led to cell differentiation (Kömüves et al., 2000; Kozak et al., 2002). It is plausible that 2-AG and PEA interact directly on PPARα receptor in the opposite way.

CONCLUSION

While endocannabinoids are promising regarding treatment of neuronal diseases, and their neuroprotective properties are known for a while, little is known how they are mediated. 2-AG and PEA are both protective agents with different targets. Their positive effect is not enhanced by co-incubation. The understanding of interactions between signaling pathways of

different endocannabinoids will help to elucide the in part conflicting results reported in the literature.

Bioscaffold-Induced Brain Tissue Regeneration

Michel Modo[1,2,3,4]*

[1] McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, PA, United States, [2] Center for the Neural Basis of Cognition, University of Pittsburgh, Pittsburgh, PA, United States, [3] Department of Bioengineering, University of Pittsburgh, Pittsburgh, PA, United States, [4] Department of Radiology, University of Pittsburgh, Pittsburgh, PA, United States

Brain tissue lost after a stroke is not regenerated, although a repair response associated with neurogenesis does occur. A failure to regenerate functional brain tissue is not caused by the lack of available neural cells, but rather the absence of structural support to permit a repopulation of the lesion cavity. Inductive bioscaffolds can provide this support and promote the invasion of host cells into the tissue void. The putative mechanisms of bioscaffold degradation and its pivotal role to permit invasion of neural cells are reviewed and discussed in comparison to peripheral wound healing. Key differences between regenerating and non-regenerating tissues are contrasted in an evolutionary context, with a special focus on the neurogenic response as a *conditio sine qua non* for brain regeneration. The pivotal role of the immune system in biodegradation and the formation of a neovasculature are contextualized with regeneration of peripheral soft tissues. The application of rehabilitation to integrate newly forming brain tissue is suggested as necessary to develop functional tissue that can alleviate behavioral impairments. Pertinent aspects of brain tissue development are considered to provide guidance to produce a metabolically and functionally integrated *de novo* tissue. Although little is currently known about mechanisms involved in brain tissue regeneration, this review outlines the various components and their interplay to provide a framework for ongoing and future studies. It is envisaged that a better understanding of the mechanisms involved in brain tissue regeneration will improve the design of biomaterials and the methods used for implantation, as well as rehabilitation strategies that support the restoration of behavioral functions.

INTRODUCTION

Acute brain injury and progressive neurodegenerative disease represent some of the most challenging medical conditions. The financial burden of these conditions in the US alone amounts to nearly $800 billion per year (Gooch et al., 2017). With an aging population, this cost will continue to rise, especially considering the lack of effective treatment options. There are currently no approved therapies to limit or revert cell loss. In a few conditions, such as Parkinson's disease, pharmacological agents can compensate for the loss of a specific neurotransmitter (e.g., dopamine). However, the continued cell loss due to neurodegeneration is not reversed. This continued loss of

cells produces a tissue atrophy that gradually shrinks brain tissue. In contrast to tissue atrophy, acute brain injuries, such as a stroke and penetrating traumatic brain injuries, produce a volumetric tissue loss that is characterized by cavitation, i.e., cell and matrix loss (Moreau et al., 2012). Tissues surrounding this cavitation are also damaged and typically undergo an acute and sub-acute neuronal loss associated with reactive gliosis and angiogenesis. Atrophy in peri-cavity damaged tissue can also occur. Pharmacological therapies, such as neuroprotective agents, are primarily focused on rescuing acutely dying neurons, whereas anti-inflammatory agents target the immune system's response to the inflicted damage, aiming to reduce secondary tissue damage (Neuhaus et al., 2017). Neither approach replaces lost cells or tissues.

In contrast to these pharmacological interventions, biological interventions aim to replace cellular components that have been lost (Modo et al., 2018). For example, in the case of Parkinson's disease, ectopic transplantation of dopaminergic cells attempts to restore the local neurotransmitter tone, whereas in Huntington's disease the goal is to replace lost neurons and to integrate these new neurons into existing neuronal circuitry (Barker and TRANSEURO consortium, 2019). In the case of acute brain injuries, two paradigms have found clinical translation, with one focused on influencing the immune response using intravenous or intra-arterial injections of mesenchymal stem cells during the acute phase of injury, whereas the other focuses on intracerebral implantation of cells into damaged tissue in the sub-acute to chronic phase by supplementing endogenous repair mechanism (Ghuman et al., 2018; Borlongan, 2019). Emerging evidence suggests that brain regeneration is feasible if the appropriate conditions are engineered (Ghuman et al., 2018; Nih et al., 2018; Modo and Badylak, 2019). An endogenous repair response to tissue damage and injury is crucial for this process and replicates certain aspects of peripheral wound healing. Herein, we review putative mechanisms involved in brain tissue regeneration and contrast these mechanisms with peripheral soft tissue regeneration following injury.

TISSUE REPAIR VERSUS REGENERATION

Progressive neurodegeneration or acute brain injury lead to cell death by several mechanisms, including apoptosis, necrosis, oncosis, autophagy, and pyroptosis. The resulting cell debris activates resident immune cells, such as microglia, and is associated with reactive astrocytes that change morphology and function (Donnelly and Popovich, 2008; Chapman et al., 2015; Gabel et al., 2016). These cell and tissue responses mitigate the impact on surrounding healthy cells and tissues. In the case of penetrative and ischemic injuries, liquefactive necrosis occurs in the core of the injured tissue, with an associated loss of the tissue structure itself. The liquefactive debris, including cell debris and the disrupted extracellular matrix, are removed, leaving behind a tissue cavity. These events occur in up to 94% of patients with an ischemic stroke (Moreau et al., 2012). Still, tissue cavitation remains a poorly understood phenomenon with location and time post-injury being key factors. Some species, such as rat and human, are more prone to this process than others, such as mice (Surey et al., 2014). Inflammation may play a key role in this process and explain differences between species, as well as location (Chung et al., 2018). The liquefactive debris is itself neurotoxic upon permeation into peri-cavity tissue (Zbesko et al., 2018) and might provoke a pro-inflammatory response. The tissue inflammatory response eventually results in a structural barrier in the form of gliosis and scarring that prevents the spread of neurotoxic debris to limit further tissue damage.

In addition to the formation of a glial scar, local astrocytes and oligodendrocyte progenitor cells proliferate to produce an expanded cell population that can support tissue function. A small proportion of these cells may have the potential to replace lost neurons (Donnelly and Popovich, 2008; Chapman et al., 2015; Gabel et al., 2016), but evidence for this remains controversial. The local vasculature also responds to tissue damage with the formation of new small blood vessels that improve nutrient supply to hypoxic tissue containing dying or at-risk cells (Manoonkitiwongsa et al., 2001; Senior, 2001).

The brain possesses a neurogenic potential that is involved in maintaining tissue homeostasis during normal aging. However, recent evidence suggests that neurogenesis in adult human brain is very limited (Kempermann et al., 2018). After injury or during ongoing neurodegeneration, neurogenic regions, such as the subventricular zone (SVZ) upregulate the proliferation of progenitor cells, which then migrate toward the area of damage (**Figure 1A**) (Lindvall and Kokaia, 2015). This repair response is still active more than 1 year after a stroke (Kazanis et al., 2013), but survival and integration of newly generated cells is generally considered poor (Magavi et al., 2000; Arvidsson et al., 2002), potentially due to a non-permissive environment. New blood vessels might serve as a guidance conduit toward areas of damage (Kojima et al., 2010). Intraparenchymal cell transplants aim to supplement this endogenous tissue repair response (**Figure 1B**), without replacing lost tissue (Smith et al., 2012). For the present review, we define tissue repair to consist of the changes that occur in and around damaged tissue without the replacement of any lost brain tissue (**Table 1**).

Tissue regeneration or replacement of lost tissue requires the infiltration and organization of functional neurons, glial cells and support structures (e.g., vascularization). Infiltration of cells into the lesion cavity requires the presence of a matrix substrate to facilitate cell migration. Provision of inductive bioscaffolds, such as those composed of extracellular matrix (ECM) derived from decellularized tissues, can facilitate endogenous tissue regeneration in the brain (**Figure 1C**). Other materials, such as cross-linked hyaluronic acid might serve the same function (Nih et al., 2018). *In vitro* morphogenesis of brain tissue, i.e., organoids, have also been reported to spontaneously arrange into structures that resemble cortical layers. This further indicates that there is an inherent potential in brain cells to structurally organize into tissue if the appropriate conditions are provided (Mansour et al., 2018). A further example of this tissue morphogenesis is provided by the co-implantation of a dense mixture of NSCs and endothelial cells (ECs) into a stroke cavity (Nicholls et al., 2015). Implantation of essential brain tissue components (i.e.,

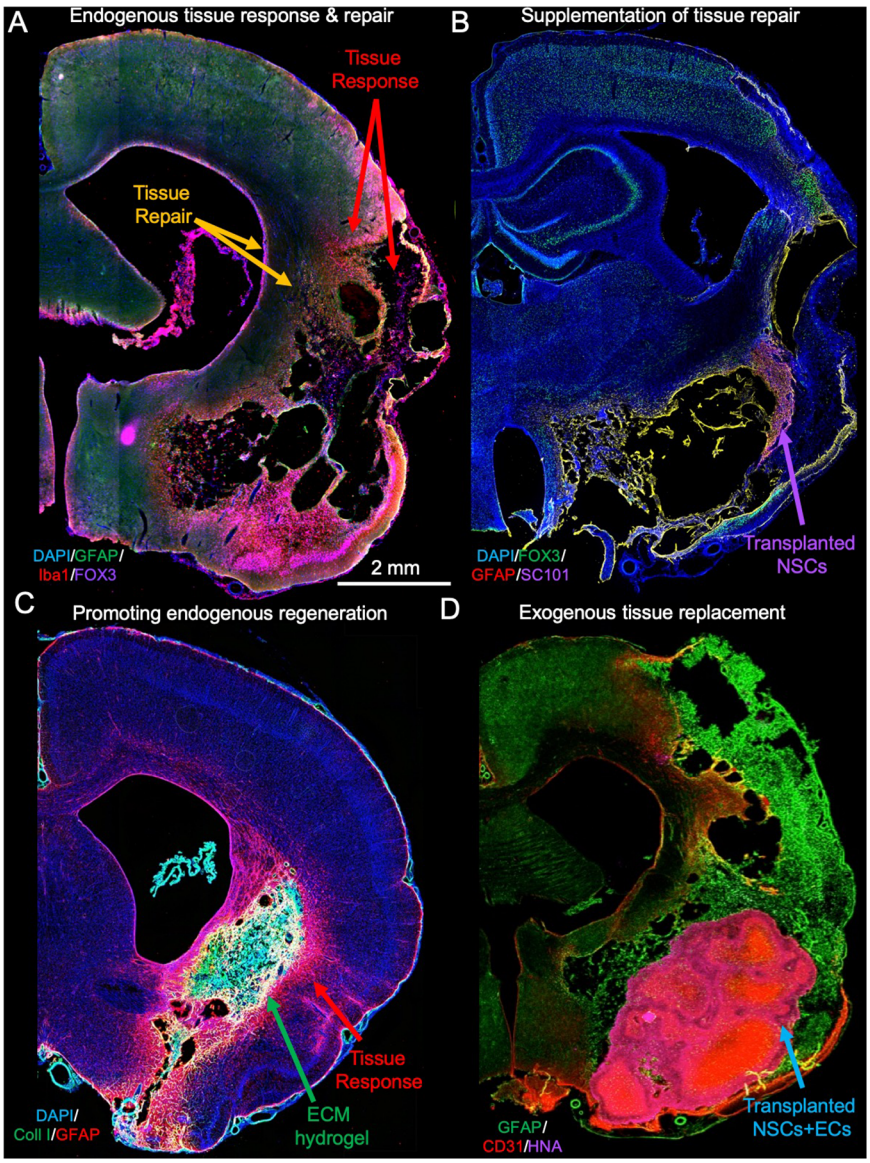

FIGURE 1 | Tissue response, repair, and regenerative response. **(A)** After acute brain injuries, such as stroke, astrocytes and microglia get activated to respond to tissue damage that at its core eventually produce a loss of cells, as well as the extracellular matrix, leaving behind a cavity. The glial scar is aimed at providing structural support but also preventing neurotoxic fluid to permeate into the peri-infarct tissue. In addition to this tissue response, the brain mounts reparative activities, which include an upregulation of neurogenesis in the subventricular zone. **(B)** To supplement the endogenous repair response, neural stem cells (NSCs) can be transplanted into damaged tissue where these differentiate and integrate with host cells, but they also increase local angiogenesis providing a better blood supply to poorly perfused tissues (Smith et al., 2012). **(C)** In contrast to cell transplantation, implantation of inductive extracellular matrix (ECM) bioscaffolds promotes a restoration of tissue inside the lesion cavity from endogenous cells that invade the material (Ghuman et al., 2018). **(D)** An alternative approach to tissue regeneration using an inductive bioscaffolds is to implant a mixture of NSCs and ECs that spontaneously organize into a vascular and neuropil compartment, potentially accelerating the restoration process and overcoming the potential limitation of the reservoir of endogenous cells (Nicholls et al., 2015).

NSCs, ECs, ECM) could therefore provide an alternative or supplementation to endogenous tissue regeneration (**Figure 1D**).

THE BRAIN'S FAILURE TO REGENERATE

Ramon y Cajal professed that "*In adult centers the nerve paths are something fixed, ended, immutable. Everything may die, nothing may be regenerated. It is key for the science of the future to change, if possible, this decree*" (Ramon y Cajal, 1928). The discovery of neurogenic zones in the adult mammalian brain and their participation in response to tissue injury partially refuted this long-held dogma that neurons in the brain cannot be replaced (Kempermann et al., 2018). However, the belief that the brain cannot regenerate (i.e., form new functional tissue) has mostly remained unchallenged (Fry, 2001;

TABLE 1 | Terminology used to define different aspects associated with tissue regeneration.

Terminology	Description
Angiogenesis	The process of a new artery branching out from an existing artery
Anastomosis	Establishment of a cross-connection between two blood vessels to create a new supply network
Arteriogenesis	The process of creating a new artery, including engineering of engraftable arteries
Axonogenesis	The formation of new axons
Behavioral Recovery	Improvements observed in solving behavioral tasks (e.g., walking)
Cell Replacement	Replacement of cells lost due to injury either through endogenous processes or through cell implantation
De novo tissue	Tissue that has newly formed where there was none, includes tissue that is established through endogenous means (i.e., regeneration) or through implantation (e.g., cells plus bioscaffold)
Developing tissue	Tissue that is undergoing development, i.e., cells invade and mature
Functional Recovery	Re-establishment of an electrophysiological connectivity (e.g., evoked potential between motor and somatosensory cortex)
Functional Tissue	The establishment of a tissue that supports brain activity (e.g., metabolic response to glucose)
In situ tissue engineering	Creating a new tissue through use of cells and biomaterials in the location where it is needed
Neovascularization	Formation of new blood vessels in a tissue void of vasculature, as in the case of tissue regeneration
Neuro/Gliogenesis	The formation of new neurons and glial cells
Tissue Response	Biological activity in tissue that responds to injury (e.g., glial scarring, cavitation)
Primitive tissue	Tissue that is not completely formed (e.g., tissue containing cells, but lacking appropriate cytoarchitecture or connectivity)
Revascularization	Re-establishing a vascular supply in a tissue that was lacking it, as in poorly perfused peri-infarct tissue
Synaptogenesis	The formation of new synapses
Tissue construct	A pre-formed *ex vivo* tissue that can be implanted
Tissue neogenesis	Newly developing tissue in a cavity, as opposed to damaged tissue being repaired to establish a functional tissue again
Tissue Regeneration	Establishment of a new tissue in a cavity through endogenous cells, including axonal connections
Tissue Repair	Cellular response to tissue damage trying to restore function (e.g., neurogenesis, angiogenesis)
Tissue Restoration	Establishment of a new tissue in a cavity through endogenous or exogenous means
Tissue engineering	Use of cells and biomaterials to create a new tissue *in vivo*, *ex vivo*, or *in vitro*
Vasculogenesis	The process of creating a new vasculature, including veins
Veterate tissue	Organ tissue that is established and remained after injury (e.g., peri-infarct tissue), as opposed to partially formed or newly forming tissue

Bechmann, 2005; Illis, 2012). By many, regeneration of brain tissue is considered the ultimate challenge for regenerative medicine (Obernier et al., 2014): by others, it is considered a biological impossibility (Price, 2011). Essentially, two main arguments are postulated as to why brain tissue regeneration is impossible: (1) The central nervous system of adult mammals is an inhibitory environment that "irreversibly" seals off tissue cavities to protect the remaining brain and consequently prevent tissue regeneration; and (2) The brain arises through a complex interplay between cells during development to form long-distance connections within and between brain regions, which cannot be recreated in the adult. Both viewpoints have merit, but do not consider the possibility that certain engineering strategies could overcome the scarring around the tissue cavity, or that functional brain tissue can develop via alternative mechanisms from normal brain development. Indeed, most tissue regeneration (e.g., liver) utilizes certain developmental processes, but does not strictly recapitulate fetal development.

When considering tissue regeneration across multiple organ systems and species, it is evident that tissue regeneration is reduced as a function of age and the complexity of the organ system (**Figure 2A**). Less complicated organ systems, such as the hematopoietic system, readily replenish. With increasing tissue complexity, as evidenced in most solid organs, there is less replenishing of cells during homeostasis, less cell replacement after injury and more limited regeneration after tissue loss compared to the hematopoietic system. A notable exception is the liver, which can completely regenerate from only 25% of remaining tissue (Michalopoulos and DeFrances, 1997). However, the reasons for a disparate regenerative potential of tissues and organs remains unknown at the present time.

A differential capacity to regenerate complex tissue exists across the evolutionary ladder (Tanaka and Ferretti, 2009; Ferretti, 2011), with species such as zebrafish and newts able to "regenerate" brain tissue after ablation (Kroehne et al., 2011; Urata et al., 2018). Inflammation at the site of injury and the invasion of macrophages are increasingly emerging as a key signaling axis to initiate and regulate this tissue regeneration (Kyritsis et al., 2012; Godwin et al., 2013). In the brain, the presence of neurogenic regions is considered a *conditio sine qua non-for* tissue repair and regeneration (Ferretti, 2011). Indeed, the size of the neurogenic reservoir directly correlated with the degree of tissue regeneration in carp (Kirsche and Kirsche, 1961). Large neurogenic regions persist into zebrafish adulthood, which respond to ablations in nearby brain regions (Kizil et al., 2012). The requirement for adequate neurogenic tissue would suggest that the proximity to a neurogenic region will be a determining factor in promoting tissue repair and regeneration. Relative distances in larger mammalian brains might hence be more difficult to bridge than those in smaller brains.

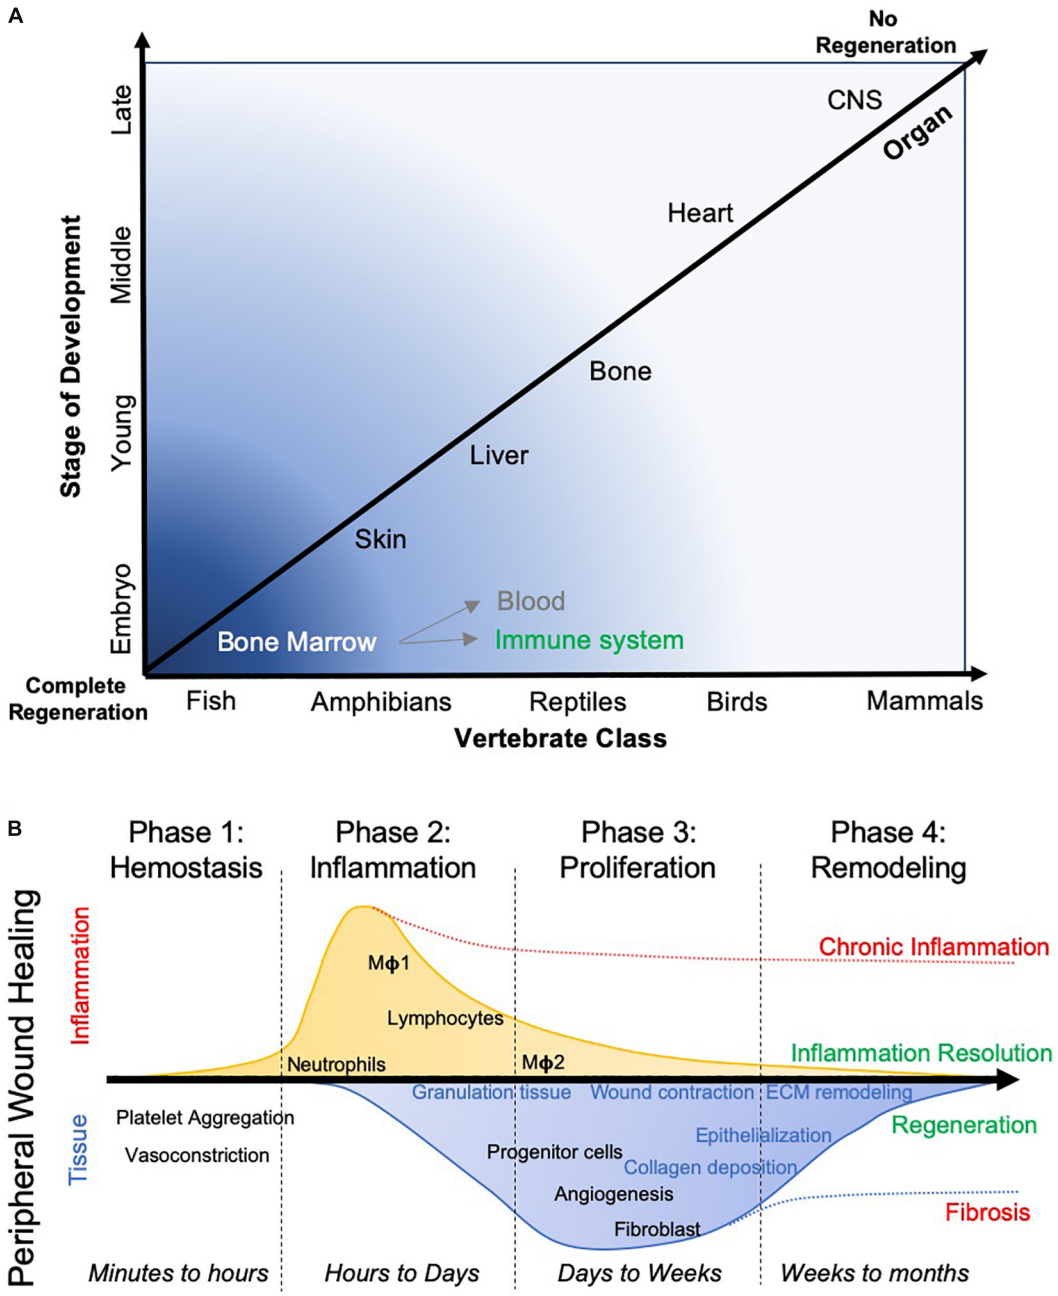

FIGURE 2 | Evolutionary aspects of tissue regeneration. **(A)** The capacity of different species to regenerate different organ tissue over their lifespan widely varies. Anatomical complexity of the species, as well as tissues, is a major factor in their ability to regenerate. Lower species more readily regenerate more complex tissue, whereas more complex species, such as mammals, are only able to regenerate very few organs. It is pertinent to contrast a replenishing of blood and immune system from the bone marrow, which essentially restitutes single cells, from constructing a tissue that involves multiple cell lineages and the deposition of ECM to create a geometric arrangement of cells. **(B)** In wound healing, where a cut in a tissue, such as the skin, restores tissue integrity, typically follows 4 phases. These phases are characterized by a major difference in inflammation, which peaks in phase 2, but also by changes in tissue characteristics, with the deposition of a transient granulation tissue that is being remodeled by the infiltration of host tissue cells. The formation of blood vessels and epithelization of the tissue are further key events required to ensure that a seamless wound closure occurs. Depending on which process is interrupted, a wound breakdown can occur or scarring occurs that limits tissue function. This process can take months to complete.

Alternatively, this required cellular reservoir may be supplied through implantation, as is the case in the transplantation of neural stem cells (NSCs). The neurogenic region's supply of NSCs and neural progenitors that can participate in tissue repair and regeneration is therefore a crucial element in brain tissue regeneration.

Time is a separate factor to consider, with a "perfect" tissue replacement being a slow process (>1 year) and dependent on wound closure through a tubular arrangement of ependymoglia cells (Urata et al., 2018). In axolotls and newts, true tissue regeneration after a volumetric defect can occur (Amamoto et al., 2016; Urata et al., 2018). However, alterations in cytoarchitecture and a failure to re-establish long-distance connections can happen in regenerated tissue in adult axolotls, even though cells were electrophysiologically appropriate for the tissue (Amamoto et al., 2016). It is nevertheless unclear if an altered cytoarchitectural arrangement will not allow the tissue to function as needed. Anomalies in spontaneously regenerated tissue were evident in axolotls (Amamoto et al., 2016) and zebrafish (Kroehne et al., 2011; Kaslin et al., 2017), whereas adult newt exhibit a more complete structural and cellular regeneration (Urata et al., 2018). Studies in neuro-regenerative species can therefore provide unique insights into the key factors that are required to engineer functional brain tissue regeneration in adult mammals.

WOUND HEALING VERSUS TISSUE REGENERATION

In adult mammals, healing of the skin is often considered a key example of how adult tissue can regenerate. Typically, four phases are recognized in this "regenerative process": (1) Hemostasis; (2) Inflammation; (3) Proliferation and tissue growth; and (4) Remodeling and maturation (**Figure 2B**). During injury to the skin, blood vessels are disrupted and platelets are released in the area of damage (Eming et al., 2014). The adherent platelet plug assumes an amorphous shape covering the lesion. Fibrin acts as "glue" that bridges the edges of tissue, essentially restoring the physical support for the next phase of wound repair, the invasion of inflammatory cells. Neutrophils and mast cells are among the first cells invading the clot and initiate a cascade of cytokines and chemokines that promote further cell invasion (e.g., macrophages), eventually leading to the removal of the cellular debris and the clot. The cytokine milieu also facilitates the recruitment of tissue-specific cells to repopulate the area of damage. During this proliferation phase new tissue is gradually assembled, including a restoration of vascular supply and deposition of tissue-specific ECM. Granulation tissue is formed, but is remodeled and replaced during the tissue maturation process. It is important to note the sequence of events, as these are dependent on each other for a successful wound healing process. A delay in blood clotting or a lack of re-epithelization will result in scar formation and prevent wound healing (Martin and Nunan, 2015).

It has been proposed that the repair of CNS injury resembles peripheral tissue wound healing, with the key difference being that in the CNS an insufficient resolution of pro-inflammatory events occurs (Shechter and Schwartz, 2013). The brain's response to injury therefore is akin to an unresolved wound healing process, in which a lack of a timely re-epithelization leads to scar formation. Scar formation is commonly seen as the main obstacle to the repair and regeneration of CNS tissues (Silver and Miller, 2004). However, it is also notable that peripheral tissue wound healing typically occurs following an acute disruption of tissue due to a cut or a superficial wound. The injuries typically involve a shallow loss of cell layers (i.e., more of a repair than regenerative response) or a very narrow disruption between layers occurs. Typically, these injuries do not involve a major volumetric loss of tissue. This is comparable to traumatic brain injury caused by penetration of a sharp object, such as a knife or an injection tract. We here argue that this type of injury and its associated repair response is quite different from what is required to regenerate a large volumetric tissue loss, as would occur after a stroke or removal of parts of the liver. The wound healing paradigm is therefore useful to understand how a reparative response is mounting to a particular type of tissue injury, but it fails to account for major tissue loss, which might require additional strategies to re-grow lost tissue.

The best known example of tissue regeneration in adult mammals is liver tissue regeneration (Cordero-Espinoza and Huch, 2018). A liver can regenerate within 5–7 days in a mouse and 8–15 days in humans (Michalopoulos, 2007). Tissue regeneration occurs in cases of volumetric tissue loss, as exemplified by a partial hepatectomy, but not in cases of certain types of liver disease, such as liver cirrhosis, further showing a difference between a tissue repair and regenerative response. Regeneration of tissue occurs from undamaged lobes by creating new tissue rather than expanding existing tissue. Akin to the inflammation phase in wound healing, macrophages resident in the liver (i.e., Kupffer cells), as well as those recruited from the blood, initiate an inflammatory cascade that stimulates hepatocyte progenitor proliferation and migration.

Myofibroblasts deposit matrix at the tissue boundary. This is degradable by matrix metalloproteinases (MMPs) and replaced by ECM deposited from stromal cells that integrate into the matrix. Upon integration, cells differentiate into appropriate phenotypes. The creation of a transitional ECM is similar to the formation of granulation tissue in wound healing and might indicate that remodeling of a temporary matrix is a key component of actual tissue creation. In addition to progenitor cell proliferation, de-differentiation and re-differentiation of stromal cells occurs. This cell pool is an important contributor to re-populate the regenerating tissue (Gilgenkrantz and Collin de l'Hortet, 2018). The extent of tissue regeneration might hence depend on the available cellular pool that can supply sufficient cells to regrow the needed tissue.

However, in the brain the pool of cells being able to replace lost tissue is thought to be restricted to neurogenic regions in the subventricular zone (SVZ) and the subgranular zone (SGZ) of the hippocampus (Ming and Song, 2011). This restricted endogenous neurogenic potential of brain tissue might therefore need to be complemented. Implantation of fetal tissue that can develop into site-appropriate brain tissue potentially provides all the required elements to

regenerate lost brain tissue and complement the endogenous tissue repair process.

FETAL CNS TISSUE TRANSPLANTS AND BRAIN DEVELOPMENT

Transplantation of fetal brain tissue is providing a substrate that contains all required elements to construct brain tissue, notably neural cells, a vasculature, microglia, as well as ECM. To ensure optimal survival, post-lesion implantation time and the age of the donor are two crucial variables. Implantable tissue should be derived from the neurogenic period of the developing brain (E11-17 in mice/rats, GW8-30 in humans) (van den Ameele et al., 2014). Earlier tissues are likely to still contain embryonic stem cells that could form teratocarcinomas, whereas more developed tissues will contain partially differentiated neurons, which are likely to die due to axotomy that results in apoptosis. The neurogenic phase is followed by the gliogenic phase (>E18), which produces astrocytes and oligodendrocytes, limiting the yield of neurons required to support function (Sauvageot and Stiles, 2002). The neurogenic tissue hence provides appropriate conditions to produce new brain tissue after implantation into a tissue cavity. A 2–3 weeks post-lesion time frame is considered to be a favorable pro-repair environment for fetal tissue transplants into a cavity, whereas integration and survival at later time points is potentially reduced by the maturation of a glial scar limiting access to host tissue (Grabowski et al., 1994).

Preclinical rodent studies using fetal tissue implanted into the stroke cavity showed the formation of new tissue that filled the cavity (Grabowski et al., 1992b, 1994; Hadani et al., 1992). This fetal tissue developed a vasculature that integrated with the host vasculature and afforded normal metabolic functioning of the tissue (Miyoshi et al., 1995a,b). However, grafts were easily identifiable and distinguishable from host tissue. A tissue mass was created in the cavity, rather than developing a homogenous transition of cytoarchitecture between the host and grafted tissues (Sorensen et al., 1996). A distinct scar separates host and graft highlighting limits to integration (Zeng et al., 1999). Still, implanted tissue fragments matured with neuronal differentiation that led to efferent and afferent axonal projections (Grabowski et al., 1992a, 1993; Sorensen et al., 1996). Although tissue grafts improved behavioral deficits (Grabowski et al., 1995), it remains unclear if this efficacy was due to neuronal connections being formed or if it was mainly due to a trophic factor support reducing secondary degeneration (Mattsson et al., 1997). Nevertheless, these studies demonstrated that new brain tissue can develop in a cavity formed after a stroke.

A regional specificity is observed with brain tissue implants. Cortical grafts implanted into the striatum developing as cortical rather than striatal tissue (Wictorin et al., 1991). This result reflects the positional specification of different brain regions during development (**Figure 3**). Cortical tissues typically develop from the pallium through Pax6-dependent positional specification, whereas the striatum (i.e., caudate-putamen) develop from the lateral and medial ganglionic eminence (LGE and MGE) (Campbell, 2003). The LGE is specified by Gsx2 and Ascl1, whereas the MGE is defined by both Gsx2 and Nkx2.1 (Evans et al., 2012). In the adult, this positional specification is mostly restricted to the SVZ with the dorsal element reflecting the pallial specification (i.e., Pax6 and Emx1/2), the middle section expressing Gsx2 and the ventral part Nkx2.1 (Chaker et al., 2016; Delgado and Lim, 2017). Neurogenesis in the SVZ in the adult therefore produces progenitors that contain some positional specification, which can affect their potential to repair site-appropriate tissue.

NEURAL STEM CELLS: FROM TISSUE REPAIR TO REGENERATION

The differential expression of positional specification in the adult SVZ has profound implications for tissue repair and regeneration. If the neural progenitors are already pre-specified to develop into cortical or striatal phenotypes, their migration across the corpus callosum could direct these into heterologous tissues (**Figure 3**). Commonly, only the SVZ region affected by damage is mounting a repair response with a transient proliferation of NSCs and a more prolonged activation (>1 year) of neural progenitors (Kazanis et al., 2013). If only a restricted portion of the SVZ is responding to tissue injury, this might limit the type of cells available for tissue regeneration. It remains to be determined if this positional specification can be re-specified upon final differentiation. Although fetal tissue experiments suggest that cortical cells will develop into cortex even if implanted into the striatum (Wictorin et al., 1991), these transplants are considerably different from individual cells migrating and interacting with a striatal environment. It is also unclear what the functional effects of differentiated cortical neurons in striatal tissue would be. Cortical NSCs implanted into the stroke-damaged striatum integrate positionally into peri-infarct tissue, in some cases extensive (17%) neuronal differentiation is observed (Darsalia et al., 2007), whereas in others only very few transplanted cells (<2%) actually become neurons (Smith et al., 2012). It therefore remains unclear to what degree the tissue region influences individual transplanted NSCs. For instance, typically striatal projection neurons are produced by cells from the LGE, whereas striatal GABAergic and cholinergic interneurons are derived from the MGE (Marin et al., 2000). Neuroblasts responding to stroke co-express markers for striatal projection neurons (i.e., Pbx and Meis2), indicating their regional specificity stemming from the LGE region (Arvidsson et al., 2002). Hence, both a contribution of MGE and LGE regions of the SVZ are required to produce a functional striatal tissue. Multiple SVZ regions therefore need to respond to striatal tissue damage to reconstruct functional circuitries. In the case of tissue damage encompassing both striatal and cortical tissue, it is further tantalizing to speculate that cortical and striatal cells would sort themselves into their respective territories to restore a pallio-subpallial boundary. Some local cell proliferation is occurring and participating in the tissue response, for instance, glial scarring, but also by producing a small number of neural progenitors (Buffo et al., 2008; Gabel et al., 2016). Astrocytes from the

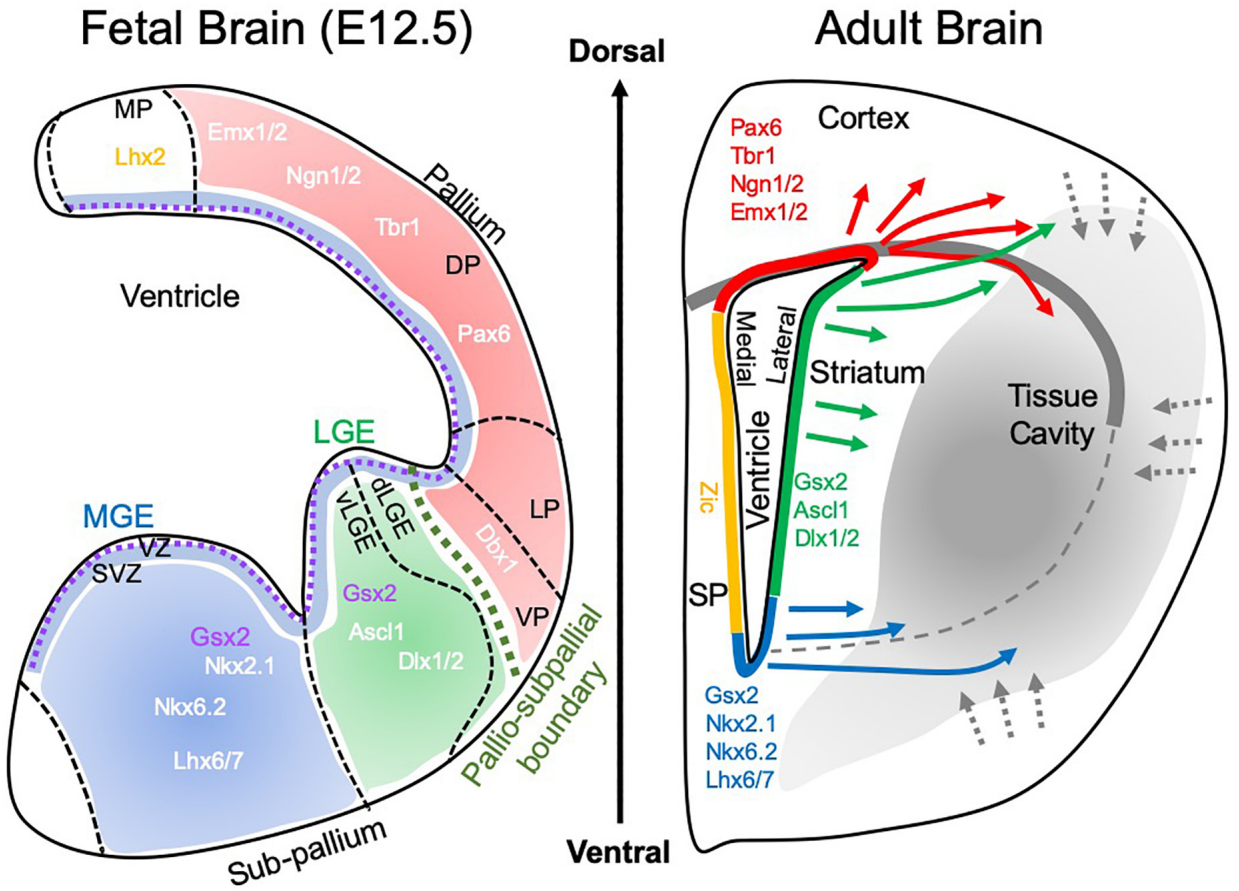

FIGURE 3 | Brain development and tissue repair. During brain development, the pallio-subpallial boundary defines the divide between regions that mature into cortical and striatal tissues. The subventricular zone (SVZ) lies beneath the ventricular zone (VZ) and during development is the birthplace for cells that colonize tissue by migrating along radial glia. Within these tissues, particular gene expressions define the positional specifications of cells to become neurons that characterize the functions of individual regions. The medial ganglionic eminence (MGE) produces striatal interneurons (i.e., calretinin, paravalbumin, calbindin, cholinergic positive), whereas the lateral ganglionic eminence (LGE) is the main source of striatal projection neurons, which constitute 90% of neurons in the striatum. Of these 98% are DARPP-32 positive neurons. A further sub-division of the LGE into the ventral (vLGE) and dorsal (dLGE) has emerged, with vLGE producing a subset of projection neurons. The dLGE is thought to be the main source of interneurons in the olfactory bulb. In contrast, the pallium (a.k.a. telencephalon) is giving rise to the cortex with subdivisions of the ventral pallium (VP), lateral pallium (LP), deep pallium (DP) and medial pallium (MP). These regions produce different subdivision of the cortex, such as the motor cortex and somatosensory cortex. In the adult brain, this positional specification is retained within the subventricular zone (SVZ), the site of adult endogenous neurogenesis. Neurons born along different segments of the SVZ therefore contain a certain positional specification to produce region-specific cells. In response to acute brain injury. These cells respond and migrate through damaged tissue. In the context of tissue regeneration, the SVZ is the main source of cells to replenish lost cells. It remains currently unclear if these cells will cross the pallio-subpallial division that is defined by the lateral corpus callosum in adults. It also remains unknown if cells can change their positional specification and what functional consequence ensue if cells are not expressing a site-appropriate neuron differentiation.

lesion environment gain the potential to produce neurons *in vitro* (Buffo et al., 2008), but *in vivo* the restrictive non-permissive environment suppresses this potential (Seidenfaden et al., 2006; Costa et al., 2010; Robel et al., 2011). This local response is therefore not considered a major source of neuronal replacement in damaged tissue, but these cells are in a position to rapidly invade a cavity and initiate tissue regeneration.

An enhanced proliferation and mobilization of neuroblasts is likely to be advantageous to promote a more extensive tissue repair, but will be essential to produce a sufficient cell pool to replace lost tissue. Intracerebral infusion of growth factors, such as glial cell line derived neurotrophic factor (GDNF), enhanced striatal neurogenesis in the SVZ, but also improved the survival of cells migrating into the stroke-damaged striatum (Kobayashi et al., 2006). A continued infusion of growth factors, such as EGF or betacellulin (Gomez-Gaviro et al., 2012), into the lateral ventricle can hence increase the proliferation of NSCs and/or neuroblast to improve invasion into the damaged striatum and cortex. However, at present it is unclear if these different SVZ sub-regions can be stimulated separately to control tissue specificity of neural progenitors. Proliferating peri-infarct cells could also provide a source of cells that can be expanded to provide a cellular population

that can promote tissue regeneration. Stimulation of the progenitor pool prior to tissue regeneration could be important to ensure that a sufficient invasion of progenitors is available in the damaged tissue to afford invasion into the cavity to replace lost tissue.

INDUCTIVE BIOSCAFFOLDS TO PROMOTE BRAIN TISSUE REGENERATION

The tissue repair response mediated by endogenous neurogenesis, however, does not lead to an invasion of progenitors into the lesion cavity to replace lost tissue. The tissue boundary is undergoing an injury response that seals off the cavity and aims to preserve viable tissue from ill effects of liquefactive necrosis. Unlike in wound healing, no substrate, such as a granulation tissue, is available in the cavity that can sustain the migration of brain cells to repopulate tissue. Indeed, this is evident in the peri-infarct area, where the repair response is using the available tissue substrate for migration and guides cells into position. A physical substrate to sustain cells within the cavity is therefore needed. Akin to fetal tissue transplants, experimentally this principle was demonstrated by implanting NSCs on scaffolds into a tissue cavity formed by a stroke. Provision of a structural support afforded a primitive *de novo* tissue formation by NSCs (Park et al., 2002; Bible et al., 2009, 2012a), although vascularization of this tissue was an issue (Bible et al., 2012b). It was also noted that large degradable solid microparticles produced a spiderweb-like tissue (Bible et al., 2009), hence producing an unfavorable condition to produce a homogenous tissue that integrates with the host. In contrast, implantation of NSCs in a hydrogel made out of ECM from decellularized urinary bladder matrix (UBM) and brain tissue resulted in an excellent cell survival in the tissue cavity, while producing a homogenous tissue that was distinct from host brain tissue (Bible et al., 2012a). These experiments indicated that a hydrogel formulation of a bioscaffold is favorable for replacing brain tissue. The hydrogel bioscaffold readily conforms to the cavity topology if a magnetic resonance imaging (MRI) guided injection-drainage approach is adopted (Massensini et al., 2015).

ECM scaffolds are widely used in peripheral soft tissue repair, including bladder (Santucci and Barber, 2005; Pearlman et al., 2018), dermis (Tchanque-Fossuo et al., 2017; Jeon and Kim, 2018), muscle (Sicari et al., 2014; Zhao and Bass, 2018), heart (Badylak et al., 2006; Khalil et al., 2018), and peripheral nerve (Nectow et al., 2012; Prest et al., 2018). These biomaterials can be sourced from different organs, such as the UBM (Freytes et al., 2008; Crapo et al., 2012, 2014; Dziki et al., 2017; Faust et al., 2017), umbilical cord (Koci et al., 2017), peripheral nervous system (Prest et al., 2018), spinal cord (Tukmachev et al., 2016), as well as the brain (Crapo et al., 2012; Medberry et al., 2013; Faust et al., 2017). It is important to note that the bioscaffolds are natural products that contain soluble (e.g., VEGF-A, BDNF) and juxtracrine factors (e.g., vitronectin, laminin), as well as structural proteins (e.g., collagen, hyaluronic acid) that can affect cellular functions (Saldin et al., 2017). The relative composition is dependent on the organ of origin, rather than being specifically designed, as in the case of synthetic materials (Wolf et al., 2015). Sheets of ECM are often used in peripheral tissue regeneration, but a minimally invasive implantable approach through narrow needles is desirable for brain applications, as this reduces damage to tissues overlying the cavity (Massensini et al., 2015). The formulation of ECM as a lyophilized digest that is reformulated as hydrogel serves this purpose (Freytes et al., 2008; Badylak et al., 2009) and affords reconstitution at different protein concentrations that determine bioscaffold stiffness (Massensini et al., 2015) and biodegradation (Ghuman et al., 2018).

Pre-gel ECM preparations are cytocompatible, while enhancing proliferation and migration of neural progenitors (Crapo et al., 2012; Crapo et al., 2014). Differentiation and neurite outgrowth of neural progenitors with UBM-ECM was higher compared to central nervous system (CNS)-derived ECM (Crapo et al., 2012; Faust et al., 2017), potentially demonstrating that non-CNS scaffolds might be favorable to induce tissue regeneration (Chan and Leong, 2008). In the spinal cord for instance, UBM-ECM performed as well as spinal cord-derived ECM, but provided favorable degradation kinetics (Tukmachev et al., 2016). Non-gelling UBM- and brain-ECM injections after traumatic brain injury revealed improvements in behavioral deficits, further highlighting their potential for therapeutic CNS applications (Zhang et al., 2013; Wu et al., 2016), but no tissue regeneration was reported due to the low concentration and small volume of injectate in these studies. However, these materials might have created a more favorable environment in damaged tissues to promote the survival of newly generated endogenous neural progenitors. Sourcing of homologous CNS tissues also poses a challenge due its low yield (Faust et al., 2017). It is important to point out that these acellular bioscaffolds are used to induce a host regenerative response and not to replicate the existing ECM that is found in a target organ. Heterologous organ sources therefore potentially exert a greater pro-repair effect than CNS-derived ECM.

IMMUNE SYSTEM RESPONSE TO IMPLANTATION

The initial inductive event after ECM implantation remains essentially unknown. It is conceivable that the physical implantation of a bioscaffold into a damaged tissue induces a pressure gradient that provokes a pro-inflammatory response from the immune system. Mechanotransduction in host tissue has also been associated with a good outcome in wound healing, but is generally neglected as an initiating event (Barnes et al., 2018). Invasion of cells needs to occur through existing tissue, as there are no blood vessels in the cavity that could support an invasion into the scaffold. Neutrophils and macrophages are dominant cell types acutely invading these scaffolds in peripheral tissues (Brown et al., 2009; Valentin et al., 2009), as well as the brain (Ghuman et al., 2016, 2018). However, cells resident within veterate tissue could provide the first response with low concentrations of ECM hydrogel permeating into damaged tissue (Massensini et al., 2015). The presence of juxtacrine

and/or paracrine factors, as well as nanovesicles, released from the scaffold into tissue are potentially factors that induce an immune response in peri-cavity tissues (Sciari et al., 2014; Slivka et al., 2014; Dziki et al., 2017; Huleihel et al., 2017a). The acute invasion of immune cells is likely a reflection of innate immunity. This arm of the immune system involves neutrophils, eosinophils, basophils, dendritic cells, as well as macrophages (**Figure 4A**).

However, the acute immune response to inductive bioscaffolds in the brain remains poorly understood. The main focus has been on the role of macrophages, which constitute 23% of all cells found within ECM hydrogel implanted into the brain (Ghuman et al., 2016). Still, 66% of cells in the hydrogel at this time point have not been associated with a particular cell phenotype (**Figure 4B**) and could reflect other immune cells (i.e., neutrophils) contributing to a rapid innate response (Ghuman et al., 2018). It is unclear if macrophages found in the ECM hydrogel in the brain are derived from peripheral macrophages or if these are mostly brain-resident microglia that respond. More detailed studies of the mode of action (i.e., cellular level) involved in this early phase are required to gain a better understanding of the factors (i.e., mechanisms of action) that elicit the initial response and provoke a regenerative cascade (Badylak and Gilbert, 2008). Understanding this process is especially important for the design of synthetic bioscaffolds aiming to replicate the tissue regeneration achieved with natural materials (Drury and Mooney, 2003; Zhu and Marchant, 2011; Aurand et al., 2012).

Immune cell recruitment is most likely mediated through soluble factors that can diffuse through a large volume of tissue, although it is influenced by tissue density and other structures (e.g., scarring) that provide barriers (Nicholson, 2001). Notch and PI3K/Akt signaling in ECM bioscaffolds, for instance, have been associated with the phagocytic activity of immune cells (Slivka et al., 2014). The migration of macrophages is dependent on monocyte chemoattractant protein-1 (MCP-1/CCL2), which guides cells to their target (Deshmane et al., 2009). During the acute phase of macrophage invasion, most of these monocytes (>35%) exhibit an M1-like phenotype (CD86+), but by 14 days this proportion is reduced and mostly (>20%) M2-like (CD206+) characteristics are found (Ghuman et al., 2018). This shift in macrophage phenotype is also thought to affect the differentiation of organ-specific cells, such as neurons, in the case of the brain (Faust et al., 2017). In wound healing, a shift toward an M2-like phenotype is thought to be influenced by lymphocytes (i.e., T and B cells) that invade as part of the adaptive immune response (**Figure 4C**). IL-4 is commonly associated with this shift in macrophage phenotype, but juxtacrine factors, such as MEK/ERK and integrin signaling are also known to decrease phagocytic activity and promote a repair phenotype (Slivka et al., 2014). There is also recent evidence that ECM bioscaffolds produce a macrophage activation that might be distinct from the characteristics associated with M0, M1 or M2 activation (Huleihel et al., 2017b), but this might merely be a reflection of the activating signals rather than the cells' function (Novak and Koh, 2013). Other classifications, such as division of macrophages into pro-fibrotic and pro-repair phenotypes have also been proposed to be more relevant to the processes involved in tissue repair and regeneration (Sadtler et al., 2019).

Although macrophage activity within ECM bioscaffolds has been extensively investigated, their interaction with other cells remains poorly understood, especially in the context of an adaptive (delayed) immune response (**Figure 5A**), which has also been reported to participate in tissue regeneration (Strbo et al., 2014; Sadtler et al., 2019). The use of xenogenic matrix grafts raises the question of the role of an adaptive immune response to foreign proteins. The blood-brain barrier (BBB) produces an immune-privileged tissue environment, but drainage of solutes through the glymphatic system leads to a sensitization of B and T cells in the cervical lymph nodes (Verheggen et al., 2018). There is evidence that T helper cells respond to xenogenic proteins in ECM bioscaffolds, suggesting that a specific immune response develops (Allman et al., 2001). Still, it remains unclear if an "adaptive immune response" is an indication of an incomplete decellularization, which might lead to remnants of cells being retained with the bioscaffold to produce a sensitization of the immune system. It is generally thought that ECM molecules by themselves do not elicit an adaptive immune response. Still, the complexity of molecules contained within decellularized materials (e.g., microvesicular bodies) can provide a range of targets for an adaptive immune response that is distinct from the ECM molecules *per se*. An adaptive immune response to even endogenous proteins can follow an innate immune response, as in the case of stroke for instance (Rayasam et al., 2018). The division between an innate and adaptive immune response is based on infection studies and might therefore not be an adequate description of the response observed after tissue damage and repair (Sadtler et al., 2019). A greater focus on the role of the immune system in these conditions is likely to provide a more adequate understanding and conceptualization of the role inflammation plays in modulating a tissue response toward repair and regeneration.

BIODEGRADATION OF SCAFFOLDS

The recognition that the same immune cells can exert different functions is part of this evolving conceptualization. For instance, the polarization toward an M2-like phenotype is thought to be crucial for the repair response, even though M1-like macrophages persist for 90 days and are thought to play an essential role in the degradation of the bioscaffold (Ghuman et al., 2018). Ablation of peripheral macrophages prevents structural remodeling of ECM bioscaffolds, further highlighting their crucial role in this process (Valentin et al., 2009). Macrophages secrete proteases that degrade cross-linked collagen scaffolds (Yahyouche et al., 2011; Madsen et al., 2013), as is the case with ECM hydrogel. Especially, MMP-2 and MMP-9 (**Table 2**) are upregulated after acute brain injuries, such as stroke, by secretion from brain microglia reacting to the tissue insult (del Zoppo et al., 2007), but so are MMP-3, MMP-7, MMP-10, and MMP-11 (Rempe et al., 2016). UBM-ECM hydrogel is especially high in collagen I (Saldin et al., 2017), which is primarily degraded by MMP-1, MMP-2, MMP-8, MMP-12, and MMP-13 (Webster and Crowe, 2006;

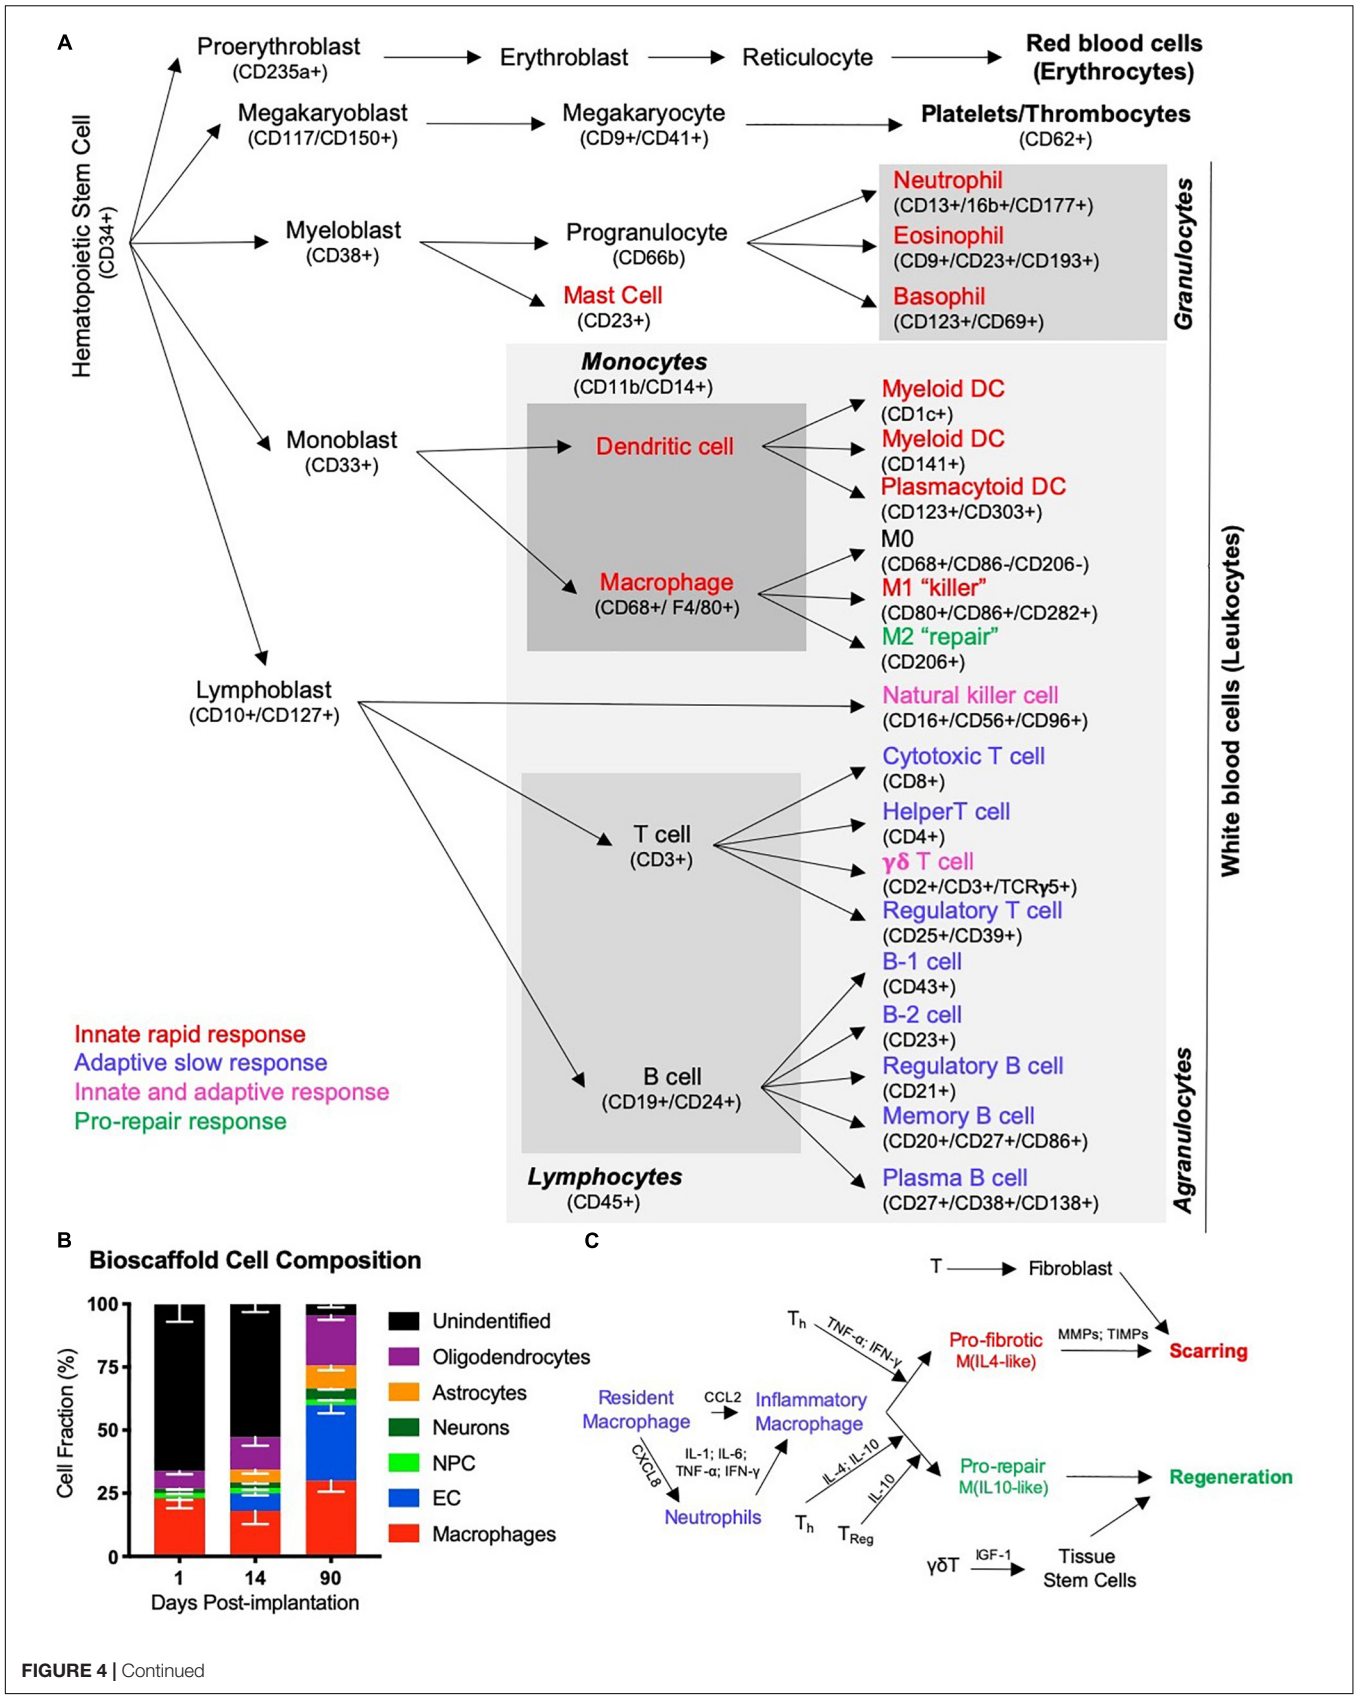

FIGURE 4 | Continued

FIGURE 4 | The immune response in tissue regeneration. **(A)** The inflammatory response is driven by the immune system. Although the immune system is a complex network of circulating and tissue-resident cells, these originate from a hematopoietic stem cell. Traditionally the immune system was characterized in studies of infection and cells have therefore been divided into those that contribute to an innate rapid response versus those that produce an adaptive slow response. Only a few types of cells, such as natural killer cells and γδT cells, have been thought to contribute to both. However, more recently the importance of inflammation in tissue repair and regeneration has revealed distinct phenotypic changes in cells, such as macrophages, that questions the traditional division into an innate and adaptive immune response to recognize a pro-repair response of the immune system. It is likely that a range of immune cells are involved in this pro-repair response, but that the function of cells might be different to their role in response to an infection. **(B)** A characterization of cells infiltrating an ECM bioscaffold implanted into a stroke cavity revealed that >75% of cells (mean – standard deviation) at 1 day post-implantation are not of a brain origin (Ghuman et al., 2018). Although the majority of these are currently unidentified phenotypes, it is likely that these are of an immune origin, such as neutrophils and eosinophils, which respond rapidly, but also transiently, to tissue changes. **(C)** Inflammation in wound healing is thought to be initiated by resident macrophages that release inflammatory cytokines (IL-1; IL-6, TNF-; IFN-) in response to detection of an injury. The chemokine CXCL8 is released and drives the rapid invasion of neutrophils into the damaged tissue from the blood. A secondary invasion response is recruiting inflammatory macrophages, as well as lymphocytes, such as helper (T_h), regulatory (T_{reg}) and γδT cells. T cells are thought to play a key role in modulating macrophage activity and promoting a pro-fibrotic response that results in tissue scarring or a pro-repair response that leads to tissue regeneration.

Lu et al., 2011). In contrast, MMP-9 is mostly associated with degradation of the basement membrane around blood vessels, which is rich in collagen IV, laminin, and vitronectin (Fukuda et al., 2004; Underly et al., 2017). Neutrophils also produce MMP-9 and are known to be involved in ischemic tissue regeneration in peripheral limbs (Heissig et al., 2010). Other proteases, such as A Disintegrin And Metalloproteinases (ADAMs) and Meprins, are also likely involved in ECM remodeling, but their role remains poorly understood, especially in the context of tissue regeneration (Bonnans et al., 2014). How different immune cells and their activation state drive protease production and bioscaffold degradation also requires more mechanistic studies to understand their role in initiating the tissue regeneration process.

Although collagen I is considered a major structural target for biodegradation, the role of the biodegradation of other ECM molecules remains poorly understood. In ECM hydrogels implanted into the brain, for instance, fibronectin and chondroitin sulfate were mostly degraded within a week, even though collagen I was still abundantly present (Jin et al., 2017). Laminin, collagen IV and hyaluronic acid (HA) were also present at 1 day post-implantation (Massensini et al., 2015), but it remains unclear if these molecules are rapidly degraded or if the degradation profile of the ECM molecules is equivalent to collagen I. Less abundant molecules could be degraded faster than more abundant one's, even though the rate of biodegradation is the same. A quantitative comparison between different ECM molecules and their degradation is needed to address these key questions. While bioscaffolds from different sources are thought to exert similar regenerative effects (Keane and Badylak, 2015; Tukmachev et al., 2016), their biodegradation is likely to be influenced by their composition. Understanding how individual ECM molecules are degraded and lead to the release of other factors (e.g., VEGF-A) will be essential to design novel biomaterials that afford a greater control over biodegradation (Sridharan et al., 2015; Kelly et al., 2017).

Biodegradation of ECM bioscaffolds in the brain potentially follows a different dynamic than in peripheral organs. Stiffer ECM hydrogel (8 mg/mL) undergoes a slow degradation in the brain, with only a 32% reduction in volume by 90 days, whereas softer bioscaffolds (3 and 4 mg/mL) were almost completely absorbed (>95%) (Ghuman et al., 2017, 2018). Stiffer brain-compliant 8 mg/mL UBM-ECM hydrogel was rapidly invaded by macrophages compared to the weaker gels, but the density of cells inside the scaffold decreased over time indicating that a poor biodegradation occurred (Ghuman et al., 2018). Softer gels produced a more consistent cell density (∼4000 cells/μL) with a vasculature forming, which was absent in stiffer material. Although these differences indicate a potential mode of action for biodegradation, it remains unclear how stiffness or the higher protein concentration adversely affected biodegradation, considering that there was an extensive cellular response at 1-day post-implantation in the bioscaffold that did not readily degrade (Ghuman et al., 2016). In peripheral tissues, a complete replacement with host tissue between 75 and 90 days has been associated with tissue regeneration (Record et al., 2001; Gilbert et al., 2007; Valentin et al., 2009; Carey et al., 2014; Dearth et al., 2016) and is consistent with the time course observed with softer gels in the brain (Ghuman et al., 2018). However, in peripheral tissues most biodegradation studies investigate the use of ECM sheets, rather than hydrogel. It is therefore unclear if ECM hydrogel will follow a similar time course in peripheral tissues. Crucially, the lack of biodegradation in the brain did not lead to tissue regeneration (Ghuman et al., 2017), whereas biodegradation of the scaffold produced *de novo* tissue (Ghuman et al., 2018). Biodegradation gradually removed the bioscaffold and provided the structural basis for new cells to invade the cavity. These newly invading cells showed assembly in and inbetween the ECM hydrogel to initiate the formation of new tissue. This process is very similar to that described in peripheral tissues, where biodegradation or the remodeling of a "transient" ECM is a key step to replace lost tissues (Swinehart and Badylak, 2016).

NEURAL TISSUE FORMATION AND CONNECTIVITY

Tissue-specificity is determined by the cells that invade from the host organ into the degrading bioscaffold. The continued proliferation and response of the SVZ to brain injury (Kazanis et al., 2013; Chang et al., 2016) provides a ready supply of local (i.e., peri-cavity) neural progenitors that can respond to the implantation of a bioscaffold. Inflammatory factors released from microglia and invading immune cells provide a trail of ligands, such as CCL2 (a.k.a. monocyte

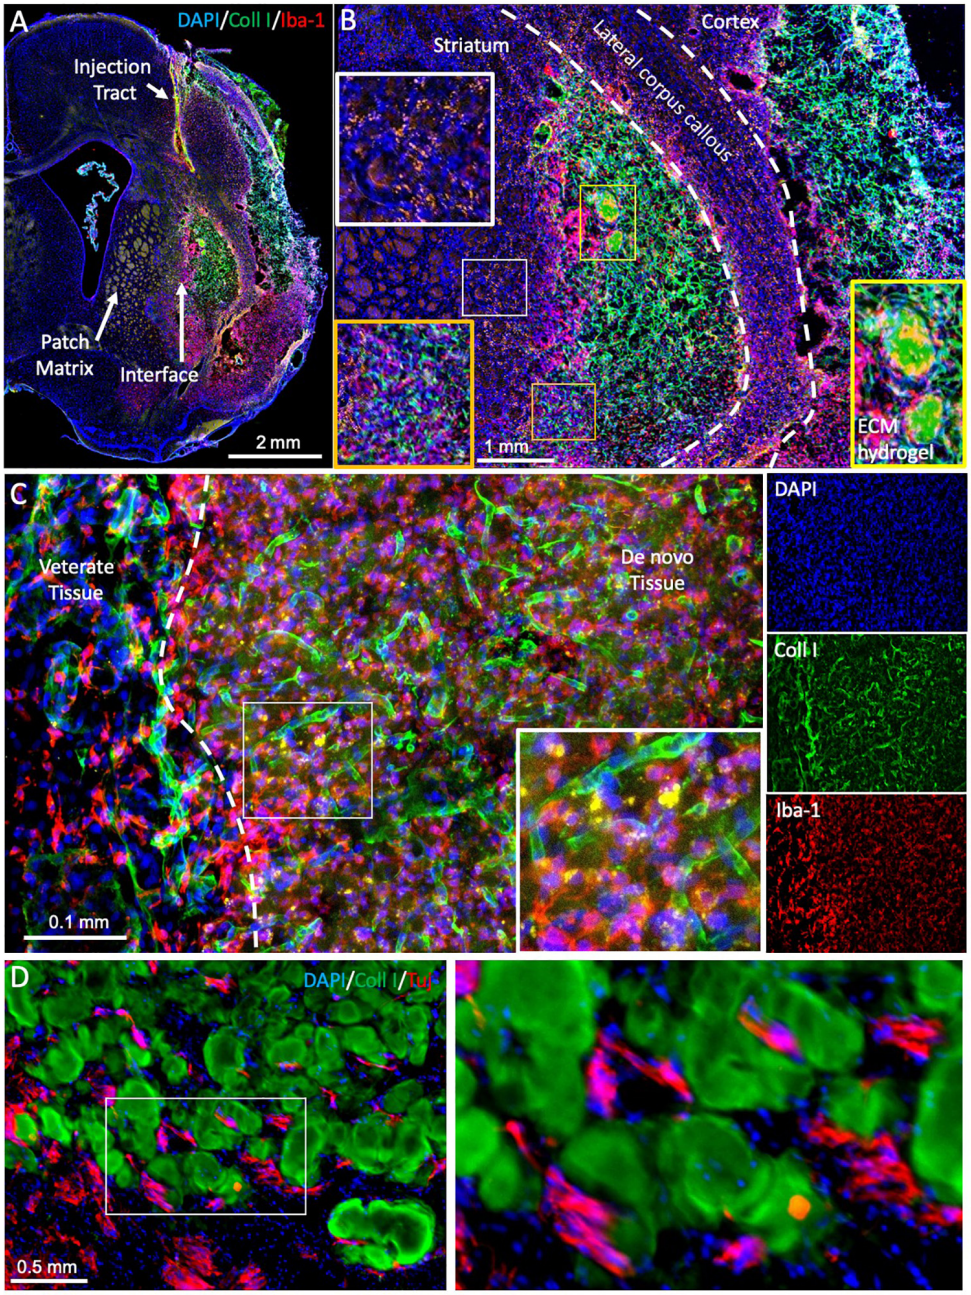

FIGURE 5 | Evaluating brain tissue regeneration. **(A)** A bioscaffold is implanted into the lesion cavity through a narrow bore needle that produces an injection tract and defines the trajectory of the injection. The aim of the procedure is to fill the tissue cavity and to produce a close-fitting interface with host tissue that affords invasion of cells into the scaffold and produces a seamless integration between veterate and *de novo* brain tissue (Ghuman et al., 2018). *De novo* tissue growing inside the cavity can be identified based on collagen I staining of the ECM hydrogel and the neovasculature, surrounded by veterate tissue, as indicated by the peri-infarct area and a dense presence of microglia (Iba1 + cells). **(B)** At 90 days post-implantation, the bioscaffold is almost completely degraded. In this case, two small remnants of the ECM hydrogel, characterized by a dense collagen I content are still undergoing cell invasion and degradation (yellow box). However, the rest of the scaffold is degraded and replaced with *de novo* tissue, in which blood vessels contain a higher level of collagen I compared to host tissue. Regenerated tissue (orange box) has blood vessels high in collagen I, but a dense tissue structure is evident with a reduced number of Iba-1 positive microglia/macrophages. It was also noted that in *de novo* tissue, some particulates were present that were not evident in veterate brain (white box). **(C)** In regenerating tissue, the bioscaffold is degraded, but there is still a higher collagen I background compared to host brain. Morphologically it is also distinct with a higher content of microglia/macrophages and strongly collagen I positive blood vessels. Nevertheless, more robust unique identifiable markers are desirable to contrast these different microenvironments. **(D)** In between patches of ECM bioscaffold, tissue is developing that contains neurons (Tuj) at a higher density than within the bioscaffold. However, at present there are no robust markers that allow a reliable identification of this as *de novo* tissue, complicating the quantification of the regenerative process.

MMPs can be divided into several sub-domains consisting of MMPs with basic domains (i.e., prodomain + catalytic domain + hemopexin-containing ancillary domain) (1); MMPs with minimal domains (i.e., prodomain + catalytic domain) (3), MMPs with fibronectin-domain inserts (2), Membrane-bound MMP anchored by GPI or a transmembrane domain (4). There is a further distinction in MMPs either being secreted or membrane-associated. A variety of aliases have been used to refer to different MMPs, depending on their original discovery. MMPs typically also act as activators of other MMPs, further enhancing their potential to degrade different types of collagen, as well as other types of ECM molecules. A few MMPs have been associated with acute brain injury, as indicated by italics, but other have been found to be upregulated in different types of neurodegenerative disease, as well as synaptic plasticity. MMPs therefore serve important roles in maintaining a healthy brain environment, as well as being propagators of tissue damage in disease conditions (n.d., not defined).

chemoattractant protein 1) and CXCL12 (a.k.a. stromal-derived factor-1α), for neural progenitors to follow (Bye et al., 2012; Kaneko et al., 2017). Some local proliferation might also occur in response to factors, such as bFGF (FGF2) and VEGF-A, released by activated astrocytes (Gabel et al., 2016). Release of these factors can occur from the ECM bioscaffold and lead to the initial cell invasion of neural progenitors and astrocytes observed within 1 day in implanted gels (Ghuman et al., 2016). However, the continued recruitment of neural progenitors from veterate brain is likely dependent on the secretion of appropriate factors, such as CCL2 and CXCL12, from microglia and/or macrophages that are degrading the scaffold. It can be surmised that in the case of the 8 mg/mL ECM hydrogel implanted into a stroke, the very slow biodegradation associated with very few macrophages present in the scaffold provided insufficient chemokines to drive host cell invasion, including blood vessels (Ghuman et al., 2018). Blood vessels are likely to play a triple role. Their formation in the scaffold affords a direct route for macrophage invasion to accelerate biodegradation, but they also provide

a migration substrate for neural progenitors and are required to meet the metabolic demands of a newly forming tissue (Serbo and Gerecht, 2013).

The cellular composition inside the bioscaffold shifts from predominantly immune cells, such as macrophages, being present to endothelial cells, as well as neural cells, such as oligodendrocytes, neurons, neural progenitor cells, and astrocytes. These constitute over 70% of cells at 90 days (**Figure 4B**) (Ghuman et al., 2018). This suggests that some cellular composition required for *de novo* tissue formation precedes the degradation of the implanted ECM. This is consistent with new ECM being deposited by site-appropriate cells, rather than immune cells. Still, the density of neurons (6% of cells) inside the hydrogel is considerably lower at 90 days compared to intact tissue (42%) (Ghuman et al., 2018). This is also the case during development, where radial glia provide the substrate for neuron progenitors to migrate into position and gradually produce the neuronal density of an adult brain (Malatesta and Gotz, 2013). Astrocytes present within the bioscaffold, however, do not morphologically or topologically resemble radial glia (Ghuman et al., 2016). The transitional microenvironment in the bioscaffold, where neural cells are found, does not contain strands of radial glia along which neural progenitors migrate.

Regenerating tissue produces unique microenvironments not present in development. Notably, intact brain tissue borders on peri-cavity damaged tissue, with this damaged tissue transitioning into *de novo* tissue (**Figure 5A**). This *de novo* tissue borders in turn on the bioscaffold still undergoing constructive remodeling. The cytoarchitecture within the bioscaffold does not reflect the density of *de novo* or damaged tissue (**Figure 5B**). Identification of neural cells inside the bioscaffold is facilitated by visualizing the ECM hydrogel, traces of which often remain even at a low concentration (**Figure 5C**). However, a definition of *de novo* tissue, which can develop in between patches of degrading bioscaffolds (**Figure 5D**), is more challenging. Its cytoarchitecture and composition therefore currently remains unknown. To contrast *de novo* from damaged peri-cavity veterate tissue is challenging, as there are no specific markers for these microenvironments. Positional specification markers might provide some guidance to identify the differentiation of site-appropriate cells, but these are likely to be expressed inside the bioscaffold, damaged and *de novo* tissue. Deposition of ECM molecules might have greater potential to distinguish these different microenvironments. For instance, the formation of new blood vessels follows a sequential deposition of vitronectin, fibronectin, laminin, collagen I and collagen IV (Chou and Modo, 2016). Establishing a similar deposition pattern for the interstitial ECM could lead to a better characterization of microenvironments. The use of specific tags for the bioscaffold would further afford a distinction from veterate tissue that does not rely on the abundancy of ECM molecules in the hydrogel (Park et al., 2019).

Akin to the transplantation of fetal tissue, the integration between newly forming and veterate tissue will be a key aspect to produce behavioral recovery that is dependent on neuronal circuitry. Axons containing neurofilament are found within ECM hydrogel implanted in a stroke, as well as in *de novo* tissue forming in between patches of remaining scaffold (Ghuman et al., 2018). Oligodendrocytes were the most abundant neural cell phenotype within the ECM hydrogel, but it remains unclear if these myelinate axons. Implantation of angiogenic HA hydrogel indicated axonal regeneration through a cortical cavity along newly forming blood vessels (Nih et al., 2018). Wider connectivity with veterate tissue or the formation of neuronal circuitry in *de novo* forming tissue remain to be investigated. Extensive work on axon regeneration has been focused on the spinal cord (Anderson et al., 2018), but a more complex topology of connections is required to establish neuronal circuitries in the brain, as well as to establish a functional integration between *de novo* and veterate tissue. Although fetal tissue transplants and implantation of HA hydrogel indicate that new axonal connections can be formed in or through cavities, it is unclear if guidance to newly forming connections is required to ensure the appropriate development of neuronal circuitry. So far, no epileptic fits have been reported, potentially suggesting that spontaneously appropriate connections are formed or that there is a lack of functional integration (Modo and Badylak, 2019). The use of conductive hydrogels and specific stimulation might provide a new perspective to promote an integration of newly forming tissues (Oh and George, 2019). The time course of establishing axonal connections and their potential underpinning of behavioral functions remain to be investigated, but it is expected that neuronal differentiation in *de novo* tissue formation precedes axonogenesis.

CELL-BIOSCAFFOLDS AND ENGINEERED MICRO-TISSUE CONSTRUCTS FOR REPAIR AND REGENERATION

Endogenous tissue regeneration is preferable, as it will use the patients' own cells and avoid potential immune rejection. However, endogenous tissue regeneration is a lengthy process, potentially taking over 1 year to complete. Moreover, the reservoir of neural progenitors in the brain might be insufficient to supply sufficient neurons to repopulate a large *de novo* tissue. Alternative engineering strategies therefore need to be considered to expand the neural substrate required for tissue restoration (Chen et al., 2016). Implantation of allogenic neural cells in a biomaterial can potentially increase the neural substrate required to restore lost tissue. Most studies to date have focused on the use of biomaterials, such as hydrogels, to improve the delivery of cells to the brain (Ho et al., 2019). Only a few studies have aimed at restoring tissue inside the cavity. Bioscaffolds combined with neural stem cells will provide the structural support to retain cells in the cavity and allow them to differentiate (Park et al., 2002; Bible et al., 2009, 2012a). Implantation of fetal-derived neural stem cells has the potential to produce a cell substrate that is positionally specified to be striatal or cortical tissue (Bible et al., 2012a,b), but so far no evidence for the generation of region-specific tissue has been reported. Induced pluripotent stem cells

(iPS) will require positional specification *ex vivo* or *in vivo*. Implantation of NSCs requires the invasion of host endothelial cells to form a vasculature, as well as microglia to provide their support function. NSCs implanted with a non-angiogenic bioscaffold do not facilitate a neovascularization (Bible et al., 2009) and require additional instructive signals, such as release of VEGF-A, to ensure a re-vascularization (Bible et al., 2012b). Moreover, implantation of NSCs can exert an anti-inflammatory effect that prevents or reduces the infiltration of microglia. In the case of inductive bioscaffolds, this could lead to a reduction in bioscaffold degradation (Bible et al., 2012a). The inductive properties of the bioscaffold are, however, less important in this approach. In contrast to endogenous brain regeneration, implanted cells should provide a rapid replacement of tissue and hence a site-appropriate ECM might be more important. It is noteworthy that neural stem cells in brain ECM accelerate the formation of neuronal circuitry (Lam et al., 2019).

A rapid tissue restoration might therefore require the key "ingredients" for brain tissue, notably NSCs, ECs and ECM. The ratio between NSCs and ECs is crucial to promote the formation of a vasculature *in vitro* (Chou et al., 2014; Chou and Modo, 2016), as well as *in vivo* after implantation into a stroke cavity (Nicholls et al., 2015). ECs are highly immunogenic and upon formation of a vasculature in *de novo* tissue will lead to exposure of the endothelial wall to circulating immune cells, as in the case of fetal tissue or whole organ transplants. This will require a continued immunosuppression that potentially compromises the quality of life of patients. However, it is not expected that immunosuppression, such as cyclosporin A, will affect the regenerative response *per se*, as these pharmacological agents affect the indirect chronic immune response mediated through lymphocyte stimulation and not microglia/macrophages (Karam and Wali, 2015). The low immunogenicity of NSCs does not raise this issue, with good survival in the absence of immunosuppression (Modo et al., 2002, 2003). In contrast, implantation of microglia could potentially cause greater concerns, as these are highly immunogenic, and could mount a graft-versus-host response (Nassereddine et al., 2017), where implanted microglia would attack host cells. Cellular sourcing hence will be an issue with the co-implantation of cells that are immunogenic. iPS cells can circumvent these issues, but the protracted time to grow sufficient cells *ex vivo* would be a concern that would need to be balanced against the time course of endogenously induced tissue regeneration.

Beyond the co-implantation of NSCs and ECs to "spontaneously" form a tissue *in situ*, the *ex vivo* construction of micro-tissues is also considered a potential therapeutic intervention aimed at replacing lost tissue. Stem cell niches can be engineered for implantation to provide a continuous supply of new cells to repair or reconstruct brain tissue (Lampe and Heilshorn, 2012). Preformed neurovascular units can also be envisaged for implantation (Potjewyd et al., 2018). *Ex vivo* growing of brain organoids for transplantation can potentially accelerate *in vivo* tissue growth, as an essential cytoarchitecture and rudimentary connectivity can be pre-established (Mansour et al., 2018). Larger constructs with pre-formed axonal projection can also be envisaged (Struzyna et al., 2015, 2017) and in some cases be designed to specifically replace a major fiber tract, such as the nigrostriatal pathway, which is almost completely lost in Parkinson's disease (Struzyna et al., 2018). Pre-assembly of micro-tissue is potentially an exciting approach to pre-define an cytoarchitecture using bio-printing to produce homologous constructs more rapidly than spontaneously forming tissue (de la Vega et al., 2019). Delivery of these complex constructs will, nevertheless, be more challenging through a narrow bore needle without deforming or destroying the construct (Wahlberg et al., 2018). Creating a tight interface with veterate tissue also needs considering to ensure integration, as the topology is very different between subjects. Preformed connections could adversely affect cell viability, if these connections are cut or damaged during the implantation process, similar to fetal tissue transplants in Parkinson's disease (Schierle et al., 1999). Implantation of tissue constructs is therefore likely to be a more complex procedure to achieve, especially in terms of intracerebral delivery and cell sourcing.

TRAINING OF FUNCTIONAL CIRCUITRY

Axonal projections lead to connectivity between regions, but synaptic connectivity is required to avoid synaptic pruning and a potential die-back of axons. To avoid synapse pruning, functional synapses need to be established between axons and dendrites (Butz et al., 2009). Synaptogenesis will establish connections, but it is their activation through a common input that renders these functionally dependent and avoids pruning. These so called Hebbian synapses underpin plasticity in the damaged brain, which is exploited during rehabilitation training (Dalise et al., 2014; Takeuchi and Izumi, 2015). Transplantation of NSCs and their functional integration into neuronal circuits is also dependent on synaptic integration between grafted and host cells (Tornero et al., 2013, 2017). However, mapping these connections across a whole brain poses a formidable challenge (Doerr et al., 2017). Although day-to-day activities lead to some functional recovery, this is further enhanced by providing an enriched environment to animals to increase activity and improve the establishment of functional synapses. An enriched environment leads to diverse changes in function, as well as anatomical markers of grafted cells (Dobrossy and Dunnett, 2001). However, introduction of a rehabilitation paradigm does not always lead to an improvement in graft-mediated recovery (Hicks et al., 2009). Only a few studies have investigated the interaction between rehabilitation after intra-striatal grafting of fetal tissue into striatal lesions modeling Huntington's disease (Dobrossy and Dunnett, 2004, 2008) or stem cells after a stroke (Hicks et al., 2007, 2008, 2009). Although the effects of rehabilitation on synapse formation in transplanted cells is potentially profound, our current state of knowledge about these interactions is unsatisfactory and requires more extensive studies that define appropriate rehabilitation paradigms and how these differ from interventions without cell therapy (Ghuman et al., 2018). Establishing optimal intervention periods for when these programs should be administered, as well as how long a rehabilitation program is needed in conjunction

with "regenerative therapies" to achieve a maximal integration requires detailed investigations to ensure clinical efficacy (Savitz et al., 2014; Ross et al., 2016).

The role of training new tissue in the context of brain tissue regeneration remains unaddressed. However, there is evidence from ECM bioscaffolds regenerating muscle tissue that rehabilitation training is an essential element to produce functional tissue (Gentile et al., 2014; Sicari et al., 2014). Rehabilitation tasks are likely to be dependent on behavioral deficits after brain injury, as these are dependent on the regional location of damage (Feys et al., 2000). The rehabilitation paradigm will therefore need to adapt depending on the functional deficit (Kreber and Griesbach, 2016), which will complicate group-wise comparisons as no one rehabilitation paradigm will be suitable for all subjects (Gentile et al., 2014). In the case of damaged tissue, neuronal progenitors from the SVZ will integrate and supplement existing neuronal networks to improve their function. In contrast with tissue regeneration, a complete new set of neuronal networks is created that needs to form a functional circuit based on a behavioral input. Tissue replacement is expected to restore function of lost tissue, but akin to learning in development it can be expected that new tissue needs to be trained to function appropriately (Dobrossy and Dunnett, 2001; Dobrossy and Nikkhah, 2012). In conventional rehabilitation, plasticity of existing networks can be induced by exercise (Dobkin, 2008), which leads to the release of growth factors, such as BDNF, that support synaptogenesis (Dalise et al., 2017). To ensure a functional synapses formation, task integration is required (Rensink et al., 2009). In animal models, behavioral testing can be considered a form of task integration. However, ideally a separate task will be used to integrate and evaluate functional effects (Ghuman et al., 2018). Compensation (i.e., solving the same task using an alternative strategy) might occur, which will confound the assessment of efficacy. Extensive testing on a particular behavioral task could increase compensation effects, as the animal is learning novel ways to solve the task (Boltze et al., 2014). Separating training and testing should therefore be considered the gold standard for a behavioral evaluation of tissue regeneration and the use of rehabilitation to train *de novo* tissues.

CRITERIA TO EVALUATE FUNCTIONAL BRAIN TISSUE REGENERATION

The evaluation of behavioral effects of brain tissue regeneration needs to be performed in contrast to subjects that only experienced brain injury, as some spontaneous recovery of deficits occurs. Learning and compensatory strategies could be adopted to improve performance that would not reflect a therapeutic benefit. Inclusion of appropriate non-injured controls is required to establish a performance baseline over time, as well as an effect size for the deficit and potential recovery. Considering the invasiveness of the procedure to deliver a bioscaffold, appropriate surgical controls (e.g., needle implantation, vehicle injection) need to be evaluated, but only need to be included consistently in studies if there are significant behavioral effects. Eventually, more detailed studies are required to determine the influence of biological variables (e.g., age, sex) on brain tissue regeneration. Specifically, subject age is known to affect inflammation, ECM composition and its potential to induce a regenerative response (Brown et al., 2017; Hachim et al., 2017; LoPresti and Brown, 2018). Inflammation is another biological variable that is known to be affected by age and sex, but little is known about regenerative differences between sexes. To gain a robust mechanistic understanding, effects of all these variables need to be accounted for.

Although improvements in behavioral deficits are the ultimate aim of this approach, it cannot be expected that initial studies defining the important variables to achieve tissue regeneration will reveal behavioral improvements. Initial studies should aim to achieve a robust and reproducible tissue formation by defining key rules, such as the formation of a tissue cavity prior to bioscaffold implantation etc. (**Table 3**). Histological analyses need to establish robust methods that can contrast damaged tissue from regenerating tissue. Particular ECM molecules might provide differential markers for this purpose, but need to be validated. In the absence of this validation, it is possible that mechanistic interventions will target damaged veterate brain, rather than regenerated brain. This would lead to erroneous interpretations of functions in regenerated brain tissue.

A distinction between behavioral and functional effects is made to differentiate overt observations related to performing a specific task (i.e., behavior) from brain activity and tissue metabolism (i.e., function). We further propose that the claim of establishing a *de novo* functional brain tissue should be provided by non-invasive imaging techniques, such as MRI. A pre-implant image of the tissue cavity and the host brain should be provided with further images charting how the cavity is transformed by tissue regeneration (Ghuman et al., 2017). This *in vivo* time-lapse in combination with histology should

TABLE 3 | Emerging rules for an induced brain tissue regeneration.

Rules	Description
1	The adult mammalian brain does not spontaneously restore lost tissue.
2	Preserved neurogenic regions are required to produce endogenous neurons.
3	Distance of neurogenic regions to areas of damage is crucial to induce a response.
4	Extent of cellular reservoir in neurogenic regions is crucial to produce sufficient cells to promote repair and regeneration.
5	Neurogenic regions need to produce cells with site-appropriate positional specification.
6	A tissue substrate needs to be introduced to provide support for cell invasion.
7	A continuous interface between scaffold and tissue is required to ensure a homogenous tissue integration.
8	Formation of a mature glial scar prior to introducing a tissue substrate will complicate tissue regeneration and integration.
9	A rapid invasion of cells is required to ensure a regenerative cascade is initiated.
10	The tissue substrate needs to be degraded to >90% within 3–4 weeks to allow *de novo* tissue to form.

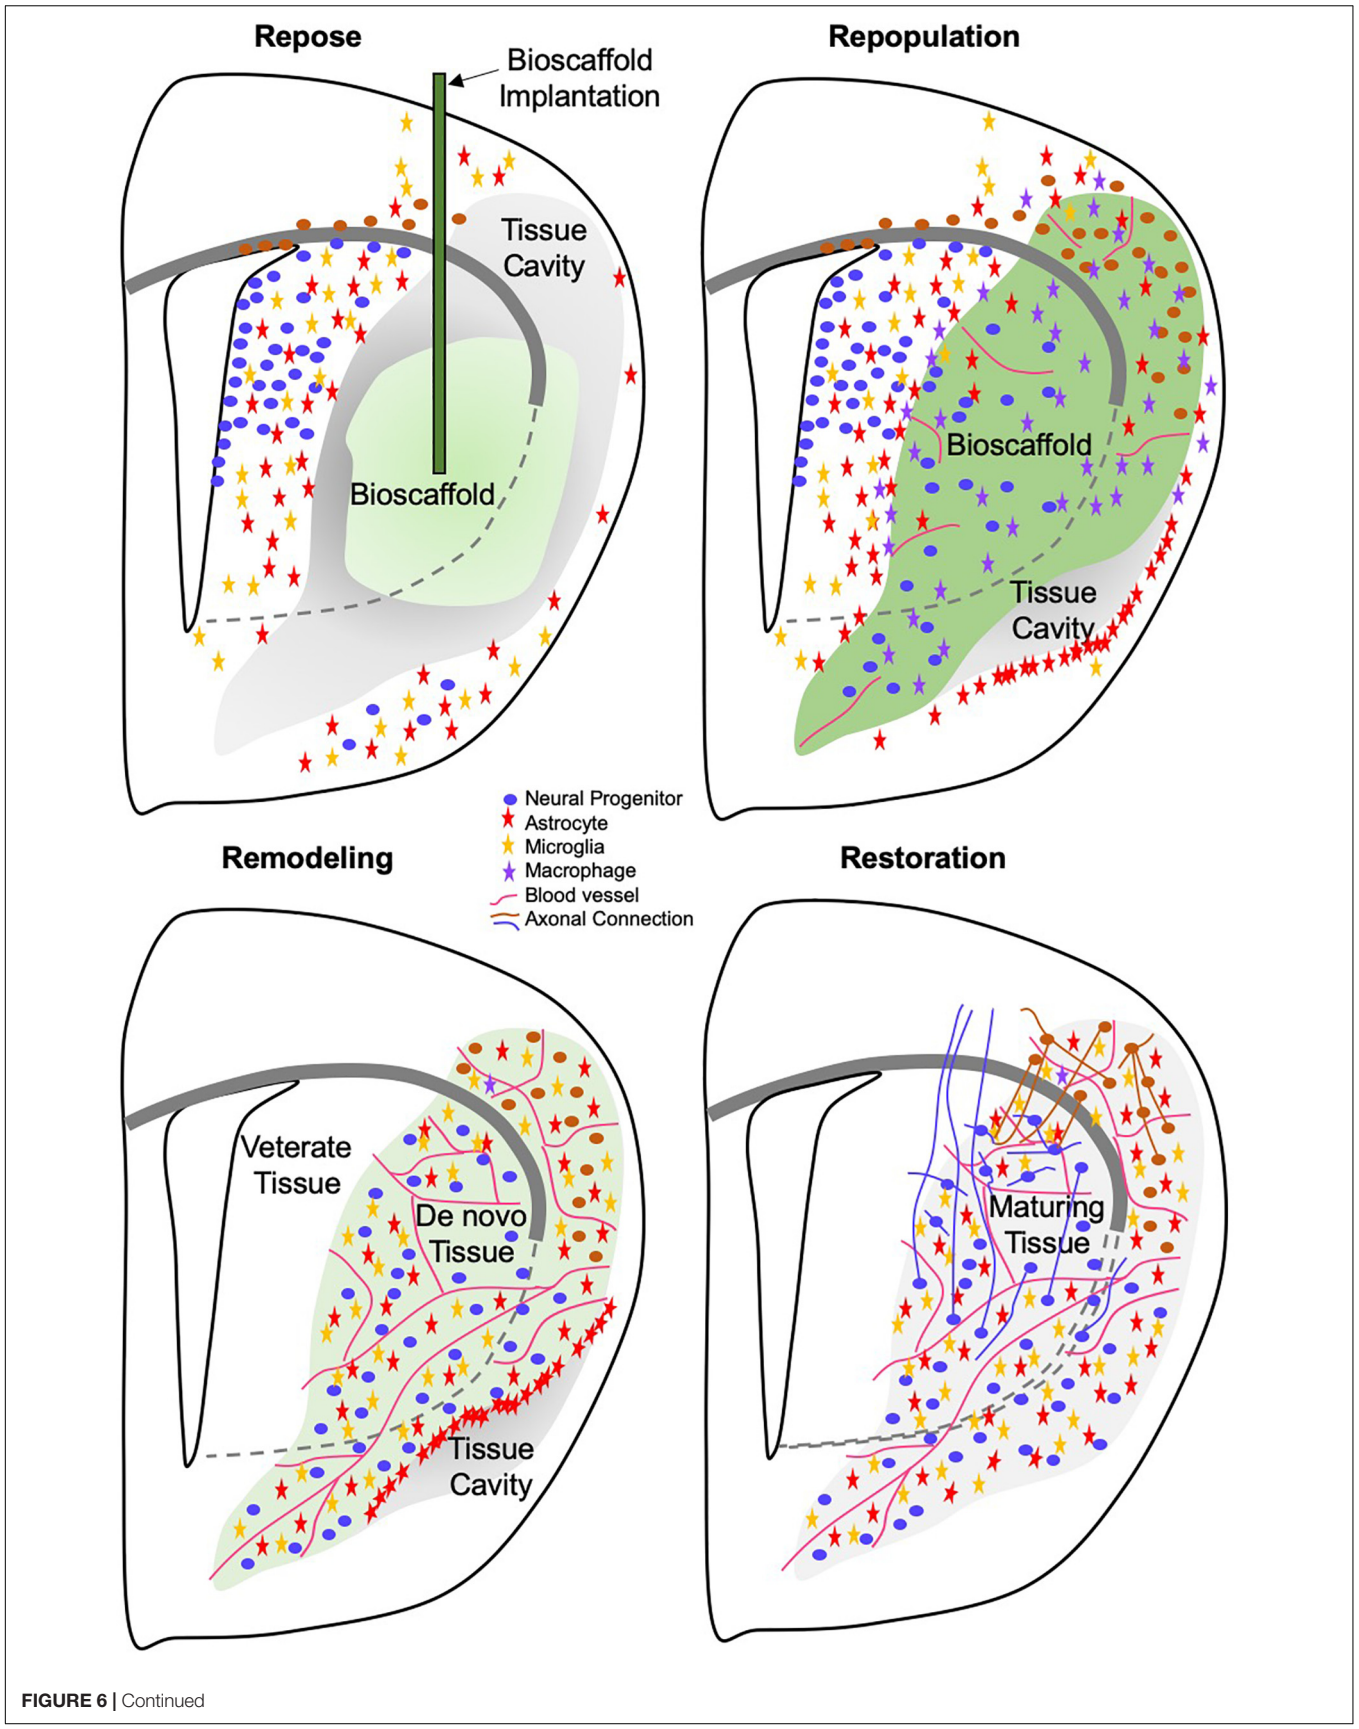

FIGURE 6 | Continued

FIGURE 6 | Four phase of brain tissue regeneration. Phase 1: The repose phase is characterized by tissue loss being mostly complete and a repair response having been instigated. Although gliosis is ongoing, no defining scar along the tissue cavitation has emerged. During this phase, a bioscaffold can be implanted to initiate the tissue regeneration process. In the absence of an introduction of a bioscaffold a scar is forming around the cavity. Phase 2: During the repopulation phase, host cells are invading the bioscaffold. Even during the acute invasion phase, brain derived cells, such as neural progenitors and astrocytes, are infiltrating the biomaterial, but immune cells are more rapidly invading and provide additional soluble and juxtracrine signaling to recruit host brain cells to repopulate the tissue cavity. Phase 3: Invading cells deposit transient matrix molecules and take-up positions inside the bioscaffold that leads to a gradual degradation of the scaffold. Blood vessel formation during this phase plays a key role to promote biodegradation, but also to remodel individual compartments that will develop into neuropil. Within the vascular compartment, cells are depositing appropriate matrix molecules, such as vitronectin, laminin and collagen. In the neuropil, neural cells deposit matrix molecules, such as laminin, aggrecan, decorin, thrombospondin that are involved in maintaining structure and juxtracrine signaling. At the end of this phase, the bioscaffold is completed degraded and replaced with host matrix. Phase 2 and Phase 3 overlap within different parts of the cavity. Phase 4: Once host brain cells are in position and formed a neuropil in between blood vessels, tissue maturation is occurring with terminal differentiation of neurons through interaction with astrocytes, oligodendrocytes and ECM molecules. It can be anticipated that *de novo* tissue formation in phase 3 and maturation processes, such as axonal and dendritic branching, can occur side-by-side. Axonal and dendritic processes are required to form a functional neuronal circuitry.

be the gold standard to accept claims of tissue restoration. The cytoarchitectural organization of *de novo* tissue should be contrasted with intact brain tissue, as well as the phenotypes of cells within the bioscaffold. These two microenvironments provide benchmarks that contrast regenerating and target tissue. Proof of tissue dynamics and a restorative process occurring over time are required to substantiate the processes involved in brain tissue regeneration, eventually leading to mode and mechanism of action studies.

To this end, we further suggest that proof of the bioscaffold's presence, retention, distribution and degradation are required to indicate their pivotal role in tissue regeneration. Although a reliance on morphological and protein concentration difference can serve at early time points post-implantation to identify the bioscaffold (Massensini et al., 2015), as these materials are degraded, protein concentrations are increasingly similar to veterate brain and regenerating tissue is morphologically increasingly similar to damaged or intact brain tissue (Ghuman et al., 2016; Jin et al., 2017). Ideally, unique identification strategies for bioscaffolds are implemented (e.g., labeling) without affecting the biological activity of the material (Park et al., 2019). This should allow the identification of even small quantities of bioscaffold that might still undergo degradation or be incorporated into the new tissue. *In vivo* monitoring of the bioscaffold (Liang et al., 2015; Jin et al., 2017; Piejko et al., 2019), as well as cells (Nicholls et al., 2015, 2016) would further improve our understanding of how biomaterials and cells interact to form an integrated brain tissue.

Finally, it is important to develop a framework that will define the sequence of cellular dynamics (e.g., neutrophils invade first and facilitate macrophage recruitment) that drive different phases of brain tissue regeneration. Are these events dependent on each other? What happens if we interfere with individual processes? Does this lead to a disruption of the regenerative cascade or does it lead to a different type of tissue? In contrast to wound healing, which mainly focuses on reintegrating adjoining tissues, we here propose that (1) brain tissue needs to repose (i.e., cavitation needs to be mostly complete without maturation of a surrounding glial scar) to receive an inductive bioscaffold; (2) the lack of scarring permits the rapid invasion of immune and neural cells to repopulate the tissue void: (3) a remodeling of the bioscaffold and newly deposited ECM is required (4) to allow the establishment of a tissue architecture that matures and restores function (**Figure 6**). However, these phases merely provide a general descriptive framework that needs to be refined by detailed mechanistic studies to elucidate how each cell type influences the overall process. Considering the range and dynamics of molecules each cell produces, this poses a formidable challenge.

CONCLUSION

With the discovery of adult neurogenesis, Ramon y Cajal's decree on the lack of regeneration in the CNS has been undergoing a rigorous reassessment. Although spontaneous tissue regeneration does not occur in the mammalian CNS (Illis, 2012), engineering strategies are gradually overcoming the biological and physical challenges imposed by brain injury through harnessing the potential of endogenous neurogenesis (Modo and Badylak, 2019). In this context, it is important to contrast conditions with volumetric tissue loss (i.e., a chunk of tissue is missing) versus neurological disease in which tissue gradually shrinks (i.e., tissue atrophy). We here described putative mechanisms involved in tissue regeneration after a volumetric loss of brain tissue. Some of these strategies, such as enhancing endogenous neurogenesis, can potentially provide benefits to both scenarios, but provision of, for instance, a scaffold, will only be amenable to conditions in which a tissue cavity formed. In a clinical scenario, it can be expected that a patient will receive rehabilitation training shortly after a stroke and this could be combined with an enhancement of neurogenesis. Bioscaffold implantation would only occur after cavitation is complete, with concomitant neurogenesis and rehabilitation training being required to yield an optimal outcome. Although the aim is to define specific modes and mechanisms of action, we have to recognize that these at present can merely be putative. Investigations first have to define zero and first orders of approximation of the variables and conditions required to produce brain tissue regeneration. Consequently, the therapeutic value of restoring lost tissue currently remains unclear. Although fetal tissue transplant suggest that *de novo* brain tissue can integrate into the host and reduce behavioral impairments, we currently have a poor understanding of what cellular substrates are required to support behavioral changes. Studies in axolotl suggest that regenerated tissue is unlikely to exactly replicate the tissue structure that emerged through brain development, but might support restoration of function. Still, a

functional tissue requires integration with veterate brain regions to support behavior and cognition. The utility of brain tissue regeneration is not to perfectly restore the damaged brain, but to produce a sufficient tissue substrate that can reduce behavioral deficits. It is expected that this review provides the context for future studies to improve engineering strategies that will produce a robust regeneration of brain tissue.

AUTHOR CONTRIBUTIONS

The author confirms being the sole contributor of this work and has approved it for publication.

FUNDING

This study was supported by the NINDS (R01 NS08226), NIBIB (R01 EB016629), ReNeuron Ltd., ACell, Vertex Pharmaceuticals, and C. R. Bard. None of the funders had a role in the design of the studies.

ACKNOWLEDGMENTS

The author gratefully acknowledges Dr. Stephen Badylak who provided useful discussions and crucial insights to the topic of tissue regeneration.

Traumatic brain injury (TBI) is the principal cause of death and disability in children and young adults. Clinical and preclinical research efforts have been carried out to understand the acute, life-threatening pathophysiological events happening after TBI. In the past few years, however, it was recognized that TBI causes significant morbidity weeks, months, or years after the initial injury, thereby contributing substantially to the overall burden of TBI and the decrease of life expectancy in these patients. Long-lasting sequels of TBI include cognitive decline/dementia, sensory-motor dysfunction, and psychiatric disorders, and most important for patients is the need for socio-economic rehabilitation affecting their quality of life. Cerebrovascular alterations have been described during the first week after TBI for direct consequence development of neuroinflammatory process in relation to brain edema. Within the brain–immune interactions, the complement system, which is a family of blood and cell surface proteins, participates in the pathophysiology process. In fact, the complement system is part of the primary defense and clearance component of innate and adaptive immune response. In this review, the complement activation after TBI will be described in relation to the activation of the microglia and astrocytes as well as the blood–brain barrier dysfunction during the first week after the injury. Considering the neuroinflammatory activity as a causal element of neurological handicaps, some major parallel lines of complement activity in multiple sclerosis and Alzheimer pathologies with regard to cognitive impairment will be discussed for chronic TBI. A better understanding of the role of complement activation could facilitate the development of new therapeutic approaches for TBI.

TRAUMATIC BRAIN INJURY

Traumatic brain injury (TBI) is a consequence of a direct or indirect external mechanical impact on the brain inducing the disruption of the normal structure and function of the brain. Despite its simple mechanical definition, TBI is a very complex and heterogeneous injury with various severities graded in clinic. The severity of TBI is predicated on alteration of consciousness, organized according to the Glasgow Coma Scale (GCS) for assessment of neurological function and neuroimaging as mild, moderate, or severe (Maas et al., 2008).

TBI is a major burden worldwide, and in the United States, it represents more than 30% of all injury-related deaths (Faul et al., 2010). In Europe, it is about 75,000 deaths each year (Maas et al., 2015), and it affects all ages. It is important to underline that pediatric and elderly populations are more vulnerable than adults (Faul et al., 2010). Therefore, TBI has an economic toll on the society that includes medical expenses and losses of productivity (Corso et al., 2006; Gustavsson et al., 2011). A widespread research on TBI pathophysiology is still sparse compared to other brain diseases such as Alzheimer's disease (AD) and the progressive chronicity of multiple sclerosis (MS).

Pathophysiology following TBI is grouped into the following: (1) The primary acute event is the mechanical injury that can give extracranial and intracranial complications like epidural hematoma, subarachnoid hemorrhage, or hypoxia. Thus, TBI is particularly heterogeneous depending on the primary injury severity, location, and the age and sex of the patient. Important in the TBI pathogenesis is that the functional outcomes may deteriorate over time after initial admission of the patient (Baethmann et al., 1988). For example, the patient can communicate early after TBI and then worsen with loss of consciousness, with an early small contusion that becomes a much larger injury the day after. This evolution is due to the secondary injury events (Plesnila, 2016). (2) The secondary injury cascade includes the following landmarks: glutamatergic excitotoxicity, calcium overload, vascular dysfunction, and inflammation/neuroinflammation. Inflammation/neuroinflammation can last for several months and could contribute to chronic TBI (Plesnila, 2016). The pattern of "chronic brain disease" has been leading the concept of accelerating of brain aging post-TBI (Johnson et al., 2010; Pop and Badaut, 2011; Smith et al., 2013). Patients can present long-lasting behavioral dysfunctions including some psychiatric disorders after TBI (Smith et al., 2013). Very recently, a nationwide population cohort study was done in Denmark to monitor individuals who had TBI from 1977 to 2013. Over the study period, 4.7% of recruited people had at least one TBI, and about 112,218 (85.0%) of 132,093 individuals had a mild TBI for their first TBI diagnosis; those people were 24% more likely to develop dementia than those without a history of TBI. Additionally, the younger the person was at the time of the injury, the higher the risk of dementia development over time (Fann et al., 2018).

Several animal models have been developed in order to extend our understanding of the cellular and molecular mechanisms in post-TBI secondary injuries (Prins and Hovda, 2003; Petraglia et al., 2014). Having a wide variety of preclinical models is a good sketch to mimic the heterogeneity in human TBI. However, it is important to highlight that the definition of the degree of TBI severity differs between animal models, and it is difficult to compare findings between models (Badaut et al., 2019). Sometimes, it is challenging to make the translation with clinical severities. The molecular and cellular mechanisms of secondary injuries are dependent on injury severity and brain location. The post-TBI outcome is more severe for younger patients; therefore, it is important to consider the age of the animal in the preclinical models (McMillan and Teasdale, 2007; Himanen et al., 2011; Pop and Badaut, 2011). In fact, neuroinflammation/inflammation response will vary in function of the location and severity of the impact as well as the age of the animal. The review focuses on some of the cerebrovascular alterations and the importance of the inflammation through the exploration of the complement system as a new potential mechanism. Actually, the role of the complement pathway in TBI pathogenesis is not yet well-understood.

NEUROVASCULATURE IMPAIRMENT POST-TBI

The neurovascular unit (NVU) is composed of neurons, a vascular tree with endothelial cells, smooth muscle cells, pericytes, astrocytes, and microglia (Zhang et al., 2012). Immune cells have been included as part of this physiological unit (Zhang et al., 2012). Cognitive impairments in AD as well as in healthy aging have been paralleled with NVU alterations (Iadecola, 2004; Raz et al., 2016). Similarly, NVU alteration is a typical landmark of the secondary injuries after TBI with, for example, a decrease of blood–brain perfusion with consequences on the good operation of the neurons (Pop and Badaut, 2011; Jullienne et al., 2016). In fact, preclinical TBI models unveil blood–brain barrier (BBB) disruption, hemorrhage, and cerebral blood flow alterations with hypo-perfusion, which are illustrations of the NVU alterations (Golding, 2002; DeWitt and Prough, 2003; Pop and Badaut, 2011). Cerebrovascular dysfunction has been described for almost two decades as a poor prognostic outcome. In fact, early decrease of the cerebral blood flow (CBF) post-injury induces hypoxic events in the brain tissue that directly contribute to the loss of neurons. In addition, the changes in BBB permeability play a role in edema formation with disruption of brain homeostasis. It exacerbates the cascade of secondary injury events including excitotoxicity (glutamate release and resulting higher metabolic demand) and inflammation (with the complement pathway, see below). TBI is a chronic brain disorder with molecular changes at the BBB several months after the initial injury (Jullienne et al., 2016). As it has been suggested in AD, the long-term alterations at the blood–brain interface could therefore be associated with premature aging of the brain after TBI (Pop and Badaut, 2011; Keightley et al., 2014; Jullienne et al., 2016).

Brain Perfusion Alterations

Early decrease of CBF is a landmark of the pathophysiology post-TBI and its recovery represents a prognostic factor for outcome post-TBI (Bouma et al., 1991, 1992; DeWitt and Prough, 2003). Preclinical models appropriately reproduce CBF changes observed in clinic. Decreased CBF is observed after TBI using controlled cortical impact (CCI) and lateral fluid percussion (LFP) injury models and it is described up to 8 months after injury in adult rats (Bouma et al., 1991; Bryan et al., 1995; Plesnila et al., 2003; Hayward et al., 2010), which probably feeds the inflammatory process. Even for mild TBI, a decrease of CBF has also been described (Villapol et al., 2014; Long et al., 2015). In a mild CCI model, the reduction of CBF was described with restoration at 30 days post-TBI in young adult

mice (Villapol et al., 2015). Importantly, hypo-perfusion adds to the development of the secondary injuries after TBI by decreasing glucose and oxygen delivery. Moreover, an ischemic event could be aggravated by the presence of cell hyper-metabolism during the first 6 h after concussion in rats (Yoshino et al., 1991). Consequently, decreased CBF and hyper-metabolism occurring early after TBI result in a mismatch between demand and supply, known as uncoupling of CBF and glucose metabolism, with direct consequence and aggravation of the secondary injuries and directly feeding the inflammation and neuroinflammation process. At the time, dysfunction in vascular perfusion is paralleled with BBB hyper-permeability and edema process.

BBB Dysfunction Post-TBI

The presence of hemorrhage is a marker of acute vascular dysfunction, and it is frequently observed in moderate and severe TBI. BBB and cerebral blood vessel alterations are frequently shadowed by edema formation with dramatic consequences on morbidity and mortality because it induces intracranial hypertension and contributes to the vicious cycle of the secondary injury cascade (Unterberg et al., 2004). Even for mild TBI characterized by the absence of major bleeding, the BBB structure can be damaged or altered during the acute period after the injury. Very importantly, the BBB dysfunction is not only an acute event; it could also be observed several months and years after the traumatic event in human post-mortem tissue (Hay et al., 2015) and in preclinical models (Pop et al., 2013; Jullienne et al., 2014).

The consequences of primary injury on the BBB properties significantly differ according to the age, the type, and the severity of the lesion. The "opening" of the BBB can be observed as early as 3 min after injury in a model of concussion (Povlishock et al., 1978). The "opening" of BBB can be characterized with the presence of two types of lesions on the luminal surface of pial arterioles: crater-shaped indentations and dome-shaped projections of the endothelial cell surface, suggesting necrotic cells (Wei et al., 1980). The tight junction protein complex is potentially altered after TBI. In fact, pial, and intracerebral blood vessels demonstrate decreased claudin-5 and occludin expressions early after injury (Nag et al., 2007). Similar changes in tight junction protein complex have been described in rodent models of mild TBI induced by blast shock waves, with specifically decreased expression in occludin, claudin-5, and *zonula occludens* protein-1 at 6 h and 24 h post-TBI (Abdul-Muneer et al., 2013). The changes in tight junction proteins have been paralleled with an increase of immunoglobulin G extravasation from 5 min to 48 h post-injury (Yeoh et al., 2013; Shetty et al., 2014). However, it is important to underline that tight junction complexes appear intact under electron microscopy during the first hours after a mild TBI; then, the expression of the tight junction protein is altered (Rafols et al., 2007). Therefore, the changes in expression of the tight junction proteins and increased IgG extravasation are not directly linked with physical rupture of the tight junctions in electron microscopy (Knowland et al., 2014; Haley and Lawrence, 2017). Similarly, IgG extravasation is increased close to the site of impact and surrounding tissue in the absence of a direct relation with changes in claudin-5 expression in a model of juvenile CCI (Pop and Badaut, 2011; Badaut et al., 2015). Similarly, IgG extravasation has been observed in the corpus callosum at 24 h after mild closed head injury, suggesting BBB hyper-permeability even for mild injury (Rodriguez-Grande et al., 2018).

Changes of expression of the tight junction proteins are accompanied by up-regulation of various matrix metalloproteases (MMPs), which have been involved in BBB alteration. In fact, MMP-9 and MMP-2 increase acutely after TBI in rodents (Wang et al., 2000; Zhang et al., 2010). MMP-3 activity is increased chronically after TBI and possibly plays a role in synaptic remodeling (Zhang et al., 2010). Up-regulation of MMPs alters proteins of the extracellular matrix and participates in BBB alteration and neurovascular unit dysfunction.

In summary, it is important to highlight that neurovascular unit disturbance, encompassing BBB and blood flow changes, fuels the inflammation and neuroinflammation process.

Astrogliosis, Neuroinflammation, and Consequences on Blood Perfusion and BBB

Astrocyte endfeet wrap the blood vessels and they play a key role in BBB properties in collaboration with pericytes (Zhang et al., 2012). Astrocytes become "reactive" and proliferate to form a glial scar in various severe brain injury models (Burda and Sofroniew, 2014). Depending on the timeline of the pathological process after injury, astrogliosis can be both beneficial and detrimental to the brain tissue adjacent to the lesion (Sofroniew, 2009). Astrocytes have various physiological functions such as providing energy substrates for neurons, regulating ion and neurotransmitter homeostasis, participating in synapse development and transmission, and regulation of CBF. Then, transformation of astrocyte in "reactive astrocyte" can have a direct and weighty impact on the brain functions on the post-injury outcomes (Sofroniew and Vinters, 2010). Astrocytes are among the first responder brain cells to TBI, and the mechanical forces of the primary injury trigger reactive astrocyte or astrogliosis (Burda et al., 2016). In fact, stretch injury or shear stress involves a rapid calcium influx in the astrocytes (Rzigalinski et al., 1998; Maneshi et al., 2015), by potential activation of astrocytic mechano-receptive channels (Burda et al., 2016). In parallel, activation of the astrocyte potentially contributes to the release of vasoactive substances (Howarth, 2014). In fact, release of isoprostanes (Hoffman et al., 1997, 2000) and endothelin 1 (Ostrow et al., 2000), powerful vasoconstrictors, have been described to increase after TBI in preclinical models (Petrov and Rafols, 2001; Armstead and Kreipke, 2011; Armstead and Raghupathi, 2011). Then, any changes in the calcium concentration within astrocytes could have a direct or indirect consequence on the regulation of CBF and perfusion post-injury. Then, calcium changes in astrocytes could contribute to the NVU dysfunction post-TBI with the increase of vasoconstrictor molecules.

Astrocytes play an important role in the integrity of the BBB (Abbott et al., 2006). Cytokines and inflammatory mediators are released by the astrocytes after injury with consequences

on BBB properties (Chodobski et al., 2011; Sofroniew, 2014). For example, chemokines (Chodobski et al., 2011) and three isoforms of transforming growth factor–β (TGF- β) (Constam et al., 1992), potentially released by the astrocytes, have been implicated the BBB alterations after TBI (Shen et al., 2011). Very interestingly, increased TGF-β expression has been observed in patients with severe TBI where it parallels BBB dysfunction (Morganti-Kossmann et al., 1999). As already discussed, MMPs disturb the structure of the BBB after TBI and they are extensively produced by reactive astrocytes (Chen and Swanson, 2003). In the vicinity of the perivascular astrocyte endfoot, the water channel aquaporin 4 expression is altered after TBI, which is related to the formation of cerebral edema (Badaut et al., 2014; Gatto et al., 2015; Zhang et al., 2015). Increased aquaporin expression associated to edema brain formation event is also described in earlier stages of several neurodegenerative diseases (Sun et al., 2016; Yang et al., 2016; Gatto et al., 2018). There is a correlation between the level of aquaporin 4 expression and disruption of BBB (Fukuda and Badaut, 2012). The astrocyte endfeet play a critical role in the BBB integrity, and very interestingly, the physical interaction between astrocyte endfeet and the brain vasculature can also be altered after TBI (Villapol et al., 2014), with a direct contribution to the vascular dysfunction after injury.

Altogether, astrocyte phenotypic transformation can feed forward the brain-vascular pathology observed after TBI in relation to neuroinflammation and the complement pathway. In addition, the neurodegeneration proposed after TBI could be a result of astrocyte activation and chronic inflammation (Faden and Loane, 2015). Interestingly, astrocyte plays a potential role in immune response in the brain with expression of the specific receptors to complement proteins (see *part 3*). Therefore, it may be important to consider the contribution of reactive astrocytes into the long-term consequences of vascular dysfunction and a target of the activation of the complement pathway. This pathway could represent a new avenue for drug development targeting the NVU.

GENERAL DESCRIPTION OF THE COMPLEMENT PATHWAY

The complement system is part of an innate and adaptive immune response after infection acting as a primary defense and mechanism of clearance in order to preserve the organ against pathogens. It includes a wide collection of blood and cell surface proteins (C3, C5, CFB, CFD, CFH, C1q, etc.), whose activation results in a self-amplifying cascade of proteolytic reactions (Walport, 2001). Most of the plasmatic complement proteins (90%) are produced by the hepatocytes in the liver (C3, C5, CFB, CFH), released in the bloodstream to circulate as inactive forms. However, a local expression of complement proteins is also observed in cells (microglia/macrophages/astrocytes and neuronal cells) in the brain and the eye, mainly for C3 and its cleavage regulators (CFH and CFB).

The complement system is a key molecular pathway in various cellular and molecular activities, ranging from cell lysis to increase in the local inflammatory response. The complement activation is composed of three main pathways: classical, lectin, and alternate. They converge to the common effector pathway by forming the membrane attack complex (MAC) as illustrated in **Figure 1**.

The Classical Pathway

The classical pathway activation is antibody-dependent. It happens when the complement protein C1 complex, formed by C1q, C1r, and C1s proteins, interacts with antigen–IgM or aggregated antigen–IgG complex, or is antibody-independent. It also happens when poly-anions (e.g., heparin, protamine, DNA and RNA from apoptotic cells), gram-negative bacteria, or bound C-reactive protein reacts directly with the C1 complex. Once the C1 complex is activated, then C1s cleave C4 and C2 into C4a/C4b and C2a/C2b, respectively, and forms the C3 convertase of the classical pathway (C4b2a). C4b2a cleaves C3 into C3a and C3b fragments. The classical pathway is regulated by C1 inhibitor (C1-INH).

The Lectin Pathway

The lectin pathway is activated when mannose-binding lectin (MBL), a serum protein, binds to mannose or fructose groups on bacterial cell walls, yeast walls, or viruses, independently of the antibody complex. The lectin pathway shares similarities with the classical pathway.

The Alternative Pathway

The alternative pathway is activated after cleavage of a small amount of complement compound C3 caused by microbial cell surfaces or immunoglobulin. This pathway is functionally present in physiological situation, with a spontaneous (hydrolysis) cleavage of C3 to C3a/C3b. The C3b product is rapidly inactivated by its binding to proteins complement factor H (CFH) and associated with complement factor I (CFI) as a co-factor, and then its opsonization functions (tagging pathogens, immune complexes apoptotic cells for phagocytosis) are aborted. After injury, C3b product binds to complement factor B (CFB) and its co-factor complement factor D (CFD) to form a molecular complex "C3bBb," called C3 convertase complex, which acts on additional C3 to form more C3b and C3a products (**Figure 1**). This function of C3b contributes to a positive feedback loop and amplifies a first C3 cleavage that is induced by either the classical pathway or both classical and alternative pathways, in order to produce high-level C3b and C3a proteins. It is important to highlight that each complement pathway (classical, lectin, and alternative pathways) activation ends up into the cleavage of C3.

Complement Cleavage Products Functions

Once activated, the complement pathway produces a high concentration of anaphylactic C3a/C5a and opsin C3b proteins (**Figure 1**). The receptors of these complement proteins (C3aR, C5aR, and CD11b, respectively) are expressed on cell membranes in various cerebral cell types such as endothelial cells, microglia/macrophage cells, and astrocytes. The wide distribution of the complement receptors underlines the variety of cellular functions to this system. Importantly, the complement system makes the link between the innate and acquired immunity

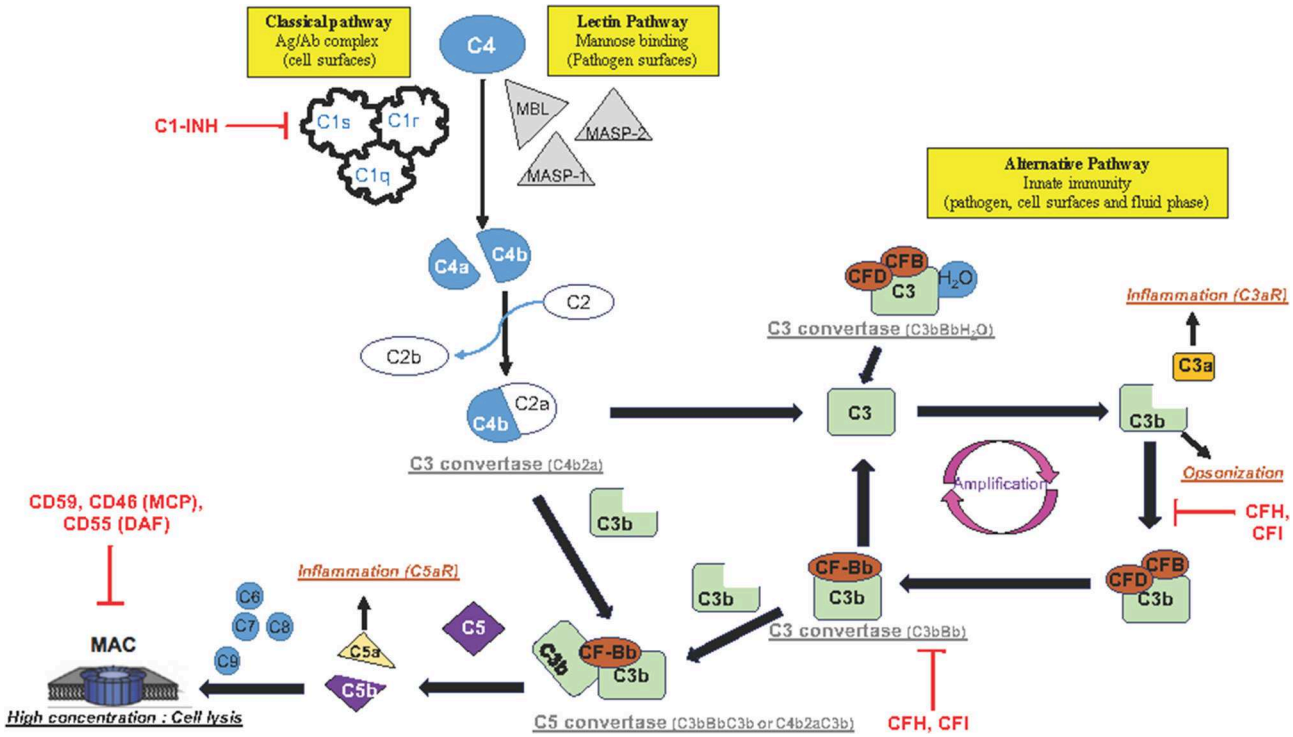

FIGURE 1 | Schematic representation of complement activation pathways: The complement system is composed of three pathways (classical, lectin, and alternative pathway) that involve a collection of blood and cell surface proteins to eliminate pathogens from organism or damaged cells. This system consists of a series of proteins that interact with one another in a highly regulated manner. The classical pathway helps antibodies and phagocytic cells to clear pathogens or damaged cells. The lectin pathway is activated when MBL binds to mannose residues on the pathogen surface. This pathway is very similar to the classical pathway. The alternative pathway is an important part of innate immune system in which proteins cleave one another to form enzymatic complex able to initiate amplification of further cleavages and finally promotes inflammation by production of anaphylactic fragments. The final product of each activated complement pathway is the formation of the MAC in the target cell membrane. Once activated, the complement system has several major functions: lysis of pathogens or damaged cells, activation of inflammation, opsonization, and immune clearance.

by (a) enhancing antibody response and immunologic memory, (b) lysing the pathogens, and (c) clearing immune complexes and apoptotic cells.

The anaphylactic C3a molecule has a remote result because it diffuses away to play the role of an inflammation and chemotactic factor. In contrast, the produced C3b binds to the C3 convertase complex (C3bBb) to form a C5 convertase complex (C3bBbC3b). The C5 convertase complex is located in the cell membrane or in the bloodstream and cleaves complement 5 (C5) into C5b and C5a fragments. Similarly to C3a, the C5a product is described in the bloodstream to act remotely as an anaphylactic protein inducing a general inflammatory reaction. In contrast, C5b initiates the MAC in the cell membrane (**Figure 1**). Sequentially, C5b interacts successively with C6, C7, and C8 complement proteins, and finally with a number of C9 complement proteins to form MAC. Importantly, MAC is organized in a circle with, in its center, a pore that produces a hole in the cell membrane. High concentration of MAC induces lysis of the foreign cell (such as microbes or bacteria) or apoptosis (of host cell).

Very interestingly, MAC has been found to contribute to secondary damages in various preclinical models of human brain diseases (Leinhase et al., 2006; Stahel et al., 2009; Fluiter et al., 2014; Ruseva et al., 2015). However, depending on the level of expression of MAC, opposite physiological responses can be observed. In fact, a low level of the MAC (C5b9) complex on the cell surface promotes cell-cycle progression instead of cell lysis or apoptosis (Fosbrink et al., 2005). The role of MAC in cell-cycle progression is due to the transactivation of receptor tyrosine kinases, a regulator of cytosolic free Ca^{2+} concentration (Cybulsky et al., 1999), and activation of protein kinase C and cytosolic phospholipase A_2-α (Cybulsky et al., 1995; Panesar et al., 1997).

It is important to have a fine-tuned regulation of MAC formation with a full panel of specific inhibitor proteins. Many of the complement regulator proteins are found in the blood plasma and on the cell membranes, and among them, CFH acts on the activity of the upstream C3 convertase complex (C3bBb) in the blood and on the cell surface. CFH removes "Bb fragment" from the C3 convertase enzymatic complex and inactivates C3 cleavage by competition with CFB for binding C3b; it stops the main amplification loop of the alternative complement pathways (**Figure 1**). Downstream, CD55 (or DAF: decay accelerating factor), CD46 (or MCP: membrane cofactor protein), and CD59 (known as protectin) have also been described as inhibitors of

MAC formation in the cell membrane for both classical and alternative complement pathways (**Figure 1**).

INVOLVEMENT OF COMPLEMENT PATHWAY IN TBI PATHOPHYSIOLOGY

The secondary injury events post-TBI include inflammatory mechanisms with early activation of the innate immune system, and then the chronic inflammation post-injury possibly contributes to the progressive neurodegenerative process (Francis et al., 2003; Schmidt et al., 2005; Stahel and Barnum, 2006).

The complement pathway represents a key element in the inflammatory response, and it contributes to neuronal cell death, edema, and infiltration of inflammatory cells after injury using rodent models of moderate and severe TBI (Kaczorowski et al., 1995; Ruseva et al., 2015; Rich et al., 2016). Involvement of the complement pathway observed in rodent TBI models has been confirmed with up-regulation of CFB (Kossmann et al., 1997), C3, C1q, and C4 (Stahel et al., 1998), and increase of soluble terminal complement complex C5b9 has been detected in ventricular cerebrospinal fluid (CSF) of severe TBI patients for up to 10 days after trauma, possibly due to the alteration of the BBB integrity (Stahel et al., 2001). CSF increase of complement proteins is paralleled by higher concentration of complement proteins in blood plasma of TBI patients (Manek et al., 2018). Expression of complement protein C3 and C9 has been described up to 6 months post-injury (Bao et al., 2018) in patients, suggesting a continuous complement pathway activation in the chronic TBI. Very interestingly, similar observations have been found in various preclinical rodent models, with higher levels of C9 and CFB in serum of rat during the first days after TBI (Thelin et al., 2018). Deposits of C3 have also been described in the peri-lesion tissue, while C9 protein has been reported in damaged neurons after cortical contusion in the adult rat (Bellander et al., 1996). Thus, a similar change in activation of the complement pathway has been described in clinical and in preclinical rodent models.

As presented above, C3 protein is common to the three complement pathways. In this line with the complement pathway inhibition in TBI, $C3^{-/-}$ mice exhibit less brain edema and microglia activation/infiltration compared to WT after TBI, suggesting a role of the complement pathways in the secondary injury cascade (Sewell et al., 2004; Yang et al., 2006) and inhibition of C3 could be a therapeutic strategy. Interestingly, severe TBI swine resuscitation with valproic acid (a histone deacetylase inhibitor) induces a down-regulation of the complement system activation, resulting in a significant decrease of lesion size after resuscitation (Dekker et al., 2014a,b; Bambakidis et al., 2016). Similarly, inhibition of MAC has been proposed to be protective. In fact, over-exuberant MAC formation contributes to neuronal cell death after severe TBI injury in mice lacking CD59, an inhibitor of MAC formation on the membrane cells (**Figure 1**) (Stahel et al., 2009). The inhibition of MAC formation using C6 antisense oligonucleotide or an inhibitor of C5 convertase complex reduces not only MAC deposition but also accumulation of microglia/macrophages, neuronal death, and axonal loss and enhances neurologic performances as compared to the placebo-treated TBI group (Fluiter et al., 2014).

The current paradigm is that MAC formation is predominantly implicated in development of post-TBI process neuropathology and neuroinflammation, but it is not excluded that C3 cleavage inhibition could prevent inflammation and/or cell death. Then, C3 and MAC would be good therapeutic targets to reduce TBI damage. Studies show that inhibition of C3 cleavage reduces post-injury of microglial and astrocyte activations, C3 deposits, and the extent of neuron cell death, and then triggers improvements in cognitive and functional recovery (Rich et al., 2016; Alawieh et al., 2018). It demonstrates a critical role of the complement system and mainly of the alternative pathway in the TBI neuropathology process.

Targeted deletion of *cfb* gene expression, the activator of alternate complement pathway by activation of C3 convertase, in transgenic mice clearly reveals a significant decrease of neuronal cell death post-TBI (Leinhase et al., 2006). In support to these results in transgenic mice, inhibition of the CFB by injection of anti-CFB monoclonal antibody attenuates both inflammation and cell death in TBI animals (Leinhase et al., 2007), confirming a key role of the alternative complement system in TBI.

Both the classical and lectin pathways have also been assessed in preclinical TBI models and human studies: (1) C1-inhibitor injection after TBI mitigates motor deficits, cognitive dysfunction, and contusion volumes (Longhi et al., 2009), arguing for a role of the classical complement pathway in TBI secondary injuries. (2) Activation of the lectin complement pathway has been shown to be involved in secondary ischemic/inflammatory injury after severe TBI along with an increase of MBL protein in plasma of patients at 48 h post-injury (Osthoff et al., 2017). However, there is no correlation between lectin complement pathway activation and mortality/consciousness after severe TBI (Osthoff et al., 2017). In human and mice, MBL is expressed in the injured cortex from 30 min and persists up to 1 week post-TBI (Longhi et al., 2014). The inactivation of the lectin complement pathway induces a decrease of cortical cell death (Longhi et al., 2014), arguing that this deletion has a protective effect in TBI damages. Until now, no specific pharmacological compound has been found to limit TBI damages, but targeting complement pathway would be a novel therapeutic way.

CHRONIC TBI AND NEURODEGENERATIVE LANDMARKS

Neurodegenerative Landmarks After TBI

Brain vasculature alterations and inflammatory processes implicating complement pathways are very likely hand in hand in the early secondary events post-injury. Several works clearly indicate that TBI is a chronic brain disorder with development of neurodegenerative disease landmarks such as accumulation of the amyloid-β (Aβ) (Johnson et al., 2010; Pop and Badaut, 2011; Pop et al., 2013). We and other groups have shown changes in the

brain vasculature and their involvement in functional outcome after TBI, with BBB dysfunctions several months and years after the injury (Pop et al., 2013; Hay et al., 2015). We previously described increase of claudin-5 expression in large blood vessels, decrease of the efflux pump P-glycoprotein (P-gp), and increase of the perivascular matrix proteins perlecan and fibronectin up to 6 months post-injury in a juvenile TBI model (Pop et al., 2013; Jullienne et al., 2014). The matrix changes observed up to 6 months after juvenile TBI (Jullienne et al., 2014) have also been described in AD patients (Lepelletier et al., 2017). Changes in the matrix properties possibly participate in neurodegenerative processes by leading to the accumulation of Aβ, decreasing its clearance and its perivascular drainage (Pop et al., 2013; Jullienne et al., 2014). P-gp has been suggested to be a key player in Aβ clearance from the brain parenchyma. P-gp knock-out models have increased Aβ deposition after injection of Aβ in the brain compared to the wild type (Cirrito et al., 2005). Moreover, P-gp expression is decreased on endothelial cells in aged human and AD brains as well as in aged rodents (Silverberg et al., 2010). In addition to the vascular dysfunction, the presence of Aβ deposition could contribute to amplify the pathophysiology with activation of the complement pathways around the Aβ deposition, and the vicious cycle of chronic inflammation would accelerate the brain aging.

Complement Pathway Activation in Neurodegenerative Disease

A number of chronic neurodegenerative diseases of the central nervous system (CNS) are characterized by prominent neuroinflammation marked by activated astrogliosis and microgliosis. In AD and MS affections of CNS, similar to what is seen in TBI, there is strong evidence of complement involvement in the pathogenesis that arises from a confluence of histochemical, genetic, and model data. The involvement of the complement system in the AD process comes from the identification of complement receptor 1, the C3b receptor expressed on macrophage/erythrocyte or monocyte cells, as a genetic risk to develop this neurodegenerative disease (Lambert et al., 2009; Crehan et al., 2012). In fact, erythrocyte cells capture complement-opsonized Aβ through CR1 receptor expressed on their membrane and facilitate clearance mechanism, which is relevant in AD pathophysiology (Brubaker et al., 2017). On the other hand, Aβ deposition promotes complement pathway activation by inhibition of CFI enzymatic activity, a cofactor of CFH (Lashkari et al., 2018). Thus, accumulation of Aβ contributes to increase C3 complement protein and ends up giving rise to the anaphylactic C3a/C5a proteins and MAC formation (Bradt et al., 1998; Lian et al., 2015). In fact, accumulation of these complement proteins generates damaged neurons, increases numbers of activated glial cells (Bradt et al., 1998), and, through neuronal C3a/C3aR signaling, disrupts dendritic morphology and network function (Lian et al., 2015). The Aβ-induced neuroinflammation response is also exaggerated by C5a/C5aR signaling (An et al., 2018), demonstrating another link between Aβ and complement activation. Similarly, the role of the complement pathway has been investigated in the context of the neuroinflammatory autoimmune neurodegenerative disease MS. Comparatively, these studies would help to understand the potential role of complement pathways in the long-term outcomes after TBI. With the aim to better understand the cause of MS, a demyelinating and neurodegenerative disease of the CNS, several investigations defined and quantified complement compounds in the blood circulation and CSF. In relation to the inflammatory activity of MS, to define potential biomarkers of the various MS disease forms, levels of C3, C4, and C9 were mostly investigated, providing convincing evidence of the role of complement compounds in MS disease development. The data obtained from various cohorts of patients, however, generated controversies. Indeed, early studies in patients with progressive MS revealed elevated levels of C4 in MS-serum and reduced C4 levels in MS-CSF (Jans et al., 1984). These findings were, however, not supported by others (Jongen et al., 2000). A more recent study defined elevated plasma C4a levels and elevated C3 levels in CSF of patients with active relapsing-remitting MS (RRMS) potentially providing furthermore follow-up markers for therapeutic efficacy (Tatomir et al., 2017). The levels of C9 compound and terminal complement complex (MAC) in CSF and/or blood also give heterogeneous quantitative data found to be reduced, unchanged, or increased (Ingram et al., 2009). Differences in the presence of the complement compounds in the CSF and blood circulation might be related to the modulation of the BBB by the inflammatory disease activity at the various disease MS forms. Histophathological post-mortem investigations of MS brain tissues revealed complement deposition and activation. Activated microglia is commonly observed in contact with axons suffering from demyelination. In brain tissue from patients with progressive MS, a combined immunohistopathology and *in situ* hybridization study showed the local expression of compounds of the complement activation pathways. Both transcripts for C1qA, activation fragment and opsonin C3b, and immunostained proteins C1q of the classical complement pathway and the activation CFB-fragment Bb of the alternative complement pathway were observed in neurons and/or glia within and in the vicinity of cortical and deep gray matter lesions. Furthermore, activated microglia expressing complement *anaphylatoxin receptor* were observed in these lesions in post-mortem brain tissue (Watkins et al., 2016). The deposits of activated C3 fragment on microglia in such chronic cortical lesions, but not in acute disease, indicate that C3 could function as a mediator for the removal of damaged nervous cells in the MS animal model of the relapsing experimental autoimmune encephalomyelitis (EAE) (Michailidou et al., 2017). The formation of MAC as a final complement product has been reported in acute and chronic white matter lesions of MS and would have a direct impact on nervous tissue destruction (Compston et al., 1989; Storch et al., 1998). Many experimental animal studies of MS support the complement-mediated role of nervous tissue degeneration. Further evidence for MAC in the inflammatory disease progression is documented in the EAE mouse model by the systemic curative administration of MAC inhibitors that prevents relapses after a first clinical attack (Michailidou et al., 2018). In EAE gray matter neurodegeneration, a significant synapse loss in the CA1 statum radiatum of the hippocampus reflecting cognitive impairment is caused by increased complement production and deposition of Cq1 and C3d that could make

synapses vulnerable to phagocytosis by microglia. In particular, C3 mediates microglial activation and EAE motor impairments (Hammond et al., 2019). Altogether, there is convincing evidence that the complement activation is involved in MS disease development and the cerebral complement over-activation in inflammatory CNS lesions may be essential for the irreversible progression of MS. The knowledge gathered on the role of the complement pathway activation in MS patients and animal model of MS can be useful for understanding the chronic brain disorders post-TBI. The presence of the complement in serum can serve as a biomarker in TBI patients, and the potential inhibition of the complement can be a therapeutic strategy for the long-term consequences of TBI.

CONCLUDING REMARKS

Complement pathway activation is present early after TBI and can contribute to the development of the secondary injuries by inducing neuronal cell loss and synapse pruning (**Table 1**). Very likely, the complement activation is still present in the long term after TBI (**Table 1**). The knowledge on complement activation in AD and MS strongly suggests that the activation of the complement pathways in the long term after TBI could be an interesting mechanism in order to develop new therapeutic approaches for chronic TBI. It is possible that the pruning of synapses by complement-mediated microglia activation causes long-term neurological handicaps including cognitive impairment in various models of neurodegenerative diseases such as Alzheimer's disease, viral encephalitis, TBI, and MS and potentially contributes to schizophrenia (Stevens et al., 2007; Paolicelli et al., 2011; Ingram et al., 2014; Hong et al., 2016; Sekar et al., 2016; Vasek et al., 2016; Alawieh et al., 2018; Hammond et al., 2019). Therefore, inhibition of the long-term complement activation could improve TBI outcomes.

Temporary middle cerebral artery occlusion (MCAO) in sheep allows modeling of acute large vessel occlusion stroke and subsequent vessel recanalization. However, rapid and precise imaging-based assessment of vessel occlusion and the resulting perfusion deficit during MCAO still represents an experimental challenge. Here, we tested feasibility and suitability of a strategy for MCAO verification and perfusion deficit assessment. We also compared the extent of the initial perfusion deficit and subsequent lesion size for different MCAO durations. The rete mirabile prevents reliable vascular imaging investigation of middle cerebral artery filling status. Hence, computed tomography perfusion imaging was chosen for indirect confirmation of MCAO. Follow-up infarct size evaluation by diffusion-weighted magnetic resonance imaging revealed fluctuating results, with no apparent relationship of lesion size with MCAO at occlusion times below 4 h, potentially related to the variable collateralization of the MCA territory. This underlines the need for intra-ischemic perfusion assessment and future studies focusing on the correlation between perfusion deficit, MCAO duration, and final infarct volume. Temporary MCAO and intra-ischemic perfusion imaging nevertheless has the potential to be applied for the simulation of novel recanalization therapies, particularly those that aim for a fast reperfusion effect in combination with mechanical thrombectomy in a clinically realistic scenario.

Keywords: CT perfusion, DSA, MCAO, reperfusion, sheep stroke model, cerebral ischemia, translational research, brain imaging

INTRODUCTION

Several recent randomized-controlled trials have shown that endovascular mechanical thrombectomy is highly beneficial for patients with acute ischemic stroke and large vessel occlusion (LVO) (1). This breakthrough in acute stroke treatment has led to steadily increasing numbers of patients undergoing endovascular treatment with recanalization, providing options for novel combined treatment strategies. For instance, companion neuroprotective therapies are believed to augment the beneficial impact of recanalization therapies in future settings (2, 3).

Although ischemia/reperfusion rodent models exist, these models have limitations in simulating endovascular approaches under conditions which are similar to a clinical intervention in humans. The major limitation are the much smaller vessels which, for instance, would not allow to test intravascular test devices used for or to support thrombectomy. Large animal models can fill this gap by providing a suitable vascular anatomy and size for preclinical evaluation of new endovascular or combination treatment concepts for LVO stroke (4). Non-human primate and canine stroke models are restricted by ethical concerns and high mortality in the acute and subacute stages after stroke, preventing long-term assessment of functional outcome and final lesion size as the most important clinical endpoints. Alternatively applied porcine and ovine models are more suitable to monitor long-term impact of an intervention, but exhibit a rete mirabile which does not allow direct endovascular access to the middle cerebral artery (MCA) for occlusion (MCAO). Stroke models using these species therefore require surgical access to the MCA. Recently, ovine permanent and transient MCAO stroke models were established (5, 6). Effective occlusion of the MCA main trunk or its branches was reported to depend on the qualitative visual assessment of the operating surgeon, but this may only be predictive in permanent occlusion studies. In reperfusion studies, the individual extent and capacity of collaterals can cause significant variations in final lesion volume similarly to the situation in human LVO stroke. Thus, a reliable, rapid and unbiased estimation of the perfusion deficit during MCAO is an important prerequisite for acute and long-term MCA recanalization studies. Investigating how the initial diffusion deficit corresponds to final infarct size is another important aspect awaiting clarification.

In this feasibility study, we tested several imaging modalities for application in acute ovine MCAO modeling human LVO stroke. We specifically aimed to assess (i) the reliability to confirm successful transient MCAO, (ii) MCA territory hypoperfusion, and (iii) feasibility of the imaging strategy in an experimental MCAO setting only offering a short imaging time window between vessel occlusion and reopening. This work is also intended to report pitfalls and challenges we faced during this development. We finally want to share the experience we have gained with other groups in the field, or trying to access it.

MATERIALS AND METHODS

Animal Baseline Data

The study involved 10 merino sheep half breed (age, 1–3 years; weight, 80.2 ± 7.4 kg), kept in the CEMT-FR (Center for Experimental Models and Transgenic Service, Freiburg, Germany) under following conditions: straw boxes, daily grazing, water and hay *ad libitum*, concentrated feed pellets as reward and to foster human familiarization.

Anesthesia

Anesthesia was prepared by intramuscular injection of midazolam [0.5 mg/kg bodyweight (BW)] and ketamine hydrochloride (20 mg/kg BW), and was induced by intravenous propofol administration (2–4 mg/kg BW). Following endotracheal intubation, 12–15 breaths/min were provided by a volume-controlled ventilator at a 10–15 mL/kg BW tidal volume and 5-mbar positive end-expiratory pressure. Settings were adjusted to normalize oxygen and carbon dioxide tension, and pH values.

Anesthesia for surgical and endovascular procedures was maintained by isoflurane in oxygen/air ($FiO_2 > 0.4$), intravenous ketamine (10 mg/kg BW/h) and fentanyl (2–3 μg/kg BW/h) administration. For CT perfusion and CT angiography as well as brain MRI and angiography anesthesia was maintained by intravenous propofol (15–18 mg/kg/h).

Fluid homeostasis was maintained by intravenous infusion of Ringer solution (10 mg/kg BW/h). Electrocardiogram and blood pressure were monitored continuously. A postsurgical antibiotic (dihydrostreptomycin sulfate 12.9 mg/kg, benzylpenicillin-procaine 8 mg/kg) and analgesic (carprofen 4 mg/kg) treatment was performed.

Surgical MCA Preparation, Occlusion, and Recanalization

Sheep were placed in the supine position slightly elevating the right shoulder. The head was then tilted to the left by ninety degrees. The wool between the ear and eye was shorn, and sterile draping was applied to cover the surgical field.

Two different approaches to the MCA were performed. MCAO surgery in the first series of experiments (series a, cases 1–3) was carried out as described by Wells et al. (6), with the following modifications (**Figure 1B**). A 5 cm vertical incision was made, terminating at the zygomatic arch. Temporal and other mastication muscles were divided and stripped from the coronoid process of the mandible. Partial removal of the coronoid process was omitted when accessing the proximal MCA. The remaining masticators were then divided and stripped from the outer table as far rostral as the fibrous ring attaching the posterior orbit to the concave border of the parietal bone. Thereafter, a small craniectomy over the junction of the parietal and squamous temporal bones was performed using an electric high-speed drill (microspeed, Aesculap, Tuttlingen, Germany) to access the floor of the middle cranial fossa directly behind the orbita. The dura was then opened carefully. A 3 Head VM-900 surgical microscope (Möller-Wedel, Wedel, Germany) was used for surgical preparation of the proximal MCA and terminal ICA. The proximal MCA was occluded by a Yasargil temporary titanium clip (Aesculap) for 2 h.

Surgery in the second series (series b, cases 4–10) was carried out as described by Boltze et al. (5) (**Figure 1C**). The skin between the eye and ear was incised at 5–7 cm along the superior

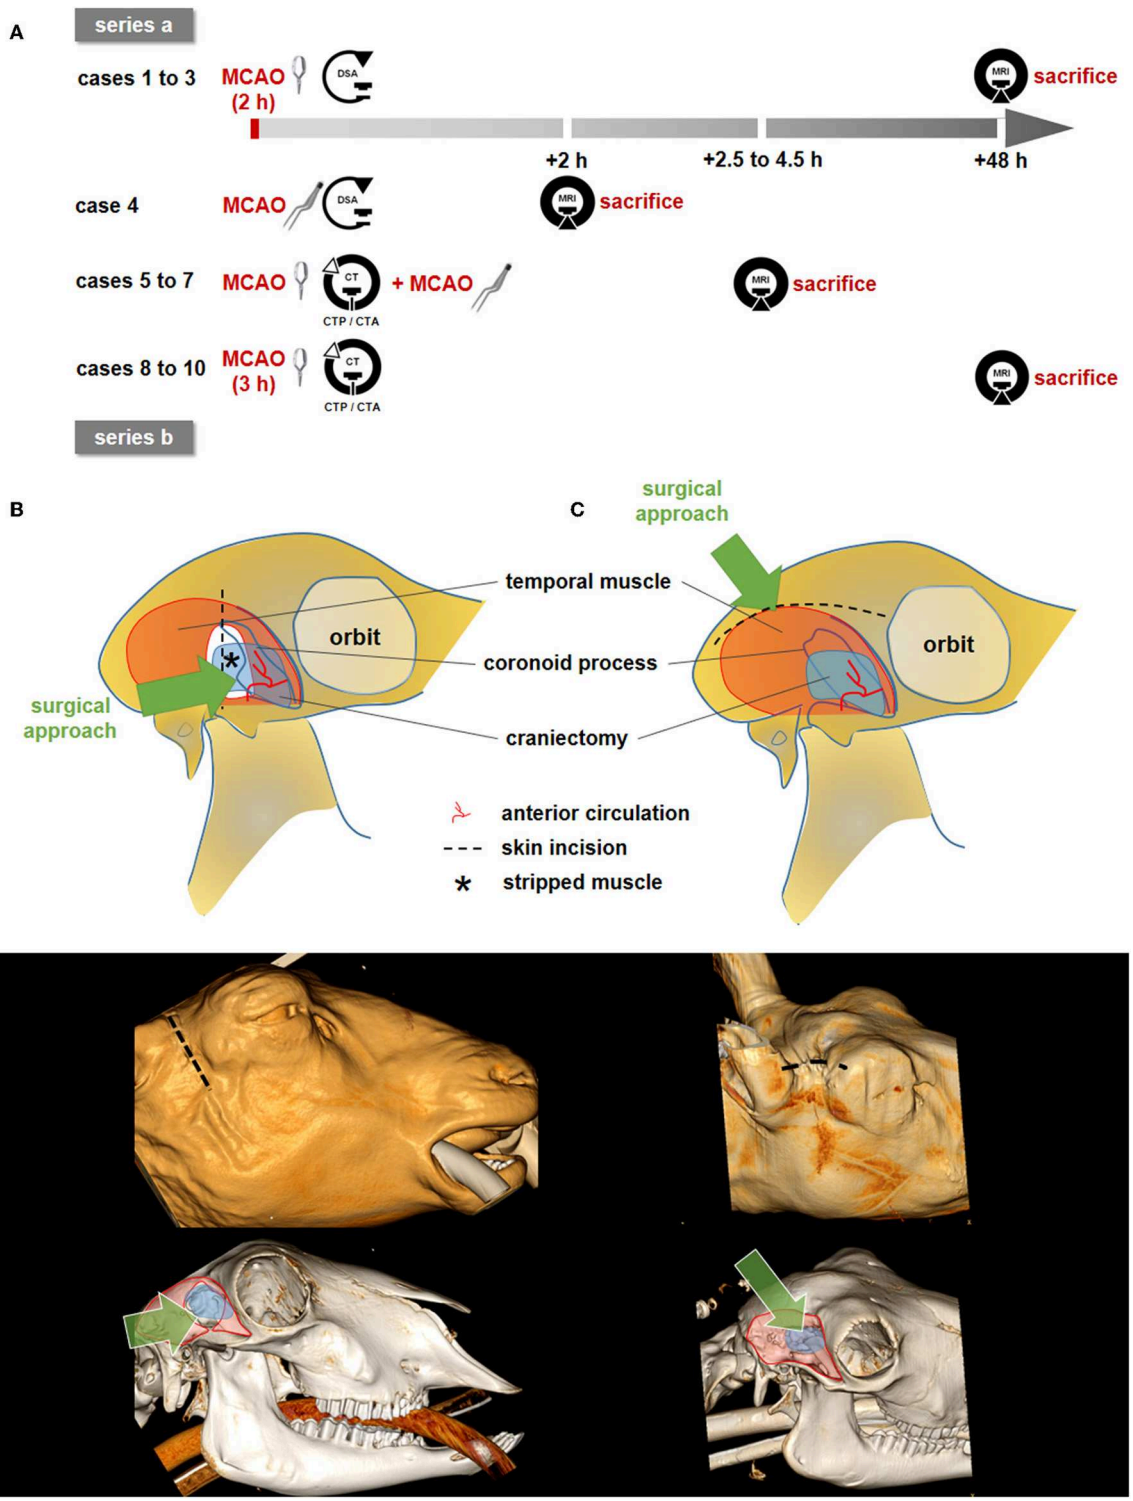

FIGURE 1 | Study design and surgical approaches. **(A)** Overview on study design with two experimental series. Clip pictograms indicate (transient) MCAO by vessel clipping whereas the forceps indicate MCAO by electrocoagulation. **(B,C)**: Schematic illustration of the surgical approaches (top), 3D-Reconstruction showing the skin incision (middle), 3D-bony-reconstruction with muscle (red), and craniectomy (blue) overlays (bottom). **(B)** The surgical approach according to Wells et al. (series a). The proximal MCA and terminal ICA were reached easily. Bony CT reconstruction shows the partial removal of the coronoid process. **(C)** Approach according to Boltze et al. (series b), in which the distal branches of the MCA were followed proximally until the optic nerve and the terminal internal carotid artery (ICA) had been identified. A partial resection of the coronoid process was not necessary (CT reconstruction). Dotted lines: skin incision; blue areas: craniectomy; *: muscle dissection (series a only). The green arrows describes the surgeon's approach and the approximate line of vision.

temporal fossa. The fascia of the temporal muscle was opened and the muscle was stripped away in lateral manner to expose the temporal fossa. During this maneuver, the coronoid process was lateralized and thereafter kept laterally with a self-holding spreader. The remaining masticators were then stripped from the outer table of the cranium as far rostral as the fibrous ring attaching the posterior orbit to the concave border of the parietal bone.

Craniectomy was performed as described for series a. The distal branches of the MCA were followed proximally until the optic nerve and the terminal internal carotid artery (ICA) had been identified. The MCA was permanently occluded using an electrocoagulation device (KLS Martin, Mühlheim, Germany) in case 4. This was performed to control for the influence of the exact occlusion site. In cases 5–7, a clip was placed on the MCA and left in place during CT imaging. The clip was then removed and the vessel was immediately electrocoagulated at the same location (**Figure 1A**). MCAO varied between 2.5 and 4.5 h depending on the particular research question to be addressed in each case. In cases 8–10, the clip was placed on the MCA and removed after 3.0 h without subsequent electrocoagulation (**Figure 1A**).

Endovascular Procedure

MCAO was immediately followed by surgical cut down of the femoral artery for introduction of a 12F sheath by an experienced veterinarian (J.H.). An 8F 90-cm sheath (Flexor Shuttle Guiding Sheath; Cook, Bloomington, Indiana, USA) was then inserted into the right common carotid artery (CCA) using a coaxial 125 cm 5F vertebral or Simmons-2 shaped inner catheter for vessel selection by an experienced interventional neuroradiologist (S.M., C.M.). Selective digital subtraction angiography (DSA) with injections of contrast media (Solutrast 300, Bracco Imaging Deutschland, Konstanz, Germany) into the right CCA that was performed using a C-arm monoplanar angiography system (XA BV300, Philips Health Systems, Hamburg, Germany). Angiographic imaging for visualization of the clip-occluded right MCA was performed in variable angulations.

Brain MRI and MR Angiography

Magnetic resonance imaging (MRI) was performed on a 3T MRI Scanner (Trio, Siemens, Erlangen Germany) using a combined 12-channel head/neck coil. The MRI protocol included sequences as shown in **Table 1**.

Volumetric analysis of ischemic volume (on coronal DWI) and volume of edema (ischemic area plus surrounding edema on coronal T2w) was based on manual segmentations using the medical imaging platform NORA (http://www.nora-imaging.org). Ischemic areas were classified as such after correlation with generated ADC maps. Image evaluation and infarct localization was performed by an experienced neuroradiologist (S.M., C.M.) on a PACS station.

CT Perfusion and CT Angiography

Cases 5 to 10 in series b were transferred to a 16-slice computed tomography (CT) scanner (Somatom Sensation 16, Siemens) immediately after surgical clip placement. Plain CT of the brain was performed in coronary plane sequential acquisition (5-mm slice thickness) to localize the surgical clip and to rule out intracranial hemorrhage. Then, a CT perfusion (CTP) scan was performed covering a 2.4 cm slab of the sheep brain which was centered on the tips of the MCAO clip within the MCA territory (four slices; 6-mm slice thickness). Post-processing of standard perfusion maps (CBV, CBF, and Tmax) was conducted using a dedicated commercial software package (SyngoVia, Siemens). These perfusion maps were rated by an experienced neuroradiologist (S.M.) for presence and degree of MCA territory hypoperfusion using the following semiquantitative score: 0 = no lesion visible on Tmax/CBF/CBV, 1 = lesion visible on Tmax only, 2 = lesion visible on Tmax and partially visible on CBF/CBV, 3 = lesion visible on Tmax/CBF and partially on CBV. Finally, thin-section CT angiography of the craniocervical arterial vasculature (slice thickness; 0.75 mm) was performed with arterial bolus tracking. Assessment of CTA 3D datasets was conducted by an experienced neuroradiologist (S.M., C.M.) on a PACS station.

End of Experiments

Sheep were killed in deep anesthesia by an intravenous potassium chloride overdose at the end of each experiment (after MRI acquisition on day 2 in cases 1–3 and 8–10 and on day 0 in cases 4–7). Death by cardiac arrest was certified by an independent veterinarian.

RESULTS

All procedures were performed without major complications. No sheep suffered from any clinical complications except for neurological deficits after MCAO. Physiological parameters were continuously monitored before and directly after MCAO, and were in normal ranges throughout the experiments. Mean arterial blood pressure (MAP, median [IQR]) was 93 [82.25–103.75] mmHg/92 [82–107] mmHg, and pulse rate was 78 [71–99] beats/min/81 [73–97] beats/min before/after MCAO, respectively. Both parameters did not differ significantly between pre- and intraischemic measurements ($p = 0.903$ for MAP and $p = 0.451$ for pulse rate). Imaging results from all experiments are summarized in **Table 2**.

Results From Series a

Case 1

DWI and T2w MRI on day 2 after MCAO showed a small ischemic lesion (1.7 mL; **Figure 2A**) in right thalamic and midbrain regions after 2 h of transient clip MCAO. The midbrain ischemia suggested an erroneous confusion of the MCA main trunk (M1 segment) with the terminal ICA, resulting in occlusion of terminal ICA and thus of perforating and choroidal artery branches with mesencephalic supply. This appears likely since the proximal segment of the MCA trunk forms a steep 180° curvature with an almost parallel course to the terminal ICA at the anterior skull base of sheep (please also see case 2, **Figure 2B**; and case 4, **Figure 4**).

TABLE 1 | Summary of 3 Tesla MRI sequence parameters.

MRI sequence	Sequence parameters	Orientation	Voxel size	Acquisition time
3D FLAIR	TE/TR, 395 ms/5,000 ms; TI, 1,800 ms; FA, 15°; NA, 1; IPAT, 2	sagittal	1.0 × 1.0 × 1.0 mm	5.52 min

**refers to time interval from start of MCAO until MRI DWI was performed in cases 4–7 (vessel coagulation). § refers to semiquantitative visual assessment of hypoperfusion in MCA territory: 0, no lesion on Tmax/CBF/CBV; 1, lesion visible on Tmax only; 2, lesion visible on Tmax and partially visible on CBF/CBV; 3, lesion fully visible on Tmax/CBF and partially on CBV.*

NV, not visible; NA, not available.

Case 2

Transient clip MCAO was performed for 2 h. Selective DSA of the CCA could not unequivocally demonstrate MCA main trunk occlusion despite variable angulations of the DSA images during angiography (**Figure 2B**). MRI on day 2 showed a large-sized MCA territory infarct (**Figure 3**, upper panels) with recanalized MCA on 3D TOF MRA.

Case 3

Transient clip MCAO was performed for 2 h. Selective DSA of CCA during MCAO again failed to demonstrate MCA main trunk occlusion despite variable angulations of the DSA images during angiography. MRI on day 2 showed no relevant ischemia on DWI (DWI lesion volume, 0.5 ml). A small area of vasogenic edema with scattered and small hemorrhagic foci was found in the area of the surgical access to the MCAO (**Figure 3**, lower

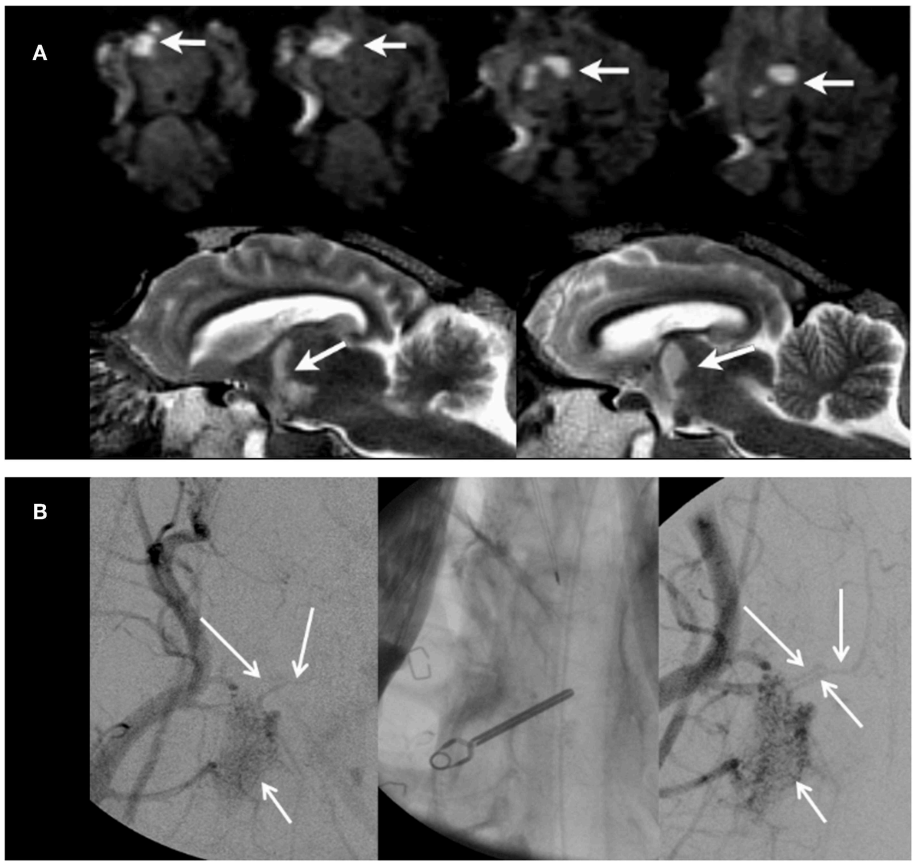

FIGURE 2 | Results from case 1. **(A)** MRI images on day 2 after MCAO from case 1. Upper panels show DWI images in coronal view with ischemic lesions of the midbrain tegmental area within the right crus cerebri and right thalamus (white arrows). Lower panels show consecutive edema on T2w images in mid-sagittal views. **(B)** CCA DSA images before and after clip MCAO. After clip MCAO, no clear cut-off of MCA main trunk was visible with possible faint MCA filling (DSA image in left panel) at the clip level (unsubtracted image in mid panel). After clip removal (DSA image in right panel), filling of the main MCA trunk was visible. However, the distal MCA branch vasculature was not seen due to vessel overlap from rete mirabile and larger extracranial arteries.

panels). The MCA showed a normal flow signal on 3D TOF-MRA images at day 2 after temporary clip occlusion. The neuro-deficit of the animal was light.

The chosen approach in series a (cases 1–3) resulted in a highly variable infarct configuration for two potential reasons. First, the vessel location for the surgical clip placement was inappropriate in case 1 (resulting in mid brain infarcts). Second and similar to the human situation, there might be a variable extent of MCA vessel collateral flow resulting in highly different infarct sizes between cases 2 and 3. Thus, we decided to modify the surgical approach in series b. We further tested whether the chosen MCAO location was correct by using an optimized imaging algorithm during the ischemia phase.

Results From Series b

Case 4

In this case, we tested whether DSA of the CCA with additional superselective views from injection of the right rete mirabile is capable of proofing MCAO. For immediate comparative assessment of the vessel status after MCAO on 3D TOF MRA, the MCA main trunk was electrocoagulated to avoid MRI artifacts emerging from the clip. A 0.021 inch microcatheter (Prowler Select Plus, Codman & Shurtleff, Inc., Raynham, USA) was introduced into the largest inferior arterial branch supplying the rete mirabile via long sheath endovascular access to right CCA directly after MCAO. Despite multiple angulated vessel views on superselective DSA (**Figure 4**, left panel), MCAO could not be correctly visualized. Further distal microcatheter navigation toward the rete mirabile led to subsequent vasospasm with impaired demonstration of downstream vasculature. MRI was performed directly at 2 h following vessel occlusion. MRA visualized the MCAO site at the MCA main trunk (**Figure 4**, right panel). The resulting early MCA territory infarct was visible on DWI images (DWI lesion volume 13.3 ml) with beginning edematous change on T2w images (T2 lesion volume 5.8 ml).

Case 5

Since DSA (including superselective views used in case 4) failed to demonstrate adequate vessel occlusion, we decided to further amend the imaging protocol by introducing CTA with CTP imaging in cases 5–7. Since electrocoagulation is not a feasible technique for transient MCAO, we decided to first perform

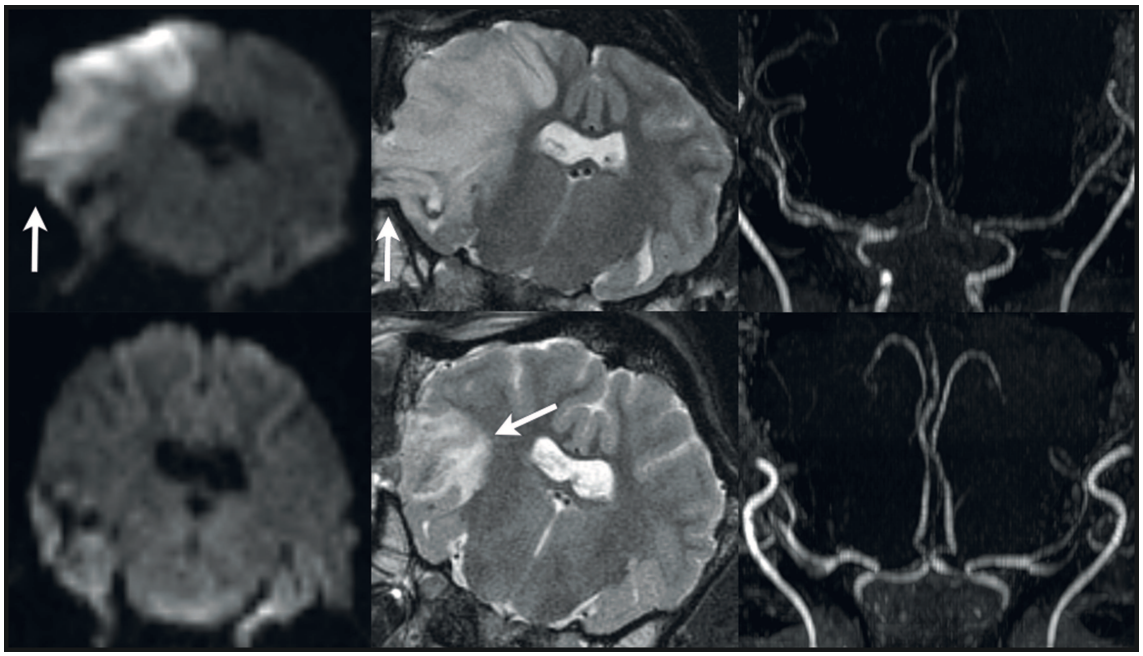

FIGURE 3 | Results from cases 2 and 3. MRI images of case 2 **(upper panels)** and case 3 **(lower panels)** on day 2 after 2 h of transient MCAO. DWI and T2w images show a large right MCA territory infarct lesion (DWI lesion volume, 25.6 ml) with swelling and mild herniation through the craniectomy site (arrows in **upper left** and **mid panels**). MRA **(upper right panel)** demonstrates adequate MCA recanalization after right temporary MCAO. In case 3, no relevant MCA territory ischemia is seen on DWI images (**lower left panel**; DWI lesion volume, 0.5 ml), whereas T2w images exhibit vasogenic edema in the area of the craniectomy with mild hemorrhagic foci (arrow in **lower middle panel**). Again, MRA demonstrates adequate MCA vessel recanalization after right temporary MCAO **(lower right panel)**.

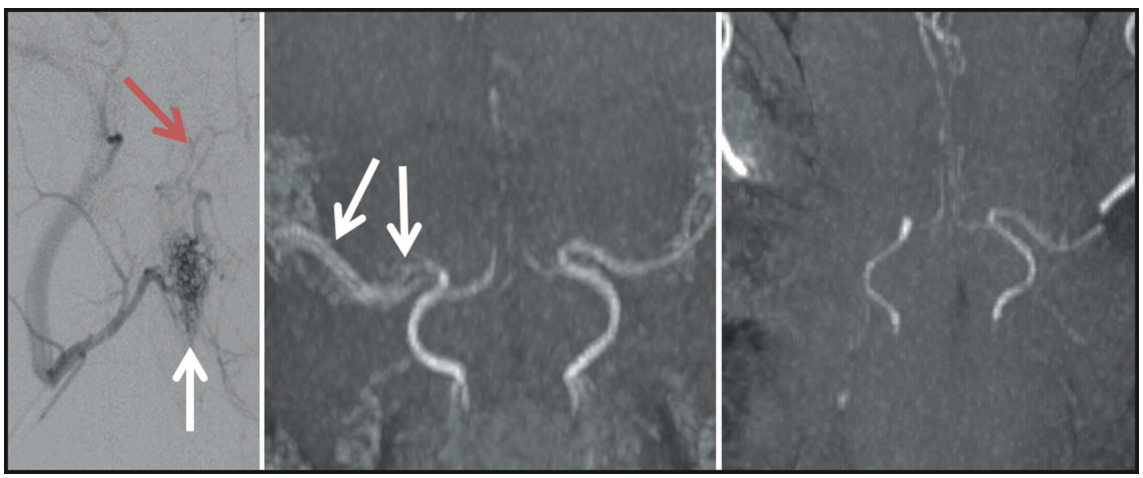

FIGURE 4 | Results from case 4. DSA image **(left panel)** showing superselective rete mirabile injection (red arrow) after permanent MCAO (animal 4) without clear evidence of MCA main trunk occlusion (red arrow). 3T TOF MRA showing duplicated right MCA main trunk post temporary MCAO (**mid panel**, arrows) and clear evidence of right MCA occlusion after permanent MCAO **(right panel)**.

MCAO with a clip followed by immediate transfer to CTA/CTP imaging. Thereafter, the clip was removed and the vessel was occluded in the same location by electrocoagulation in order to perform subsequent MRI without clip-borne artifacts. Thus, CTP findings could be correlated with the results of MRI simulating a temporary MCAO with ischemia duration of 2.5 h (time interval from initial vessel occlusion to MRI acquisition).

On CTP, a large area of right MCA territory hypoperfusion was seen on Tmax, whereas CBF and CBV maps showed no areas hypoperfusion (perfusion score 1; **Figure 5**). Missing flow signal of the MCA main trunk was seen on 3D TOF MRA. Visualization of the MCAO at the main trunk was not possible on CTA images due to beam hardening artifacts originating from skull bone and the clip. On DWI, signs of a small infarct in the MCA territory

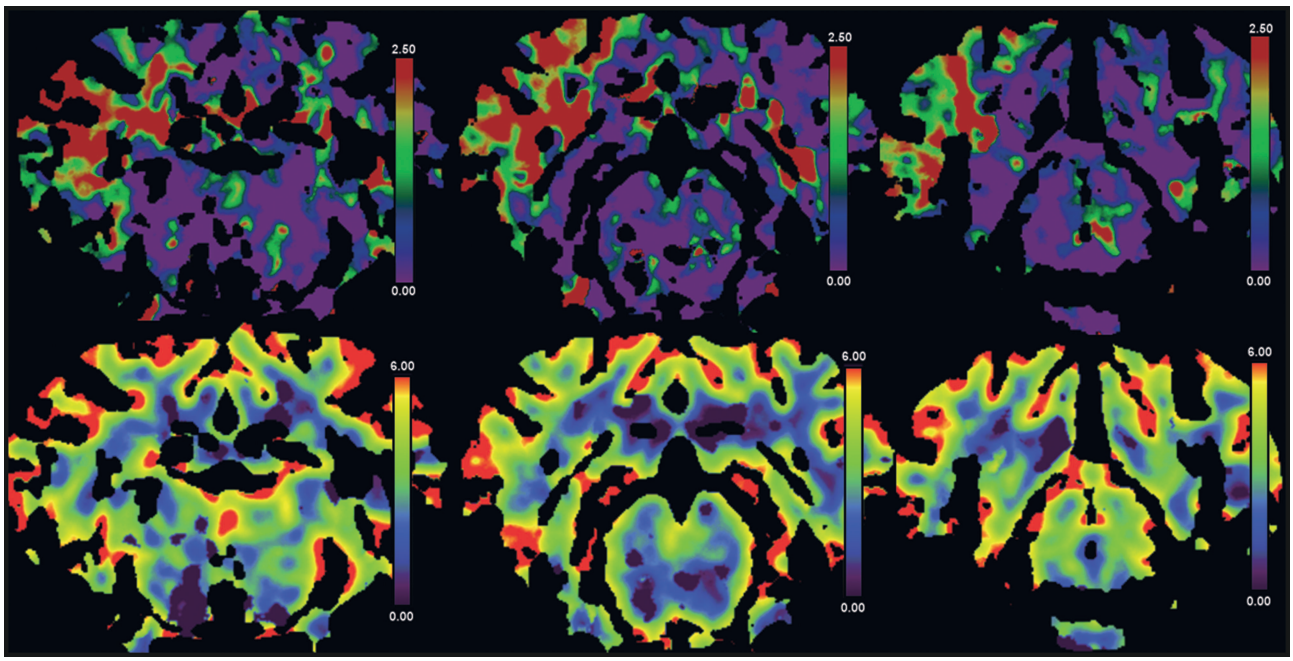

FIGURE 5 | Results from case 5. CTP images from case 5. Directly after clip MCAO profound hypoperfusion is visible on Tmax maps **(upper panels)** without reduction in CBV **(lower panels)**. False color scale indicates Tmax from 0 (purple) to 2.5 s (red) in upper panels and CBV from 0 ml/100 g (purple) to 6 ml/100 g (red) in lower panels, respectively.

were detected (lesion volume 2.2 ml) without edematous change on T2w images. In this case, evidence of correct temporary MCAO at the main trunk by visualization of CTP hypoperfusion during the time window of clip occlusion was first demonstrated with good correspondence to findings in immediate MRI. Hence, duration of MCAO for 2.5 h may still have been too short to detect a fully evolved infarct.

Case 6

MCAO and imaging procedures were performed as described in case 5 except for the longer (4.5 h) duration of ischemia at the time of the MRI measurements in order to avoid a small final infarct due to premature recanalization. Perfusion in the right hemisphere could not be evaluated on CTP due to major streak artifacts from extensive jugular venous contrast media reflux. Correct MCA main trunk occlusion could be reliably demonstrated using 3D TOF MRA, but CTA again failed to do so due to beam hardening artifacts. Four and a half hours of ischemia led to a rather large-sized MCA infarct that was seen on DWI MRI (lesion volume 14.5 ml) with resulting early edematous changes on T2w images.

Case 7

MCAO was performed as described in case 5 and 6 except for a modification in the positioning of the animal during CTP acquisition in order to avoid streak artifacts originating from contrast media reflux into the jugular veins. To this end, the animal was placed in left anterior-lateral position on the CT scanner table to relieve paunch-related increase in central venous pressure. DSA was also added directly after CTP and before removal of the clip, and subsequent permanent electrocogaluation of the MCA. However, as in the previous cases, DSA images could not clearly demonstrate correct vessel occlusion. MRI was performed at 4.0 h after MCAO. MRA was able to correctly visualize MCA main trunk trunk occlusion. On CTP, a large area of MCA territory hypoperfusion was seen on and on CBF maps with hypoperfusion also visible on CBV maps (perfusion score 3). There were no major artifacts on CTP images. However, MCAO was not visible on CTA images due to beam hardening artifacts similar to cases 5 and 6. Likewise, a rather large-sized MCA territory infarct was seen on MRI (DWI volume, 16.8 ml) without significant early edematous change on T2w images after 4 h of ischemia.

Cases 8–10

During an interim summary of cases 5–7, the utilization of CT perfusion for demonstrating MCA territory hypoperfusion as an indicator of correct MCAO was found successful except for extensive beam hardening artifacts in case 6, caused by jugular venous reflux. Thus, we planned to gain further experience with this CT perfusion protocol (applied with modified animal positioning as described in case 7) in combination with the modified surgical approach of series b. However, we decided to continue by performing a transient clip MCAO only (omitting electrocoagulation) and infarct size measurement by MRI on day 2. The latter modifications were chosen in order to establish an imaging-based MCAO model which is designed for testing novel combined endovascular approaches of LVO stroke therapy in the future. Such transient MCAO stroke model should not only allow for ultra-early MRI but also for delayed imaging assessment

of final infarct evolution and clinical follow-up as additional outcome measures.

The clip was removed after an ischemic period of 3.0 h. CTP imaging was performed directly after clip placement with modified animal positioning on the scanner table as described in case 7. Ultra-early MRI scanning was skipped and animals were allowed to wake-up and recover from the procedure. Infarct size measurement was performed on MRI at day 2 after MCAO in all three cases. On CTP, MCA territory hypoperfusion was visible on Tmax in all three cases. In addition, CBF reduction 9 and mild CBV reduction within the MCA territory was found in case 9 (perfusion score 3). In case 10, there were streak artifacts within the MCA territory from clip placement which, however, did not severely impair visibility of hypoperfusion (perfusion score 2). The MCAO was again not visible at all on DSA of the CCA in cases 8 and 9 after clip placement, and only poorly visible in case 10. On MRI at day 2, medium-sized MCA territory infarcts were evident on both DWI and T2w images (DWI volume, 6–8.5 ml) in cases 8 and 9. In contrast, the MCA territory infarction was rather small-sized (DWI volume, 0.9 ml) despite proved MCA territory hypoperfusion on CTP in case 10. This surprising result was explained by MRA on day 2 showing an early duplication of the MCA vessels as a normal variation in this case (**Figure 4**, mid panel). This variant may be a source for strongly improved collateralization within the MCA territory in some individuals. Identification and occlusion of the duplicate MCA main trunk can be challenging as it could be located deeply within a cerebral sulcus or the brain parenchyma.

DISCUSSION

The aim of this case study was to establish a feasible imaging modality for MCA territory hypoperfusion assessment in an ovine transient MCAO model, and to document our experience collected on the way toward this aim. Final infarct size on MRI represents a meaningful efficacy surrogate in experiments on acute stroke therapeutic interventions. However, in studies using transient MCAO this is only valid when the extent of brain hypoperfusion and thus the expected final lesion size without reperfusion or therapeutic intervention is known in order to compare it to the final lesion volume with recanalization and/or accompanying therapeutic intervention.

We evaluated different imaging protocols for both intra-ischemic and post-ischemic perfusion and infarct assessment, and performed a step-wise amendment of the imaging procedures and protocols. The finally resulting imaging strategy was feasible to demonstrate temporary MCA territory hypoperfusion during clip occlusion prior to vessel reopening in the intra-ischemic phase of temporary MCAO. Furthermore, we performed a "two-step" occlusion by MCA clipping prior to CTP, and electrocoagulation after CTP at the exact same vessel location to validate the results by means of TOF MRA without the risk of clip-derived artifacts.

We also determined CTP using standard post-processed image maps (Tmax, CBF, and CBV). This imaging technique was feasible to confirm hypoperfusion and thus the correct clip placement during MCAO. Such confirmation is an important quality assurance method when later removing the clip to model successful recanalization. Although derived from a relatively small number of animals undergoing CTP, our results indicate that final infarct size may be highly variable at least within a time window of 3–4.5 h of MCAO. These results are in-line with previous experiments done by Wells et al. (7) that demonstrated DWI volumes ranging from 7 to 15% of whole brain tissue after 2 h of ischemia with proximal clip MCAO in six animals. In principle, this variability may arise from incomplete MCA occlusion or a variable extent of collateral circulation to the MCA territory. Although a definite conclusion is hard to make, we argue for the latter as the most likely explanation due to numerous reasons. First, the Yasargil clips used in our experiments are also used in humans and exhibit closing forces (>150 g, 1.47 N) that should be absolutely sufficient to occlude the ovine MCA. Complete vessel coverage by the clip was confirmed after thorough visual inspection by the surgeon (M.J.S.). Of note, the ovine MCA is smaller than the vessels Yarsagil clips are usually placed on, so it is not difficult to cover it entirely. Second, we report cases of considerable infarcts (e.g., cases 2, 8, and 9). This points at a factor being different between individual subjects rather than a technical failure. Indeed, the extent of collateral circulation determines the extent of the core infarct size very early after onset of human LVO stroke of the MCA (8, 9), and the situation can be similar in sheep. If this assumption was right, it would underpin the translational value of the model described herein, but also calls for pretest assessment of collateral status to exclude extreme outcomes. In the sheep model, collateral circulation of the MCA may further be enhanced by dedicated variants of the ovine cerebral arteries such as a duplicated MCA main trunk (see case 10). Permanent MCAO by electrocoagulation as employed in our study was previously reported to result in reproducible infarct volumes throughout a 7 week surveillance period, starting 24 h after MCAO (5). Similar findings were reported for swine (10). This might come in line with our assumption, as the initially tissue-preserving effects of collateralization will become less prominent over time in case a critical hypoperfusion/complete blood flow disruption is present. During the acute stage, however, individual differences in collateralization capacity would result in much more variable lesion volumes.

The volume of hypoperfused brain tissue at early time points of vessel occlusion may be later correlated to the final lesion size. In our series, some cases that demonstrated profound hypoperfusion at the time of vessel occlusion (score 3) showed rather large-sized infarct volumes on follow-up DWI MRI. However, owing to the small number of cases with well-evaluable CTP images ($n = 4$) we were not able to clearly prove a suggested association between the extent of hypoperfusion early after clip application and final infarct on DWI by using a semiquantitative analysis of perfusion deficits. In order to provide a robust estimation of final infarcts, more data from CTP before clip removal (simulating the endovascular recanalization) should be compared to final infarct size on MRI or infarct histology in future studies.

Surgical Approach

Reproducible and reliable infarcts could not be induced in series a, and effective occlusion depended on qualitative visual assessment by the surgeon. Due to the basal approach, the proximal MCA and terminal ICA could be reached easily. However, the narrow loop between the terminal ICA and the proximal MCA may have led to erroneous terminal ICA occlusion, resulting in brain stem infarct presumably from associated choroidal vessel occlusion with the absence of any MCA territory ischemia (case 2). Surgical knowledge of this dedicated anatomy being different to human basal brain arteries is crucial to avoid such complication. Moreover, duplication of MCA main trunk (M1 segment, see case 10 and **Figure 4**) represents a relatively frequently observed anatomical variant in sheep, and is also supposed to be the source for of a high degree of collateralization within the MCA territory. Such duplication may not be entirely visible during neurosurgical exposure.

According to the impression from our experienced vascular neurosurgeon (M.J.S.), the surgical approach chosen in series b was technically more suitable for MCAO, as long as possible early duplication of the MCA was ruled out and the proximal MCA (vascular loop near the optic nerve) was clearly identified.

MCAO Imaging

DSA, superselective DSA of vessels supplying the rete mirabile, and CTA were not suitable to confirm correct MCAO. This was presumably due to the tiny caliber of intracranial arteries distal to the rete mirabile on superselective DSA and CTA, and many overlapping large-sized extracranial branches of the carotid artery on non-selective DSA, respectively. 3D rotational DSA might be an alternative option to visualize the occlusion of the MCA main trunk which was however not possible due to limited technical capabilities of our experimental angiography suite. Imaging of leptomeningeal collateral status in MCAO may be of interest as it could serve as an estimate for clinical outcome and final infarct size. However, the same methodological limitations of DSA and CTA as in the confirmation of correct MCAO may also account for the poor visualization of the tiny pial vessels in the sheep brain that impair a sufficient analysis of collaterals. However, in analogy to human large vessel occlusion stroke, CT perfusion penumbral imaging may also provide indirect information on the presence or absence of collaterals (11, 12). Non-human primate (NHP) models of ischemic stroke [for review see (4)] might be advantageous when assessing small-caliber intracerebral vessels and the cranial anatomy in NHPs is even closer to the human situation. However, the use of NHPs is ethically restricted in many contains, and costs related to using the species by far exceed those of other large animal stroke models. In turn, this restricts sample sizes and often severely limits endpoints that can be addressed quantitatively.

Beam-hardening metal artifacts were visible on CTA during temporary MCAO induced by titanium clip application. 3D TOF MRA at 3T reliably showed MCAO, but required (permanent) occlusion by electrocoagulation to avoid clip-borne artifacts (13). This issue might be mitigated by the use of newly developed and improved, but extremely expensive MRI-compatible clips. These are made of special titanium based alloys or Phynox, an alloy composed of cobalt, chrome, nickel, and molybdenum (e.g., Aesculap Yasargil mini clips) and cause only minimal artifacts. However, in transient MCAO, this imaging modality may be less efficient and also difficult to apply during a short ischemic time window between two neurosurgical procedures for clip placement and subsequent removal. This is particularly relevant for experiments that add additional time for endovascular procedures, e.g., for intra-arterial neuroprotective therapy, which necessitate additional navigation and placement of a catheter into the brain supplying arteries. Nevertheless, MRI-compatible clips might allow perfusion-weighted imaging sequences to assess the perfusion deficit during occlusion.

Positron emission tomography (PET) has been reported as a gold standard for experimental perfusion deficit assessment and is applicable in sheep (14, 15). Moreover, PET imaging is hardly susceptible to metal artifacts from a placed clip. However, PET imaging requires a dedicated infrastructure while its application and in particular full data analysis may be too time-consuming to be applied in acute experimental settings during a short time window of temporary vessel occlusion.

We found that CT perfusion reliably provided indirect evidence of MCAO by demonstrating MCA territory hypoperfusion already in a small number of cases. Importantly, it was the most feasible modality that could be applied in a time-efficient manner during temporary neurosurgical clip MCAO among the tested imaging techniques. In our experience, streak artifacts related to venous reflux into the internal jugular vein may be reduced by placing the animal in a left anterior-lateral position on the CT scanner table to relieve paunch-related venous pressure. This finally resulted in good diagnostic quality of the CTP images.

Study Limitations

In this pilot study with small number of consecutive animals, no complete blinding or randomization could be performed which may potentially bias the analysis of study outcomes. However, the investigators who performed the volumetric analysis of infarct volume on MRI images were blinded to the respective animals' treatment protocols. Detailed information derived on correlation of infarct size with hypoperfusion volume could not be obtained due to variable imaging protocols and the small number of animals that finally underwent CTP, warranting additional research on this aspect. Consequently, further studies with a fixed CTP imaging protocol and ischemic time window of temporary MCAO are necessary.

DATA AVAILABILITY STATEMENT

The datasets generated and/or analyzed during the current study are available from the corresponding author on request.

ETHICS STATEMENT

This study was carried out in accordance with the recommendations of the German animal protection law

and the animal care guidelines of the European Community (2010/63/EU). The protocol was approved by the local ethics committee (Regierungspräsidium Freiburg, Germany; reference numbers #35-9185.81/G-14/85 and #39-9185.81/G-15/38). Study design is illustrated in **Figure 1A**. ARRIVE guidelines were followed as applicable for a pilot study.

Proteostasis in Cerebral Small Vessel Disease

*Christof Haffner**

Institute for Stroke and Dementia Research, Klinikum der Universität München, Ludwig-Maximilians-Universität München, Munich, Germany

Maintaining the homeostasis of proteins (proteostasis) by controlling their synthesis, folding and degradation is a central task of cells and tissues. The gradual decline of the capacity of the various proteostasis machineries, frequently in combination with their overload through mutated, aggregation-prone proteins, is increasingly recognized as an important catalyst of age-dependent pathologies in the brain, most prominently neurodegenerative disorders. A dysfunctional proteostasis might also contribute to neurovascular disease as indicated by the occurrence of excessive protein accumulation or massive extracellular matrix expansion within vessel walls in conditions such as cerebral small vessel disease (SVD), a major cause of ischemic stroke, and cerebral amyloid angiopathy. Recent advances in brain vessel isolation techniques and mass spectrometry methodology have facilitated the analysis of cerebrovascular proteomes and fueled efforts to determine the proteomic signatures associated with neurovascular disease. In several studies in humans and mice considerable differences between healthy and diseased vessel proteomes were observed, emphasizing the critical contribution of an impaired proteostasis to disease pathogenesis. These findings highlight the important role of a balanced proteostasis for cerebrovascular health.

INTRODUCTION

Proteome homeostasis or proteostasis refers to the maintenance of all proteins of an organism in a conformation, concentration, and location that is required for their correct function (Balch et al., 2008). Safeguarding proteostasis under a wide range of environmental and metabolic conditions is a fundamental task of cells and tissues and ensured by a proteostasis network, which controls protein synthesis, folding, trafficking, and degradation/clearance (Hipp et al., 2019). The surveillance of protein folding is a particularly challenging problem, since incompletely folded and misfolded proteins are common byproducts of the cell metabolism and represent a considerable risk due to their high aggregation potential. Molecular chaperones counteract aggregation by facilitating the folding/refolding of proteins on a physiological timescale or by initiating the degradation of terminally misfolded proteins through the ubiquitin–proteasome or the autophagosome–lysosome system (Hartl et al., 2011). Chaperones shield hydrophobic amino acid residues and unpaired β-strands of incorrectly folded proteins from the aqueous cellular environment and abolish the formation of intermolecular contacts between non-native protein states. Yet, excessive protein misfolding due to increased environmental stress or genetic mutations is a frequent cause of pathological conditions (Wyatt et al., 2013; Chiti and Dobson, 2017). These

proteinopathies are characterized by an overload and failure of the proteostasis network and a subsequent predominance of aggregation-mediated proteotoxicity over aggregate clearance inside and/or outside the cell. Prominent examples are degenerative disorders of the brain associated with protein aggregates adopting well-ordered structures referred to as amyloid. The progressivity of these conditions with age is likely linked to the age-dependent decline of the proteostasis network capacity (Labbadia and Morimoto, 2015; Hipp et al., 2019). How protein aggregates cause toxicity and cellular dysfunction is only partially understood, but once aggregation has been initiated a further collapse in proteostasis is likely to occur due to the sequestration of chaperones and other proteostasis components into pathologic inclusions (Balchin et al., 2016).

While the molecular details of intracellular proteostasis have been investigated extensively, our understanding of the mechanisms maintaining proteostasis in the extracellular space is limited. The discovery of a small but growing number of constitutively secreted chaperones has advanced our knowledge about processes counteracting extracellular proteotoxicity (Wyatt et al., 2013). These chaperones share functional similarities with the family of intracellular small heat shock proteins in that they recognize targets via exposed hydrophobic regions and serve as sensors as well as disposal mediators of misfolded proteins. However, they lack ATPase activity and cannot refold proteins, limiting their role in safeguarding against proteotoxicity to protein degradation and aggregate removal. The clearance of misfolded proteins from the brain parenchyma is a particular challenging task and believed to occur to a substantial extent via transport along glymphatic/perivascular routes (Morris et al., 2016; Rasmussen et al., 2018). The impairment of this process is likely to facilitate protein aggregation and deposition within the brain vasculature and to promote the development of cerebrovascular pathologies (Carare et al., 2013; Weller et al., 2015). Two important examples are cerebral amyloid angiopathy (CAA), an important cause of intracerebral hemorrhage, and cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), the most prevalent monogenic form of lacunar (ischemic) stroke in adults. Both are characterized by excessive protein accumulation in brain vessel walls highlighting the importance of a balanced extracellular proteome for brain health.

CEREBRAL SMALL VESSEL DISEASE

Cerebrovascular disease resulting in vascular cognitive impairment (VCI)/vascular dementia (VD) is increasingly recognized as important cause of dementia in the elderly and has become a major challenge for aging societies (Iadecola, 2013). It can occur in "pure" form without concomitant cerebral pathologies or, much more frequently, in "mixed" form together with pathologies of neurodegenerative disorders, most prominently Alzheimer's disease (AD) or Parkinson's disease (Jellinger, 2013). Cerebral small vessel disease (SVD), a major cause of VCI, describes a heterogeneous group of conditions affecting small arteries, arterioles, capillaries and sometimes venules of the brain and comprises CAA as well as non-amyloid arteriopathies (Pantoni, 2010; Kalaria, 2018; Vinters et al., 2018). CAA is clinically characterized by microbleeds, microinfarcts and hemorrhagic stroke and histologically clearly defined by the accumulation of insoluble amyloid-β (Aβ) peptides in the walls of small, mainly cortical and leptomeningeal vessels (Charidimou et al., 2017). In contrast, non-amyloid SVD results in both lacunar stroke as well as intracerebral hemorrhage and encompasses common sporadic pathologies such as small vessel arteriosclerosis, lipohyalinosis and arteriolosclerosis as well as rare hereditary syndromes (Pantoni, 2010; Wardlaw et al., 2019). Histopathological features include concentric hyaline vessel wall thickening, luminal stenosis, accumulation of amorphous proteinaceous material and plasma proteins in the vessel matrix as well as loss of mural cells [vascular smooth muscle cells (VSMC), pericytes] from the tunica media (Grinberg and Thal, 2010; Pantoni, 2010). Some insight into the underlying molecular mechanisms has been gained from hereditary SVD forms with defined genetic etiology and the analysis of the biology and physiology of the underlying genes (Haffner et al., 2016; Tan et al., 2017; Yamamoto and Ihara, 2017). The following sections provide an overview of the molecular etiologies and pathological features of the SVD forms relevant for the topic of this review.

CADASIL AND CARASIL

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy is the most common heritable cause of stroke and VCI in adults (Chabriat et al., 2009; Joutel, 2011). It is a progressive neurological syndrome associated with ischemic events and cognitive decline affecting young or middle-aged individuals and leading to a terminal stage of being bedridden and demented within a mean of 25 years. In magnetic resonance imaging (MRI) patients display the typical signs of chronic small artery disease of the brain such as white matter damage, lacunar infarcts and dilated perivascular spaces (Chabriat et al., 2009). Histological analysis of vessels shows a marked thickening of the walls of small and medium-sized, leptomeningeal and penetrating arteries, luminal stenosis and the presence of ultrastructural, non-amyloid protein deposits termed granular osmiophilic material (GOM) in the extracellular space of the tunica media (Kalimo et al., 2002; Tikka et al., 2014). Although a structural and functional impairment of mural cells of the vessel wall has been reported (Ghosh et al., 2015; Capone et al., 2016b), many aspects of the pathophysiological processes leading to vessel degeneration and dysfunction are still unknown. CADASIL is caused by mutations in the *NOTCH3* gene (Chabriat et al., 2009; Rutten et al., 2014), which encodes a signaling receptor essential for VSMC survival, blood vessel integrity, blood-brain barrier function and regulation of vascular tone (Henshall et al., 2015; Kofler et al., 2015). Notch3 is a large, single-pass transmembrane protein with an extracellular domain ($Notch3^{ECD}$) mainly consisting of 34 tandem epidermal growth factor (EGF)-like repeats and an intracellular domain acting as a transcriptional coactivator when proteolytically released from the membrane-bound receptor upon ligand-mediated activation

(Siebel and Lendahl, 2017). Although a loss of Notch3 function cannot be completely ruled out as driving force for CADASIL pathogenesis (Machuca-Parra et al., 2017; Coupland et al., 2018), a gain of toxic function is currently widely accepted as disease mechanism (Joutel, 2011; Haffner et al., 2016). Typical CADASIL mutations are missense variants in the Notch3^{ECD} causing a gain or loss of cysteine residues and resulting in a disruption of the highly conserved disulfide bond pattern characteristic for EGF repeats (Chabriat et al., 2009). As a consequence, mutant receptors are likely to engage via unpaired sulfhydryl groups in abnormal intermolecular interactions leading to Notch3^{ECD} aggregation (Duering et al., 2011) and the formation of focal protein deposits corresponding to the ultrastructural GOM (Joutel, 2011). Notch3^{ECD} aggregates are believed to confer toxicity by dysregulating ECM homeostasis, but the underlying molecular processes are largely unknown (Joutel et al., 2016).

Another monogenic SVD related to CADASIL is CARASIL (cerebral autosomal-recessive arteriopathy with subcortical infarcts and leukoencephalopathy), a rare familial form of non-hypertensive SVD with an age of onset in the second or third decade of life (Fukutake, 2011; Nozaki et al., 2014). As the acronym implies, it shows an overlap in clinical and histopathological features with CADASIL, with cardinal neurological features being early onset lacunar stroke primarily in the basal ganglia or brainstem, extensive white matter abnormalities and premature cognitive decline. Clinically, it can be differentiated from CADASIL mainly due to the recessive inheritance pattern and the extraneurological symptoms such as premature baldness and spondylosis. Histological analysis typically reveals extensive pathological alterations of the cerebral vasculature including vessel wall thickening, vessel lumen narrowing, elastic lamina splitting and VSMC loss (Oide et al., 2008; Tikka et al., 2014). CARASIL is caused by mutations in the conserved serine protease HTRA1 (high temperature requirement A1) through a loss-of-function mechanism attributed to a reduction of its proteolytic capacity or to mRNA instability (Hara et al., 2009; Shiga et al., 2011; Beaufort et al., 2014; Nozaki et al., 2014). Heterozygous HTRA1 mutations were further found to cause a dominant, late-onset form of SVD with a milder phenotype (Verdura et al., 2015), but whether this condition results from haploinsufficiency or a dominant-negative effect is an unresolved issue (Nozaki et al., 2016). HTRA1 is a primarily secreted protease and a member of a conserved protein family, which has well documented roles in cellular quality control processes in bacteria and plants (Clausen et al., 2011). The function of human HTRA1 is less clear, but findings over the last decade including the proteomic studies described below indicate a crucial role in balancing the extracellular proteome.

CEREBRAL AMYLOID ANGIOPATHY

Cerebral amyloid angiopathy is a brain condition frequently associated with Alzheimer's disease (AD) and characterized by the accumulation of Aβ peptides in the cerebral vasculature (Charidimou et al., 2017). Its major clinical presentations are spontaneous intracerebral hemorrhage, cognitive impairment and dementia, with MRI signatures including multiple, strictly lobar cerebral microbleeds, white matter hyperintensities, cortical microinfarcts and enlarged perivascular spaces. Despite its close molecular and clinical relationship with AD, CAA remains clinically distinct (Viswanathan and Greenberg, 2011). The overall cognitive profile of CAA patients, which primarily comprises executive dysfunction and impaired processing speed with relatively preserved episodic memory, is more similar to that seen in classic VCI (Charidimou et al., 2017). The vasculopathic changes include fibrinoid necrosis, VSMC loss and vessel wall thickening (Attems et al., 2011), degenerative processes also observed in ischemic SVD. Nevertheless, CAA differs from non-amyloid SVD in various aspects: First, it preferentially affects small arterioles and capillaries of the leptomeninges and cerebral cortex, without necessarily involving white matter vessels; second, it lacks association with hypertension, arteriosclerosis and other common vascular risk factors; and third, it is mainly observed in posterior lobar brain regions (especially the occipital lobes), whereas basal ganglia and brainstem are usually spared (Reijmer et al., 2016). Two different types of CAA can be distinguished, with type 1 (capillary CAA) being characterized by Aβ deposition in capillaries (with or without involvement of larger vessels), and type 2 showing Aβ pathology exclusively in leptomeningeal and cortical arteries (Attems et al., 2011). Current evidence suggests that cerebrovascular Aβ accumulation is largely driven by a failure to efficiently clear parenchymal Aβ via perivascular routes (Carare et al., 2013; Weller et al., 2015). While the molecular mechanisms leading to the arteriopathy are largely unknown, alterations in ECM structure and composition, similar to ischemic SVD, likely play a critical role (Morris et al., 2014).

PROTEOMIC STUDIES IN SVD

Liquid chromatography/tandem mass spectrometry (LC-MS/MS) has become an invaluable technology for global proteomic analyses of tissues under physiological and pathophysiological conditions, allowing the elucidation of disease-relevant molecular processes and pathways (Aebersold and Mann, 2016). In recent years a number of proteomic studies have been conducted on cerebrovascular tissue isolated from CADASIL and CAA post-mortem samples to determine the disease-specific proteome profiles and revealed a distinct set of proteins enriched in both disorders with unexpected consistency (**Table 1**). In two of the four CADASIL studies, laser-capture microdissection was used to isolate brain artery material, resulting in the identification of a relatively low total number of proteins (Arboleda-Velasquez et al., 2011; Nagatoshi et al., 2017). Arboleda-Velasquez et al. (2011) used subcortical white matter tissue from two patients and two healthy control individuals and semiquantitative evaluation based on peptide counts revealed a small set of proteins enriched in patients. One of the most strongly accumulating proteins was clusterin, an extracellular chaperone with functional features similar to heat shock proteins (see below). Clusterin enrichment was confirmed by immunohistochemistry and shown to also occur in the cerebrovasculature of a CADASIL

TABLE 1 | Summary of major proteins with increased abundance in proteomic SVD studies.

Disease	Study	Tissue/vessel type	Proteins					
			SAP	TIMP3	VTN	APOE	CLU	HTRA1

↑ Increased abundance = no significant abundance difference ND not detected or data not available. Proteins investigated in more detail in individual studies are highlighted. SAP, serum amyloid P component; TIMP3, tissue inhibitor of metalloproteinases 3; VTN, vitronectin; APOE, apolipoprotein E; CLU, clusterin; HTRA1, high temperature requirement A1 protease.

mouse model (Arboleda-Velasquez et al., 2011). Furthermore, immuno-electron microscopy analysis suggested its presence in human GOM deposits. An independent histological analysis of a larger number of post-mortem samples confirmed the clusterin enrichment in patient vessels, especially in white matter arteries, but a colocalization with GOM deposits could not be observed (Craggs et al., 2016). In the proteomic study by Nagatoshi et al. (2017) leptomeningeal arteries from two autopsied patients and the superficial temporal artery from one biopsied patient were used, but LC-MS/MS analysis yielded only a few proteins consistently detected in both the patient and control group. Label-free quantification revealed serum amyloid P component (SAP), annexin A2, and periostin as most strongly enriched proteins, but only SAP accumulation could be confirmed by immunohistochemistry. It was further shown to colocalize with Notch3^{ECD} aggregates in patient brain tissue sections and to interact with a recombinant Notch3^{ECD} fragment *in vitro* indicating involvement in GOM formation. The plasma protein SAP is a well-known universal constituent of human amyloid deposits and might be a general component of extracellular protein aggregates (see below) (Pepys, 2018).

In the study by Monet-Lepretre et al. (2013) the proteomics work on CADASIL was extended by establishing a method to isolate brain vessels from human autopsy material and by enriching GOM using a biochemical fractionation procedure. After nanoLC-MS/MS performed on material from one CADASIL patient and one control subject and subsequent quantification by peptide counting, a number of proteins with increased abundance were identified including clusterin and SAP. Enrichment was also observed for the two matrisomal proteins tissue inhibitor of metalloproteinases 3 (TIMP3) and vitronectin as well as for HTRA1, the serine protease genetically associated with CARASIL (see above). TIMP3 and vitronectin were shown to colocalize with GOM deposits, to bind to Notch3^{ECD} *in vitro* and to also accumulate in brain vessels of a CADASIL mouse model. From these and other studies (Kast et al., 2014; Lee et al., 2014; Zhang et al., 2015), it became increasingly clear, that the accumulation of ECM proteins represents a critical step in CADASIL pathogenesis likely causing a dysregulation of ECM homeostasis and multifactorial toxicity (Joutel et al., 2016). To provide further support for this hypothesis in a larger cohort and with increased proteome depth, Zellner et al. (2018) conducted label-free quantitative LC-MS/MS on brain vessels from six patients carrying five different Notch3 mutations and six age-matched healthy controls. For the first time, a truly quantitative comparison in combination with meaningful statistical evaluation of protein abundance changes in CADASIL was performed. An improved protocol of the brain vessel isolation technique published by Monet-Lepretre et al. (2013) was used, but no fractionation applied, resulting in the determination of a proteomic whole-vessel profile, in which matrisomal components were strongly overrepresented. The set of significantly enriched proteins included clusterin, TIMP3, vitronectin, SAP as well as HTRA1. Accumulation of HTRA1 was confirmed by quantitative immunoblotting, and its colocalization with Notch3^{ECD} deposits demonstrated by confocal immunofluorescence microscopy (Zellner et al., 2018). In addition, enrichment of several ECM proteins previously reported as HTRA1 substrates was noticed, suggesting reduced HTRA1 activity in the cerebrovasculature of CADASIL patients. To further substantiate this finding, the brain vessel proteome from HTRA1 knockout mice was determined to obtain a definite HTRA1 deficiency profile. Proteins accumulating in this profile were considered likely HTRA1 substrates and thus indicators for a loss of catalytic function. The comparison with the CADASIL profile indeed revealed a significant overlap which included clusterin, TIMP3, vitronectin and a number of other, mostly matrisomal proteins. Several previously uncharacterized, putative substrates were shown to be processed by HTRA1 in an *in vitro* assay (Zellner et al., 2018). These findings indicated the presence of a HTRA1 loss-of-function signature in the CADASIL vessel proteome and provided an unexpected mechanistical link between CADASIL and HTRA1-related SVDs. Proteomic analyses in CARASIL patients with genetically compromised HTRA1 activity have so far not been reported, likely due to the rareness of the disease. The discovery of affected heterozygous

mutation carriers might facilitate the realization of such studies in the future (Verdura et al., 2015).

Proteomic approaches have also been applied in CAA to determine protein abundance changes associated with excessive vascular Aβ deposition (**Table 1**). Manousopoulou et al. (2017) performed quantitative LC-MS on leptomeningeal vessels isolated from autopsy tissue of four patients with severe arterial and capillary CAA. From the set of proteins with increased abundance, clusterin and TIMP3 were selected for immunohistochemistry analysis and shown to be enriched in leptomeningeal, but not cortical arteries and to largely colocalize with Aβ deposits. In the study by Inoue et al. (2017) laser capture microdissection was used to isolate vascular material from leptomeningeal arteries and neocortical arterioles from eight cases with severe CAA. Quantitative LC/MS-MS revealed enrichment of a variety of proteins including apolipoprotein E (APOE), vitronectin and clusterin. Sushi repeat-containing protein X-linked 1 (SRPX1), an apoptosis inducer in tumor cells previously described as SRPX, was investigated in more detail and shown in brain sections to co-accumulate with vascular Aβ deposits. SRPX mRNA levels were found to be increased in patient vessels and in primary cultures of cerebrovascular smooth muscle cells treated with Aβ peptides, indicating a transcriptional effect as cause of the observed enrichment (Inoue et al., 2017). SRPX was further shown to bind Aβ peptides *in vitro* and to enhance Aβ-induced caspase activity in cultured VSMCs. It was therefore proposed to promote Aβ-induced cerebrovascular degeneration in CAA. SRPX1 was not found to be enriched in most of the other proteomic studies and is therefore not further discussed.

The study by Hondius et al. (2018) investigated capillary (type I) CAA as a frequent comorbidity in AD and compared the proteomic profiles of microdissected gray matter material (including vessels) from AD cases with and without vascular amyloid pathology. After label-free quantification clusterin emerged as most significantly enriched protein in the CAA group extending the results of an earlier histological investigation (Verbeek et al., 1998). CAA-specific accumulation was also observed for norrin (NDP) and collagen α2(VI) (COL6A2) and colocalization with perivascular Aβ deposits demonstrated by immunohistochemistry. In contrast, APOE and SAP were found to be enriched in both the CAA and the AD group. HTRA1 was detected in none of the control samples and in only one AD sample, but in all CAA samples prompting the authors to claim its CAA-specific accumulation (Hondius et al., 2018). In partial agreement with this, immunohistochemistry staining associated with Aβ deposits was more intense in CAA than in AD tissue sections, a finding confirming the results of an earlier study (Grau et al., 2005). Vascular APOE and HTRA1 accumulation was also reported in Tg-SwDI mice, a CAA model carrying three human amyloid precursor protein (APP) mutations (Swedish, Dutch and Iowa) (Searcy et al., 2014). A quantitative comparison of the proteomic profiles of older mice exhibiting prominent vascular amyloid pathology with younger mice showing minimal Aβ deposition revealed APOE and HTRA1 as the proteins with the largest abundance increase. For both, the accumulation was confirmed by immunohistochemistry, but no clear colocalization with Aβ deposits could be observed. In the proteomic study by Endo et al. (2019) quantitative analysis was performed on biopsied, microdissected samples of leptomeningeal and cortical vessels obtained from six CAA patients who had underwent surgery for large lobar hemorrhages. Clusterin and APOE were most strongly enriched and their effects on Aβ aggregation investigated using an *in vitro* model of CAA recapitulating the intramural periarterial drainage process. Physiological concentrations of APOE and clusterin delayed the initiation time of Aβ aggregation kinetics in a concentration-dependent manner and thus, both were proposed to represent extracellular chaperones inhibiting vascular Aβ deposition.

EXTRACELLULAR PROTEOSTASIS IN SVD

Despite the substantial differences in sensitivity, depth and quantification methodology of the described proteomic studies in CADASIL and CAA, they yielded a shared set of proteins showing enrichment with a relatively high consistency (**Table 1**). However, these proteins differ substantially in structure and function and are thus likely to contribute to disease pathogenesis in different ways (**Figure 1**). SAP, TIMP3 and vitronectin might associate with pathologic protein deposits primarily for structural reasons resulting in aggregate stabilization and/or growth. SAP is an abundant plasma protein of the pentraxin family and has gained a great deal of attention through its role as universal constituent of human amyloid deposits of all types including senile plaques in AD and vascular Aβ deposits in CAA (Pepys, 2018). It has been shown to avidly bind to and stabilize amyloid fibrils, possibly in an attempt to opsonize them for phagocytosis. Its depletion from the blood circulation was reported to result in the destabilization of amyloid deposits leading to the initiation of clinical trials in systemic amyloidosis and AD to investigate its therapeutic potential (Richards et al., 2015). SAP was also found to inhibit the heat-induced formation of amorphous aggregates, an activity believed to be relevant in protein misfolding during inflammatory processes (Ozawa et al., 2016). A role in non-amyloid protein aggregation is now further suggested by its accumulation observed in three of the four proteomic CADASIL studies as well as by its colocalization with $Notch3^{ECD}$ deposits and its binding to $Notch3^{ECD}$ *in vitro* (Nagatoshi et al., 2017).

Tissue inhibitor of metalloproteinases 3 (TIMP3) is a matrisomal protein well known for its role in ECM homeostasis. It controls the activity of proteases degrading matrix components and catalyzing the shedding of ectodomains from cell surface proteins (Arpino et al., 2015). Although TIMP3 enrichment was found in only one of the CAA studies, the presented immunohistochemistry results clearly support the conclusion of Aβ-associated accumulation (Manousopoulou et al., 2017). Similarly, TIMP3 was shown to colocalize with $Notch3^{ECD}$ deposits in CADASIL-affected vessels (Monet-Lepretre et al., 2013). Moreover, increased TIMP3 levels were also observed in a CADASIL mouse model and follow-up experiments suggested an impairment of a signaling cascade regulating arterial smooth

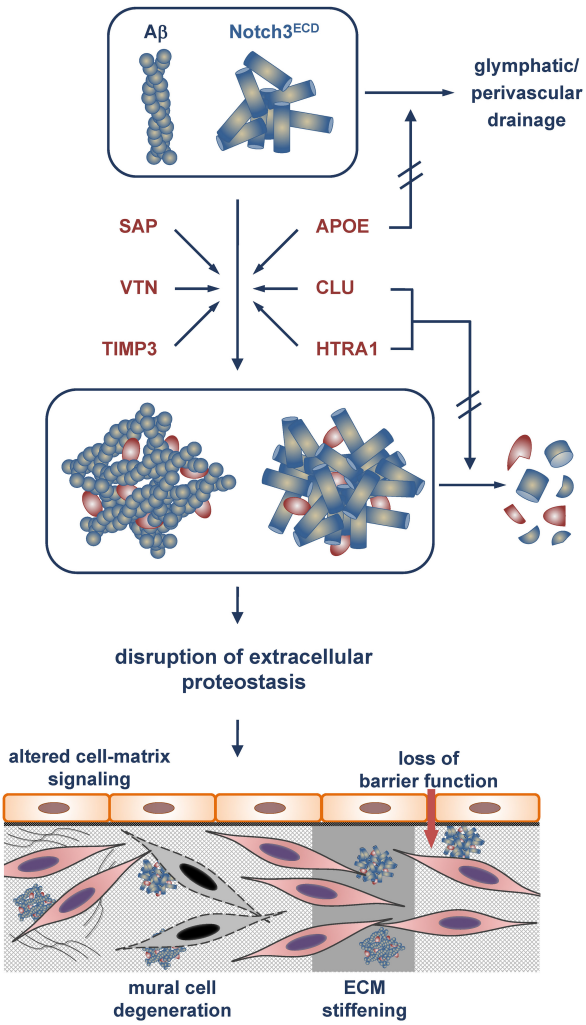

FIGURE 1 | Model of Aβ and Notch3^{ECD} aggregate formation and proteostasis disruption in the brain vessel wall. Incorporation of the metastable proteins SAP, vitronectin (VTN) and TIMP3 with an increased tendency toward misfolding stabilizes Aβ and Notch3^{ECD} aggregates and/or accelerates aggregate growth. Excessive recruitment of the chaperones/clearance factors APOE, clusterin (CLU) and HTRA1 results in their depletion from the proteostasis network and a reduction or even loss of their activity. While APOE is impaired in its role in clearing of Aβ (and other misfolded proteins) from the brain (e.g., via glymphatic/perivascular pathways), clusterin and HTRA1 are compromised in their tasks to promote aggregate removal or degradation. The eventual disruption of extracellular proteostasis initiates a variety of pathophysiological processes including dysregulation of cell-matrix signaling, mural cell degeneration, alteration of physical ECM properties such as stiffness and loss of barrier function.

muscle cell activity leading to cerebral blood flow deficits (Capone et al., 2016b), a symptom known to occur early in CADASIL pathogenesis. Genetic mutations in the *TIMP3* gene result in Sorsby fundus dystrophy (SFD) (Anand-Apte et al., 2019), a rare, dominantly inherited, adult-onset retinal dystrophy clinically and histopathologically related to age-related macular degeneration, the most common cause of blindness in adults. SFD is characterized by the presence of drusen, extracellular deposits located below the basement membrane of the retinal pigment epithelium. TIMP3 shows a striking structural similarity to Notch3 in that its primary sequence contains an even number of cysteines all forming disulfide bonds (Anand-Apte et al., 2019). Very similar to CADASIL mutations SFD-causing variants are typically missense mutations altering the number of cysteine residues and enhancing TIMP3 multimerization/aggregation. It is thus conceivable that the recruitment of TIMP3 to Aβ and Notch3^{ECD} aggregates promotes TIMP3 misfolding resulting in a further enhancement of the aggregation process. Also vitronectin is a well-known ECM component and a major adhesive protein of the extracellular environment (Leavesley et al., 2013). It interacts with a multitude of proteins and promotes cell adhesion, spreading, and migration. Its accumulation in three of the four proteomic CAA studies extends previous histological studies which showed enrichment in the senile plaques of AD patients (Shin et al., 2008; Winter et al., 2015). Vitronectin was furthermore reported to be able to form spherical oligomers as well as typical amyloid fibrils *in vitro* which are toxic for cultured cells (Shin et al., 2008). Its role in Notch3^{ECD} aggregation has not been investigated yet, but its genetic reduction in a CADASIL mouse model led to a reversal of white matter pathology, although the underlying molecular mechanisms remained unclear (Capone et al., 2016a). Thus, SAP, TIMP3 and vitronectin might represent metastable proteins, whose tendency toward misfolding and multimerization is enhanced upon recruitment to Notch3^{ECD} or Aβ deposits.

In contrast, APOE, clusterin and HTRA1 accumulation in CADASIL and CAA is likely to follow a different mechanism due to their established or presumed ability to act as molecular chaperones. APOE has long been known for its role in modulating AD and CAA risk (depending on the combination of the three human isoforms APOE2, APOE3 and APOE4) and for its ability to bind Aβ peptides and to be recruited to amyloid deposits (Yu et al., 2014). It has been suggested to modulate Aβ deposition in a variety of ways: (1) acceleration of Aβ aggregation and deposition, (2) facilitation of Aβ uptake by microglia, astrocytes and neurons, (3) enhancement of enzymatic Aβ degradation, and (4) facilitation of Aβ clearance via transport across the blood-brain barrier or by drainage via the interstitial fluid or the perivasculature. The identification of APOE as major accumulating factor in all the proteomic CAA studies as well as in the Tg-SwDI mouse model extends previous histological analyses (Verbeek et al., 1998) and provides further support for an important role of APOE in CAA pathogenesis. Some insight into a potential mechanism was gained in the study by Endo et al. (2019) in which an *in vitro* model of CAA recapitulating the intramural periarterial drainage pathway was used and an inhibitory role of APOE on the early phase of vascular Aβ deposition reported. The impact of APOE on Notch3^{ECD} in CADASIL is more difficult to assess, since no follow-up studies have been published to date. The influence of the APOE genotype on clinical CADASIL features was investigated in two studies, but while in one increased white matter hyperintensity volumes in *APOE2*, but not *APOE4* carriers were reported (Gesierich et al., 2015), in the other no association with MRI lesion volumes or disease phenotype (age of onset, presence of stroke) could

be detected (Singhal et al., 2004). Interestingly, two studies demonstrated proteolytic APOE processing by HTRA1 (Chu et al., 2016; Munoz et al., 2018) providing a potential link to HTRA1-related SVDs.

Clusterin is a ubiquitously and constitutively expressed protein present in a wide range of tissues and body fluids (Wilson and Zoubeidi, 2017). It is involved in a number of cellular processes including inhibition of the complement system, lipid transport, regulation of cell survival and cell death pathways and has often been referred to as an extracellular chaperone. Its accumulation reported in all four CAA proteome studies is in agreement with earlier histological findings (Verbeek et al., 1998; Craggs et al., 2016) and its well-established link to AD (Foster et al., 2019). Clusterin is able to bind a wide range of Aβ oligomers (from dimers to 50-mers) and to interfere with Aβ peptide aggregation and amyloid fibril formation *in vitro* (Narayan et al., 2012). It further promotes Aβ clearance in a variety of experimental settings (Wojtas et al., 2017; Endo et al., 2019). From these observations, an anti-amyloidogenic role of clusterin due to its chaperone function was deduced, but studies on clusterin knockout mice have not provided clear answers on its neuroprotective function and fueled the ongoing controversy about its beneficial role in amyloid diseases (Foster et al., 2019). The detection of clusterin enrichment in three of the four proteomic CADASIL studies suggests a role also in non-amyloid protein aggregation. However, conflicting results have been reported about its precise colocalization with Notch3^{ECD} aggregates. Whereas Arboleda-Velasquez et al. (2011) reported the presence of clusterin in GOM deposits, Craggs et al. (2016) were unable to confirm this finding and even showed a clear separation of clusterin and Notch3 immunofluorescence staining patterns in patient vessels. They nevertheless observed a correlation between clusterin levels and white matter pathology scores, not only in CADASIL, but also in other leukoencephalopathies, suggesting a more general role of clusterin in ischemic SVD.

The proteomic results on the serine protease HTRA1 might have the most far-reaching impact on our understanding of SVD pathomechanisms. Its involvement in cerebrovascular disease had first become clear with the discovery of its genetic association with monogenic recessive and dominant hereditary SVD forms (Hara et al., 2009; Verdura et al., 2015). The realization of the loss-of-function nature of pathogenic HTRA1 mutations indicated a critical role of its catalytic activity for normal cerebrovascular function. However, the substrates involved in SVD pathogenesis as well as the molecular processes affected by HTRA1 deficiency including a possible dysregulation of TGFβ signaling have not yet been clearly determined (Hara et al., 2009; Shiga et al., 2011; Beaufort et al., 2014). The accumulation of HTRA1 in CADASIL and the high degree of colocalization with Notch3^{ECD} deposits *in vivo* provided further support of its key role in the brain microvasculature (Monet-Lepretre et al., 2013; Zellner et al., 2018). Moreover, the phenotypic similarities between CADASIL and the HTRA1-related SVDs as well as the extensive overlap between the proteomic CADASIL signature and the murine HTRA1 loss-of-function profile strongly suggest a role of HTRA1-mediated substrate processing also in CADASIL (Monet-Lepretre et al., 2013; Zellner et al., 2018). APOE, vitronectin and TIMP3 have all been shown in earlier studies to be processed by HTRA *in vitro*, and for APOE even isoform-specific differences were reported, with APOE4 more efficiently cleaved compared to APOE3 (An et al., 2010; Chu et al., 2016; Munoz et al., 2018). Thus, a loss in HTRA1 catalytic activity might contribute to the accumulation of these proteins under pathophysiological conditions. A link between HTRA1 and Aβ metabolism was first indicated by the demonstration of HTRA1-mediated degradation of Aβ peptides *in vitro* and the colocalization of HTRA1 with parenchymal and perivascular Aβ deposits (Grau et al., 2005). In subsequent studies, HTRA1 was shown to also degrade tau protein in monomeric and fibrillar form (Tennstaedt et al., 2012). The degradation of tau fibrils was furthermore reported to involve the disintegration of the fibrillar core structure and the subsequent solubilization of fibrils allowing productive interaction of aggregated polypeptides with the active site of HTRA1 for rapid degradation (Poepsel et al., 2015). Thus, HTRA1 apparently combines chaperone and protease activity in a single polypeptide and might be able to efficiently dissolve and degrade pathological protein aggregates thereby antagonizing neurodegeneration caused by excessive protein aggregation (Shorter, 2017). The proteomic findings in CAA patients and the Tg-SwDI mouse model, most importantly those of the Hondius et al. (2018) study, showing preferential HTRA1 accumulation in vascular Aβ deposits, suggest that its function might especially be important in cerebrovascular Aβ biology.

CONCLUSION

Proteomic studies on human cerebrovascular tissue have identified several extracellular proteins accumulating with unexpected consistency in CADASIL and CAA, two neurovascular conditions caused by protein misfolding and aggregation. The enrichment of the same set of proteins in two different types of protein deposits suggests the contribution of shared pathways to pathogenesis. A search for these proteins within the mouse brain vasculome, a previously determined transcriptome of cerebral endothelial cells (Guo et al., 2012), revealed only a marginal overlap, arguing against this cell type as a major source of the accumulating proteins. Although the molecular details of cerebrovascular protein aggregation are still largely unknown, the identified proteins might facilitate disease progression by two different mechanisms (**Figure 1**). SAP, TIMP3 and vitronectin appear to be incorporated into preexisting protein deposits mainly due to their metastability, thus contributing directly to aggregate stabilization or growth and exerting a gain-of-toxic-function effect. In contrast, APOE, clusterin and HTRA1 are possibly actively recruited to pathological protein aggregates due to their chaperone function within the extracellular proteostasis network. Under physiological conditions they facilitate the refolding of misfolded proteins or promote their removal either by degradation or

by clearance via vascular routes. The permanent encroachment of chaperone capacity under pathophysiological conditions, e.g., during aging or due to genetic mutations, will inevitably result in a network overload. This process is aggravated by the excessive recruitment of chaperones to protein deposits resulting in their sequestration and depletion, tantamount to a loss-of-function mechanism (Balchin et al., 2016). Thus, cerebrovascular disease might be the result of a combination of a gain-of-toxic-function and loss-of-function effect, similar to scenarios discussed in neurodegenerative disorders such as Parkinson's disease (Winklhofer et al., 2008; Benskey et al., 2016). The consequences of a disruption of extracellular proteostasis on the functionality of cerebral vessels are largely unknown, but they are likely to include the dysregulation of cell-matrix signaling, the degeneration of mural cells, alterations of physical ECM properties such as stiffness, and loss of barrier function (**Figure 1**). Whether impaired extracellular proteostasis might also contribute to pathologies of the brain microvasculature not associated with excessive protein aggregation such as arteriolosclerosis is currently difficult to assess, largely due to the lack of appropriate proteomic studies. While substantial alterations in the vessel architecture are a key pathological finding in sporadic SVD, a causal link to disrupted proteostasis has so far not been established. The further elucidation of proteostasis mechanisms will undoubtedly advance our understanding of the physiological and pathophysiological processes underlying brain health and disease.

Brain regenerative strategies through the transplantation of stem cells hold the potential to promote functional rescue of brain lesions caused either by trauma or neurodegenerative diseases. Most of the positive modulations fostered by stem cells are fueled by bystander effects, namely increase of neurotrophic factors levels and reduction of neuroinflammation. Nevertheless, the ultimate goal of cell therapies is to promote cell replacement. Therefore, the ability of stem cells to migrate and differentiate into neurons that later become integrated into the host neuronal network replacing the lost neurons has also been largely explored. However, as most of the preclinical studies demonstrate, there is a small functional integration of graft-derived neurons into host neuronal circuits. Thus, it is mandatory to better study the whole brain cell therapy approach in order to understand what should be better comprehended concerning graft-derived neuronal and glial cells migration and integration before we can expect these therapies to be ready as a viable solution for brain disorder treatment. Therefore, this review discusses the positive mechanisms triggered by cell transplantation into the brain, the limitations of adult brain plasticity that might interfere with the neuroregeneration process, as well as some strategies tested to overcome some of these limitations. It also considers the efforts that have been made by the regulatory authorities to lead to better standardization of preclinical and clinical studies in this field in order to reduce the heterogeneity of the obtained results.

Keywords: stem cells transplantation, brain, neuronal integration and survival, adult brain plasticity, regulatory framework

INTRODUCTION

In 1868, the German biologist Haeckel coined the term "stem cell" (Haeckel, 1868), proposing in Natural Creation Story (Natürliche Schöpfungsgeschichte) that each organism came from one cell. Since then, many authors have contributed to the growing knowledge of the stem cell research field. Dunn's (1917) study is credited as the first clear evidence of successful transplantation of central nervous system (CNS) tissue into the brain of adult mammals, with clear survival of the transplanted neonatal cortex tissue (Dunn, 1917). Others followed her steps, providing more evidence of the successful introduction of new brain cells into the adult mammalian brain.

Nevertheless, the prevailing dogma at the time that the adult brain is devoid of plasticity would impair a real paradigm change, and therefore the field of cell transplantation into the brain would have to wait until the 1970s and 1980s to be really launched (reviewed in Bjorklund and Stenevi, 1985; Dunnett, 2010).

A remarkable study in the field of neural cells transplantation has been the work conducted by Perlow et al. (1979), producing the first robust evidence of functional recovery upon rat fetal brain tissue implantation in rat adult brain whose dopaminergic input to the caudate had been destroyed. Additionally, in the same year, Beebe et al. (1979) demonstrated for the first time that transplants of embryonic brain tissue originate extensive axonal networks forming synaptic connections with the host brain. Other landmark studies were the improvements in motor function of patients with Parkinson's disease (PD) observed by Lindvall et al. (1990), promoted by transplantation of grafts of fetal dopaminergic neurons (Lindvall et al., 1992), as well as the more recent observation that a patient with PD, 24 years upon being transplanted with human cells derived from embryonic ventral mesencephalon, presented graft-derived dopaminergic reinnervation of the putamen (Li et al., 2016).

Moreover, in the last decades important studies promoted the development of new sources of stem cells prone to be tested for human transplantation, such as the establishment of lines of human embryonic stem cells (ESC), and cell reprograming that culminated in the development of induced pluripotent stem cells (iPSC) and their derived cells (Gurdon, 1962; Gurdon et al., 1975; Davis et al., 1987; Thomson et al., 1998; Takahashi and Yamanaka, 2006).

These studies carried us to the concept of stem cell-based personalized medicines and to the possibility of generating potentially any type of cell from a specialized cell by reprograming it. Thus, presently, we must ask what should be the next steps to keep moving forward. Certainly, there is much to know about the stem cells' potential and safety as regenerative approaches, but there is much more to know about the limitations caused by the restricted plasticity of the adult brain, hampering the migration and functional integration of enough new graft-derived neurons, and glial cells to promote strong neuroregeneration upon brain injury. Moreover, the standardization of preclinical and clinical studies enabling comparison of results obtained in different studies and triggering a faster development of cell-based therapies is also essential.

CELL-BASED THERAPY FOR BRAIN REGENERATION

Cell therapy consists of the use of cells or cell-based products in order to replace dead or defective cells with the purpose of restoring the tissue or organ functions lost in the disease or trauma process (Lindvall et al., 2004; Kim and de Vellis, 2009). There are different types of cells to be considered as a source of cells or as precursors of neural progenitors to be used in brain regeneration (**Figure 1**), namely, ESC obtained from the inner cell mass of the embryo's blastocyst, iPSC obtained by cell reprograming, and neural stem cells that can be isolated from the nervous system at different stages of development, such as fetal and adult neural stem cells (Rippon and Bishop, 2004; Takahashi and Yamanaka, 2006; Kim and de Vellis, 2009). All of these cell types have strengths and drawbacks (Lo and Parham, 2009; Mendonca et al., 2018) and have been tested in different preclinical studies that proved them to be effective in the treatment of PD (Bjorklund et al., 2002; Wernig et al., 2008; Hargus et al., 2010), Huntington's disease (HD) (Dunnett et al., 1998; Johann et al., 2007), and Machado-Joseph disease (MJD) (Mendonca et al., 2015). Importantly, some clinical trials have also demonstrated the great potential of these therapies in diseases like PD (Piccini et al., 1999; Olanow et al., 2003; Li et al., 2016; Bjorklund and Lindvall, 2017) and HD (Freeman et al., 2000). Despite the large number of preclinical studies and some clinical assays, describing positive results with cell therapy approaches for brain transplantation, the mechanisms behind such positive modulation as well as the types of cells promoting it are not fully understood.

Understanding the Mechanism of Recovery Promoted by Stem Cell Transplantation

It has been described that the transplanted cells improve disease symptoms through the integration of new cells derived from the graft, provide trophic support to endogenous cells, and trigger immunomodulation (**Figure 2A**; Pluchino et al., 2005; Xu et al., 2011; Steinbeck and Studer, 2015). Nevertheless, the exact contribution of each of these positive mechanisms in the general improvements observed is unknown.

The functional integration of the graft-derived neurons into the host neuronal networks holds the potential to fully repair the damaged brain areas and rescue behavioral impairments. In fact, it has been suggested in different preclinical studies that the observed behavioral recovery is in part a result of the establishment of new synaptic connections between the brain and the graft (Clarke and Dunnett, 1993; Thompson et al., 2008; Cardoso et al., 2018), and clinical data support this evidence. In a remarkable study, cells derived from human embryonic ventral mesencephalon were transplanted in a PD patient, and 24 years upon the transplantation, authors observed graft-derived dopaminergic reinnervation of the putamen (Li et al., 2016). Nevertheless, most studies indicate that only a small number of graft-derived new neurons functionally integrate into the neuronal network (Cossetti et al., 2012; Forraz et al., 2013; Dunnett and Rosser, 2014). Additionally, given the described glia impairments in various conditions such as stroke, multiple sclerosis (MS), amyotrophic lateral sclerosis (ALS), PD, and Alzheimer's disease (AD) (Miller et al., 2004; Lindvall and Kokaia, 2006; Dzamba et al., 2016; Kokaia et al., 2018), promoting the replacement of these cells has been tested and resulted in important positive outcomes (Windrem et al., 2004; Ericson et al., 2005) (described in more detail in section "Glial Cells Transplantation").

Grafted cells are capable of increasing the survival and recovery of the host neurons by secreting neurotrophic factors

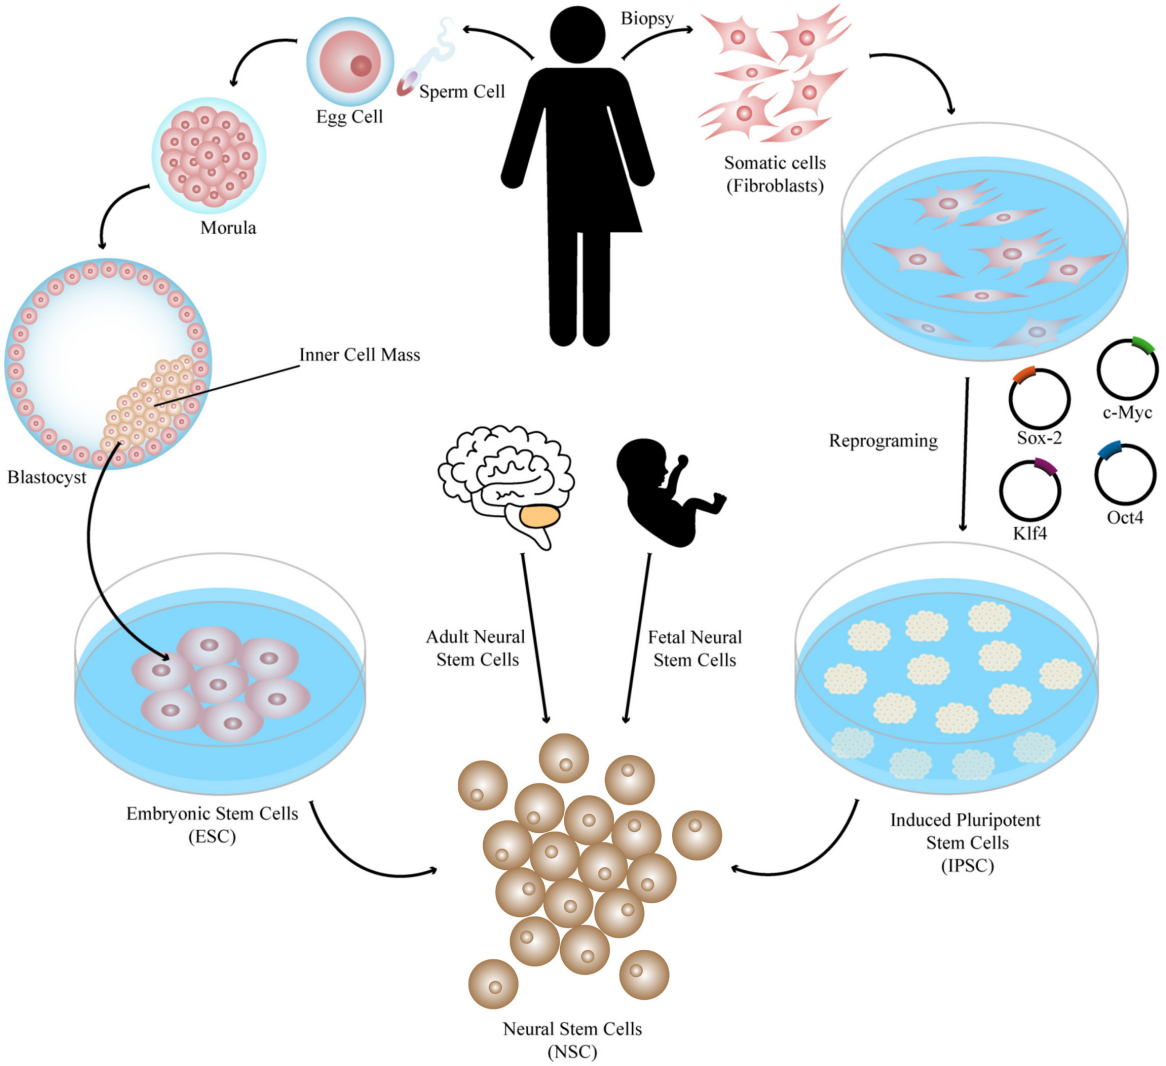

FIGURE 1 | Different sources of stem cells to be used in brain regeneration. Pluripotent stem cells such as ESC obtained from the inner cell mass of the embryo's blastocyst and iPSC obtained by cell reprograming of somatic cells by several protocols, such as expression of the reprograming factors Sox-2, Klf4, c-Myc, and Oct4, can be patterned and differentiated into different types of neural cells to be transplanted such as neural stem cells, which can also be isolated from the nervous system at different stages of development (fetal and adult neural stem cells).

such as brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and glial cell-derived neurotrophic factor (GDNF) (Wang et al., 2013; Mendonca et al., 2015; **Figure 2B**), known to positively impact neural cells by promoting survival of host neurons, and survival, migration, and differentiation of the transplanted cells (Kamei et al., 2007; Xu et al., 2011; Ma et al., 2012).

The crosstalk between transplanted stem cells and the immune system (**Figure 2C**) in the brain is another important therapeutic mechanism (Kokaia et al., 2012). In fact, some studies demonstrated that transplanted stem cells decrease neuroinflammation, reducing neuronal death. The work of Pluchino et al. (2005, 2009) provided evidence that replacement of the affected or dead cells might not necessarily be the main mechanism behind the observed recovery upon stem cells transplantation, and it is instead the immune regulation that plays an important role in the observed improvements.

Thus, the transplantation of stem cells into the brain triggers several therapeutic mechanisms, and it would be of great importance to understand which cell type produces the positive effects, how these mechanisms are regulated, and to comprehend which features might be hindering better outcomes, namely in neuronal migration and integration in neuronal circuits of adult brain.

Migration of Transplanted Cells

The brain is an organ with highly complex tissues composed of numerous different types of cells precisely organized. When damaged by trauma or disease, tissue regeneration involves complex processes. For instance, it is necessary that the

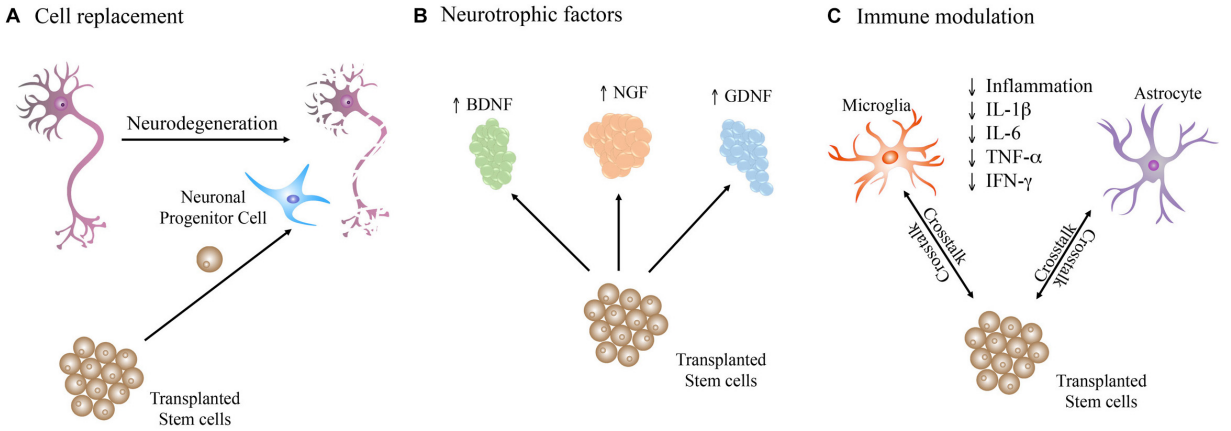

FIGURE 2 | Therapeutic mechanisms triggered by stem cells upon transplantation in the diseased brain. Stem cells may act by **(A)** directly replacing the dead and impaired neurons in the neuronal network. **(B)** Production of neurotrophic factors that support the brain cells homeostasis. **(C)** Crosstalk with brain cells, such as astrocytes and microglia, which play important roles in immune regulation, leading to a reduction in inflammation through decrease of pro-inflammatory cytokines such as IL-1β, IL-6, TNF-α, and IFN-γ.

transplanted cells be able to migrate to the affected areas in order to reach the proper and desired place and to be integrated (Fricker et al., 1999). The brain presents a limited capacity of structural repair after damage, not being able to fully recover from injuries. And in many cases, even if any amelioration of disease symptoms is visible, when the graft is analyzed it is perceived that transplanted cells into the adult brain tend to form clusters close to the site of transplantation demonstrating the low capacity of migration, thus limiting its regenerative capacity (Ladewig et al., 2014). To explain the lack of migration of the transplanted cells and also the low integration into the host brain, many several hypotheses have been suggested and investigated.

The maturity of the donor cells at the time of transplantation is an important aspect of the engraftment success. Different studies have achieved different rates of success when the transplanted cells presented different maturity. Ganat et al. (2012) used three mouse ESC cell lines, modified through the induction of specific cell stage transcription factors that mimic the *in vivo* progression of midbrain dopaminergic neuron development, namely early (Hes5), middle (Nurr1), and late (Pitx3) differentiation. These cells were transplanted into the striatum of adult unilateral 6-OHDA-lesioned immunocompromised mice, a PD mouse model. Authors observed that all cell lines, including the control cell line (parental cell line), originated robust tyrosine hydroxylase positive neurons. Nevertheless, the cell line corresponding to the earlier stage of development (Hes5) had a slightly lower yield than the other two cell lines. Nurr1 cells promoted more robust improvements on behavioral tests, indicating that cells in the middle stage of differentiation were ideal for ESC-derived dopaminergic neuron engraftment (Ganat et al., 2012). In a similar study performed by Payne et al. (2018), cortically specified neuroepithelial stem cells (cNESC) derived from iPSC were transplanted into a stroke-injured rat model 7 days post-injury, and transplantation success was analyzed 7 days later. Similarly to the previous study, the authors attempted to mimic three different stages of cell development. The cNESC were submitted to *in vitro* differentiation, promoted by the withdrawal of factors that maintained the immature state, plus BSA fraction V addition to the culture medium, establishing three different stages of cell maturation: early-differentiated cells at day 0, mid-differentiated at day 16, and late-differentiated stage at day 32 of differentiation. A higher number of graft-derived cells was observed in rats transplanted with the early and mid-differentiated cell groups. The higher number of cells observed was attributed to the survival of the initial transplanted population, demonstrating the importance of cell maturity for cell therapy success. Ladewig et al. (2014) also demonstrated that purified neurons presented increased migratory potential as opposed to neurons transplanted together with neural precursor cells. The authors found that factors such as FGF2 and VEGF expressed by neural progenitor cells, and not by mature neurons, acted as chemoattractants and were responsible for attracting neurons, reducing their migration. Authors demonstrated that chemoattraction inhibition through the pretreatment of cells to be transplanted with FGF2 and VEGF tyrosine kinase receptor inhibitor, the small molecule BIBF1120, or with neutralizing antibodies of FGF2 or receptor-blocking VEGF antibodies resulted in better migration. Furthermore, pretreated cells transplanted into the striatum of adult mice showed an increased extension of the graft, further spreading and generation of a less packed engraftment 1 week after transplantation (Ladewig et al., 2014).

Another hypothesis for the limited cell migration in the adult brain after transplantation lies in the differences between the developing and the adult brain. Looking at the nervous system dynamic composition during development, the role played by radial glial cells in this process is widely known. These cells are highly present during brain development but only a few persist in the adult brain (Barry et al., 2014) making them obvious targets of inquiry concerning possible altered processes in adult brain hindering cell migration. Briefly, the development of the CNS begins as an epithelial sheet that bends and forms

the neural tube, composed by neuroepithelial cells, and then it expands at different rates to form the different areas of the CNS. Afterward, neuroepithelial cells change into radial glial cells retaining epithelial characteristics but becoming highly elongated. Radial glial cells then either directly generate neurons or other radial glial-like cells (intermediate progenitors and basal radial glia), which might later become neurons themselves. When neurons are produced in this stage, they migrate following the radial glia fascicles as a guide from their birthplace to their final locations. Radial glial cells ultimately differentiate into astrocytes and oligodendrocytes, and only a few remain in the adult brain in neurogenic niches (Merkle et al., 2004; Bonfanti and Peretto, 2007). Therefore, radial glial cells are crucial for the correct development of the brain and play a critical role on the migration of new neurons to their right locations (Nulty et al., 2015; Kelava and Lancaster, 2016). Besides the difference in the number of radial glial cells, the environment is also totally different (Gotz et al., 2016). During embryonic development, the surrounding environment promotes neurogenesis, inhibiting gliogenesis, while in the adult brain the predominant fate is gliogenesis (Kempermann et al., 2004; Miller and Gauthier, 2007). The impact of some extrinsic neurogenesis regulators change from the developing to the adult brain, for example, in the adult brain elements such as the blood-brain barrier, astrocytes, oligodendrocytes, and neuronal networks are elements that were absent during early development, which leads to different responses to extrinsic factors like neurotransmitters and growth factors by radial glial cells. This is the case for neurotransmitters like GABA and Glutamate that show opposing effects in the embryo and in the adult brain (Haydar et al., 2000; Nakamichi et al., 2009; Giachino et al., 2014; Gotz et al., 2016).

Other structures that play a role in the limited adult brain plasticity are the perineuronal nets (PNNs), described as a layer of lattice-like extracellular matrix aggregates surrounding the soma and proximal axons and dendrites of some neurons in different locations in the CNS such as the visual cortex (Pizzorusso et al., 2002), deep cerebellar nuclei (Carulli et al., 2006), substantia nigra (Bruckner et al., 2008), and hippocampus (Hylin et al., 2013). These PNNs are composed of different extracellular matrix molecules strongly present in the nervous system, namely chondroitin sulfate proteoglycans (CSPGs), hyaluronan, and link proteins (Kwok et al., 2011). These structures appear after neurodevelopment and are thought to contribute to the stabilization of synapses, limiting neuroplasticity. Nevertheless, PNNs can be modulated (in response to learning, stress or CNS injury/diseases), usually by the action of CSPG-degrading proteases (Lemarchant et al., 2016). A study has shown that degrading PNNs using chondroitinases ABC that remove chondroitin sulfate glycoaminoglycans (side chains attached to CSPG) can render the environment of the damaged CNS more permissive to axon regeneration (Moon et al., 2001). Thus, it is important to better understand the complete role of PNNs and if modulating its function might improve the migration and integration of newborn neurons after transplant.

The limited migratory capacity of the transplanted cells might be a result of a cocktail of conditions hindering cell migration, such as the inadequate maturation stage of the transplanted cells, the absence of guiding cues, and the presence of a supporting extracellular matrix in the adult brain that blocks cell migration. Thus, it is necessary to better comprehend the role played by these processes in the restricted migration that is usually observed in cell-based therapies and to exploit ways to mitigate these issues.

Integration and Survival of New Neurons

The correct integration of graft-derived neurons into the host neuronal circuits is necessary to restore tissue functionality (Isacson et al., 1986; Steinbeck and Studer, 2015). Moreover, the transplanted cells must be capable of extending their neurites over long distances (Quadrato et al., 2014), which is quite demanding in the adult brain. Therefore, one aspect that has been addressed to increase graft integration is the axonal outgrowth, i.e., the projection of axons from the cell body to the target cells. This process is still present in the adult brain but is weakened as compared to the young brain and might contribute to the smaller regenerative capacity of the adult brain (Scheff et al., 1980; Ronn et al., 2000).

Therefore, several strategies have been tested to improve axonal outgrowths, such as genetically modifying the cells to be transplanted to overexpress described factors, exposure of donor cells to modulating compounds (**Table 1**) or making the host more prone to cell migration and axonal outgrowth (Steinbeck and Studer, 2015). Glaser et al. (2007) demonstrated that overexpression of polysialic acid (PSA) in embryonic stem cell-derived glial precursors enhances the cells' sensitivity to migration guidance cues, and recent studies also tested the effect of PSA in axonal outgrowth. PSA is a carbohydrate expressed by neural precursors in both embryonic and adult brain (Hoffman and Edelman, 1983; Rutishauser and Landmesser, 1996) and has a major involvement in important steps of brain development, such as neural precursors migration, neuronal guidance, and synapse formation (Rothbard et al., 1982; Di Cristo et al., 2007; Jiang et al., 2016). Thus, its ability to reduce cell-to-cell interactions has been explored, which, consequently, promotes tissue plasticity (Battista et al., 2014). Battista et al. (2014) observed that the overexpression of the enzymes responsible for PSA synthesis, the polysialyltransferases (PST), resulting in higher PSA levels, led to an increase in axonal growth and enhanced behavioral recovery upon cell transplantation in a PD mouse model. In fact, ESC-derived dopaminergic neuron precursor cells overexpressing PST (Nurr1/PST) and control cells were transplanted into the striatum of 6-OHDA-lesioned mice. Control cells failed to produce any behavioral recovery, whereas with augmented PSA expression, the same number of cells produced significant recovery on PD motor impairments. Two months post-transplantation Nurr1/PST cells presented higher graft survival, more dopaminergic neuronal processes (dendrites and axons), increased axonal outgrowth, and increased synaptic marker synapsin that was correlated with functional recovery. Overall, these data demonstrate the crucial role of axonal outgrowth and graft-host innervation in the behavioral recovery.

Axonal growth in the CNS is often inhibited by molecules associated with adult myelin such as Nogo (Chen et al., 2000), myelin-associated glycoprotein (MAG)

CSPGs, chondroitin sulfate proteoglycans.

(McKerracher et al., 1994), and oligodendrocyte myelin glycoprotein (OMgp) (Kottis et al., 2002). Poplawski et al. (2018) recently investigated the interaction of adult myelin with axons extending from stem cell grafts. Plating different types of cells in different substrates, they confirmed that neurite growth from adult dorsal root ganglion (DRG) is inhibited by myelin and increased by laminin. Thus, different studies explored the potential of neutralizing these interactions in order to increase axonal outgrowth. Konishi et al. (2004) showed that inhibiting the anaphase-promoting complex (APC – highly expressed in postmitotic neurons and essential for cell cycle transition) by knockdown of Cdh1 (required for APC activity) enhanced axonal growth in primary cerebellar granule cells from postnatal day 6. Furthermore, they tested these cells' ability to grow axons over myelin substrate. Here, axonal growth in control cells was significantly inhibited whereas the knockdown of Cdh1 reverted the myelin inhibition on axonal growth.

Lipid rafts have also been investigated when it comes to axonal growth and guidance. Lipid rafts are membrane microdomains enriched in cholesterol, glycosphingolipids and many proteins, namely proteins involved in cell signaling (Pike, 2003). As these lipid rafts are important for signaling transduction, they also play a role in neural development, namely the spatial and temporal control mediated by extracellular signals on axonal growth and guidance refereed by extracellular cues (Guirland et al., 2004; Kamiguchi, 2006; Guirland and Zheng, 2007). Age-associated loss of cholesterol in plasma membranes leads to loss of membrane lipid rafts, and consequently a decrease in its function (Egawa et al., 2016). Thus, it is important to investigate whether the age-related loss of membrane lipid rafts might play a critical role in axonal growth and guidance of the transplanted cells in the adult brain. Overall, different approaches have been tested to improve axonal elongation while trying to increase the success of cell-based therapies.

Besides the modulators assessed in this review (**Table 1**), several other molecules and mechanisms play an important role in neuronal migration and integration, such as neurotransmitters (Platel et al., 2010), neurotrophic factors (Waterhouse et al., 2012), and even pathological situations such as neuroinflammation (Whitney et al., 2009; Ryan and Nolan, 2016), which should also be taken into consideration.

Glial Cells Transplantation

Glial cells are crucial for maintaining brain homeostasis, providing support and protection to neurons. Thus, cell therapies aiming at cell replacement in the brain, besides integration of new neurons into the neuronal network, should also consider promoting glial cells replacement, given the aforementioned impairment of these cells in several diseases (Miller et al., 2004; Lindvall and Kokaia, 2006; Dzamba et al., 2016; Kokaia et al., 2018) and also because upon transplantation glial cells promote brain functional recovery, namely by increasing axonal myelination, clearing aggregated proteins, reducing reactive oxygen species, and increasing survival, proliferation, and neural differentiation (Almad and Maragakis, 2012; Kokaia et al., 2018).

Brain trauma and diseases like MS, AD, PD, and leukodystrophy impair the production of new oligodendrocytes and their mediated axonal remyelination process (Bartzokis, 2004, 2011; Braak and Del Tredici, 2004; Franklin and Goldman, 2015). Windrem et al. (2004) showed that after oligodendrocyte progenitor cells transplantation into the forebrains of a leukodystrophy mouse model, the transplanted cells were capable of wide migration and differentiation into astrocytes and oligodendrocytes, showing increased myelin production and axonal myelination 12 weeks post-transplantation, resulting in phenotype improvement. Moreover, Piao and collaborators demonstrated that human ESC-derived oligodendrocytes upon transplantation into the brain of a rat model of radiation-induced demyelination are capable of migrating throughout white matter tracts, resulting in both structural and functional recovery (Piao et al., 2015).

In AD, astrocytes promote neuroprotection by reducing nitric oxide production mediated by microglia (Vincent et al., 1997) and by capturing and degrading Aβ plaques (Koistinaho et al., 2004). Nevertheless, the inability to

continuously degrade these species confers aberrant and cytotoxic properties to astrocytes. Pihlaja and colleagues demonstrated that the transplantation of astrocytes into AD mice expressing human Aβ mediated a 70% reduction of Aβ plaques (Pihlaja et al., 2008) through proteolytic mechanisms (Pihlaja et al., 2011), demonstrating the ability of astrocytes transplantation to reduce the burden of Aβ plaques in the brain of AD mice. Moreover, the transplantation of glia restricted precursors (GRP) in the spinal cord of an ALS rat model, expressing human mutant SOD1, resulted in successful migration, differentiation, and integration of mature astrocytes. These increased the mice lifespan and survival of the motor neurons by neuroprotection mediated in part by the primary astrocyte glutamate transporter GLT1 (Lepore et al., 2008), demonstrating the potential therapeutic potential of astrocytes transplantation for ALS treatment. The transplantation of glial cell progenitors into spinal cord has also been shown to trigger neuroprotection in ALS by Haidet-Phillips and Maragakis (2015). Moreover, the co-transplantation of NSC with astrocytes into the ischemic striatum of a mouse model of stroke (middle cerebral artery occlusion) resulted in better outcomes when compared to transplantation of NSC alone, namely higher survival, proliferation, and neural differentiation of the transplanted NSC (Luo et al., 2017).

In a different approach, Thomsen et al. (2018) targeted cortical neurons through the transplantation of human cortical-derived neural progenitor cells engineered to secrete GDNF into the cortex of a transgenic mouse model of ALS ($SOD1^{G93A}$). The transplanted cells migrated and differentiated into GDNF-releasing astrocytes, which resulted in motor neuron protection, delayed pathology, and extended animal lifespan. Ericson et al. (2005) have previously employed a similar strategy for PD treatment through the transplantation of rat astrocytes, transduced with lentivirus encoding for GDNF, into the striatum or substantia nigra of an adult rat model of PD. Results indicate that GDNF-expressing astrocytes maintained GDNF expression for 12 weeks and promoted neuroprotective effects on nigral tyrosine hydroxylase-positive cells. Moreover, Lundberg et al. (1996) also demonstrated that the transplantation of DOPA-secreting astrocytes into the striatum of a PD rat model (6-hydroxydopamine unilaterally lesioned rats) resulted in significant reduction of motor impairments 2 weeks post-transplantation, providing evidence of the therapeutic potential of *ex vivo* modifying glia to secrete L-DOPA, a keystone neurotransmitter in PD treatment, before transplantation.

Altogether, it has been demonstrated that the transplantation of glia and glial progenitors to improve the survival of other transplanted cells and trigger neuroprotective mechanisms has the potential to be used in the treatment of neurodegenerative diseases.

Impact of Comorbidities in Stem Cell-Based Therapy Outcomes

Most preclinical studies using cell-based therapies have been performed without taking into account comorbidities, which might influence the outcomes of therapeutic strategies (Hermann et al., 2013; Sandu et al., 2015; Pradillo et al., 2017). Evidence indicates that neuroinflammation is one possible common pathway to several diseases, being fueled by conditions such as hypertension, diabetes, atherosclerosis, PD, HD, AD, and aging (Nguyen et al., 2002; Denes et al., 2012; Sandu et al., 2015). Aging is one of the most common risk factors for CNS-related diseases affecting brain function (Mattson and Arumugam, 2018). As the brain ages, several cellular and molecular functions become impaired (Niccoli and Partridge, 2012), leading to multiple modifications such as extensive neuronal loss, decreased neurotransmitters and their receptors levels, impaired myelination, reduced neurotrophic factors levels (Yang et al., 2012; Roozbehi et al., 2015), increased neuroinflammation (Currais, 2015; Deleidi et al., 2015), and decreased neurogenesis (Jinno, 2016) and brain plasticity (Badan et al., 2003). Considering that cell therapies applied to the treatment of brain diseases are frequently used to treat age-related diseases, such as neurodegenerative diseases with late-onset and stroke, aging effects in the therapeutic outcomes must be considered. As described above, the microenvironment of the aged brain is refractory for cell migration, proliferation, and differentiation, hindering the success of the transplanted cells (Della Porta et al., 2014; Conboy et al., 2015). Thus, in order for cell-based therapy preclinical tests to be clinically relevant, they must also be performed in aged animals so as to better predict the *in vivo* efficacy and capacity of the transplanted cells to promote beneficial effects (Popa-Wagner et al., 2014; Tatarishvili et al., 2014; Sandu et al., 2017).

Impact of Combined Therapies in Stem Cell-Based Therapies Outcomes

Given that diseases are frequently multifactorial, combining different therapeutic strategies directed to different molecular and cellular targets may potently improve outcomes. Therefore, a promising therapeutic strategy is the combination of cell transplantation with drugs that act at comorbidities or enhance graft integration and corresponding brain regeneration. An interesting example is the combination of cell transplantation with the growth factor granulocyte colony-stimulating factor (G-CSF) that induces stem cell mobilization. Popa-Wagner et al. (2010) have shown that G-CSF administration after stroke in aged rats enhances neurogenesis and motor function parameters. Balseanu et al. (2014) demonstrated in a stroke rat model that daily intravenous injection of G-CSF led to robust and consistent improvement of neurological functions, which in combination with a single intravenous administration of mesenchymal stromal cells (MSC) resulted in significantly higher density of new blood vessels in the infarct core. However, the combination of G-CSF with bone marrow-derived mononuclear cells (BM MNC) also for stroke treatment led to no advantage over G-CSF treatment alone, suggesting that different outcomes might be achieved depending on the type of cells used (Buga et al., 2015). Sanchez-Ramos et al. (2009) tested G-CSF combination with human umbilical cord blood cell transplantation in a transgenic mouse model of

AD and observed increased neurogenesis, reduced expression of amyloid proteins and inflammation, which resulted in an overall improvement of cognition in these animals. Similarly, another group tested the effect of G-CSF combined with human umbilical cord blood cells (hUCB) on traumatic brain injury (TBI), which reduced neuroinflammation and hippocampal cell loss, enhanced endogenous neurogenesis, and improved motor function, attaining better results than hUCB or G-CSF treatments alone (Acosta et al., 2014). Finally, the combination of statins, such as atorvastatin or simvastatin [promoting reduction of oxidative stress in the brain and clearing disease-causing proteins (Barone et al., 2011; Schultz et al., 2018)], with bone marrow stromal cells and MSC in a rat model of TBI, also resulted in increased cellular proliferation and differentiation, enhanced vascular density and neurological improvements, and behavioral amelioration (Mahmood et al., 2007, 2008).

Overall, the results obtained with combined therapies, including cell transplantation for brain regeneration and neuroprotection, indicate that better outcomes can be attained with this strategy.

STANDARDIZATION OF PRECLINICAL AND CLINICAL STUDIES – THE REGULATORY FRAMEWORK IN THE PARTICULAR CASE OF CELL-BASED THERAPIES

The heterogeneous results obtained upon cell transplantation in some patients (Bachoud-Lévi et al., 2006; Cicchetti et al., 2009; Keene et al., 2009; Mendonca et al., 2018) and the increasing notion that the standardization of the procedures in cell transplantation field would accelerate development and guarantee the safety of new therapeutics (Bachoud-Lévi and Perrier, 2014) resulted in the establishment of several guidelines.

Cellular and gene therapies as well as tissue-engineered products, commonly known as advanced therapy medicinal products (ATMPs), are complex pharmaceutical products that represent a unique and challenging scientific and regulatory framework. Accordingly, to the regulatory framework scope, a cell-based medicinal product must contain viable human cells (of allogenic or autologous origins) that underwent a manufacturing process and may be combined with non-cellular components (such as scaffolds or matrixes) or be genetically modified (CHMP, 2008a). The major concern of regulators is to ensure the safety of these products for the patients, the population, and the environment, as well as to guarantee the efficacy of such treatments and their rapid entry into clinical practice to treat diseases that very often have no other therapeutic alternative (Lapteva et al., 2018).

The creation of regulations and guidance regarding ATMPs are under the responsibility of the European medicines agency (EMA) and the food and drug administration (FDA), in Europe and the United States, respectively. In particular, the advanced therapies are regulated by the committee for advanced therapies (CAT) and the office of cellular, tissue and gene therapies (OCTGT), from the EMA and FDA, respectively. Despite some differences, there are efforts for the harmonization of procedures between all markets under the international council for harmonization (ICH) of technical requirements for pharmaceuticals for human use, composed by the EMA, FDA, and the Japanese regulatory agency (Gee, 2018).

In this section, we review the processes and regulatory particularities regarding cellular and gene therapy from early manufacturing setting, to the definition of non-clinical profiling, and extrapolation to clinical assessments. The inclusion in this review of regulatory guidelines regarding gene therapy is justified by the common use of genetic modifications in cell-based products.

Risk Evaluation

The complexity of these products makes the creation of a single regulatory strategy for the evaluation of risk difficult. Both the EMA and FDA recommend a risk-based approach and a case-by-case analysis for each product regarding their risk assessment. Not only the cellular nature but also the *ex vivo* manipulation, storage and shipment conditions, and pre-application procedures are a source of variability. Thus, EMA suggests that the risk analysis should cover the entire manufacture and non-clinical and clinical assessment of the product. The risk posed by cell-based therapies is dependent on the origin of the cells, the manufacturing process, the non-cellular components, and the therapeutic application, namely the action mechanism of the final product. The risk of cross-contamination of the product in any stage of manufacture is of utmost importance since it can threaten the quality of the final product. In addition, the environmental impact of the reagents used in cell culture must also be assessed (CHMP, 2008b; CAT/CPWP, 2013). The data presented when submitting a clinical trial application or a marketing authorization application must have in consideration the risks presented in risk management plan so that the safety of the product is assured (EMA, 2018).

From a clinical point of view, the main concern regarding cell-based medicinal products is the risk of tumor formation. Hence, cells must not be transplanted in a pluripotent state, which is associated with increased tumor formation. The *in vivo* microenvironment may also induce the cells to acquire tumor-like characteristics and, in turn, cells might induce host-derived tumors. The use of cells with short cell culturing periods is encouraged, given that cell manipulation may cause mutations responsible for tumor formation or loss of therapeutic potential. Moreover, the use of viral vectors for cell reprograming and gene correction might be responsible for the activation of oncogenes, depending on the site of gene insertion. The administration route of the cells is also crucial; intravenous administration is discouraged since cells can aggregate, causing emboli, or can accumulate in undesired peripheral organs, such as lungs, spleen or liver. The immune activation promoted by the cells is also a major issue that needs to be evaluated. Taken together, these represent risks associated with the use of cell-based products that strongly impact the success of these

therapies (Herberts et al., 2011). The type of tests used to characterize the cells and their effects is a critical issue as well. For example, the establishment of tests for the evaluation of a cell's potency, i.e., their biological activity, is particularly demanding given the frequent multiple action mechanisms of the cell-based products that might differ from product to product, and therefore regulatory entities adopted a flexible strategy. EMA, for example, allows the establishment of a product development adapted to its specificities, without a rigid framework with predefined requirements, and the FDA released technical recommendations although they are not mandatory (CBER, 2011; Pimpaneau et al., 2015).

Manufacturing Process

It is often difficult to make the manufacturing process of cell-based medicinal products comply with the regulatory good manufacturing practices (GMP); nevertheless, these processes should be able to characterize, as full as possible, the product at several stages of manufacture and ensure product quality and yield at defined stages. The development of standard operating procedures (SOPs) is critical and the creation of in-process checkpoints to validate product quality and consistency is crucial (CBER, 2008; Carpenter, 2017; EC, 2017, 2018).

For example, in the manufacture of iPSC-derived products, the reprograming *per se* already represents a considerable manipulation of the cells, and it requires the use of manufacturing grade (instead of research grade) reagents that should also be used in the expansion and differentiation steps. The safety testing for infections, such as human immunodeficiency virus (HIV), of the starting materials is essential. For iPSC, the interclone variability after the reprograming should also be taken into consideration, and therefore the selection of the adequate clone for production is crucial since the reprograming could lead to severe karyotype abnormalities and mutations,

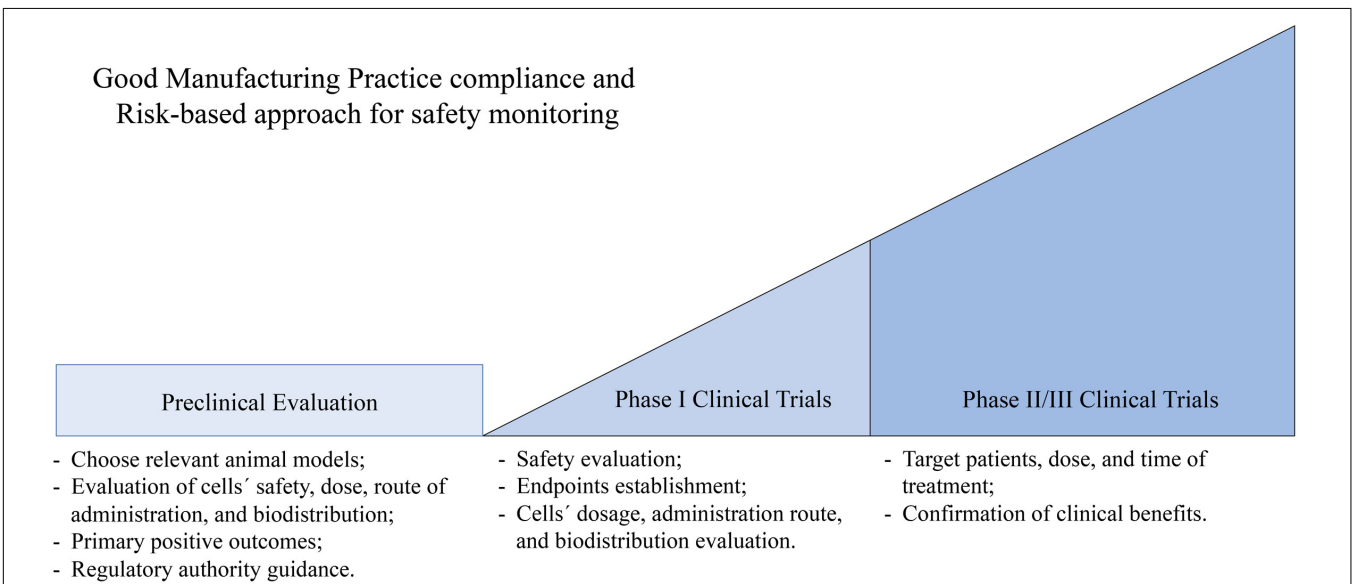

FIGURE 3 | Illustration of some golden checkpoints in the preclinical and clinical evaluation process of cell-based therapies. At a preclinical level when testing cell-based therapies it is important to (i) choose a relevant disease model, (ii) assess cells' safety, dose, biodistribution, and ideal route of administration, (iii) establish primary positive outcomes, and (iv) enter conversations with the regulatory authority. Considering phase I clinical trials, the key points are (i) safety evaluation, (ii) establishment of clearly defined endpoints, and (iii) cells' dosage, administration route, and biodistribution evaluation. In phase II/III clinical trials it is important to establish (i) target patients, dose, and time of the treatment, (ii) clear primary and secondary endpoints, and (iii) sample size should provide statistical power to the endpoint evaluations.

TABLE 2 | Clinical trials using pluripotent stem cells-derived cells in nervous system.

CT	Condition/phase	Title	Type of cells	Sponsors and collaborators
NCT03482050	Amyotrophic lateral sclerosis phase I/IIa	A study to evaluate transplantation of astrocytes derived from human embryonic stem cells in patients with amyotrophic lateral sclerosis (ALS)	AstroRx: Astrocytes derived from human embryonic stem cells	Kadimastem
NCT03119636	Parkinson's disease phase I/II	Safety and efficacy study of human ESC-derived neural precursor cells in the treatment of Parkinson's disease	Embryonic stem cells-derived neural precursor cells	Chinese Academy of Sciences
NCT02452723	Parkinson's disease phase I	A study to evaluate the safety of neural stem cells in patients with Parkinson's disease	Parthenogenetic neural stem cells*	Cyto Therapeutics Pty Limited
NCT02302157	Spinal cord injury phase I/IIa	Dose escalation study of AST-OPC1 in spinal cord injury	Embryonic stem cell-derived oligodendrocyte progenitor cells	Asterias Biotherapeutics, Inc.

*CT, clinical trial number; *, derived from unfertilized oocytes; AST-OPC1, asterias -oligodendrocyte progenitor cell 1.*

which may interfere with the efficiency and safety of the final product. Thus, extensive characterization of phenotype, karyotype, and genotype of these cells is mandatory to ensure compliance with GMP. Furthermore, the expansion, cryopreservation, and differentiation protocols may also affect the quality, safety, and efficacy of the final product. Thus, valid biomarkers for each cell state are imperative; nevertheless, these biomarkers are not yet specified for any cell type used and strongly depend on a case-by-case analysis and on the desired characteristics of the final product (Carpenter, 2017; Stacey et al., 2018).

Non-clinical Evaluation

Non-clinical evaluation of any medicinal product is a crucial step in their development to establish important clinical features such as pharmacodynamics, pharmacokinetics, or toxicology. These tests should be designed in order to establish the initial safe cell doses to be used in humans, the ideal route of administration, the biodistribution of the cells (accessing the organs more susceptible to the therapy/toxicity), and to assess potential side effects (CHMP, 2008a; CBER, 2013b; **Figure 3**).

The correct design of non-clinical testing for cellular therapies should start with the selection of a relevant animal model, which should mimic as closely as possible the pathology in humans, and should allow precise characterization of the treatment. The use of at least two different animal models, desirably from different species, is strongly encouraged. For a clear-cut assessment, animals from the Hominidae family may represent a good model to be used. Nevertheless, the use of the animal model must be clearly justified from a scientific point of view and the limitations of the use of such a model must be acknowledged (Salmikangas et al., 2015).

Another important aspect to be evaluated at this stage is the tumorigenicity of the cell therapy *in vivo*. The ability of the cells to migrate, uncontrollably grow or to differentiate should be defined. The non-clinical studies must also determine the long-term survival of the cells, their capacity to induce long-term toxicity, genotoxicity, and reproductive/developmental toxicity. In this regard, there are no specific recommended tests, and the analysis should depend on the product, its intent, and the risk management plan (Salmikangas et al., 2015).

Overall, this stage of testing of the cell-based medicinal product must, above all, indicate the safe use of this therapy in humans. Moreover, signs of its efficacy may be given, which can be demonstrated by the correct localization of the cells *in vivo*, their correct differentiation on the cell type desired, the improvement of the pathological characteristics of the disease (such as reduction of neuronal loss in neurodegenerative diseases), and by the alleviation of the animal's phenotype (Salmikangas et al., 2015; Lapteva et al., 2018; Stacey et al., 2018).

The preclinical testing of a medicinal product may be quite costly. Thus, the initiation of an early conversation with regulatory authorities to seek their recommendation and input on the study design, as well as desired endpoint evaluations, becomes of the highest importance. Noteworthy is the fact that, at this point, the EMA and FDA have some regulatory differences. The EMA requires full compliance of GMP by the time the cell therapy is ready for Phase I human clinical trials. As for FDA regulations, their flexibility allows products not to be fully GMP compliant at early stage clinical trials (Carpenter, 2017).

Clinical Studies

The complexity and invasive nature of cellular therapies define that all clinical testing must be performed in patients. The phase I trials should be designed taking into consideration the limitations of the preclinical tests performed and enroll a minimal number of patients sufficient to confirm the safety and efficacy. Standardization of all medical procedures, including administration route, dosage, and evaluation parameters, should be established at this stage and maintained throughout the clinical trial. Furthermore, the assessment of the cell's behavior in the human body regarding its migration and differentiation capacity is also important. The results obtained at this stage must support and justify the testing of the medicinal product in a larger cohort of patients (CBER, 2013a; Salmikangas et al., 2015). Phase II/III clinical trials must clearly define the target population, dose and time of the treatment, the primary and secondary endpoints to be assessed during the clinical trial, and patient specificities, such as concomitant medication allowed. Moreover, the sample size must be sufficient to give statistical power to the observations and the endpoint evaluation enough to justify the attribution of marketing authorization by the regulatory authority (Salmikangas et al., 2015).

Several clinical trials using ESC- or iPSC-derived cells to treat a wide range of conditions are currently ongoing. **Table 2** summarizes ongoing clinical trials using these types of cells in nervous system conditions. To this day, the approval of cellular therapies is somehow limited and, when granted, cases of withdrawal after short periods of time occurred (Carpenter, 2017).

CONCLUSION

Presently, there are different types of stem cells and their derived neural progenitors prone to being tested in cell-based therapies for brain disorders treatment. Preclinical studies have demonstrated the undeniable potential of these cells to promote functional recovery of neurodegenerative diseases as well as other brain conditions through cell replacement and neuroprotection. Nevertheless, the integration of new functional neurons into adult neuronal circuits is a demanding and not yet fully understood process. A better comprehension of the modulating factors of the route taken by the graft-derived neurons during the migration, differentiation, and integration into the adult brain is of great importance in order to identify potential players and mechanisms that might be hindering a wider integration of new neurons and the restoration of neuronal circuits.

On the other hand, the higher complexity of cell-based products represents a challenge, since the manufacturing process becomes more difficult to standardize as compared with the

classical chemical compounds or even with biologic products with more straightforward manufacturing processes and simpler therapeutic mechanisms. Nevertheless, the EMA and FDA have established a regulatory framework guiding procedures of preclinical and clinical assays to reduce heterogeneity, which is expected to enable comparison of results between studies.

Great hopes are set in cell-based therapies applied to neuroregenerative medicine, and although many questions are still to be answered these therapies have the potential to become the next generation of medicinal products.

Pericytes are functional components of the neurovascular unit (NVU) that are located around the blood vessels, and their roles in the regulation of cerebral health and diseases has been reported. Currently, the potential properties of pericytes as emerging therapeutic targets for cerebrovascular diseases have attracted considerable attention. Nonetheless, few reviews have comprehensively discussed pericytes and their roles in cerebrovascular diseases. Therefore, in this review, we not only summarized and described the basic characteristics of pericytes but also focused on clarifying the new understanding about the roles of pericytes in the pathogenesis of cerebrovascular diseases, including white matter injury (WMI), hypoxic–ischemic brain damage, depression, neovascular insufficiency disease, and Alzheimer's disease (AD). Furthermore, we summarized the current therapeutic strategies targeting pericytes for cerebrovascular diseases. Collectively, this review is aimed at providing a comprehensive understanding of pericytes and new insights about the use of pericytes as novel therapeutic targets for cerebrovascular diseases.

INTRODUCTION

Pericytes are among the major components of vascular composition. They are located along the capillary walls at intervals and possess numerous biological functions and characteristics. In particular, pericytes exhibit migratory, immune, phagocytic, and cytoprotective functions as well as stem cell potential and are involved in tissue repair (Attwell et al., 2016). In the CNS, pericytes participate in brain self-regulation, which is vital for blood vessel formation, maintenance of BBB integrity, regulation of cerebral blood flow, and coagulation (Santos et al., 2018). Additionally, pericytes are involved in the pathogenesis and development of various diseases. For instance, under ischemic conditions, pericytes constrict the capillaries in rigidity and hinder the flow of blood cells, which eventually prevents microcirculatory reperfusion even if the plaque has been removed in

stroke disorders (Beazley-Long et al., 2018). Furthermore, studies have indicated that pericytes are associated with other neurovascular disorders, including WMI, cerebral hemorrhage, and hypoxic–ischemic brain damage (Hill et al., 2014). Therefore, after gaining a comprehensive understanding of the characteristics of pericytes and the in-depth studies on their relationship with diseases, scientists have regarded pericytes as good targets for the treatment of diseases. Although pericytes have been the subject matter of various studies, only few reviews have focused on discussing pericytes in cerebrovascular diseases, and data on the characteristics of pericytes and their use as therapeutic targets remain insufficient (Lange et al., 2013). Thus, we decided to conduct a review that firstly provided sufficient knowledge about this topic.

To provide a comprehensive understanding of pericytes, in this review, we summarized the biological characteristics of pericytes in detail, including their research history, distribution, isolation and culture methods, identification strategies, and biological functions. In addition, we elucidated the roles of pericytes in the pathogenesis of cerebrovascular diseases, including hemorrhagic brain injury, WMI, hypoxic–ischemic brain damage and other neurovascular dysfunctions, and clarified the progress in the treatment of cerebrovascular diseases targeted to pericytes.

BIOLOGICAL CHARACTERISTICS OF PERICYTES

Research History of Pericytes

The research history of pericytes covers several centuries. In 1873, pericytes were first discovered by Charles Rouget, who was investigating on capillary contractility. Later in 1923, Krogh named them "Rouget cells." In 1929, the concept of pericytes was formally proposed by Zimmerman, who described their relevant biological characteristics. In the 1960s, Majino et al. showed that pericytes are derived from the mesenchyme of the mesoderm and are widely distributed in the capillaries of vertebrates (**Figure 1**; Dore-Duffy and Cleary, 2011). Subsequently, accumulating studies had investigated the source and destination of pericytes. Majino et al. indicated that CNS pericytes are mainly derived from the mesenchymal stem cells of the mesoderm and the neural crest cells of neuroepithelial origin (Faal et al., 2019). Cell transplantation experiments on chicken embryos have revealed that the pericytes of the forebrain are mainly differentiated from neuroepithelial cells (Etchevers et al., 2001), whereas the pericytes of the midbrain, brainstem, and spinal cord are derived from the mesoderm (Kumar et al., 2017). Moreover, human brain pericytes also contain a large amount of acid phosphatase and have a phagocytic function, suggesting that pericytes could be originated from macrophages (Barreto et al., 2019). Further studies have shown that pericytes have rich destinations, which can differentiate into fat, muscle, cartilage, and bone cells as well as other types, indicating that pericytes have stem cell characteristics (Ahmed and El-Badri, 2018). Collectively, overall findings indicate that pericytes can be derived from various origins and are capable of producing diverse cells.

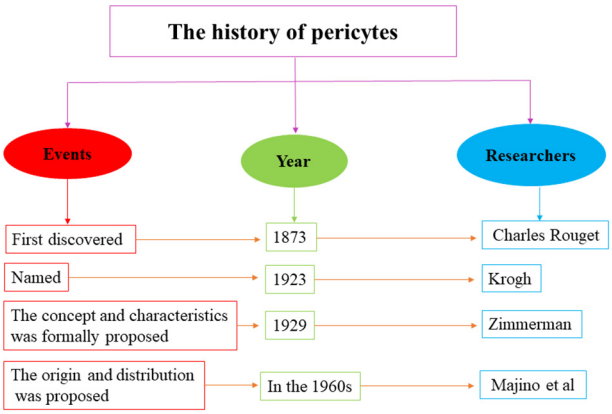

FIGURE 1 | The research history of pericytes. The research history of pericytes covers several centuries, which ranges from first discovery in 1873 to further study in the 1960s.

Morphology, Distribution, and Communication of Pericytes

Pericytes are polymorphic and usually appear as star-shaped or flat cells. The cell body of pericytes is spherical or oval and contains a large, round nucleus. The cytoplasm of pericytes contains a large number of organelles and mitochondria that can synthesize proteins, in addition to several lysosomes, which make the outer surface of pericytes appear to be granular (Jindatip et al., 2012). Studies have revealed that pericytes are constricted cells that spaced apart on capillary walls and closely linked to capillary endothelial cells. Besides, pericytes are widely distributed in the large blood vessels of the entire body, which located between the intima and adventitia of the microvascular and capillary walls, and mainly cover the capillaries, arterioles, and venules (Mazurek et al., 2017). Although pericytes are distributed throughout all organs, the number of CNS pericytes, which are important cellular components of the NVU and the BBB, is higher than that of pericytes in other organs (Armulik et al., 2011). In capillaries, pericytes are located between the endothelial cells and basement membrane, together with the endothelial cells, pericytes form a barrier between the blood vessels and interstitial space, such as the BBB, retinal blood barrier, and the like (Hall et al., 2014). Pericytes extend long protrusions along the longitudinal axis of the blood vessels that branch into two or three longitudinal and annular protrusions surrounding the blood vessels. The longitudinal protrusions are distributed along the longitudinal axis of the blood vessels, whereas the annular protrusions are perpendicular to the longitudinal axis. The neurites extended by pericytes contain large amounts of tubulin, whereas those on the surface of cell membranes that contact the endothelial cells contain dense microfilament-rich bands (Sava et al., 2017). However, when observed under a transmission electron microscope, pericytes are almost invisible, and the pericytes in mature capillaries have a disc-shaped nucleus surrounded by a small amount of cytoplasm (Liu et al., 2016). Based on the distribution and morphological

characteristics of pericytes, the transmission of information between pericytes, and other cells requires the formation of specific structures. For instance, the communication between pericytes and endothelial cells requires the formation of gap junctions, adhesion plaques, and structures such as peg–socket boxes (periosteal cells forming staples and wrapped by nail grooves formed by endothelial cells). The discontinuity of the basement membrane and the incomplete coverage of pericytes allow the endothelial cells to form a broad connection with the glial border membrane, which in turn interacts with astrocytes, and together they form the NVU (Hartmann et al., 2015). In addition, *in vitro* studies showed that pericytes could express occludin, claudin-12, and zona occludens-1 and -2 on the cell border, suggesting that tight junctions can be formed between pericytes (Shimizu et al., 2008).

Identification of Pericytes

Pericytes express a series of protein molecules, including α-SMA (Alarcon-Martinez et al., 2018), nestin (Muñoz-Fernández et al., 2018), vimentin (Bandopadhyay et al., 2001), NG2 (Sato et al., 2016), aminopeptidases A and N (Winkler et al., 2018), intercellular adhesion molecule-1 (ICAM-1) (Fan et al., 2019), vascular cell adhesion molecule-1 (Winkler et al., 2018), platelet-derived growth factor alpha and beta receptors (PDGFR-α and -β) (Wilson et al., 2018), CD34, CD146 (MCAM), CD4, CD11b (Wang et al., 2019), regulator of G-protein signaling 5 (RGS5) (Berger et al., 2005), stem cell antigen-1 (Kunisaki, 2019), and major histocompatibility complex classes I and II (Rink et al., 2017), without the expression of von Willebrand factor (Yin et al., 2019), platelet endothelial cell adhesion molecule (Nikolajsen et al., 2016), and glial fibrillary acidic protein (Winkler et al., 2018). Brain pericytes also express ATP-sensitive potassium channel protein Kir6.1 (**Table 1**; Bondjers et al., 2006).

Nonetheless, due to the heterogeneity of pericytes, the surface markers of pericytes may be different even in different areas of the same tissue and even in different stages of differentiation or different pathophysiological states of the same pericytes (Dias Moura Prazeres et al., 2017). In addition, the surface markers of pericytes may not be specific for pericytes. For example, PDGFR, the common marker for pericytes, can also be expressed in fibroblasts and smooth muscle cells (Muñoz-Fernández et al., 2018). Therefore, in view of the deficiency of specific immunological molecular markers for pericytes, current approaches to pericytes identification are mainly based on morphology and the combined application of a series of positive and negative immunological markers. For instance, to identify musculoskeletal pericytes of vascular origin, researchers use combined detection of markers for CD146, NG2, α-SMA, and PDGFR expression without CD31, CD34, CD45, and CD144 (Tonlorenzi et al., 2017).

Culture of Pericytes

The heterogeneity of pericytes makes their identification complicated and difficult. It is easy to mix other cells (e.g., adventitial cells) with pericytes after isolation. The traditional methods for pericytes isolation include sequential sieve technique and immunomagnetic bead sorting. With the sequential sieve technique, the brain tissue is first converted into a cell suspension and sequentially passes through a sieve with different pores to separate the pericytes. This method requires initial separation of the microvascular fragments, which is cumbersome. Moreover, the grinding time is difficult to control, which may result in physical damage to the microvessels. Additionally, the separated microvascular fragments are usually not conducive to progeny cells climbing out, and cell viability is weak (Boroujerdi et al., 2014). In contrast, immunomagnetic bead sorting uses antibodies for the markers of pericytes linking to the magnetic beads to separate pericytes from other cells. The commonly used markers of pericytes include NG2, α-SMA, desmin, and PDGFR-β, which vary depending on the species, tissues, and developmental stages of the origin. Similarly, this method consists of a complicated process and is costly. Moreover, the effect of separation and culture is not ideal (Primo and Arboleda-Velasquez, 2016).

Considering that traditional culture approaches have their advantages and disadvantages, recent investigations have improved the technique of separating the pulmonary microvascular pericytes through the use of mechanical shearing, enzymatic digestion, mesh filtration, and lysis by red blood cell lysate to obtain a purer microvascular fragment. Given that pericytes can secrete TGF-β to inhibit endothelial cell growth, researchers have acquired pulmonary microvascular progeny cells with a purity of 100% by extending the natural purification time. Compared with the two former methods, this method avoids damage to the microvascular fragments during grinding and has a simpler operation process, thereby reducing the procedural time and cost. Additionally, the progeny cells are easily derived from the microvascular fragments, and cell survival probability is increased. Moreover, this approach solves endothelial cell contamination, which is the main problem when isolating pericytes by using microvascular fragments

(Wertheim et al., 2019). Currently, isolation and *in vitro* culture technologies for the retinal, spinal, lung, and brain microvascular pericytes are relatively mature.

FUNCTION OF PERICYTES

As one of the most important components of the blood vessels, pericytes carry out various physiological functions. The functions of pericytes can be roughly summarized as follows.

Regulation of Vascular Genesis and Microecology

Studies have shown that the formation of new blood vessels and the maintenance of vessel wall stability require a sufficient number of pericytes (Bergers and Song, 2005). Pericytes are the dominant cells in regulating angiogenesis, primarily via secretion of different signals. The process of angiogenesis involves four major steps (Diaz-Flores et al., 2017). In the initial stage of angiogenesis, pericytes promote endothelial cell maturation and neovascular sprouting by secreting vascular endothelial growth factor and interleukin-6 (IL-6) (Eilken et al., 2017). During the stage of shaping and prolongation of blood vessels, pericytes contribute to the migration, proliferation, aggregation, and differentiation of endothelial cells by secreting vascular endothelial growth factor and fibroblast growth factor (Cross and Claesson-Welsh, 2001). In the process of generation, connection, and termination of new blood vessels, an active interaction exists between pericytes, and endothelial cells. For instance, PDGFR-β secreted by endothelial cells should firstly bind to endothelium-derived heparan sulfate proteoglycan, which promotes pericytes recruitment around the blood vessels and facilitates peripheral cell proliferation and migration by interacting with the PDGFR-β receptor on the surface of pericytes (Cuervo et al., 2017). In the last stage of angiogenesis, pericytes divide and proliferate rapidly to generate the extracellular matrix, accelerate the maturation of neovascularization, and participate in the modification and reinforcement of new blood vessels (**Figure 2**; Marchand et al., 2018).

Pericytes signals are also involved in the construction of vascular microecology after ischemia. For example, in brain tissues, brain pericytes are capable of secreting angiopoietin-1, and stromal cell-derived factor-1. Angiopoietin-1 binds to Tie2 expressed by endothelial cells and promotes Tie2 auto-phosphorylation (activation), which in turn recruits peripheral cells, such as smooth muscle cells and pericytes, to support endothelial cells in forming intact blood vessel walls, promote vascular remodeling and maturation, maintain vascular integrity, and regulate vascular function (Fukuhara et al., 2010). At the same time, stromal cell-derived factor-1 and its specific receptor CXCR4 promote endothelial cell migration, adult blood vessel formation, nerve development, and neuronal migration (**Figure 2**; Cui et al., 2013).

Regulation of Brain Blood Vessels

Pericytes have different subtypes and multiple functions. Pericytes located near the end of the capillary arteriole express more α-SMA and participate in the reflow process. These contractile pericytes contract the capillaries when ischemia occurs and are preferentially involved in the regulation of cerebral blood flow. Targeting these pericytes can reduce the no-reflux phenomenon after ischemic brain injury (Fernandez-Klett and Priller, 2015). The contraction of pericytes is involved in the following four mechanisms: (1) the endothelial cells surrounded by blood vessels show a flaky-fold structure with high and low undulations; (2) the ultrastructure of pericytes has a cytoskeletal structure capable of finely regulating cell contraction; (3) pericytes can express contractile proteins, such as α-SMA and troponin, and the expression levels of contractile proteins are distinct in different blood vessels; and (4) pericytes have some molecular receptors, such as endothelin receptors, which interact with angiotensin II and norepinephrine, causing rapid contraction of pericytes. Pericytes in the middle of capillaries express lower α-SMA and are preferentially involved in the maintenance of the BBB. Targeting these pericytes may reduce BBB damage after ischemic brain injury (Cai et al., 2017). However, the pericytes located at the end of the capillary venules are preferred to regulate the entry of immune cells into the brain parenchyma, and the amount of immune cells that enters into the brain parenchyma is significantly increased after ischemic brain injury (Navarro et al., 2016). Additionally, pericytes are capable of regulating blood pressure and coagulation. Angiotensin II secreted by endothelial cells can bind to its receptors on pericytes, causing contraction of the systemic arterioles, and elevation of arterial blood pressure, whereas vasoactive intestinal peptide secreted by endothelial cells can bind to its receptors on pericytes and has a vasodilating effect in lowering blood pressure (Fransen et al., 2016). Endothelin-1 is an endogenous vasoconstrictor regulator that is also present on pericytes (Dore-Duffy et al., 2011). During vascular injury or reconstruction, pericytes can secrete tissue factors, activate other coagulation factors, and form a positive feedback for the exogenous coagulation pathway, thereby regulating the prothrombin complex and participating in the whole coagulation process. At the same time, pericytes can also provide the necessary membrane surface for prothrombin complexes and promote the formation of thrombin with the help of coagulation factors Va and Xa. For example, human choroidal pericytes not only produce and regulate procoagulant complex but also support the functionally activated tissue factors present on its surface, which form a functional complex by binding to factor VIIa, thereby activating factors IX and X (**Figure 2**; Luo et al., 2018).

Collectively, pericytes regulate blood vessels by contracting themselves, controlling the size of capillary lumens, preventing excessive expansion of blood vessels, and maintaining homeostasis and metabolic balance of tissues.

Regulation of BBB

Pericytes are one of the constituent cells of the NVU and play an important role in regulating the permeability of the BBB. Hypoxia can lead to increased permeability of monolayer endothelial cells, and co-culture with pericytes can reduce sensitivity to hypoxia and permeability of endothelial cells (Yamamizu et al., 2017).

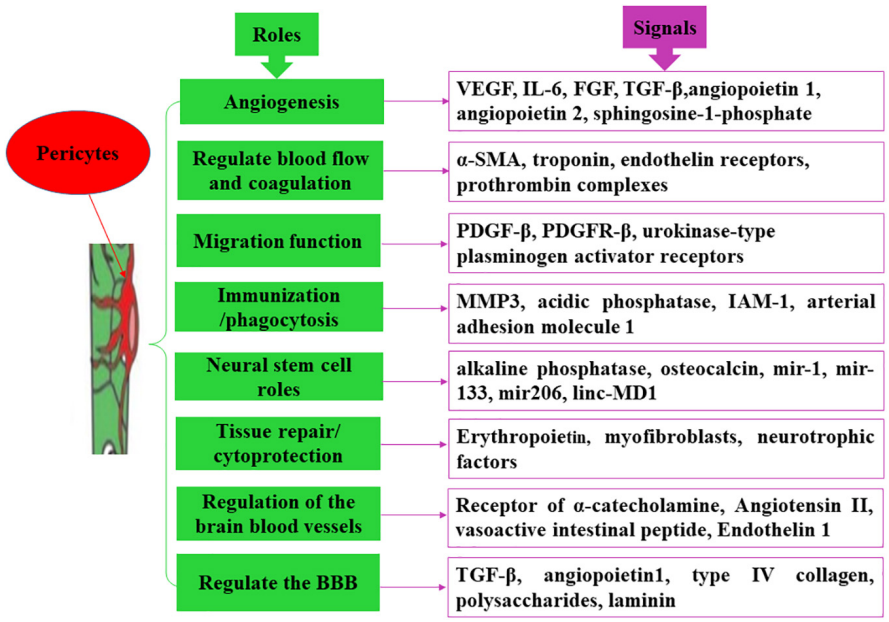

FIGURE 2 | Main functions of pericytes. Pericytes exert divers functions via secreting different molecules.

In addition, pericytes and brain microvascular endothelial cells communicate through gap junctions, tight junctions, focal adhesions, and some soluble factors, which in turn secrete growth factors to regulate the formation of tight junctions and permeability of endothelial cells that are important for the remodeling and maintenance of the vascular system (Ma et al., 2018). At the same time, pericytes can also regulate the proliferation, migration, and differentiation of endothelial cells (Zhou et al., 2016). Moreover, type IV collagen, polysaccharides, and laminin synthesized by the mouse kidney pericytes have been reported to have an effect on the formation of basement membrane (Wnuk et al., 2017). Hence, it can be speculated that pericytes are involved in the formation and maintenance of the BBB (**Figure 2**).

Migration Function

During arterial vascular development, endothelial-derived PDGF-β and PDGF-β receptors expressed by pericytes mediate pericytes migration to the endothelial cells (Thijssen et al., 2018). *In vitro* experiments that mimic capillary structures of the human BBB have shown the migration of pericytes to endothelial cells (Campisi et al., 2018). In addition, cortical pericytes can rapidly respond under brain hypoxic conditions or during brain trauma, wherein approximately 40% of pericytes migrate to the perivascular site, which may be mediated by urokinase-type plasminogen activator receptors expressed by pericytes, and exacerbate BBB damage and increase BBB permeability, leading to cerebral edema (**Figure 2**; Castejon, 2011).

Immunization and Phagocytosis

Pericytes have been reported to express matrix metalloproteinase 3 (MMP3); mice with MMP3 mutations exhibit a lower inflammatory response and a decrease in the number of permeable neutrophils, suggesting that pericytes are immunologically active in the inflammatory response (Kennedy-Lydon, 2017). At the same time, pericytes are capable of delivering antigens to T lymphocytes and participate in the immune response (Pober et al., 2017). Studies in the developing brain have revealed that lysosomes in pericytes can extensively express acidic phosphatase and exhibit phagocytic activity and that some pericytes can be directly transformed from macrophages (Prazeres et al., 2018). Furthermore, *in vitro* study found that cultured brain capillary pericytes can express a small number of adhesion molecules (such as ICAM-1 and arterial adhesion molecule-1) under the induction of inflammatory cytokines and can actively absorb and eliminate harmful small molecule particles (Pieper et al., 2014). These results indicated that pericytes have a phagocytic function that is similar to that of macrophages (**Figure 2**).

Potentiality of Neural Stem Cell

Pericytes isolated from different tissues can differentiate into other types of cells. For example, when cultured *in vitro*, the expression levels of alkaline phosphatase and osteocalcin in pericytes are increased, aggregated, and calcified, and pericytes demonstrate certain osteogenic ability (Gaceb et al., 2018). Pericytes can also differentiate into odontoblasts (Farahani et al., 2012). Furthermore, when pericytes extracted from skeletal muscle vessels are implanted into rats with muscle dysfunction, they can differentiate into skeletal muscle cells, thereby producing a large number of muscle tubules, and inducing muscle remodeling (Pierantozzi et al., 2016). When pericytes extracted from bovine renal microvessels are transplanted into the rats, they can differentiate into cartilages and

adipocytes (Konig et al., 2016; Vidhya et al., 2018). In addition, in hemorrhagic cerebral infarction, brain pericytes can differentiate into glial cells (Cheng et al., 2018). For different cell-derived and subtype pericytes, their differentiation and repair ability are not alike. For example, skeletal muscle-derived pericytes express three major myogenic RNA (mir-1, mir-133, and mir206) and unencoded myogenic RNA (linc-MD1), and their myogenic capacity was significantly higher than that of adipose-derived pericytes (**Figure 2**; Gautam and Yao, 2019).

Tissue Repair and Cytoprotection

Pericytes are involved in the repair and regeneration of various tissues and organs. Under physiological conditions, renal pericytes can produce erythropoietin to maintain microvascular stability. However, during renal injury, pericytes are exfoliated from the blood vessels, migrating, aggregating, and proliferating toward the injury, where they differentiate into other types of cells (such as myofibroblasts) to promote capillary regeneration at the site of injury and prevent the loss of capillaries (Shaw et al., 2018). Additionally, brain pericytes can express neurotrophic factors to promote neuronal survival when hypoxia occurs (Li et al., 2017). In the cardiovascular system, pericytes are involved in angiogenesis and affect the stability of arterial plaques. For instance, arterial plaques contain a large number of new blood vessels; when pericytes are absent, the permeability and fragility of new blood vessels increase, leading to plaque instability (Kennedy-Lydon, 2017). Pericytes also control effective myocardial perfusion by regulating the contractility of myocardial capillaries and participate in the reconstruction process after myocardial infarction (Costa et al., 2018). However, during the process of tissue repair, pericytes can cause excessive fibrosis. When repairing renal damage, pericytes may reduce the stability of the glomerular microvasculature, resulting in chronic hypoxia in the tubular and interstitial cells, and in turn leading to renal fibrosis (Venkatachalam and Weinberg, 2017). Pericytes can also cause pulmonary fibrosis and hepatic fibrosis. Along with increasing age, the activity of pericytes decreases and some special receptors are also lost, hindering the related signaling pathways for differentiation into other tissues, and thereby reducing the regeneration function for tissue repair (**Figure 2**; Birbrair et al., 2015).

PERICYTES AND CEREBROVASCULAR DISEASES

The neurovascular unit is a dynamic functional module composed of various members, such as neurons, glial cells, and pericytes. Studies have shown that NVU dysfunction is involved in the development of various cerebrovascular diseases, including hypoxic–ischemic brain damaged, brain WMI, and cerebral hemorrhage (Hill et al., 2014). Pericytes can regulate nerve and blood vessel events. For example, brain pericytes are involved in the regulation of cerebral blood flow, neurovascular growth, homeostasis of the NVU, and development and integrity of the BBB, and they have the potential activity of immune phagocytosis and stem cells (Sa-Pereira et al., 2012). In addition, studies on PDGFR-β-deficient rats reported that loss of brain pericytes might cause nerve damage through a reduction in chronic hypoperfusion and hypoxia by decreasing the level of brain microcirculation and through massive accumulation of plasma proteins and neurotoxic substances owing to damage to BBB integrity (Sauer et al., 2017). Both processes are related to the activity of pericytes.

Pericytes and Cerebral Hemorrhage

After cerebral hemorrhage, thrombin induces the release of MMP9, and its expression in brain pericytes is higher than that in other BBB-constituting cells, which may be related to the higher expression of thrombin receptors PAR1 and PAR4 in brain pericytes (Underly et al., 2017). Among proteins, PAR1 is the most abundant in brain pericytes, and the use of PAR1 inhibitor SCH79797 can prevent the release of MMP9 from brain pericytes, suggesting the important role of the thrombin–PAR1–MMP9 axis of brain pericytes in the pathological process of cerebral hemorrhage (Machida et al., 2017). Further studies have shown that thrombin stimulates PAR1 in brain pericytes after cerebral hemorrhage, activates PKCh-Akt and PKCd-ERK1/2 signaling pathways, and subsequently releases MMP9, leading to BBB damage, and aggravating brain damage (**Table 2**; Wang et al., 2018).

Pericytes and Hypoxic–Ischemic Brain Damage

Cerebral hypoxic–ischemic damage triggers the activity of pericytes. However, whether the activation of pericytes

TABLE 2 | The pericytes with cerebrovascular disease.

is beneficial or harmful depends on the specific tissue microenvironment, degree of activation, type of stimulation, and existing factors (Schneider et al., 2015). For instance, pericytes take on various tasks in different stages of ischemic stroke (Cai et al., 2017). (1) In the hyper-acute phase of stroke, the intracellular calcium concentration is enhanced, the number of ATP molecules is insufficient, and oxygen and nitrogen free radicals are formed in the microvasculature, leading to the contraction and death of pericytes, which finally cause no-reflow phenomenon in the capillaries of the brain. (2) In the acute phase, pericytes are stripped from microvessels and participate in inflammatory and immune responses, leading to BBB damage and cerebral edema. (3) During the late recovery phase of stroke, pericytes contribute to angiogenesis and neurogenesis, thereby promoting nerve recovery. In addition, pericytes are abnormally active and exhibit quantitative, structural, and functional changes when stimulated by certain extracellular noxious stimuli (such as acidosis, high glucose level, and reactive oxygen species), which cause pericytes dysfunction and excessive contraction, hinder red blood cells from passing through the vessels, and subsequently lead to microcirculatory disorders. For example, in a rat model of cerebral ischemia, oxidation-nitrous stress can induce constant contraction of retinopathy pericytes, and result in the disturbance of microcirculation and blood flow (Fu et al., 2016). In focal ischemic rat models, the contraction of pericytes occurred during cerebral artery occlusion and persisted even after the blood flow was restored (Zechariah et al., 2013). Thus, excessive and continuous contraction of pericytes after cerebral ischemia may be the cause of local microcirculation disorder, which may also be an important pathological mechanism of cerebral ischemia–reperfusion injury (**Table 2**).

Nevertheless, pericytes also provide benefits for neuroprotection in hypoxic–ischemic brain damage by protecting the endothelium, stabilizing BBB permeability, and releasing neurotrophins (Ishitsuka et al., 2012). For example, in the *in vitro* BBB model with mixed endothelial cells, pericytes, and astrocytes, the researchers found that the permeability of monolayer endothelial cells was significantly attenuated due to the presence of pericytes. Similarly, when co-cultured with pericytes, the sensitivity of endothelial cells to hypoxia was significantly reduced (Wang et al., 2016). Under continuous hypoxic conditions, TGF-β1 and angiopoietin-1 expressed by pericytes contributed to the maintenance of the tight junction of the BBB (Rustenhoven et al., 2016), whereas type IV collagen, laminin, and hyaluronic acid secreted by pericytes are involved in the construction of the basement membrane (Kose et al., 2007). In addition, when observing the brain tissue of rats with minimal cerebral hemorrhage via electron microscopy, researchers found that ions, and plasma components exist in the cytoplasm of pericytes (Jindatip et al., 2018). Therefore, when the tight binding of the BBB was disrupted, pericytes might act as phagocytes to play a remedial role (**Table 2**).

Pericytes and Brain White Matter Injury

Brain WMI can be induced by hypoxic–ischemia, infection, and so on (Duerden et al., 2019). Pericytes dysfunction is involved in the pathogenesis of WMI (Montagne et al., 2018). Numerous studies have confirmed that human *Notch3* gene is mainly expressed in the arterial smooth muscle cells and pericytes and that its mutations cause capillary blood flow dysregulation, thereby triggering impaired cerebrovascular reactivity and WMI disorders such as hereditary multi-infarct dementia (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) (Kofler et al., 2015). Furthermore, the observation of cerebral microvessels in patients with cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy via electron microscopy indicated that pericytes showed degeneration, the nuclei were swollen, and the basement membrane between pericytes and endothelial cells was thickened with a large amount of osmiophilic granules (Craggs et al., 2015). In rats with chronic cerebral hypoperfusion-induced WMI, the pericytes were damaged and its biomarker Kir6.1/Kir6.2 was expressed in heterogeneity, suggesting that the Kir6.1/K-ATP channel might be involved in the pathological process of chronic WMI (**Table 2**; Thomzig et al., 2005).

Pericytes and Neovascular Deficiency Disease

Pericytes maintain vascular osmotic pressure and morphology and participate in vascular genesis and maturation via signal transmissions with endothelial cells and extracellular matrix (Ferland-McCollough et al., 2017). The insufficiency of pericytes always leads to the occurrence and development of neovascular deficiency disease (Bergers and Song, 2005). The neovascular deficiency disease refers to a category of disorder which is caused by the shortage of formation or immaturities of new blood vessels, including tumors, atherosclerosis, diabetic retinopathy, and the like. Besides, neovascular deficiency often occurs following different types of brain damage such as hypoxic ischemic encephalopathy and WMI, which in turn attenuated the recovery of brain injury. Generally, this category of disorder shares the following characteristics: (1) the morphology of endothelial cells is abnormal, showing overlapping growth, and the connection between endothelial cells is reduced; (2) the morphology of pericytes is abnormal, the function is inadequate, and the coverage is decreased; and (3) the basement membrane is incomplete or missing, with uneven thickness or thinness, and is distributed in sheets (Davis et al., 2015). Studies have shown that these neovascular immaturity diseases are associated with various signaling pathways. For example, the excessive activation of angiogenic signaling pathways, such as proline hydroxylase-2 (Urrutia et al., 2016) and vascular endothelial growth factor (Bai et al., 2015), leads to excessive angiogenesis. On the other hand, the recruitment and proliferation of pericytes are inhibited and the decomposition of the basement membrane is excessive, ultimately inhibiting the maturation of new blood vessels (Cheng et al., 2018). In addition, the signals secreted by pericytes such as PDGF-β (Thijssen et al., 2018), RGS5 (Hamzah et al., 2008), secreted protein acidic and rich in cysteine (Svensson et al., 2015), and axon guidance molecule 3/neurociliary protein 1 (Sema3A/Nrp-1) (Dhar et al., 2010)

are also closely related to the occurrence of neovascularization immaturity (**Table 2**).

PERICYTES AND NON-VASCULAR BRAIN DISORDERS

Pericytes and Depression

Depression is a type of neuropsychiatric disease caused by NVU dysfunction, which is closely related to neuroinflammation that can affect serotonin levels (Liu et al., 2015). Depression is also associated with NVU dysfunction caused by abnormally high BBB permeability. For example, studies have shown that the BBB integrity in patients with depression is disrupted, and the pericytes coverage of the cortical and hippocampal capillary networks is significantly reduced (Liu et al., 2019). In addition, *in vitro* study indicated that brain pericytes secrete various cytokines, including ICAM-1, IL-6, tumor necrosis factor-α (TNF-α), and MMP, which disrupt BBB integrity and aggravate brain inflammatory factors (Dohgu et al., 2019). Numerous studies have shown that inflammatory factors such as IL-6, IL-1, and TNF-α can trigger acute pro-inflammatory effects and that the downregulation of these factors can induce depression-like behavior (Chu et al., 2019). However, the upregulation of IL-6, IL-1β, and TNF-α has been shown to impair nerve cell regeneration and aggravate cell death, leading to neurodegenerative diseases (Zou et al., 2018). In addition, neuropathological studies have reported that patients with depression have abnormally elevated ICAM-1 in the prefrontal cortex and white matter. Antidepressant treatment reduces the expression of vascular cell adhesion molecule-1 and ICAM-1 in serum. These effects are triggered primarily by the interference of these cytokines secreted by pericytes, which disrupt cell survival signaling pathways and caspase-dependent cascades, and altering the function of major receptors (Dewispelaere et al., 2015).

Pericytes and Alzheimer's Disease

Alzheimer's disease, triggered by chronic inflammation as well as the pathological accumulation of beta-amyloid (Aβ) and neurofibrillary tangles in the brain, is related to pericytes dysfunction (Yamazaki and Kanekiyo, 2017). In transgenic animals with AD pathology, researchers found that circulating white blood cells penetrate the BBB to interact with NVU components and disrupt their structural integrity and function (Zuo et al., 2017). In addition, Aβ receptors such as LRP1, LDLR, RAGE, and CD36 are expressed on pericytes in the brain of AD patients, and these receptors are involved in Aβ-mediated cerebral perivascular cell death (Miners et al., 2018). Mice with depleted pericytes showed deposition of Aβ plaques in the brain parenchyma and blood vessels, as well as an accumulation of hyper phosphorylated tau protein, suggesting that pericytes deficiency contributed to the development of tau pathology (Sagare et al., 2013).

TARGETING PERICYTES AS A THERAPEUTIC STRATEGY FOR CEREBROVASCULAR DISEASES

Pericytes play an important role in the maintenance of normal functions of blood vessels in the brain and are involved in the pathogenesis of several cerebrovascular diseases. Therefore, targeting pericytes is a potential therapeutic strategy for cerebrovascular diseases.

Regulator of G-protein signaling 5, which regulates vascular development, showed a perivascular expression pattern and was identified as a marker for brain pericytes (Bondjers et al., 2003). In a mouse model of permanent midbrain occlusion, when knocking out *RGS5* gene, the amount of pericytes and endothelial coverage were increased, and the BBB injury was also significantly attenuated. Furthermore, loss of *RGS5* in pericytes alleviated vascular leakage, maintained tight junction integrity and aquaporin-4 levels, reduced cerebral hypoxia, and protected neurons in the infarcted area (Ozen et al., 2018). Therefore, targeting pericytes RGS5 might be effective in the treatment of ischemic stroke.

In a mouse model of cerebral ischemia, when TGF-β was used, it continuously stimulated the formation of extracellular matrix and the transformation of mesenchymal cells to vascular pericytes, thereby strengthening the blood vessels, preventing the leakage of new blood vessels, and promoting the maturation of blood vessels (Dhandapani and Brann, 2003). Therefore, TGF-β might be an effective agent to treat neovascular deficiency disease.

In a rat model of cerebral ischemia–reperfusion injury, pericytes were observed to migrate from the vessel wall at an early stage, the microvascular basement membrane structure was disordered, and the BBB function was impaired. When ischemic post-conditioning was performed, the MMP9 expression of pericytes was reduced. As MMP9 is a critical factor regulating pericytes migration, the downregulation of MMP9 after post-conditioning inhibited pericytes migration after ischemia–reperfusion, and maintained the integrity of BBB structure and function (Underly et al., 2017).

DISCUSSION

As components of the NVU, pericytes play an important role in the regulation of physiological and pathological processes of the CNS and have currently attracted considerable interest (Geranmayeh et al., 2019). This review primarily discussed the basic characteristics and research dynamics of pericytes in cerebrovascular diseases, aiming to provide a comprehensive understanding of pericytes and new insights about the use of pericytes as novel therapeutic targets for cerebrovascular diseases.

Dysfunction in neurovascular coupling that results in a mismatch between cerebral blood flow and neuronal activity has been suggested to play a key role in the pathogenesis of Alzheimer's disease (AD). Meanwhile, physical exercise is a powerful approach for maintaining cognitive health and could play a preventive role against the progression of AD. Given the fundamental role of capillaries in oxygen transport to tissue, our pilot study aimed to characterize changes in capillary hemodynamics with AD and AD supplemented by exercise. Exploiting two-photon microscopy, intrinsic signal optical imaging, and magnetic resonance imaging, we found hemodynamic alterations and lower vascular density with AD that were reversed by exercise. We further observed that capillary properties were branch order-dependent and that stimulation-evoked changes were attenuated with AD but increased by exercise. Our study provides novel indications into cerebral microcirculatory disturbances with AD and the modulating role of voluntary exercise on these alterations.

INTRODUCTION

Alzheimer's disease (AD) is the most common cause of cognitive impairment in the elderly (Iadecola, 2010; Toledo et al., 2013). Dysfunction in neurovascular coupling, resulting in a mismatch between cerebral blood flow and neuronal activity, has long been suggested to play a part in the pathogenesis of AD (Iadecola, 2004, 2010; Zlokovic, 2011; Kisler et al., 2017). AD also shares many risk factors with cardiovascular diseases (Østergaard et al., 2013; Nielsen et al., 2017) and is associated with alterations in vascular function (Iadecola, 2010). Capillaries are the vessels most proximal to neurons (Stefanovic et al., 2008) and thus play a significant role in modulating oxygen extraction to support neuronal activity (Østergaard et al., 2013; Hall et al., 2014; Nielsen et al., 2017). Characterizing microvascular (dys)function in AD is of vital importance, as compromised capillary networks may lead to hypoxia, which, in turn, damages neurons and precipitates Aβ amyloid retention (Nielsen et al., 2017). The first aim of this pilot study was to quantify the changes in capillary red blood cell (RBC) dynamics with AD to provide insights into these issues.

Beyond characterizing hemodynamic dysfunction in microvessels, it is also critical to explore how to mitigate the negative impacts of AD on microcirculation. Physical exercise is a powerful approach for maintaining cognitive health and is hypothesized to play a preventive role against the progression of AD (Radak et al., 2010). Regular aerobic exercise has been found to inhibit the progression of amyloid-related neuropathology in mouse models of AD (Adlard et al., 2005) and to enhance cognitive performance in humans (Pereira et al., 2007; Brown et al., 2010; Hayes et al., 2014). Voluntary exercise has also been shown to improve vascular function in a mouse model of atherosclerosis (Shing et al., 2015). Oxidative stress associated with aging has been found to be reduced with exercise in both humans (Pialoux et al., 2009) and rodents (Durrant et al., 2009). Notwithstanding, the hemodynamic changes in microvascular networks in response to physical exercise with the onset of AD have yet to be studied. Despite a number of hypotheses that indicate the beneficial role of exercise, we still do not have a clear quantification of these changes, which can now be carried out with *in vivo* optical imaging techniques. The second aim of this study was, thus, to quantify the modulatory effect of exercise on cerebral capillaries in AD.

To address these questions, we applied multiple imaging techniques, including two-photon microscopy, intrinsic optical signal imaging (IOSI), and magnetic resonance imaging (MRI), to measure hemodynamic changes at different spatial scales. We found capillary hemodynamic alterations and lower vascular density with AD that were modulated by exercise. We further observed that capillary RBC flow properties were branch order-dependent and that the stimulation-evoked changes were decreased with AD but increased by exercise.

MATERIALS AND METHODS

Animal Groups

Animals were handled according to the Animal Research: Reporting *in vivo* Experiments (ARRIVE) guidelines and the recommendations of the Canadian Council on Animal Care. The protocol was approved by the Ethics Committee of the Research Center of the Montreal Heart Institute. An APP/PS1 mouse model (generous gift from Dr. Bernard Levy, France) and wild-type (WT) mice were genotyped by standard PCR analysis of genomic DNA isolated from ear clips to select both hemizygous APP/PS1 males and their non-transgenic control (WT) male littermates, as previously described (Radde et al., 2006). Mice were kept under standard conditions (24°C; 12-h:12-h light/dark cycle) and were fed *ad libitum* with regular chow (2019S; Harlan Laboratories, Madison, WI, United States). Initially housed four per cage, they were separated and housed one per cage following the surgeries detailed below.

Experimental Design

Experiments were performed in male wild-type mice at 6 months old (WT6: $n = 4$), transgenic Amyloid Precursor Protein Presenilin-1 (APP/PS1) mice at 6 months old (AD6: $n = 4$), and APP/PS1 mice at 6 months old for which voluntary exercise was initiated at 3 months old (AD6&EX: $n = 4$). Previous work showed a clear onset of cognitive symptoms in APP/PS1 mice at 4.5 months old (Cifuentes et al., 2015) and established at 6 months old (de Montgolfier et al., 2019), and thus, we conducted imaging at 6 months old and investigated the hemodynamic changes in this relatively early stage of AD. For the AD6&EX group, exercise was voluntary. Mice in the exercise group were housed individually from 3 months old forward in separate cages to which a running wheel was attached with a rotation counter. Mice started running on wheels at 3 months old and continued the daily exercise until 6 months old, when imaging data were recorded. The wheel (diameter 15 cm, recorded by an easyMATRIX 16 EMKA) was mounted outside the home cage, and the total number of wheel rotations was recorded daily on an LE907 individual counter. The running distance averaged across mice ranged from ∼2 to ∼4 km per day in the 3-month exercising period.

Multiple imaging techniques were used for the data collection, as shown in **Figure 1**. The order of procedures was as follows. At 6 months old, mice were imaged with MRI in anesthetized (1h30, isoflurane) condition. Ten days later, two-photon imaging was conducted to collect capillary properties in awake animals. One day later, intrinsic signal optical imaging (ISOI) was performed to collect data on changes in hemoglobin, again in awake animals. Each mouse was included in all of these experiments.

Two-Photon Imaging

For two-photon imaging, a craniotomy was performed, and mice were familiarized with the awake imaging device. On the day of cranial surgery, animals were anesthetized with isoflurane (1.5–2.0% in pure oxygen), with their physiological parameters monitored in real time. A fixation bar was attached for awake imaging. At the same time as bar fixation, a cranial imaging window was prepared to allow for two-photon imaging of the cortex following well-established guidelines (Shih et al., 2012). A cranial window with a 3-mm diameter was made over the left barrel cortex (0.5 mm posterior to bregma, 3.5 mm lateral to the midline). Agarose in artificial cerebral spinal fluid (ACSF) was placed over the exposed skull, and then a three-layer cover glass was glued onto the skull to generate a transparent cranial window. Ketoprofen (5 mg/kg, Merial, Canada) and buprenorphine (0.05 mg/kg, Reckitt Benckiser Healthcare, United Kingdom) were injected before the surgery for analgesic and antipyretic effects. Baytril (5 mg/kg, Bayer, Germany) was injected after the surgery and repeated one day after the surgery. To adapt to the device during imaging, animals were trained on the imaging wheel in four fixation-training sessions beginning after 3 days of recovery following the cranial surgery. The length of fixation time gradually increased from 10 to 45 min over the four sessions.

A home-built two-photon microscope was used to record functional capillary data and vascular density. The MaiTai-BB laser oscillator (Newport Corporation, United States) of the two-photon microscope generated a sequence of 820 nm, 80 MHz, 150 fs pulses modulated by an acousto-optic modulator for power control. The fluorescent dye (dextran-FITC) was injected through the tail vein to distinguish plasma (in bright colors) and RBCs (appearing as dark shadows) in the recorded

FIGURE 1 | Timeline of imaging experiments.

images. The line scans were performed both perpendicularly and longitudinally to each measured capillary over 250-ms time intervals to generate space-time images. In consecutive longitudinal scans, the dark shadows move toward the right or left of the scanning beam because of the movement of RBCs, resulting in tilted dark streaks in the space-time image (Kleinfeld et al., 1998). The angle of these dark streaks was used to quantify RBC velocity, with streaks closer to horizontal orientation associated with higher velocity. In perpendicular line scans, the signal is dark when an RBC is passing through the optical focus, and RBC flux can be assessed. Following line scanning, 3D angiograms were obtained over four overlapping 600 × 600 μm (400 × 400 pixels) regions at depths of 100–550 μm with 5-μm steps at a frame rate of 0.5 Hz. During all measurements, animals were awake, with the head fixed by a titanium bar and limbs free to move on the rotating wheel (Moeini et al., 2018, 2019).

Measurement of Capillary Properties

The spacetime images were used to obtain the following capillary parameters, following (Moeini et al., 2018): (1) diameter, by fitting the perpendicular scans with a Gaussian function with estimated diameter at half maximum of the distribution; (2) RBC velocity from the angle of the streaks in longitudinal scanning; (3) RBC flux, calculated by the number of dark shadows divided by the acquisition time of the images (the flux was obtained from the average of values in longitudinal and perpendicular scans); and (4) hematocrit, calculated by RBC flux × RBC volume/capillary volumetric flow [capillary volumetric flow = RBC velocity × capillary cross-sectional area; RBC volume assumed to be 55 μm^3 for C57Bl/6 mice (Wirth-Dzięciołowska et al., 2009)]. The angiogram images were used to compute the vascular density using a deep-learning segmentation approach based on the FC-Densenets architecture (Damseh et al., 2018a,b). The vascular density was quantified with each slice of the segmented two-photon angiograms by restricting the analysis to vessels with a diameter of less than 8 um.

We also divided the capillaries based on branching order. The artery region, with the diving arteriole, precapillary arteriole, and capillaries, was labeled with respect to branching order A1, A2, and A3, with A1 branching off directly from the precapillary arterioles. The vein region, with the surfacing venule and post-capillary venule, was labeled with the branching order V1, V2, and V3, with V1 linking directly to veins. In our recordings, the capillary segments ranged from 6 to 12 branch orders. We only labeled and defined the first three branch orders from arterioles (A1, A2, and A3) and venules (V1, V2, and V3). When a capillary path had more than six branching orders, these additional branch orders were merged into V3, thus enabling consistent numbering for all capillaries observed.

Magnetic Resonance Imaging (MRI)

Anatomical and perfusion MRI scanning was performed with a 30 cm 7T horizontal MR scanner (Agilent, Palo Alto, CA, United States) before two-photon imaging. The mice were in a prone position and imaged with a gradient insert coil (12-cm inner diameter, gradient strength 600 mT/m, and rise time 130 ms). The brain was imaged with a 2-channel receive-only surface coil and a quadrature transmit/receive birdcage coil (69-mm internal diameter) (RAPID Biomedical, Germany), while the animal was anesthetized with 1.4–2.2% isoflurane in air with 30% oxygen, with the body temperature kept at 37.0°C using a warm air fan (SA Instruments, Stony Brook, NY, United States). Respiration was monitored with a target of ∼100 bpm, adjusting the level of isoflurane only whenever the rate was outside 80–120 bpm. Heart rate was monitored with a pulse oximeter.

Anatomical images were recorded with a 3D true free induction with steady-state precession (TFISP) sequence (Bowen et al., 2006) at a 100-μm isotropic resolution (TR = 5.0 ms, TE = 2.5 ms, 16 frequencies, 22-min scan time). A 3D amplitude-modulated continuous arterial spin labeling scan (amCASL) was then acquired (TR = 3.0 s, labeling duration = 1.0 s, 60 × 54 × 48 matrix, 300 μm × 333 μm × 333 μm resolution, 23-min scan time).

The anatomical recordings were first aligned manually to a previously produced anatomic template using ITK-SNAP and then co-registered non-linearly with the advanced normalization tools (ANTs) (Avants et al., 2010, 2011), thus producing the ANT transformations to co-register the perfusion scans to a common referential. Perfusion was calculated voxel-by-voxel as described in Chugh et al. (2012), with assumed parameters of brain/blood partition coefficient = 0.9 mL/g, mouse arterial blood transit time = 0.08 s, tagging efficacy = 0.67, T_{1b} = 2.3 s, T_1 = 1.53 s, T_{1sat} = 0.57 s, and $M_a^z(w)$ = 0.48 s. The MarsBar toolbox in SPM was also used to extract the average perfusion data (Delafontaine-Martel et al., 2018).

Intrinsic Signal Optical Imaging (ISOI)

An ISOI system (Labeo Technologies, Inc.) was used to investigate the stimulus-evoked hemodynamic responses in all

experimental groups. Whiskers of mice were deflected at a rate of 10 Hz to activate the somatosensory cortex, with a 5-s stimulation time and a 15-s post-stimulus period. Illumination using green and red lights was positioned to illuminate the exposed skull of the mouse head. Images were acquired by a camera at a rate of 5 Hz per wavelength over a period spanning 10 stimulation repetitions. We computed changes in oxy-hemoglobin concentration (Δ[HBO](t)), deoxy-hemoglobin concentration (Δ[HBR](t)), and total hemoglobin concentration (Δ[HBT](t)), as was done in Dubeau et al. (2011a,b).

Statistical Analysis

The results are presented as mean ± SEM. Non-parametric Kruskal–Wallis tests were applied with follow-up tests for multiple group comparisons. Statistical significance was assigned at $^{+}p < 0.1$, $^{*}p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$.

RESULTS

Capillary RBC Flow Is Altered by AD and Modulated by Exercise

To better understand the role of exercise and AD on capillary RBC flow properties, we assessed the values of the resting capillary diameter, RBC velocity, RBC flux, and capillary hematocrit in all groups and their coefficient of variation (CV) using two-photon microscopy.

In **Figure 2A**, we observed that the capillary diameter had an increasing trend from the WT6 group (4.67 ± 0.06 μm) to the AD6 group (4.98 ± 0.07 um, $p = 0.09$) and significantly increased from the WT6 group to the AD6&EX group (5.15 ± 0.08 μm, $p = 0.011$). A decreasing trend of RBC velocity from WT6 (0.87 ± 0.03 mm/s) to AD6 (0.79 ± 0.03 mm/s) was also observed (see **Figure 2A**). RBC velocity increased significantly with exercise (velocity in the AD6&EX group: 0.91 ± 0.04 mm/s, $p = 0.04$, **Figure 2A**). However, there were no significant differences in RBC flux between groups (**Figure 2A**). Finally, the capillary hematocrit had a decreasing trend from the WT6 group (39.57 ± 1.15%) to the AD6 group (35.15 ± 1.30%, $p = 0.09$) (see **Figure 2A**). Exercise elevated the hematocrit (AD6&EX group, 37.32 ± 1.19%), as expected from physiology (see **Figure 2A**).

Given the hypothesis that capillary heterogeneity is a key element in oxygen delivery, we also computed the CV of these parameters. The CV represents the variations of each property within a capillary as a function of time. In **Figure 2B**, we show the CV of each parameter to explore the influence of AD and exercise on capillary heterogeneity. We observed significant variations in the velocity CV, flux CV, and hematocrit CV (see **Figure 2B**), while we did not find significant differences regarding the diameter CV in different groups. The velocity CV decreased significantly from the AD6 group (24.63 ± 1.92%) to the WT6 group (18.69 ± 1.33%, $p = 0.049$). The flux CV increased ($p = 0.01$) from the WT6 group (29.17 ± 1.25%) to the AD6 group (40.63 ± 2.13%) (see **Figure 2B**). Exercise trended to decrease the flux CV from AD6 to AD6&EX (35.50 ± 1.58%) (see **Figure 2B**). Finally, hematocrit CV increased from WT6 (14.65 ± 0.79%) to AD6 (20.95 ± 1.41%, $p = 0.008$), while exercise trended toward a reduction of the hematocrit CV from AD6 to AD6&EX (18.42 ± 1.08%, see **Figure 2B**). Taken together, the capillary velocity flux and hematocrit were reduced with AD, associated with increased variations over time, while exercise regularized parameters toward values found in WT mice. Capillary diameter was the exception to this. Given the increased heterogeneity in RBC velocity, RBC flux, and hematocrit with AD, we also analyzed the variations of these properties as a function of branch order of capillaries to explore how they varied from the upstream to the downstream segments. The results of this analysis are provided in the **Appendix**.

High Temporal Fluctuations in Capillary RBC Velocity and Flux Were More Frequent With AD

Previous studies observed spontaneous stalls in capillary RBC flux in individual capillary segments (Erdener et al., 2017; Hernández et al., 2019). We thus analyzed our data to capture the presence of highly fluctuating RBC properties in capillaries by quantifying the fraction of capillaries with outlier standard deviations of RBC flux or speed within a 5-s recording window (see **Figures 3A,B**). Although stalling was not characterized in our experiments, these capillary outliers tend to display highly fluctuating flux and velocity, which may influence oxygen extraction (Gutiérrez-Jiménez et al., 2016; Østergaard et al., 2016). Examples for capillary outliers with temporally high self-fluctuation of RBC flux and velocity were shown in **Figures 3A,B**, respectively.

We further calculated and compared the fraction of outliers in all groups and found that the proportion with high temporal self-fluctuating RBC velocity was highest in the AD6 group (10.43%, 48 outliers in 460 capillaries), followed by the AD6&EX group (9.45%, 48 outliers in 508 capillaries), and was lowest in the WT6 group (8.19%, 46 outliers in 562 capillaries) (see **Figure 3C**). We did the same analysis for RBC flux (see **Figure 3D**). We again found that the proportion with high temporal self-fluctuating RBC flux was highest in the AD6 group (18.70%, 86 outliers in 460 capillaries), followed by the AD6&EX group (15.35%, 78 outliers in 508 capillaries), and was lowest in the WT6 group (13.17%, 74 outliers in 562 capillaries) (see **Figure 3D**).

Higher Vascular Density Peak Value and Lower Average Vascular Density in the AD Group

We calculated the vascular density from two-photon angiograms (see **Figure 4A**) after binary segmentation. Interestingly, all experimental groups reached their peak values of vascular density at a depth of ∼220 μm and the values then gradually decreased with increasing depth beneath the brain surface (see **Figure 4B**). The AD groups (both AD6 and AD6&EX) had significantly higher peak values (AD: 14.60 ± 0.98%; AD6&EX: 14.48 ± 1.09%) when compared with the peak value of the WT6 group (12.74 ± 0.70%) (see **Figure 4B**). Voluntary exercise did not significantly change the peak value of vascular density (see **Figure 4B**). When integrating across depths, the AD6 group

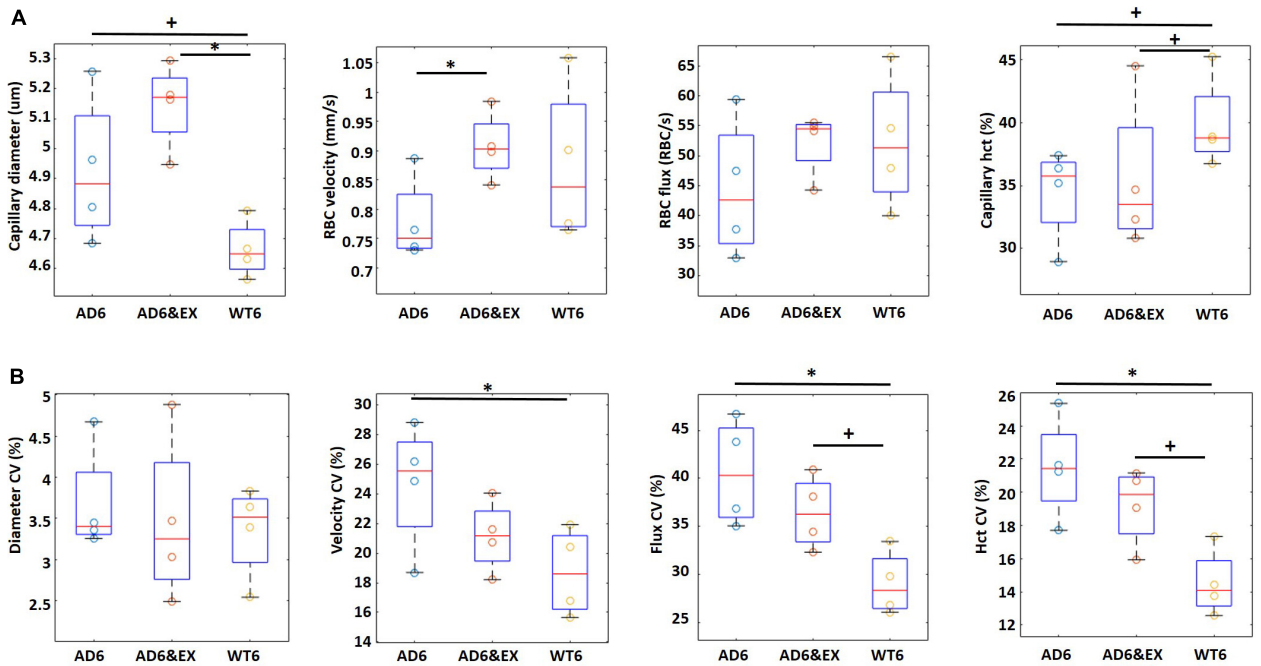

FIGURE 2 | Capillary RBC flow characteristics in different groups (four mice per group). **(A)** Capillary diameter, RBC velocity, flux, and hematocrit in different experimental groups. **(B)** Coefficient of variation (CV) for all capillary parameters. The CV in each capillary was computed based on multiple frames recorded each 0.25 s within a 5-s time window. Thus, CV represents the temporal variations of each property within a capillary. CV was computed as the standard deviation divided by the mean. $^{*}p < 0.05$ and $^{+}p < 0.1$.

showed a trend toward a lower average value (8.16 ± 0.37%) compared to the WT6 group (8.85 ± 0.29%) (see **Figure 4C**). With voluntary exercise, the AD6&EX group (8.64 ± 0.34%) exhibited a trend of higher vascular density than the AD6 group (see **Figure 4C**). Overall, higher vascular density peak values and lower average vascular densities were observed in the AD groups.

AD Reduced Brain Perfusion and Task-Related Changes, With the Latter Modulated by Exercise

We used MRI to quantify brain perfusion in each group (see **Figures 5A,B**). We observed that brain perfusion decreased from the WT6 group (2.69 ± 0.15 ml/g/min) to the AD6 group (2.16 ± 0.10 ml/g/min, $p = 0.06$) (see **Figure 5C**). However, exercise did not significantly modulate brain perfusion in AD groups (AD6&EX: 2.13 ± 0.16 ml/g/min) (see **Figure 5C**).

Intrinsic signal optical imaging was also used to investigate the response to stimulation to investigate task-related changes in hemoglobin concentration (see **Figures 5D,E**). The whiskers of mice were deflected to activate the somatosensory cortex, with a 5-s stimulation time and a 15-s post-stimulus period. We observed increased HBO with stimulation for all groups, while HBO had higher peak values in the WT6 group and the AD6&EX group when compared to the AD6 group, as shown in **Figure 5D**. We found that the Δ[HBO](t) in the AD6 group (10.75 ± 0.64 μM) was lower ($p = 0.03$) than that in the WT6 group (15.00 ± 0.85 μM). However, exercise tended to increase the Δ[HBO](t) from the AD6 group to the AD6&EX group (12.69 ± 0.85 μM, see **Figure 5F** upper panel). Finally, there were no significant differences regarding Δ[HBR](t) between groups (see **Figure 5F** lower panel).

DISCUSSION

In this study, we aimed to quantify the hemodynamic properties of and modulatory role of exercise on cerebral capillaries in AD due to the important role of microcirculation in cognitive health (Østergaard et al., 2016; Erdener et al., 2017; Zhang et al., 2017; Hernández et al., 2019). Exploiting awake microscopic vascular imaging and a transgenic mouse model of AD, we found that in this model (APP-PS1), AD is associated with hemodynamic disruption in capillaries. Voluntary exercise was seen to decrease capillary hemodynamic heterogeneity, although exercise did not increase the global cerebral blood flow in the cortex.

Capillary Flow Property Changes Due to AD and Exercise

Blood flow was slightly reduced in the AD6 group compared with WT6 mice but tended to increase with exercise in the AD6&EX group compared with the AD6 group. Specifically, RBC velocity tended to decrease with AD, with moderate modulation by exercise. The disrupted RBC velocity could

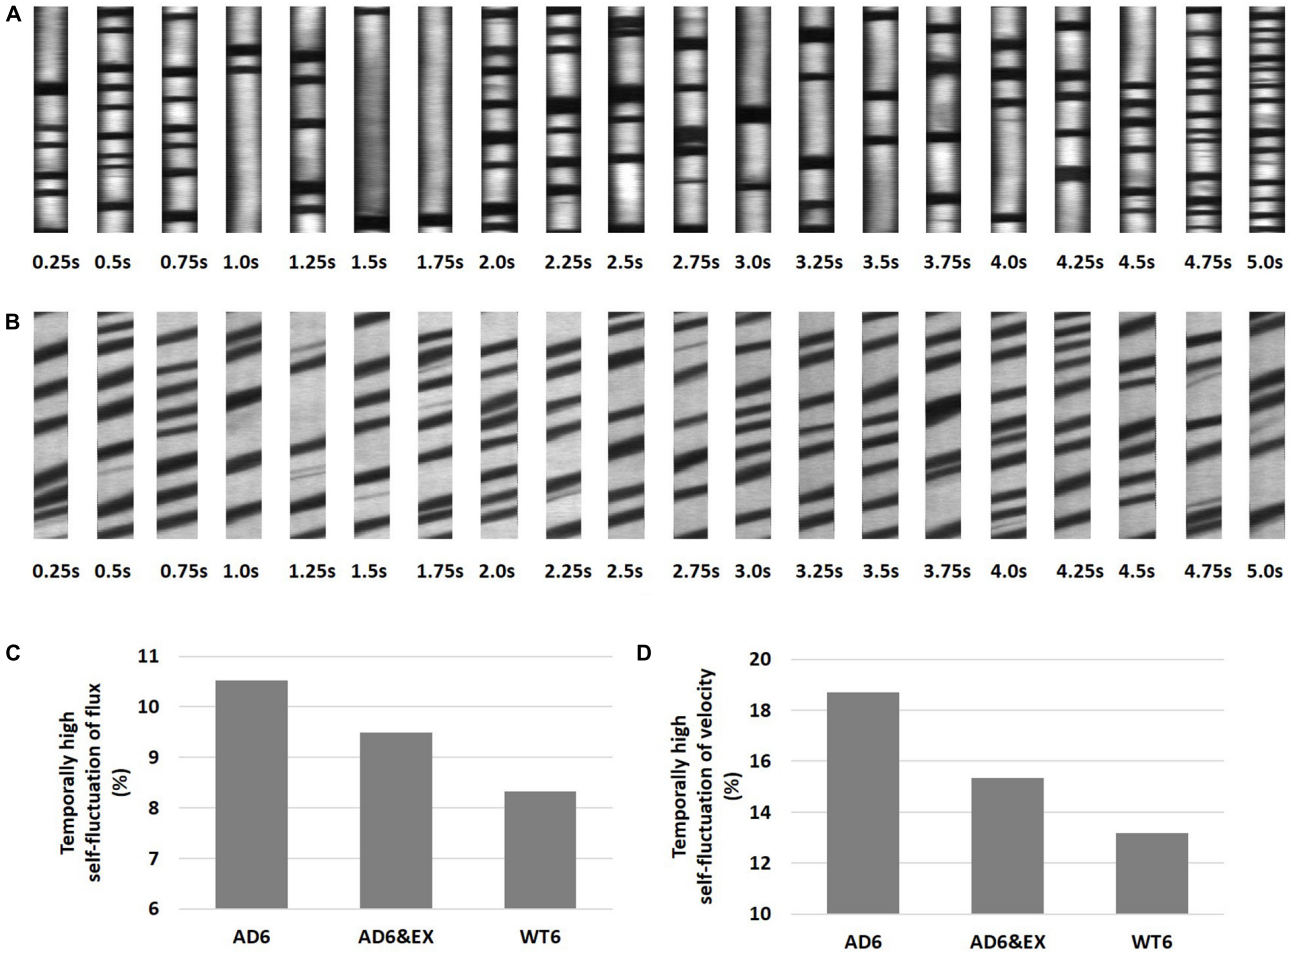

FIGURE 3 | High temporal capillary fluctuations of RBC velocity and RBC flux. **(A)** Representative space-time images with higher fluctuations of RBC flux as a function of time, with 0.25 s intervals during a 5-s recording window. The flux was obtained using both longitudinal and perpendicular scans, and the average value was used. **(B)** Longitudinal equivalent RBC velocity was calculated from the angle of dark streaks in a specific recording frame. **(C)** The percentage of capillaries with high temporal fluctuations of RBC velocity in all groups. The "isoutlier" method in MATLAB was applied to detect outliers with a standard deviation of RBC velocity exceeding three standard deviations from the mean. **(D)** Same for RBC flux.

result from the occlusion of vessels due to amyloid deposition (Arbel-Ornath et al., 2013). In another study (Lu et al., 2019), we gathered immunohistological evidence showing increased amyloid deposition with AD with a moderate, but significant, reduction due to exercise. Future research may consider immunohistological markers such as inflammation to shed light on the impact of AD on capillary properties more directly. The reduced RBC velocity could, in turn, lead to compromised perfusion in the mouse cortex, further slowing the clearance of amyloid and increasing its deposition (Kisler et al., 2017). We further observed that hematocrit was reduced with AD compared with the WT mice, with an increasing trend with exercise. A previous study (Moeini et al., 2018) found reduced hematocrit in healthy aging, thus disrupting capillary oxygen delivery efficiency. The prior literature has also observed miscrocirculation flow disruption in other cardiovascular diseases, such as stroke (Kazmi et al., 2013) and hypertension (Pialoux et al., 2009), and in even healthy aging (Dubeau et al., 2011b). The microvascular flow alterations observed in our study suggest that AD does share many similar microvessel disruptions with cardiovascular pathologies and aging. These microvessel problems could be alleviated by exercise, as is the case in other cardiovascular diseases (Pialoux et al., 2009; Brown et al., 2010).

We also found that RBC properties, especially velocity and flux, were branch order-dependent for all experimental groups. Prior study (Sakadžić et al., 2014) suggests that oxygen is in good proportion extracted in the first few branches after the precapillary arteriole in normal physiological conditions. Our results were related to previous findings and showed that RBC velocity and flux decreased from the upstream capillaries to the downstream capillaries for all groups to allow for oxygen delivery. Capillaries are responsible for transporting oxygen and nutrients to brain tissue and clearing metabolic end products from the brain to venous circulation (Kisler et al., 2017). In

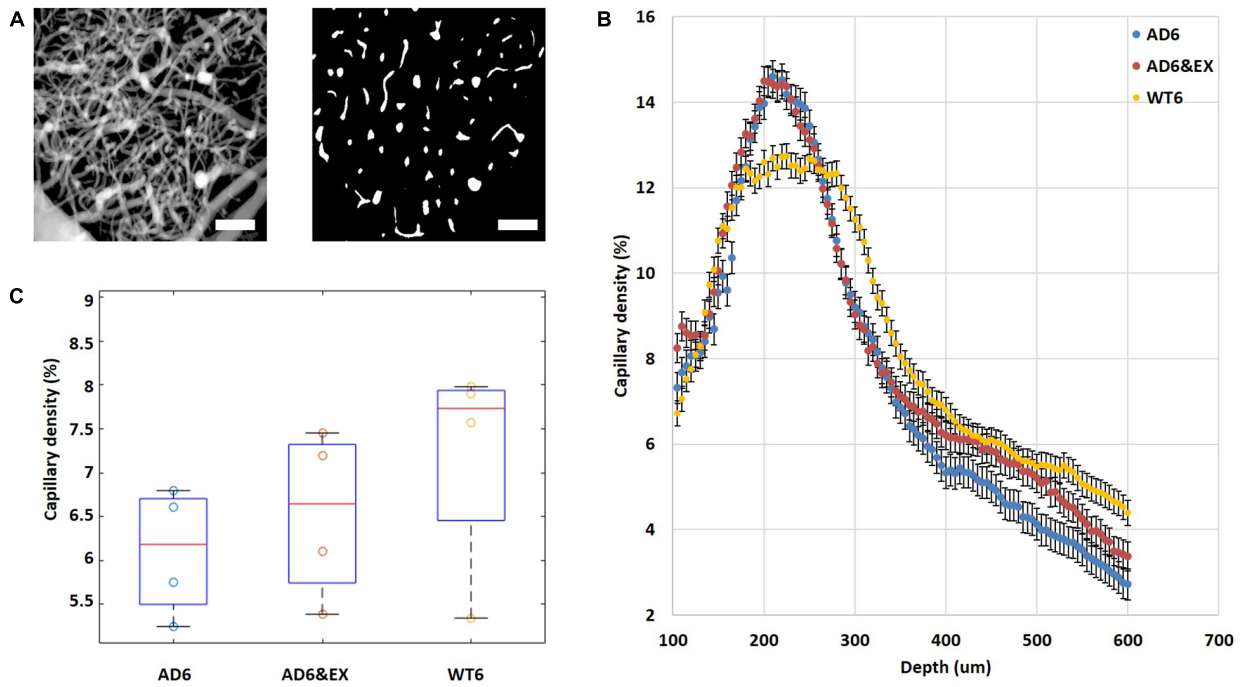

FIGURE 4 | Vascular distribution in different experimental groups and at different depths. **(A)** Binarization of microvascular angiograms was applied to calculate the vascular density. Left: MIP image with depths ranging from 100 to 550 μm under the brain surface with 5 μm steps. Right: an example of a binary segmentation of a single *en face* slice after removing the large horizontal vessels at a depth of 120 um (scale bar: 100 μm). **(B)** Average vascular density in different experimental groups as a function of depth from 100 to 550 μm under the brain surface. **(C)** Estimated vascular density (volume%). Results are presented as box plots with the median value (red line).

another paper (Lu et al., 2019), we found that indeed, tissue oxygen was reduced and more heterogeneous in mice with AD, consistent with this study. In capillary segments close to arterioles, capillaries were observed to have larger RBC velocity and flux, potentially enabling the delivery of oxygen and energy metabolites to the brain tissues. Future research may further explore the functioning of different capillary branches and investigate whether AD could lead to differentiated impacts on these segments.

Capillary obstruction due to flow dysfunction and tissue inflammation has been observed in animal models and has been shown to contribute to the development of neuron pathology and disease (Santisakultarm et al., 2014; Erdener et al., 2017; Hernández et al., 2019). Inflammation and flow disruption are well-recognized features of AD (Gaugler et al., 2018). Inflammation triggers reactive oxygen species, which lead to obstruction in capillaries (Park et al., 2008). Meanwhile, amyloid deposition may also lead to vessel occlusion by disrupting the interstitial fluid drainage pathway (Arbel-Ornath et al., 2013). Although we only focused on non-stalling capillaries in this study, the highly fluctuating RBC velocity and flux could indicate potential microvascular flow problems. We found a higher fraction of capillaries with high self-fluctuations of RBC velocity and flux in AD, slightly decreased with exercise. Previous research suggests that capillary flow patterns should homogenize to support metabolic demands, whereas heterogenous velocities across the capillary network diminish the oxygen extraction capabilities (Stefanovic et al., 2008; Gutiérrez-Jiménez et al., 2016). Our results suggest more heterogeneous flow distribution in the AD group when compared to WT but a reduced heterogeneity in the AD&EX group compared with the AD group, which may underly the benefits of exercise in AD.

Vascular Morphology Alterations in AD

Studies on morphological abnormalities of capillaries in AD have reported lower capillary densities due to deposition of Aβ amyloid (Kitaguchi et al., 2007). Previous work indicated a more rapid loss of vascular density with age, leading to compromised cerebral perfusion (Farkas and Luiten, 2001). Our results indicate that AD is associated with lower vascular density, which could contribute to reduced cerebral perfusion. This should be set against other studies that showed spatial and age-related variations in these vascular density differences between WT and APP/PS1 mice (Delafontaine-Martel et al., 2018). Here, the observed reduction in the somatosensory cortex could be potentially mitigated by exercise. Several previous studies have demonstrated the capacity of exercise to improve cognitive function (Hamer and Chida, 2008; Durrant et al., 2009; Mekari et al., 2015). Here, our data partially support the positive role of voluntary exercise on the maintenance of healthy vascular density. One intriguing observation was that at a depth of 200 um, the vascular density was higher in AD mice than in controls. The vascular density in this AD model (and others)

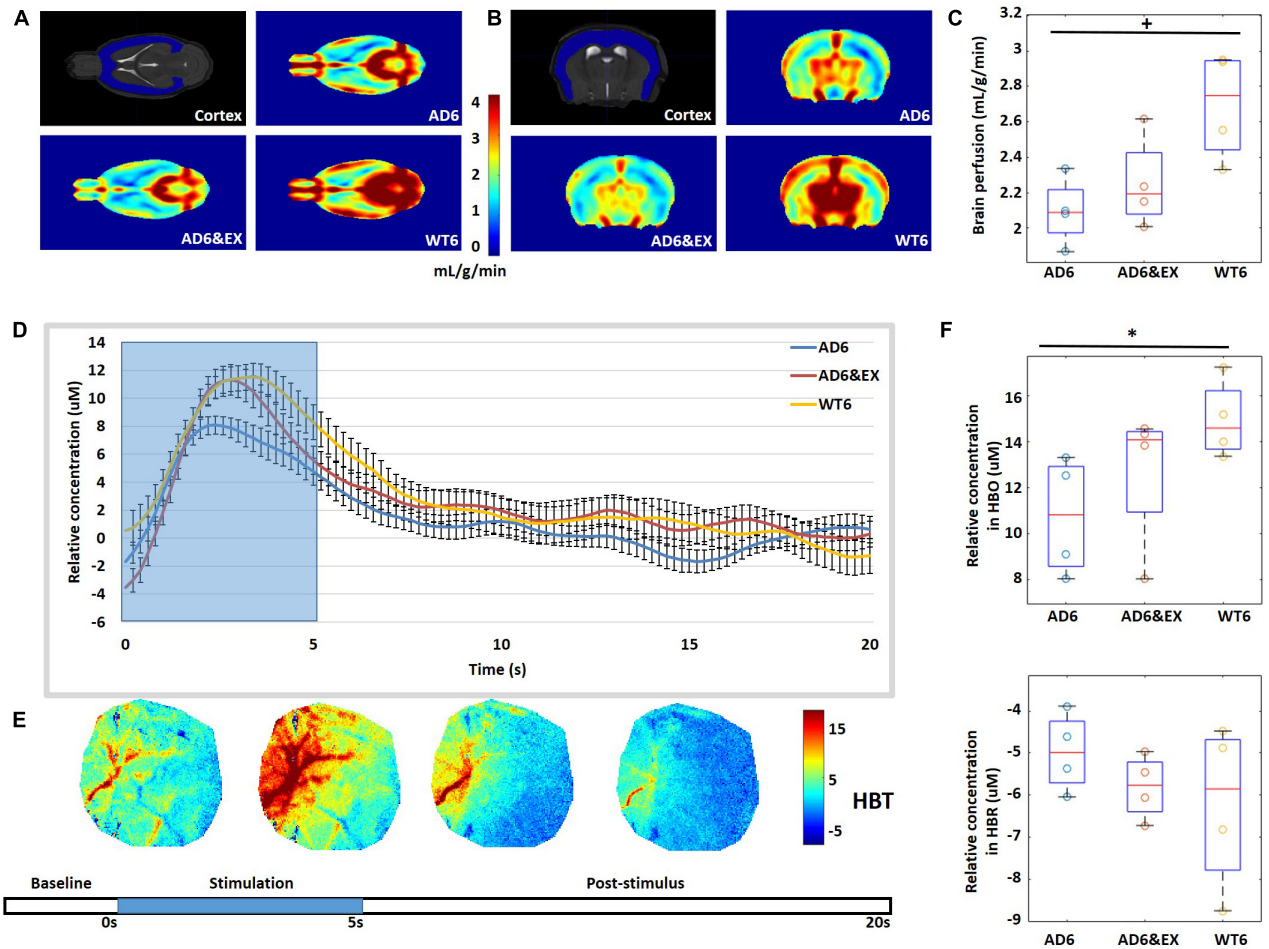

FIGURE 5 | (A,B) Typical 7-T MRI images, with coronal and axial views of the cortex. **(C)** Quantification of cerebral perfusion (ml/g/min) by MRI. **(D)** Averaged temporal response of oxy-hemoglobin (HBO) for all groups with 5-s stimulation (blue background). **(E)** Temporal dynamics of total hemoglobin (HBT) response to whisker stimulation. Stimulation lasted for 5 s, followed by a 15-s rest. **(F)** Averaged results for change in HBO (Δ[HBO](t)) and change in HBR (Δ[HBR](t)) over all mice. $^{*}p < 0.05$ and $^{+}p < 0.1$.

is age-dependent, and previous work has documented higher vascular density in AD mice when compared to WT (Cifuentes et al., 2015) in the cortex but not in the hippocampus. This indicates a potential complex distribution of vascular changes that cannot be accounted for by a single local observation. AD could also influence capillary diameter constriction and dilation, which respond to brain demands (Iadecola, 2017). Prior studies have shown that pericytes, the multi-functional cells wrapping around the capillaries, are able to influence capillary diameter to adjust oxygenation levels (Østergaard et al., 2013; Iadecola, 2017). Minimal changes in capillary diameter could produce large changes in oxygen delivery, since capillaries are closest to neurons in the vascular network and have large surface areas. Interestingly, we observed increased capillary diameters in the AD group and the exercise group. This change in diameters could be due to the compromised flow in AD groups, with the diameters dilating to compensate for the hypoperfusion. Another possible reason for the dilation of capillaries could be the occlusion of capillaries in AD due to amyloid deposition or inflammation (Park et al., 2008; Arbel-Ornath et al., 2013), as occlusion of vessels was shown to lead to vessel dilation in upstream capillaries in stroke disease (Nguyen et al., 2011).

Reduced Cerebral Perfusion and Functional Responses in AD

Using ISOI, we measured the functional hemodynamic response to stimulation (Sheth et al., 2005). Prior studies used ISOI to investigate pathological departures of neurovascular coupling in diseases such as focal epileptic seizures that exhibit an elevation in HBO (Schwartz et al., 2011). Another study applied ISOI and observed that functional connectivity strength was reduced in patients with AD, in cognitively normal elderly with elevated amyloid deposition, and in advanced aging (Bero et al., 2012). Our results corroborate previous findings showing a lower response amplitude in AD, suggesting neuro-vascular coupling changes. In contrast, the HBO response

further increased with voluntary exercise, suggesting that exercise may increase the regional oxygen delivery efficiency in capillaries but not through global increases in CBF. This finding was supported by MRI results suggesting decreased overall cerebral perfusion in both AD groups. Beyond the mesoscopic hemodynamic response to stimulation, future studies may consider characterizing the hemodynamic response to whisker stimulation at the capillary level directly using two-photon microscopy.

Limitations of the Study

The major limitation of our study is the small sample size used for the analyses, which may lead to potential type I (characterized as false-positive results) and type II (characterized as false-negative results) errors (Hackshaw, 2008). We admit that the associations we found were from a hypothesis-generating study, and a larger confirmatory study is needed in future. Additionally, the individual housing condition of the AD&EX group may cause some extent of social deprivation, which may mitigate the benefits of exercise. Future studies may need to find a balance between the social inclusion factors and the validity of voluntary exercise.

CONCLUSION

Our study provides novel insights into the hemodynamic mechanisms of cerebral microcirculatory disturbances in AD and the modulatory effects of voluntary exercise on these hemodynamic alterations. Our work suggests therapeutic targets that may alleviate microvascular complications observed in AD.

DATA AVAILABILITY STATEMENT

The datasets generated for this study are available on request to the corresponding author.

ETHICS STATEMENT

Animals were handled according to the Animal Research: Reporting *in vivo* Experiments (ARRIVE) guidelines and the recommendations of the Canadian Council on Animal Care. The protocol was approved by the Ethics Committee of the Research Center of the Montreal Heart Institute.

AUTHOR CONTRIBUTIONS

XL designed the study, carried out the experiments, analyzed the data, and drafted the manuscript. MM and PP carried out the experiments. MM, BL, YL, RD, and PP analyzed the data. ET participated in the designing of the study. FL conceived, designed, and coordinated the study, and revised the manuscript. All authors gave final approval for publication.

FUNDING

This study was funded by a Canadian Institutes of Health Research (CIHR, 299166) operating grant and a Natural Sciences and Engineering Research Council of Canada (NSERC, 239876-2011) discovery grant to FL.

ACKNOWLEDGMENTS

The authors thank Marc-Antoine Gillis and Natacha Duquette (Montreal Heart Institute) for their help with animal preparations. The authors are grateful to Sava Sakadzic (Harvard Medical School) for discussions on the pO_2 results, Sergei Vinogradov (University of Pennsylvania) for useful comments on PtP-C343 probe synthesis and calibrating the probe for us. The authors also thank the RQRV (Réseau Québécois de Recherche sur le Vieillissement, in part funded by the Fonds de Recherche du Québec-Santé) for its valued contribution to this study.

APPENDIX

Branch Dependent Investigation of Capillary RBC Properties

We used the 3D angiogram to distinguish different branching orders in capillaries (see **Appendix Figure 1a**). We investigated how capillary hemodynamics varied in different branching orders for all groups.

We observed that the average diameter showed a slight decreasing trend in WT6 group, while its value remained stable in the AD6 group (see **Appendix Figure 1b** first from the left). With exercise, the AD group remained relatively stable with a dip in the downstream capillaries (see **Appendix Figure 1b** first from the left). The smaller diameter in downstream capillaries could be linked to the stalling occuring more in the downstream capillaries (Erdener et al., 2017). The average RBC velocity showed sharp decrease in the upstream capillaries for all groups (see **Appendix Figure 1b** second from the left). The average RBC flux also had sharp reduction in all branches for the AD groups, but had a moderate decrease in the WT group (see **Appendix Figure 1b** third from the left). Finally, all groups showed increasing trends of hematocrit from upper to lower streams (see **Appendix Figure 1b** the fourth from the left).

Due to the larger reduction in the first three branching orders of capillary RBC velocity and flux, we further calculated the RBC property differences among the initial three orders for each group to explore the differences across branches. We observed that for the initial three orders (from A1 to A3), the RBC velocity dropped at least 62% [calculated by (A1-V3)/A1] (67.28, 67.70, and 62.25% for AD6, AD6&EX, and WT6, respectively), suggesting that the RBC velocity was largely modulated in the upper stream of capillaries. Additionally, for the average RBC flux, we observed that in the initial three orders (from A1 to A3), the flux dropped ~ 32% over three groups [calculated by (A1-V3)/A1] (32.74, 31.87, and 34.83% for AD6, AD6&EX, and WT6, respectively), indicating that the RBC flux modulation in the upper orders still largely contributed to the variance of overall RBC flux across all capillaries.

Reopening of the cerebral artery after occlusion often results in "no-reflow" that has been attributed to the death and contraction (*rigor mortis*) of pericytes. Since this hypothesis still needs to be confirmed, we explored the effects of oxygen glucose deprivation (OGD) on viability and cell death of primary rat pericytes, in the presence or absence of neurovascular unit-derived cytokines. Two morphodynamic parameters, single cell membrane mobility (SCMM) and fractal dimension (D_f), were used to analyze the cell contractions and membrane complexity before and after OGD. We found a marginal reduction in cell viability after 2–6 h OGD; 24 h OGD caused a large reduction in viability and a large increase in the number of apoptotic and dead cells. Application of erythropoietin (EPO), or a combination of EPO and endothelial growth factor ($VEGF_{A1-165}$) during OGD significantly reduced cell viability; application of Angiopoietin 1 (Ang1) during OGD caused a marginal, insignificant increase in cell viability. Simultaneous application of EPO, $VEGF_{A1-165}$, and Ang1 significantly increased cell viability during 24 h OGD. Twenty minutes and one hour OGD both significantly reduced SCMM compared to pre-OGD values, while no significant difference was seen in SCMM before and after 3 h OGD. There was a significant decrease in membrane complexity (D_f) at 20 min during the OGD that disappeared thereafter. In conclusion, OGD transiently affected cell mobility and shape, which was followed by apoptosis in cultured pericytes. Ang1 may have a potentiality for preventing from the OGD-induced apoptosis. Further studies could clarify the relationship between cell contraction and apoptosis during OGD.

INTRODUCTION

Pericytes wrap capillaries and express contractile proteins, so they could potentially regulate capillary diameter by constricting or relaxing their processes (Winkler et al., 2017). Whether or not they really control cerebral blood flow (CBF) *in vivo* is not clear. Local CBF is controlled by changes in smooth muscle tone around cerebral arterioles (Attwell et al., 2010). A concept has emerged from an *in vivo*/*in situ* study by Hall et al. (2014), which demonstrated that an increase in neuronal activity dilated neighboring capillaries before dilating arterioles and was accompanied by morphological changes in pericytes' shapes that were consistent with relaxation. A study that used loss-of-function pericyte-deficient mice has shown that pericyte degeneration reduces capillary blood flow responses to neuronal activity (Kisler et al., 2017). These findings have been challenged

by studies, which revealed that brain pericytes were not able to contract since the contractile proteins, such as alpha smooth muscle actin (aSMA), was only present in vascular smooth muscle cells (Hartmann et al., 2015; Hill et al., 2015; Wei et al., 2016).

Conflicting evidence exists regarding the role of pericytes in "no-reflow" following reperfusion of the occluded artery. Peppiatt et al. (2006) found that brain pericytes in mice remained contracted after the middle cerebral artery (MCA) was reopened, following 2 h occlusion. Hall et al. (2014) reported that brain pericytes die rapidly following cerebral ischemia and their processes subsequently contract (*rigor mortis*), which causes constriction of the capillaries.

To clarify whether or not conditions that occur during cerebral ischemia *in vivo* cause rapid death and/or a long contraction of brain pericytes, we cultured primary rat pericytes and then measured their viability and motility at different time points during oxygen glucose deprivation (OGD).

MATERIALS AND METHODS

Animals

Primary cultures of pericytes were obtained from 1 to 2-month-old male and female Sprague Dawley rats weighting 200–220 g. Animals were supplied by Animal Resource Center (ARC), Health Science Center (HSC), Kuwait University.

The study was carried out in accordance with the guidelines of laboratory animal care in HSC, Kuwait University, which are based on principles of the Office of Laboratory Animal Welfare, National Institutes of Health[1], and on Animal Research: Reporting of *in vivo* Experiments recommendations[2].

Primary Culture of Rat Brain Pericytes

Primary pericyte cultures were generated according to a protocol for rat brain endothelial cells (BECs) isolation (Abbott et al., 2012). For details on how this protocol was amended to produce pericytes, see **Supplemental Figure 1**. Experiments that tested cell viability were performed on >90% confluent cultures, while experiments that analyzed contractility of pericytes were performed on cultures at <50% confluence.

Immunocytochemistry

Unless stated otherwise all antibodies were from Abcam, UK. Following fixation, permeabilization and blocking, cells were incubated overnight at 4°C with the following six primary antibodies (1:100 dilution) in PBS/0.1% Tween20/1% FCS: (1) Rabbit polyclonal antibody raised against purified rat NG2 chondroitin sulfate proteoglycan; (2) Mouse monoclonal antibody raised against 22–112 sequence of human SMA, which cross-reacts with rat (DAKO-Millipore); (3) Rabbit polyclonal antibody raised against native anti-Von Willebrand factor from human plasma and also recognizes the rat homolog; (4) Rabbit monoclonal antibody raised against a recombinant fragment 400–600 of mouse CD31 and cross reacts with the rat homolog; (5) Rabbit monoclonal antibody raised against the intracellular C-terminus of the human platelet-derived growth factor receptor beta (PDGFRβ) receptor, homologous to rat; (6) Rabbit polyclonal to Tie2 receptor, raised against synthetic peptide within human TIE2 amino acid 450–500 and cross reacts with rat, mouse, and human TIE2.

After washing, the cultures were incubated for 2 h at room temperature with the following secondary antibodies (1/200–1/500 dilution), solubilized in 2 ml of PBS with 0.1% Tween20, 1% FCS: (1) goat anti-rabbit IgG conjugated to fluorescein-isothiocyanate (FITC); (2) goat anti-mouse IgG conjugated to cyanine Cy5; (3) goat anti-mouse IgG conjugated to Cy3; (4) Donkey anti-rabbit IgG conjugated to Alexa Fluor 555.

Flasks were then washed and 4′, 6-diamidino-2-phenylindole (DAPI) was added to stain the nuclei. The cells were then examined under a fluorescence microscope Zeiss Axiovert 40 CFL or Zeiss AxioObserver A1 fitted with AxioCam HRc and AxioCam MRm cameras, respectively. For Alexa Fluor 555 staining analysis, images were further processed with self-written SynoQuant Ver. 10.69 software (for details see Henkel et al., 2019). The images were deblurred with a non-linear algorithm ("Level background") that removed specifically homogenous stain corresponding to background staining, while enhancing structured any objects. The separation between background and structures was based on a local intensity standard deviation.

Oxygen Glucose Deprivation Protocols

A glove box (Plas BY Labs, Lansing, MI, USA) was maintained with 0% O_2, 5% CO_2, and 5% H_2 in N_2 at 37°C (for the justification of gas composition see Al-Sarraf et al., 2018). All cell culture media and buffers were kept in the glove box for at least 24 h prior to OGD experiments. Cell cultures were incubated in glucose- and pyruvate-free DMEM (Invitrogen) that did not contain other supplements (OGD medium) for 2–24 h. For control experiments, cultures were incubated for 2–24 h in supplement-free DMEM that contained 5 mM glucose and 1.25 mM pyruvate (control medium) in 5% CO_2 in air at 37°C.

In some cases, the following cytokines were added to the cell culture medium prior to the start of the experiments: (1) Rat recombinant EPO (rrEPO, R&D Systems, UK), 5 IU/mL, corresponding to ≈40 ng/ml; (2) Rat recombinant vascular endothelial growth factor ($rrVEGF_{A1-165}$, Abcam, UK) 10 ng/ml; (3) Rat recombinant Angiopoietin 1 (rrAng1, My BioSource, UK) 40 ng/mL.

The rationale behind choosing these cytokines was that they have been shown to be the three main cytokines released from cells of the neurovascular unit during hypoxia (Augustin et al., 2009; Becerra-Calixto and Cardona-Gómez, 2017; Hu et al., 2017). Final concentrations of these three cytokines were selected based on the available data. The concentration of rrEPO was selected according to its determined ED_{50} value for the induction of erythroleukemic TF-1 cell line proliferation (Krejci et al., 2009) and on its concentration in the cerebrospinal

fluid (Janik et al., 2010). The concentration of rrAng1 was selected according to the manufacturer's recommendation, Ang1 activation of Tie2 receptor (Bogdanovic et al., 2006) and on Ang1-induced proliferation of endothelial cells (Kanda et al., 2005). Concentration of rrVEGF$_{A1-165}$ was chosen according to the manufacturer's recommendations, dose-dependent effects of VEGF$_{A1-165}$ on BECs (Mayhan, 1999) and on its concentrations in the rat CSF (Jones et al., 2003). Also, observed effects of these cytokines on cell viability and apoptosis (Koblizek et al., 1998; Kwak et al., 1999; Papapetropoulos et al., 2000) were taken into consideration.

Assessment of Cell Viability and Apoptosis

Following completion of anoxia or control protocols, cells were detached, stained with Annexin–V PE and 7-aminoactinomycin D (7-AAD) and analyzed using Epics XL flow cytometer (Beckman Coulter, USA). Based on the staining cells were considered as viable, apoptotic or dead (see **Supplemental Figure 2**). A marginal fraction of the cells in every sample was 7-AAD-positive/Annexin PE-negative; since this fraction was independent of experimental procedure it was excluded from the analysis.

Assessment of Cell Contractility and Motility Speed

We measured the membrane dynamics and the overall contraction/relaxation of pericytes. The measurements were done on digitally segmented single cells or small connected cell groups (<3 cells). **Figure 3E** and **Supplemental Figure 3** show representative examples of pericytes in contracted and relaxed states. Additionally, we quantified the overall motility speed upon various experimental interventions in order to determine if the cellular movement apparatus was affected by the treatments. The **Supplemental Video 1** shows the typical morpho-dynamics of a small connected group of pericytes. Contraction and dynamics of large processes are quantified by the area/perimeter ratio (A/PR), while small membrane movements could be measured by the fractal dimension (D_f) of the cellular perimeter (red border around cells in **Supplemental Figure 3**). The mobility speed was quantified by spatial intensity difference changes between successive image frames; this protocol was described in detail previously (Henkel et al., 2019).

Primary cultures in flasks were transferred to a temperature–controlled (37°C) incubation microscope (Cell Observer, Zeiss, Germany). Image sections for morpho-dynamic analysis were selected, if they contained preferentially single cells, covering not more than 50% of the area. Control images were recorded at a rate of 1 per 5 min for 15 h. The culture flasks were then transferred to the glove box and exposed to OGD for variable time periods (20 min−6 h). The flasks were then transferred back to the cell observer and the same cells that were imaged before OGD were monitored again. Thus, during this second imaging protocol, cells were exposed to control conditions. Image stacks of 11–22 cells from different flasks were obtained for each experimental group before and after OGD for statistical analysis.

Image Acquisition, Processing, and Quantification

Details of all procedures have been described previously (Henkel et al., 2019). The following parameters were measured: single cell membrane mobility (SCMM), Area/Perimeter ratio (A/PR), which corresponds to cell surface–cell volume ratio and is well-suited to monitor cell process dynamics. Finally, the fractal dimension (D_f) was calculated using the segmented cell perimeter as an object, which provided a quantitative approximation of the cellular plasma membrane complexity (Popescu et al., 2010).

Co-localization of immune-stained proteins (green and red channels) was measured with SynoQuant's build in "Co-localization module" that included a background subtraction algorithm, which was based on structure elements in the image. Essentially, the analysis employed the Pearson's correlation coefficient between the red and green channels (Dunn et al., 2011) to calculate coincidental appearances of proteins inside a cell and cell structures.

Statistical Analysis

The value distribution was assessed by Shapiro-Wilk's test for normality (Shapiro and Wilk, 1965; Villaseñor and González-Estrada, 2009). Differences between experimental groups were pre-assessed by one-way or two-way ANOVA to determine the effects of OGD, cytokine presence, and viability of pericytes. The homogeneity of variances was assessed by Levene's test for equality of variances (Levene, 1960). Whenever the data was not normally distributed, the Kruskal-Wallis test was used instead of ANOVA.

For assessment of the contractility, statistical significance was calculated by paired *t*-tests between control and experimental groups, since the same cells were imaged before and after OGD. A $p < 0.05$ was considered statistically significant. Effect sizes between controls and experimental groups were calculated as Cohen's D (Cohen, 1988).

RESULTS

Purity of Primary Cultures

Overall, rat brain pericytes in culture revealed heterogeneous phenotypes and were the largely dominant cell type, while VSMCs were only marginally present.

Figure 1A shows that the majority of cells were NG2-positive (FITC), and many NG2-positive cells were also positive for SMA (Cy5). The Pearson's coefficient for cellular co-localization of both markers, after background correction, was ≈0.7, which corresponds to a colocalization of ≈48–50%. Cells with a typical pericyte-like morphology that were positive for NG2 and marginally positive for SMA could be observed in all cultures (dashed arrows). Cells that were positive for SMA and marginally positive for NG2, and thus could represent vascular smooth muscle cells (dotted arrows). Rarely, cells showed no immune-reactivity for either NG2 or SMA (solid arrows); these were possibly fibroblasts or macrophages. Since expression of SMA by pericytes largely depends on their localization, pericytes from capillaries that branch directly from arterioles and venules

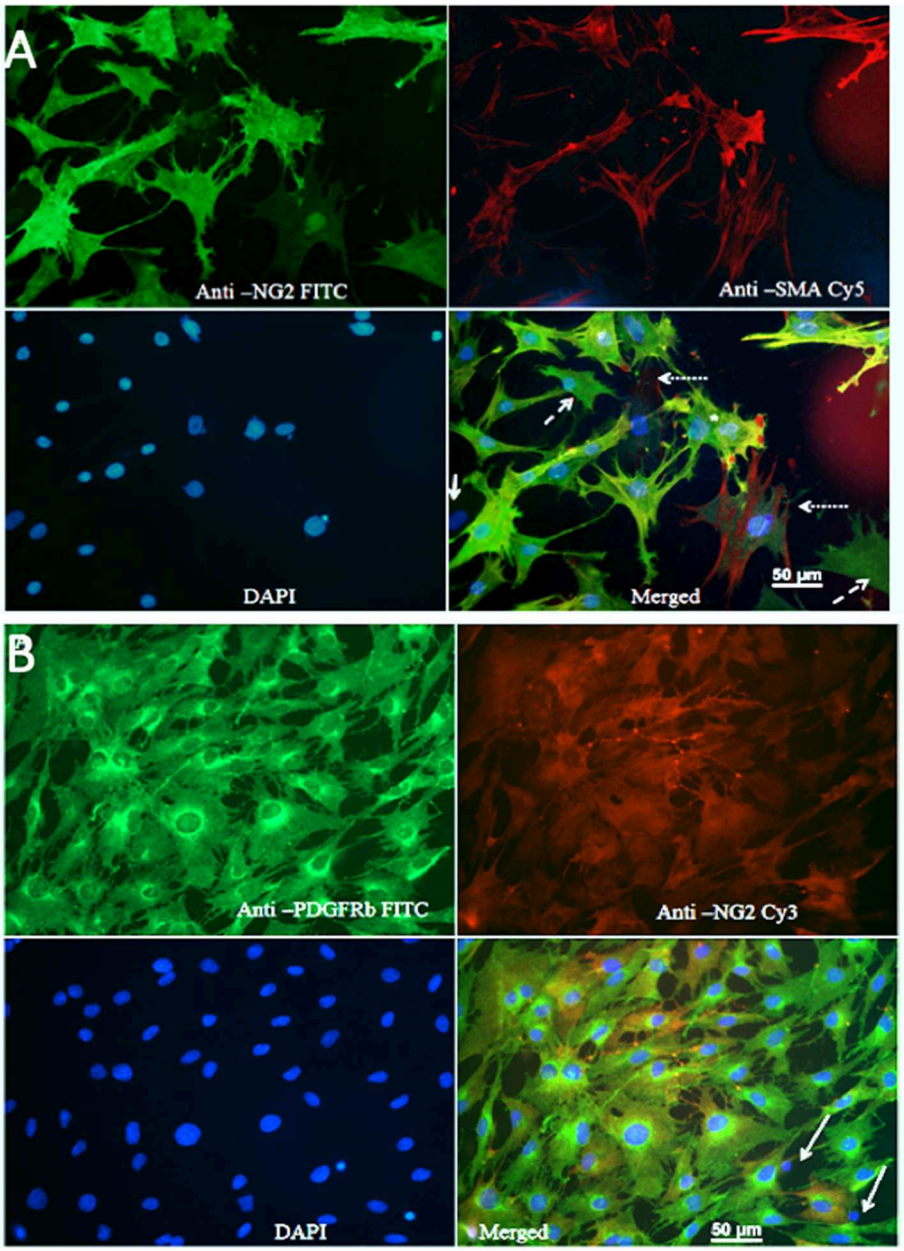

FIGURE 1 | (A) Staining of primary cultures with anti-NG2 (FITC, green channel)/anti-SMA antibodies (Cy5, red channel). These images show polygonal, pericyte-like cells with processes. Anti-NG2 was mostly diffuse diffusely, while staining with anti SMA revealed fibrillary structures, which most likely corresponded to actin filaments. Cells that were poorly stained with both NG2 and SMA could be observed rarely (arrows); some cells were positive only for NG2 (dashed arrows), while some cells were mainly SMA positive (dotted arrow). **(B)** Immunostaining for PDGFRβ. A typical image showing staining of primary cultures with anti PDGFRβ (FITC, green)/anti-NG2 antibodies (Cy3, red).

express more SMA than those in mid-capillary regions (Nehls and Drenckhahn, 1991). This may account for the absence or low abundance of SMA in pericytes from these areas. Contamination of primary cultures with BECs was marginal, which was confirmed by immunostaining with anti-Von Willebrand factor antibody and CD31 antibody (**Supplemental Figure 4**).

Since brain pericytes can be distinguished from VSMCs by PDGFRb as marker (Hutter-Schmid and Humpel, 2016), we stained primary cultures with anti-PDGFRb (FITC, green channel) and anti-NG2 (Cy3, red channel) antibodies (**Figure 1B**). The vast majority of cells were PDGFR-positive; the Pearson's coefficient for co-localization of both markers after background correction was ≈0.7, which corresponded to a co-localization of ≈48–50%. PDGFRb positive–NG2 negative cells were present in all cell cultures. A small fraction of the cells was NG2 positive but PDGFRb

negative, presumably VSMCs. Isolated pyknotic nuclei were also observed (arrows).

Viability of Pericytes During OGD and Effects of NVU-Derived Cytokines

Two and six hours OGD caused small but significant ($p < 0.05$) reduction in pericyte viability (**Supplemental Figure 5A**), which was accompanied by a small increase in the number of apoptotic (**Supplemental Figure 5B**) and dead cells (**Supplemental Figure 5C**). However, 24 h exposure to OGD caused a large reduction in viability, to 27% ($p < 0.001$ vs. control, **Figure 2A**), which was accompanied by a large and significant increase in the number of apoptotic cells (**Figure 2B**) and a moderate and significant increase in the number of dead cells (**Figure 2C**).

Presence of rrEPO in in the medium did not exert any effect on cell survival either during 2 and 6 h OGD or in control conditions during 2, 6, and 24 h (**Figure 2A** and **Supplemental Figure 5A**). However, it caused a large decrease in cell viability after 24 h OGD from 27% (OGD without rrEPO) to 8% ($p < 0.01$, **Figure 2A**). The number of apoptotic cells significantly decreased under these conditions to 35% ($p < 0.05$ vs. OGD without rrEPO, **Figure 2B**), but the number of dead cells increased significantly to 55% ($p < 0.01$ vs. OGD without rrEPO, **Figure 2C**). Interestingly, presence of rrAng1 in in the medium caused a marginal and significant reduction in cell viability in control conditions ($p < 0.05$ vs. control without any cytokine, **Figure 2A**), which was

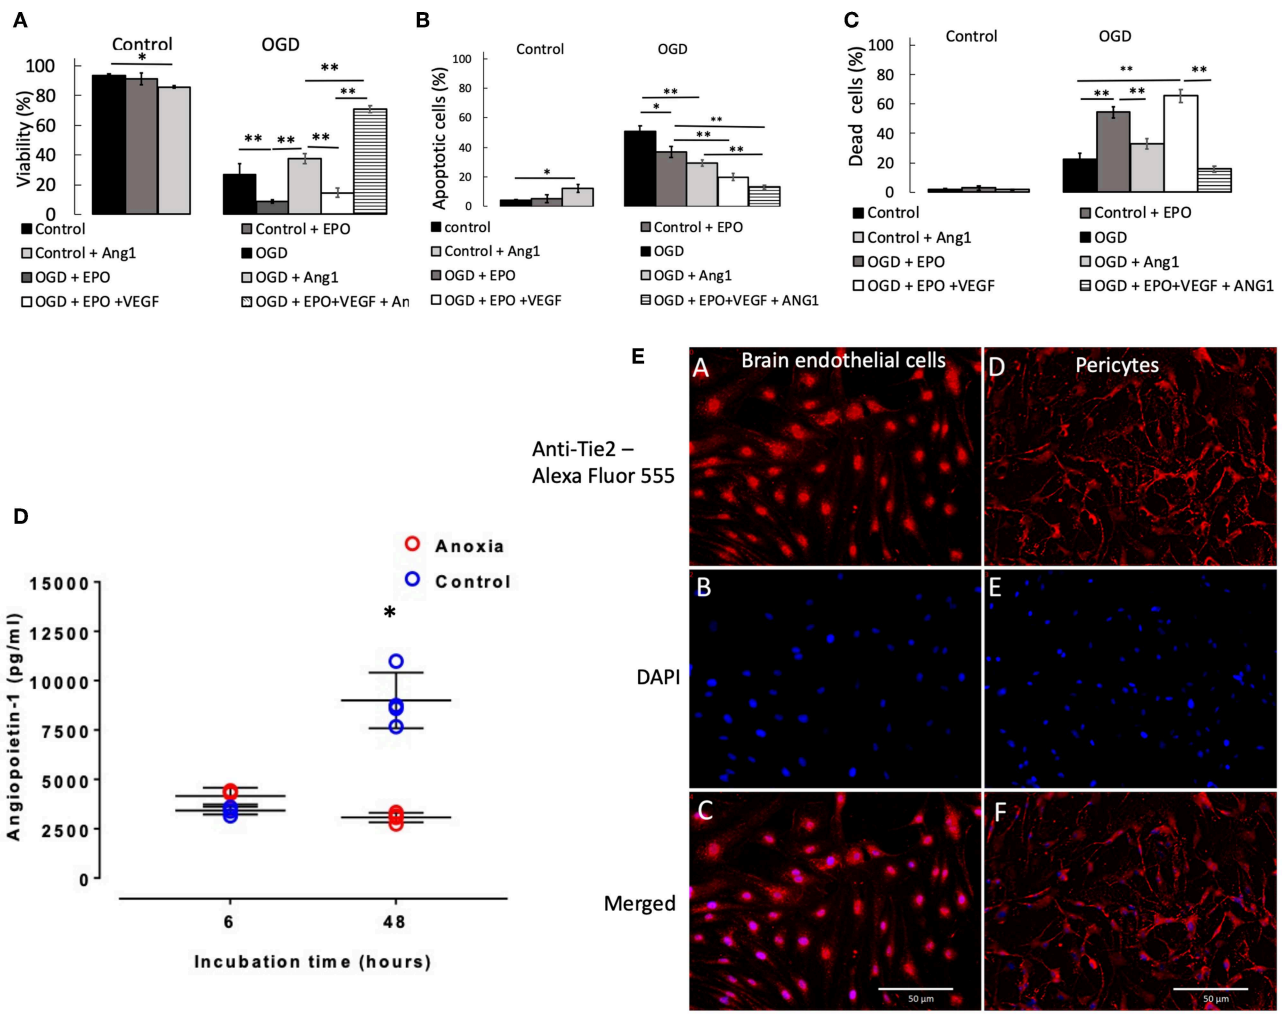

FIGURE 2 | Percentage of pericytes that were viable **(A)**, apoptotic **(B)**, and dead **(C)**, respectively after 24 h control or OGD protocols. Data were presented as mean ± SD, $n = 4$–8. Symbols indicate: $^{*}p < 0.05$, $^{**}p < 0.01$. **(D)** Angiopoietin-1 secretion by pericytes in culture during anoxia and control conditions. Values from each sample are presented as separate points. In some cases, data overlap and hence may appear to be <4 samples. The mean of the four values and SD were calculated; the latter ones being presented with solid lines. In some cases, SDs were marginal, so they appear as a single line. Symbol [*] indicates that values in anoxic groups were lower ($p < 0.05$) vs. values during normoxia (control). **(E)** Staining of rat primary brain endothelial cells (left column of images, A–C) and rat primary pericytes (right column of images, D,E) for Tie2 receptor. (A,D) Anti-Tie2 receptor staining, labeled with Alexa Fluor 555; (B,E) DAPI stain; (C,F) overlay of anti-Tie2 receptor and DAPI staining.

mainly due to a significant increase in the number of apoptotic cells (**Figure 2B**). This finding requires further investigation of the mechanism behind it, however, this was beyond the scope of the current study. Presence of rrAng1 in in the medium caused a marginal and insignificant increase in cell viability during 24 h OGD, when compared to OGD without any cytokine added ($p = 0.247$, **Figure 2A**). When $rrVEGF_{A1-165}$ and rrEPO were added together to the cell culture medium, there was a decrease in viability of pericytes after 2 h OGD to 71% ($p < 0.01$ vs. OGD and vs. OGD + rrEPO, **Supplemental Figure 5A**) and an increase in cell viability after 6 h OGD to 95% ($p < 0.05$ vs. OGD and vs. OGD + rrEPO), while after 24 h OGD cell viability under these conditions was only 14%, which was significantly lower than after 24 h OGD without any cytokine added ($p < 0.01$, **Figure 2A**). This was mainly due to a large increase in the number of dead cells (**Figure 2C**). Addition of rrEPO, $rrVEGF_{A1-165}$ and rrAng1 to the cell culture medium before exerted only small effects on cell viability after 2 and 6 h but were strongly protective to pericytes after 24 h OGD, with a cell viability exceeding 70% ($p < 0.001$ vs. OGD without cytokines, **Figure 2A**). This was due to a large reduction in the number of apoptotic cells (<13%, **Figure 2B**) and dead cells (<16%, **Figure 2C**). This observation suggests that a large number of pericytes could survive as long as 24 h without oxygen, glucose and pyruvate in the presence of these three NVU-derived cytokines. Since pericytes normally secrete Ang1 we speculated on why this secretion could not exert protective effects when primary pericytes were exposed to OGD with rrEPO and $rrVEGF_{A1-165}$, i.e., why was the difference in the survival between these two groups (rrEPO and $rrVEGF_{A1-165}$ vs. rrEPO, $rrVEGF_{A1-165}$ and Ang1) so large. To clarify this, we used ELISA kit (Boster biological technology, USA) to measure concentrations of Ang1 in cell culture media collected from the conditioned pericytes. These results are presented in **Figure 2D**. In the presence of oxygen, pericytes secreted Ang1 in the medium and there was an almost linear increase in the concentration between 6 and 24 h in the control groups. However, when they were deprived of oxygen, there was no significant increase in Ang1 concentrations between 6 and 48 h ($p > 0.05$); the concentration after 48 h was significantly lower than in controls ($p < 0.01$).

After staining for Tie2 receptor, immunofluorescence showed punctate staining on the membrane in both brain endothelial cells, which were used as a control, and in primary pericytes (**Figure 2E**). There was some nuclear staining that was more prominent in endothelial than in pericyte cells. Pericyte processes were more intense stained than cell somata, while endothelial cells showed a more homogeneous distribution and smaller puncta.

Effects of OGD Protocols on Pericytes' Morpho-Dynamics

To confirm that the reduction in SCMM actually represented contraction of the contractile filaments in pericytes, 22 cells were imaged before and after application of the vasoactive drug endothelin-1 (ET-1, 50 nM) (Rubanyi and Polokoff, 1994). The result is presented in **Figure 3A**, first bar; 19 out of 22 cells exhibited a reduced SCMM ($p < 0.01$, $n = 22$).

Exposure of pericytes to 20 min ($n = 11$) and 1 h ($n = 16$) OGD produced a similar effect as the presence of ET-1, which was a pronounced reduction of pericytes' SCMM when compared to the corresponding pre-OGD control period (**Figure 3A**, $p < 0.05$ for both time points). The effect sizes (Cohen's D) after 20 min and 1 h OGD, were 0.65 and 0.9, respectively, corresponding to medium and large effects. After 3 and 6 h OGD, the overall motility speed of their processes did not change significantly, when compared to the pre-OGD period ($n = 22$, $p = 0.02$ and $n = 16$, $p = 0.46$, respectively). In both cases the effect sizes were small (Cohen's $D < 0.4$).

The ratio between cell area and cell perimeter (A/PR) was used to check if the protrusions and process formation was affected by OGD. Initially, the A/PR increased after 20 min OGD (**Figure 3B**, $n = 25$, $p < 0.01$), which indicated that the cell became rounder and that the processes grew shorter. Later on, there were either no changes detectable (1 h, $n = 22$), or a slight decrease (3 h, $n = 18$, $p < 0.05$) compared to controls. The exposure to 6 h OGD caused a significant increase in A/PR ($n = 20$, $p < 0.01$), pointing to the retraction of processes and protrusions. In summary, the pericytes became rounder after 20 min and 6 h OGD.

Generally, we could not detect differences in pericytes' membrane complexity estimated by fractal dimension D_f (**Figure 3C**) between images taken before and after OGD, except when cells were exposed to 1 h OGD, when D_f was significantly decreased ($p < 0.05$ compared to controls, $n = 54$). In order to verify that this reduction was associated with contraction of cellular processes, we measured D_f before and after addition of ET-1 (50 nM). Despite heterogenous behavior of pericytes, ET-1 caused a significant reduction in D_f from (mean ± SD) 1.28 ± 0.04 before OGD to 1.25 ± 0.05 after OGD ($n = 65$, $p < 0.01$).

In most pericytes the plasma membrane motility was very dynamic, but on a slow time scale. **Figure 3D** (modified from Henkel et al., 2019) shows a representative A/PR trace with transient contractions and relaxations, occurring over the course of ≈15 h. At the end, most pericytes remained rounder than at the start of the experiment. The 4 insets show the segmented cell plasma membrane, acquired at corresponding times (arrows) of the experiment.

DISCUSSION

Pericytes Were Resistant to OGD

The data from this study suggest that pericytes in primary culture represented a heterogenous population of cells; they could survive OGD for relatively long periods of time, if rrEPO, rrVEGF, and rrAng1 were added in the cell culture medium. The only source of glucose during OGD could be from glycogen. In the presence of NVU-derived cytokines, astrocytes store substantial amounts of glycogen and metabolize it by glycolysis (Rischke et al., 1992; Thoren et al., 2006). Pericytes have been shown to store glycogen *in vivo* (Cataldo and Broadwell, 1986); our findings suggest that the available glucose quantity is apparently sufficient to supply ATP in the absence of oxygen.

The insets show the outlines of pericyte plasma membranes at the indicated time points in the contractility trace. **(E)** An example of a partial retractions of cell processes after OGD. I and III show a typical visual field under phase contrast microscope with 6 pericytes before, while II and IV show the remaining 5 pericytes after 6 h OGD. Images III and IV represent structure enhanced images I and II, respectively. **(F)** Using protocol that has been described already (Henkel et al., 2019), the A/P ratio for every cell in images shown in E has been calculated and then the mean and SD estimated. These data reveal that A/P ratio for each of the five cells in this particular visual field has increased, i.e., cells have partially retracted processes becoming more "round." Paired *t*-test revealed statistically significant difference ($p < 0.05$).

NVU-Derived Cytokines Exerted Differential Effects on Pericytes During OGD

EPO exerted detrimental effects on pericytes after 24 h OGD, which could be either due to a reduced ability of these cells to generate sufficient amounts of ATP through glycolysis, or to an increase in energy expenditure. These effects were similar to those observed on rat astrocytes and rat BECs during anoxia (Al-Sarraf et al., 2018) and contradict the classical concept that EPO signaling is neuroprotective during hypoxia (Mallet and Ryou, 2017). Astrocytes are the main source of endogenous EPO in the hypoxic brain (Chavez et al., 2006). Clinical trials have revealed either no effects or damaging effects of exogenous EPO in stroke patients (Souvenir et al., 2015). Cerebral glucose metabolic rate was significantly increased in constitutively EPO-overexpressing transgenic mice (Frietsch et al., 2007). This suggests that EPO enhances energy demands in brain cells. EPO is also one of the cytokines that could affect cellular metabolism through a 5′ AMP-activated protein kinase (AMPK–EC 2.7.11.31)—dependent pathway (Wang et al., 2013). AMPK
